The Vapor Pressure of Deuterium Water from 20 to 230°

BY FRANCIS T. MILES AND ALAN W. C. MENZIES

Comparative measurements of the vapor pressures of ordinary water and deuterium water were undertaken in this extended range because similar comparative measurements were contemplated on the vapor pressures of saturated solutions and on the dissociation pressures of salt hydrates containing these two varieties of water.

The Material Used.—The deuterium water was prepared in this Laboratory in the manner previously reported.[1] After electrolysis the residue, which contained NaOD, was distilled three times as follows: first, after passing carbon dioxide in excess; second, after adding barium oxide to precipitate carbonate; and third, without addition of any reagent. This yielded a product of d^{25}_{25} 1.1079 as compared with 1.1074 as reported by others.[2] Each of the two experimental runs, A and B, utilized a different sample of deuterium water. The degree of dilution of these by ordinary water was estimated from melting point determinations performed upon the water after sealing it within the completed apparatus, yielding, for sample A, 3.76 ± 0.02° and, for sample B, 3.73 ± 0.03°, as measured by a Beckmann thermometer calibrated against a platinum resistance thermometer whose readings were good to 0.01°. Linear interpolation between 3.802 and 0.00°, taken as melting points[3] of deuterium and common water, respectively, indicated concentrations of D_2O of 98.9 and 98.1% for samples A and B, respectively. The observed values of vapor pressure difference were accordingly corrected by multiplying them by the ratios of 100 to these percentages.

Pressure.—Differential tensimeters of Pyrex glass were used, with mercury as manometric liquid. For temperatures up to 100°, where small differences of pressure were of greater importance, the manometer bore (apparatus A) was 12 mm., and readings were made with a cathetometer. For the higher temperatures, the manometer bore (apparatus B) was 8 mm., and readings were made against a millimeter scale without use of a telescope. Permanent gases were eliminated from the water in A by distilling the water to a portion of the apparatus cooled by solid carbon dioxide while the vacuum pump was in operation; and in B by the customary technique of boiling out. Permanent gas was likewise expelled from glass and from mercury by the customary techniques of heating, boiling and evacuation. After sealing off, when both sides of apparatus A were cooled by solid carbon dioxide, the pressure difference found was 0.02 mm. This was attributed to permanent gas, and the appropriate correction applied to the differential pressure readings. Essential absence of permanent gas from apparatus B was shown by the agreement of the differential pressure values near 100° with those yielded by apparatus A, both before and after heating to 228°. This also showed that the results were not affected to more than ±0.1% by the solution of substances from the glass which might lower the vapor pressure more on one side than on the other. Mercury pressures were reduced to 0° by use of the densities of mercury found in "International Critical Tables."[4] For the purposes of comparative study, we used the values of the vapor pressure of H_2O up to 100°

as given in "International Critical Tables"[5] and above 100° as given by Smith, Keyes and Gerry.[6]

Temperature.—Up to 50° a water thermostat of 320 liters capacity was used, held constant to ±0.03°. Temperatures were measured to ±0.02° by use of a Reichsanstalt certificated thermometer after redetermination of the zero point. Near 100°, four measurements were made in apparatus A immersed in a thermostat of 11 liters water content. Temperatures were read on a Beckmann thermometer whose scale was known to 0.02° by measurement of the boiling point of water at different barometric pressures. Above 100°, the tensimeter B was immersed in an oil-bath of 4 liters capacity. Temperatures were measured to ±0.1° by means of completely immersed Anschütz thermometers whose readings were converted to the scale of the Bureau of Standards by comparison with certificated Allihn thermometers, whose zero points were determined after preheating. To secure uniformity of temperature, violent stirring was especially necessary at the higher temperatures. Identical pressure values were obtained upon doubling the speed of the stirrer, and also upon reversing its direction. Inspection of Table II will show that error in pressure measurement was throughout several fold more important than that due to the uncertainty of absolute temperature reported above.

Results.—The experimental results are tabulated in the first three columns of Table I. In order to obtain a smooth curve for purposes of interpolation, we were reluctantly obliged to employ a five-constant equation

$$\log \frac{p_{D_2O}}{p_{H_2O}} = -16.998671 + \frac{268.8426}{T} + 7.4971604 \log T - 9.761107 \times 10^{-3} \times T + 4.4288 \times 10^{-6} \times T^2 \quad (1)$$

Simpler equations gave values falling outside our estimated experimental error. Column 4, Table I, gives the differences of pressure at the temperatures of experiment as derived from this equation and column 5 shows the closeness of fit.

TABLE I

VALUES OF p_{D_2O}-p_{H_2O} DETERMINED EXPERIMENTALLY

Observation number	T, °C.	$p_{D_2O} - p_{H_2O\,obsd.}$, mm.	$p_{D_2O} - p_{H_2O\,calcd.}$, mm.	$\Delta p_{obsd.} - \Delta p_{calcd.}$ mm.
A1	25.0	− 3.13	− 3.18	+0.05
A2	30.0	− 3.97	− 4.01	+ .04
A3	50.0	− 9.14	− 9.14	.00
A4	100.0	−37.7	−37.7	.0
B1	122.7	−55.5	−56.4	+ .9
B2	143.2	−73.4	−72.7	− .7
B3	166.7	−87.0	−84.9	−2.1
B4	181.9	−83.9	−84.5	+0.6
B5	204.2	−61.0	−61.3	+ .3
B6	228.7	+22.4	+22.0	+ .4

The values tabulated in Table II for each 10° interval are derived from this equation, with extrapolated values in italics. For purposes of interpolation, log p_{D_2O} and $1/T_A$ should be used as variables. Column 5 of this table shows the values of Lewis and Macdonald.[7] These authors give the normal boiling point of deuterium water as 101.42° while our equation yields 101.40 ± 0.016°. We find the temperature at which the vapor pressure of these two varieties of water is identical as 224.3°, which may be within 0.5° of the truth. Urey and Teal[8] estimated this temperature as about 160° using the data of Lewis and Macdonald;[7] while Riesenfeld and Chang's[9] estimate was about 200°.

Latent Heat of Vaporization.—From the simplified approximate form of the Clapeyron–Clausius equation and equation (1) we can calculate the difference between the latent heats of vaporization of D_2O and H_2O as follows

$$L_{D_2O} - L_{H_2O} = 2.303 \times RT^2 \frac{d \log (p_{D_2O}/p_{H_2O})}{dT} = -1230 + 14.90 \times T - 0.04466 \times T^2 + 4.052 \times 10^{-5} \times T^3 \quad (2)$$

[9] E. H. Riesenfeld and T. L. Chang, *Z. physik. Chem.*, **B28**, 408 (1935).

Values for $L_{D_2O} - L_{H_2O}$ calculated from this equation are given in Table III. The estimated limits of error given in Table III are derived from the estimated limits of error of the vapor pressure results. Since the necessary simplifying assumptions depart further from the facts with rising temperature, the degree of trust we can place upon these latent heat differences is measured by the degree of similarity of behavior of the two forms of water.

TABLE III

VALUES FOR THE DIFFERENCE OF THE LATENT HEATS OF VAPORIZATION OF HEAVY AND LIGHT WATER, $L_{D_2O} - L_{H_2O}$, CALCULATED FROM EQUATION 2

T, °C.	$L_{D_2O} - L_{H_2O}$, g. cal. per mole	Estimated limit of exptl. error, g. cal. per mole
40	300	±20
60	275	±10
80	246	±10
100	216	±10
120	186	±15
140	159	±16
160	137	±10
180	121	±10
200	113	± 5
220	115	± 4

The value for this difference reported by Lewis and Macdonald[7] was based on assumed rectilinearity of the log p_2/p_1 against $1/T$ graph between 20 and 90°, and their value agrees with ours for a temperature near 70°.

Summary

The vapor pressures of deuterium water have been compared with those of ordinary water in the range 20 to 230°. The vapor pressures are identical at about 224°.

The differences of the latent heats of vaporization are evaluated approximately from the changes of vapor pressure over the same temperature range.

Sonic Activation in Chemical Systems: Oxidations at Audible Frequencies

BY EARL W. FLOSDORF, LESLIE A. CHAMBERS AND WM. M. MALISOFF[1]

During the past few years there have appeared numerous reports of oxidations, as well as other types of chemical reactions, induced or accelerated by intense ultrasonic vibrations.[2–4]

Schmitt, Johnson and Olson[3] observed the liberation of iodine from potassium iodide solution. They further reported that "upon the addition of radiated potassium bromide or chloride solution to starch–iodide reagent, a blue color developed which indicated either the oxidation of the bromide and chloride ions or that some other substance is produced in the presence of these salts which oxidizes the iodide ion instantaneously. Radiated distilled water produced the effect to a less marked degree." Hydrogen peroxide was found in small amount, insufficient to account for the observed rate of oxidation of halogen or of sulfide. Ozone production, if any, was in amounts too small to be detectable and consequently could not be considered as the oxidizing agent. It was further found that dissolved oxygen gas was essential to the oxidations and it was suggested that the gas was activated in association with ultrasonic cavitation. Direct absorption of energy by the molecules in solution was believed to be inconsistent with results that were obtained under pressures sufficient to inhibit visible cavitation.

Liu and Wu[4] confirmed the findings of Schmitt, Johnson and Olson, in the case of potassium iodide oxidation by ultrasonic radiation, with respect to the essential presence of dissolved oxygen gas and to the insufficient production of hydrogen peroxide or ozone to account for the observed effects. Liu and Wu presented experimental evidence in favor of the view that activation of oxygen gas is associated with cavitation. It is questionable, however, whether the conditions of radiation in a gel, whereby cavitation is suppressed and no oxidation is observed, are otherwise sufficiently comparable to justify without further evidence their conclusion concerning the influence of cavitation.

Beuthe[5] also has suggested that the primary effect of ultrasonic radiation is upon the dissolved gases. He concluded, however, from his study of the ultrasonic oxidation of certain halides, that the intermediate formation of hydrogen peroxide and possibly of ozone is at least partially responsible for the liberation of the free halogen. Oyama[6] has likewise reported the oxidation of pure water by ultrasonic action.

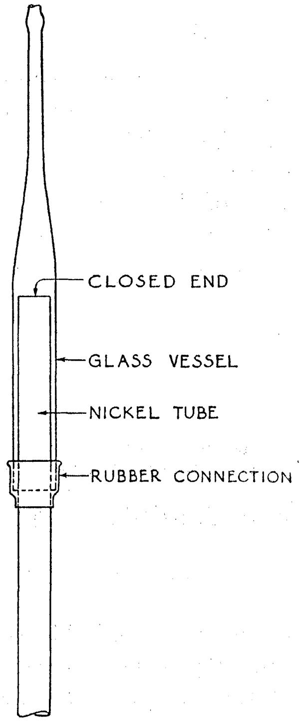

Fig. 1.—Reaction vessel, oscillator MS.

It should be emphasized that the experiments in which the above observations were made, in each case, were carried out through the use of ultrasonic vibrations (10^5 to 1.5×10^6 cycles/second). Apparatus for investigating the effects of intense sounds in the audible range (12 to 1.8×10^5 cycles/second) has been developed by Gaines[7] and used by Chambers and Gaines[8] and their collaborators, in various studies of the biological and physical actions of such audible vibrations. With this audible sound source we have extended the survey of the chemical effects of intense sound into the audible range (Flosdorf and Chambers[9]). Qualitatively, the effects produced at 9000 cycles/second seem to be similar to those previously reported for ultrasonic frequencies. Since the available sound densities are greater within the audible band the effects are greater in degree making quantitative studies less tedious and difficult and consequently more accurate.

In this paper we shall present some results of a quantitative study of certain oxidation reactions sonically activated in the audible range. We have undertaken to determine the conditions under which these sonic oxidation reactions take place in an aqueous medium, the reactants involved, the rates of reaction, and the sound intensities required. Particular attention is devoted to the question of the possible intermediate roles of hydrogen peroxide and of sonically activated oxygen. Although technical limitations have restricted the accuracy of our data, the results are instructive in a consideration of the intermediary mechanism involved not only in oxidative activation but in sonic reactions generally.

Experimental

Two types of apparatus were used, (1) the magnetostriction oscillator described by Gaines[7] and by Chambers and Gaines[8] (hereafter referred to as oscillator MS) and (2) an electromagnetic oscillator (oscillator EM).[9-11]

In oscillator MS, a cold-drawn, unannealed nickel tube, 20 mm. in diameter, vibrates in a strong electromagnetic field in resonance with a 2000 volt oscillating power circuit to which the tube imparts approximately its own natural frequency. The tubes used in these experiments, 250 mm. long, produce a frequency of about 8900 cycles per second with an acoustic output of about 15 watts (estimated) under full load. A rubber connection supports a glass vessel on the metal tube (Fig. 1). In each experiment 17–20 ml. were treated. The entire quantity was required for a single test sample which necessitated a fresh start for each time interval studied.

The diaphragm of oscillator EM is 33 cm. in diameter. The oscillator produces a frequency of about 1200 cycles per second with a maximum output of about 175 watts (Submarine Signal Co. estimate) under full load. It is of a type used in under-water signalling and depth-finding and is manufactured by the Submarine Signal Company of Boston. An iron cylinder 20 cm. deep is bolted to the periphery of the stainless steel diaphragm forming the bottom of the treatment vessel. Up to four liters of solution can be treated at one time and test samples can be removed at intervals from the same initial solution leaving sufficient for further treatment.

It has not been possible to eliminate all rubber and metal parts from contact with the reacting mixtures in either oscillator without serious impairment of intensity. Until

this is accomplished the extent of catalytic action of traces of foreign substances cannot be ascertained.

It has been found that none of the sonic oxidations previously reported[9] occur in water boiled free of oxygen and accordingly all the experiments in this study, unless otherwise stated, have been carried out with free access of air to the liquid. With the energy intensities we used, cavitation is suppressed with hydrostatic pressures over six atmospheres. Since we have found the oxidations to progress only with sonic cavitation, the experiments were carried out in the presence of air at atmospheric pressure. All the results included in this report were obtained with the solutions at a temperature of 20 to 30°.

The analytical results were obtained by the following methods. *Hydrogen peroxide* was titrated in sulfuric acid solution with 0.002 *M* potassium permanganate. Results were accurate to within ±20%. *Sodium bisulfite* was determined by titration with potassium permanganate to an estimated accuracy of ±5%. *Free chlorine* (or hypochlorite) was determined colorimetrically with *o*-tolidine in hydrochloric acid solution.[12] The readings were made seven minutes after addition of the test reagent. These determinations were accurate to within ±10%. *Chlorate* was qualitatively detected after removal of chloride and hypochlorite by reduction with sodium nitrite and subsequent precipitation with silver nitrate.

Quantitative Results

(1) **Hydrogen Peroxide Formation.**—With either oscillator hydrogen peroxide has been found to be produced from water and oxygen in quantities that are of the same order of magnitude as those reported for ultrasonic frequencies.[3,4] These quantities approach 300 micro-equivalents per liter in periods under an hour; the amounts are measurably increased by vibration in acid solution such as in 0.01 *M* sodium bisulfate. Under the latter condition the reaction is interfered with, however, by the sonically accelerated side reaction of the metal of the vibrator with the acid.[9]

The rate at which the production of hydrogen peroxide takes place in pure water is illustrated in Fig. 2. Under the conditions of these experiments the estimated power output of oscillator EM was approximately ten times that of MS, whereas for EM there was twenty times the volume of water to vibrate. The amounts of chemical change per unit of energy *output* from the two sources of sound therefore appear to be about the same, in spite of the frequency difference. The spray produced as a result of the vigorous cavitation apparently is sufficient to keep the solution adequately saturated with oxygen inasmuch as the concentration of hydrogen peroxide does not reach a constant value up to the maximum duration of treatment studied. Furthermore, a stream of air bubbling through the solution during treatment produced no detectable increase in the rate.

Iodine liberation, titrated by sodium thiosulfate as used by Liu and Wu,[4] did not yield any indication of measurable production of ozone. Hydrogen peroxide, determined by permanganate titration, was produced in sufficient quantity within the limits of experimental error to account for all the iodine liberated.

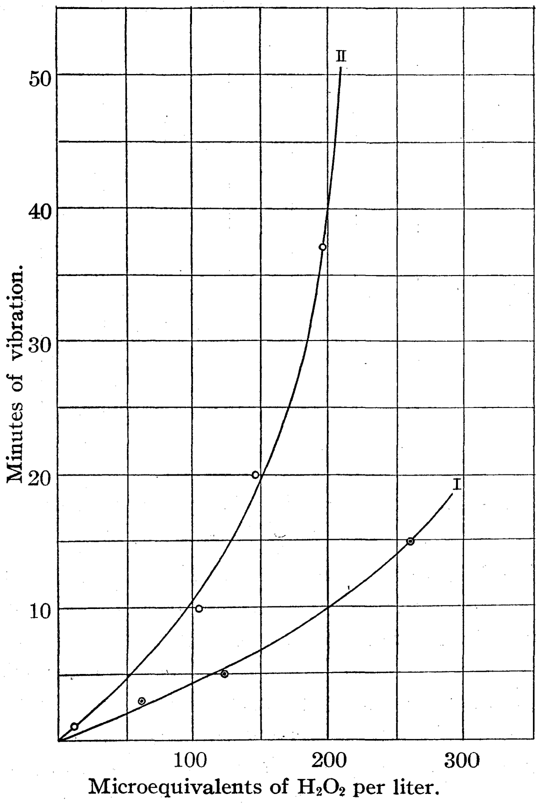

Fig. 2.—Treatment of pure water; Curve I, oscillator MS; Curve II, oscillator EM.

In alkaline solution, 0.002 *M* potassium permanganate is rapidly reduced to manganese dioxide as is to be expected on the basis of hydrogen peroxide formation. Reduction reactions of hydrogen peroxide do not lend themselves to quantitative study in the oscillators, however, because of the complicating factor introduced by the accelerated reduction reactions of the metal of the vibrators.[9] Oxidation reactions involving direct addition of oxygen therefore would seem to be simpler for study. Furthermore, in order to avoid any possible sonic action directly on a test reagent itself, analytical reagents in general

---

[12] J. W. Ellms and S. J. Hauser, *J. Ind. Eng. Chem.*, **5**, 915, 1030 (1913).

should not be added to test samples until after they are removed from sonic apparatus. We shall now proceed to the results obtained from oxidation reactions involving the addition of oxygen.

(2) **Sodium Bisulfite Oxidation.**—Sodium bisulfite oxidation has not been studied in the ultrasonic range. We have found it to be oxidized relatively rapidly in the audible range in either oscillator, the rate being dependent upon the molarity of the bisulfite. A typical result obtained in oscillator EM is illustrated in Fig. 3. In Table I it will be noted that with 0.04 molar bisulfite as much as 19.2 milli-equivalents per liter have been oxidized in sixty minutes which is about seventy times as fast as hydrogen peroxide has been shown to accumulate. Upon completion of the oxidation of the sodium bisulfite we have found hydrogen peroxide is produced at about the same rate as in sodium bisulfate solution.

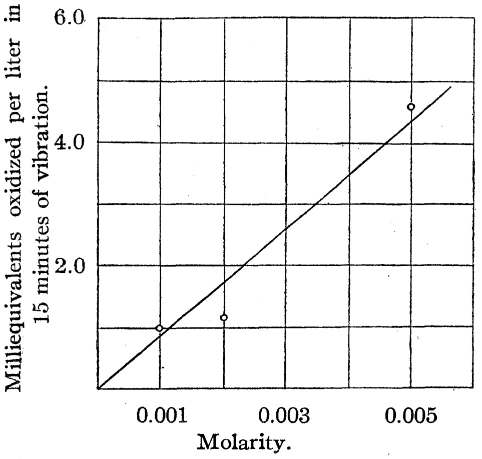

Fig. 3.—Oxidation of sodium bisulfite in oscillator EM.

Table I

Treatment of Sodium Bisulfite Solution, Oscillator MS

Molarity (approx.)	Duration, min.	Milli-equivalents oxidized per liter
0.0007	5	0.2
	15	.5
	60	1.4
.04	10	13.1
	60	19.2

Contrasted with the production of hydrogen peroxide in the two oscillators where the amounts of chemical change per unit of energy are approximately equal, the oxidation of bisulfite proceeds only about one-fifth as fast in oscillator MS as in EM. In oscillator EM there is much more vigorous spraying into the air. Because of the more rapid rate of the bisulfite reaction, this condition which controls the dissolution of oxygen to maintain the supply of gas in solution may be critical. Otherwise, we must assume that the difference in frequency is a factor in the oxidation of bisulfite and not of water.

(3) **Oxidation of Chlorides.**—In order to avail ourselves of the advantages of a system not sensitive to light, chloride was the halogen ion chosen for quantitative study. The rate of chlorine production (the test samples are acidified with the hydrochloric acid of the test reagent which completely liberates the chlorine from hypochlorite)[9] has been found to be dependent upon the concentration of chloride, Fig. 4, but not in as great degree as the bisulfite reaction. The amounts of chlorine found in solution increase with duration of treatment but reach a limiting concentration of the order of 7 to 8 microequiva-

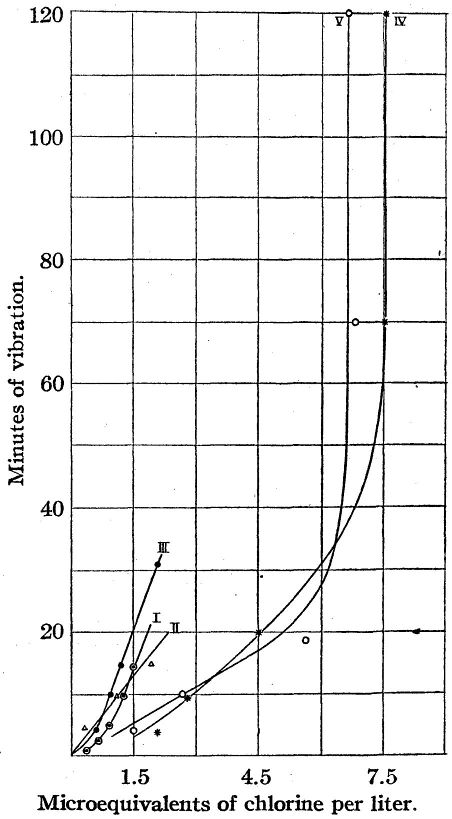

Fig. 4.—Oxidation of sodium chloride.

Chlorine determinations made after ten minutes of standing following vibration.

Oscillator MS, curve I, 0.5 Molar
Oscillator MS, curve II, 2.0 Molar

Oscillator EM, curve V, 5.0 Molar

lents per liter. This is probably a result of the loss of chlorine gas from solution. In solutions of high *p*H, oxidation of chloride is very slow. In neutral solution the *p*H increases slightly during treatment because of hypochlorite formation.[9]

The quantity of chlorine found in solution is in part dependent upon the length of time of standing before the test reagents are added, subsequent to treatment. With quantities produced under 0.3 micro-equivalent per liter, the amount is doubled after standing for ten minutes. With larger quantities the amount may be increased by as much as one micro-equivalent. This suggests that accumulated hydrogen peroxide may be responsible for at least the continued effect subsequent to removal of the solutions from the oscillators. In Fig. 5 the quantities of chlorine produced by known amounts of hydrogen peroxide and sodium chloride are given. Up to 100 micro-equivalents of hydrogen peroxide per liter would be required to produce the additional chlorine found in ten minutes of standing, which is consistent with the known rate of production of peroxide. That the rate of reaction of hydrogen peroxide with chloride is slow is evident from the fact that with 2 *M* sodium chloride and 1200 micro-equivalents of peroxide per liter, the amount of chlorine produced in ten minutes is 3.7 micro-equivalents per liter and in twenty minutes is 4.5. The effect of the concentration of chloride and of peroxide is shown in Table II.

TABLE II

EFFECT OF DILUTE HYDROGEN PEROXIDE SOLUTION ON SODIUM CHLORIDE

Concentration after mixing		Time of standing before testing, min.	Chlorine produced, micro-equivalents per liter
Hydrogen peroxide, micro-equivalents per liter	Sodium chloride, molarity		
6000	0	10	0.0
6000	2	10	6.5
1200	2	10	3.7
1200	1	20	2.5
1200	2	20	4.5
1200	5	20	7.9

It is further apparent, however, that the known rate of production of peroxide cannot account for all the chlorine formed. In ten minutes in oscillator EM, three micro-equivalents of chlorine per liter are produced from 2 *M* sodium chloride, which, on the basis of Fig. 5, would require 700 micro-equivalents of peroxide per liter for the intermediate step mechanism. We have never found in either oscillator more than 200 micro-equivalents of peroxide in ten minutes. Likewise, with oscillator EM, in thirty minutes 6000 micro-equivalents of peroxide per liter would be required to yield the observed amount of chlorine, yet there never were indications of more than 300. Furthermore, peroxide is produced at a higher rate per liter in oscillator MS and we should expect, accordingly, a greater production of chlorine in this oscillator were the intermediate peroxide step essential for the production of all the observed chlorine; but more chlorine is found in oscillator EM.

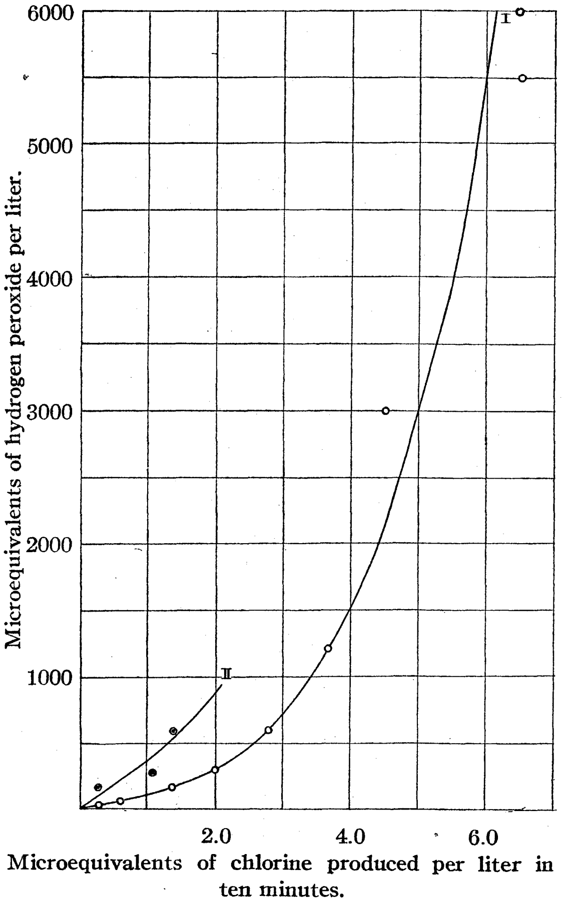

Fig. 5.—Reaction of dilute hydrogen peroxide solution with sodium chloride: curve I, 2 *M* sodium chloride; curve II, 1 *M* sodium chloride.

That sonically produced very dilute hydrogen peroxide solution can cause the production of chlorine is further evident from the data in Table III.

Water was treated by sound, removed from the apparatus after varying durations of treatment, and added to sodium chloride solution. As much as two micro-equivalents of chlorine per liter were produced. Sufficiently large samples can be ob-

Table III

Effect of Addition of Sound Cavitated Water to Sodium Chloride Solution

	400	20	147	88	2	10	1.0
	350	37	194	124	2	10	1.1

tained from oscillator EM to permit the determination of hydrogen peroxide as well as of chlorine and, within the limits of experimental error, the quantities of both which have been found agree with the values to be expected on the basis of Table II. It is again evident, however, that the hydrogen peroxide is produced in insufficient quantity to account for all the chloride that was found to be oxidized sonically.

The possibility has not been ruled out, however, that under the influence of sound, the reaction of sonically produced hydrogen peroxide with chloride is accelerated sufficiently to account for the twenty-fold increase in the rate of production of chlorine that takes place in the oscillators. On the basis of this mechanism, however, it is difficult to account for the more rapid production of chlorine in oscillator EM which takes place in spite of a lower rate of formation of peroxide. It would be difficult to understand how there could be a difference in degree of acceleration of peroxide reaction in the two oscillators because of the frequencies when there is apparently little or no frequency effect on the production of the peroxide.

The possibility that chloride-ion catalytically increases the production of peroxide to such an extent that the latter would oxidize chloride-ion at the observed rate does not seem to be tenable. This mechanism also would involve a frequency effect.

To us it seems rather that the twenty-fold increase in rate of chlorine production, and particularly the seventy-fold increase in rate of bisulfite oxidation, suggest the possibility of a chain reaction similar to that in the thermal and in the photochemical bisulfite reactions.[13] If so, this suggests the activation of oxygen and the chains should be breakable by the usual alcohol inhibitors. These possibilities are to be investigated further.

It would seem, therefore, that there are two concurrent reactions taking place in which chloride is oxidized, *viz.*, the direct oxidation with activated oxygen and secondary oxidation with sonically produced hydrogen peroxide. On this basis the curves in Fig. 4 would represent the total effect of the two reactions. The net result would seem to be that maintenance of an adequate supply of oxygen in solution becomes the critical factor which explains the difference in rates in the two oscillators, or else there is a frequency difference responsible for more rapid oxidation of chloride in oscillator EM. More probably it is a question of oxygen supply. The sonic spray is so effective in exposing solution surface to the air for dissolution of oxygen, however, that bubbling air through the solution produces no detectable effect.

(4) **Chlorate Production.**—After standing overnight, test samples of sonically cavitated chloride solutions continue to show the presence of one to two micro-equivalents of chlorine per liter, provided they have been stored in the presence of hydrochloric acid of the concentration used in the *o*-tolidine test. Solutions of chloride to which sonically cavitated water or hydrogen peroxide solution (up to 1000 micro-equivalents per liter) has been added do not continue to show chlorine after standing overnight, the gas having been completely lost. The gas remaining in solution the next day has been attributed to the slow production of chlorine from the hydrochloric acid and sonically produced chlorate. This has been confirmed qualitatively by the detection of minute amounts of chlorate in sonically treated chloride solution by reduction with sodium nitrite after removal of chloride and hypochlorite and subsequent precipitation of the reduced chlorate with silver nitrate.

(5) **Oxidation of Organic Compounds of Chlorine.**—We have determined also that organic chlorine compounds, such as chloroform and

---

[13] H. N. Alyea and H. L. J. Bäckström, This Journal, **51**, 90 (1929).

carbon tetrachloride, are oxidized as a result of sonic cavitation. Free chlorine and chloride ion are produced. Schmitt, Johnson and Olson[3] and Liu and Wu[4] have reported that a similar effect is obtained by ultrasonic vibration.

Sonic Chemiluminescence

The reaction by which light is produced as a result of the oxidation of "luminol" (3-aminophthalhydrazide) we have found to be interesting because it affords a visual confirmation of the importance of cavitation in sonic oxidation. We have determined that this reaction can be carried out sonically with dissolved oxygen gas as the only source of oxidant.

Harris and Parker[14] have shown that in the luminol reaction with hydrogen peroxide and another oxidant "the light-emitting molecule is a compound of sodium luminol and hydrogen peroxide, or this compound is the parent of the light-emitting molecule. The light-emitting molecule is brought to its energized state by reactions of the parent with some oxidizing molecule." We have found that as little as 50 micro-equivalents of hydrogen peroxide per liter is sufficient concentration to make the reaction visible in the dark without dark adaptation upon the part of the observer. It seemed reasonable, therefore, to expect luminescence by the sonic reaction in which the sound would be the sole energy source of hydrogen peroxide and oxidant. Two-tenths gram of luminol was dissolved in 20 ml. of 5% sodium hydroxide and 0.1 ml. of this stock solution in 10 ml. of distilled water was used for sonic vibration.

Upon vibration of such a solution either in oscillator MS or EM luminescence is easily visible. After allowing the observer's eyes to become dark-adapted for ten minutes the distribution of the light production becomes distinguishable. In addition to the bright glow to be seen at the top of the nickel tube (oscillator MS) streamers of light are observed to rise in spirals from the tube just as the cavitation vacuoles rise. Throughout the solution, points of light may be noticed and if these points of maximum intensity be marked and the electric lights switched on, it is seen that the spirals and the points of maximum light intensity correspond exactly with the positions of maximum cavitation. The light of greatest intensity apparently is produced in association with cavitation vacuoles.

The maximum luminescence is produced immediately or is made to vanish immediately with the turning on or off of the oscillator. After more prolonged and continuous vibration (five to ten minutes), however, a faint and homogeneous afterglow persists for five or ten minutes after the vibration ceases and it appears throughout the entire solution.

With the use of the vacuum vessel previously described in connection with the investigation of egg albumin,[11] luminescence is observed as described above. If after such vibration in which luminescence is produced, the solution in this vessel is boiled under vacuum (60 mm.) and thoroughly swept with nitrogen and finally left under one atmosphere of nitrogen, no luminescence can be observed upon subsequent sonic vibration although cavitation occurs as usual. If then this same solution is saturated once more with oxygen by bubbling air through it, luminescence is again visible as before upon sonic vibration.

It seems definitely established, therefore, that hydrogen peroxide is produced from dissolved oxygen and water upon sonic vibration and that this reacts with sodium luminol to form the light-emitting molecule or its parent substance. This parent is then brought to its energized state by reaction with some oxidizing substance. The much greater intensity of luminescence which occurs at the cavitation surface than that found existing as a faint afterglow throughout the body of the solution after more prolonged vibration (the latter presumably being entirely due to accumulated hydrogen peroxide) indicates that the oxidizing substance which brings the parent molecule to its energized state is being produced in these regions. The substance may be either activated oxygen or newly formed hydrogen peroxide in high concentrations in thin layers, as yet unmixed, or both. By analogy with the oxidation of chloride, we could expect reaction of the parent substance with both activated oxygen and with hydrogen peroxide. This greater intensity of luminescence at the cavitation surfaces by reaction with activated oxygen is analogous to that produced by potassium ferricyanide (without sonic vibration), in which case the parent substance is produced with as little as 50 micro-equivalents of hydrogen peroxide per liter.

Discussion

It is obvious from theoretical considerations

---

[14] Louis Harris and A. S. Parker, THIS JOURNAL, **57**, 1939 (1935).

that the activation of dissolved oxygen may not be attributed to sound waves *per se* in the fluid. Furthermore, the experimentally established fact that such activation occurs only during sonic cavitation of the liquid and only in the immediate vicinity of such disruptive disturbances, indicates that we must be dealing with a phenomenon not easily amenable to theoretical treatment. From the evidence at hand we may conclude that oxygen is brought into a reactive state during some phase of cavitation through a process not understood at present. The activated oxygen is then free to react with either solute or solvent molecules. A similar conclusion was drawn by Schmitt, Johnson and Olson,[3] and by Liu and Wu[4] from experimental data relative to oxidations promoted by ultrasonic cavitation.

That oxygen is not the only gas capable of activation during cavitation of its solvent has been demonstrated in previous papers. For example it already has been shown[10,11] that egg albumin is denatured by sonic cavitation in the presence of carbon dioxide as well as oxygen, while in the presence of nitrogen or hydrogen, or in gas free solution, no denaturation occurs even during vigorous cavitation.

One may assume perhaps that molecules of the high energy necessary to permit the formation of hydrogen peroxide from molecular oxygen and water are created during sonic cavitation through a process of ionization or excitation. While no theoretical justification for such an hypothesis can be drawn from acoustical theory it should be remembered that, in the events accompanying cavitation, we are not dealing with acoustical phenomena *per se*. As a matter of fact the recent observation by Chambers[15] that visible light is emitted from pure polar liquids during cavitation by sound waves of the same amplitude as those used in our experiments lends credibility to the supposition that excitation or ionization may actually be occurring.

Whatever the mechanism it would appear from the evidence in hand that activation of oxygen during cavitation offers the best explanation for the chemical changes recorded in our experiments. With improvements in apparatus it should be possible to obtain further data which will permit calculation of the reaction orders and to carry out experiments of greater theoretical significance. Some means of estimating quantitatively the relative degrees of sonic cavitation produced in liquids and means for experimental variation of this factor will ultimately be necessary.

Acknowledgment.—We wish to express our appreciation to Mr. David Lackman for the assistance he has given in the chlorine determinations.

Summary

Quantitative studies of the oxidation of water and of sodium bisulfite and sodium chloride in aqueous solution by cavitation produced at audible frequencies have been carried out. The data indicate that the oxidations are accomplished through the production of activated oxygen in association with cavitation. It was determined that a compound of sodium luminol and sonically produced peroxide may be energized to produce chemiluminescence in the absence of the usual secondary oxidants, the reaction giving visual confirmation that chemical activation occurs during sonic cavitation. The results represent an elaboration of earlier work in the audible range and an extension to the audible of effects previously observed in the ultrasonic range. Some effects new at either range have been reported and certain theoretical conclusions have been drawn which probably are general for all frequencies.

The Ternary Systems KI–K_2SO_4–H_2O and NaI–Na_2SO_4–H_2O

BY JOHN E. RICCI

In addition to the purpose of obtaining solubility data for the salt pairs KI–K_2SO_4 and NaI–Na_2SO_4 in water, this brief investigation also had as its object the question of the formation of solid solutions of the alkali iodides in the corresponding sulfates. The crystals of sodium sulfate offer a considerable number of instances of the formation of solid solutions with other salts (as, with Na_2CO_3, Na_2CrO_4, Na_2S, Na_2SO_3, $Na_2S_2O_3$, Ag_2SO_4,[1] and $NaBrO_3$[2]). As to the iodides in particular, sodium sulfate has been reported[3] to form crystals of $Na_2SO_4 \cdot 10H_2O$ containing varying quantities of NaI, KI, NH_4I and LiI, held in the form of solid solution; these results, however, are based on non-equilibrium studies, in which the decahydrate was allowed to crystallize slowly from solutions of varying concentrations of the iodides, at a roughly constant temperature near room temperature. Although the fact that such crystals contain iodide (from 0.4% in the case of NaI, to 0.65% for LiI) may well be the result of simple occlusion due to lack of equilibrium, the crystals are reported to be solid solutions ("mixed crystals") on the strength of their clearness and transparency. Since on the basis of such work there seemed to be some doubt as to the actual existence of such solid solutions as stable phases in the systems, it was thought desirable to make an equilibrium study of the particular system NaI–Na_2SO_4–H_2O.

In the present work both the system KI–K_2SO_4–H_2O and the system NaI–Na_2SO_4–H_2O were studied, from the point of view of the phase rule, the first at 25°, the second at 15, 25 and 45°. The results, which represent equilibrium in the systems, show no solid solutions to be formed in either case, within the limits of the rather small experimental error of this type of work. The only solid phases encountered are the pure anhydrous or hydrated salts themselves.

Experimental Method

The experimental procedure for the solubility measurements has already been described in previous similar publications.[4] The temperature was maintained constant to within ±0.02°. The time allowed for the attainment of equilibrium varied from three days in the case of the potassium salts, to as long as fourteen days in the case of the sodium salts; the latter system was found by experiment to require from ten to fourteen days to reach equilibrium in all complexes which involved the formation of $Na_2SO_4 \cdot 10H_2O$ as solid phase. The densities reported for the potassium salt system and for some solutions of the sodium salt system, were obtained by means of volumetric pipets calibrated for delivery. For the analysis of the solutions, the iodide was determined volumetrically by titration with 0.2 *N* silver nitrate using dichlorofluorescein as indicator, the total solid was determined by evaporation to dryness, and the sulfate was then calculated by difference. In some cases of the KI–K_2SO_4–H_2O system the sulfate was determined directly by the gravimetric method, and the iodide then calculated by difference. The results of the two methods being in sufficiently close agreement, the more rapid method (titration of the iodide) was used in general. The solid phases were in each case verified by the method of algebraic extrapolation of tie-lines,[5] the average error of the extrapolations, for both systems, being 0.18%.

Results

The experimental data for the system KI–K_2SO_4–H_2O at 25° are given in Table I and Fig. 1;

[a] The data for the 45°, and for part of the 25°, isotherms were obtained by Dr. Nicholas S. Yanick, formerly of this Department. [b] m = metastable solid phase.

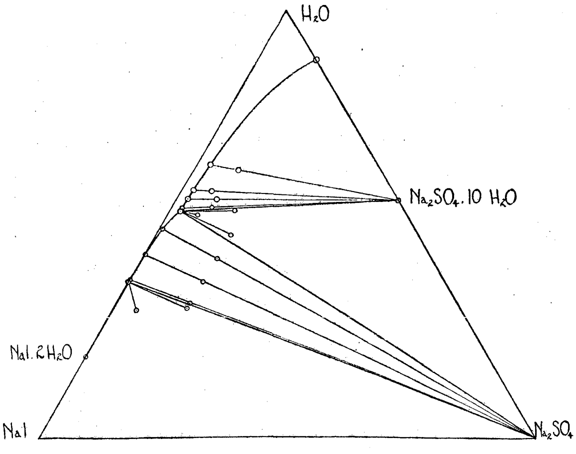

Fig. 2.—15° Isotherm: $NaI-Na_2SO_4-H_2O$.

15 and 25°, $Na_2SO_4 \cdot 10H_2O$ appears, giving three stable phases. In Fig. 3, for the 25° isotherm, the curve a-b represents the solubility of $Na_2SO_4 \cdot 10H_2O$ as stable phase in the ternary system; point b, an isothermally invariant solution in equilibrium with both hydrated and anhydrous Na_2SO_4; the curve b-c, solutions in equilibrium with anhydrous Na_2SO_4 as solid phase; point c, the isothermally invariant solution for the two solid phases Na_2SO_4 and $NaI \cdot 2H_2O$; and the very short curve c-d, the solubility curve of $NaI \cdot 2H_2O$. The curve b-e is the metastable extension of the solubility curve b-c, of Na_2SO_4, point e being the metastable solubility of anhydrous Na_2SO_4 in water at 25°.

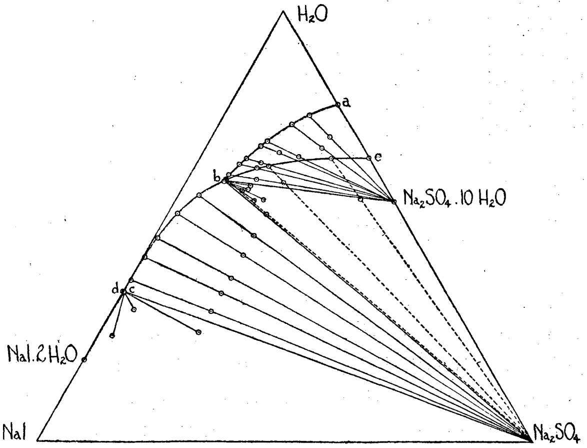

Fig. 3.—25° Isotherm: $NaI-Na_2SO_4-H_2O$.

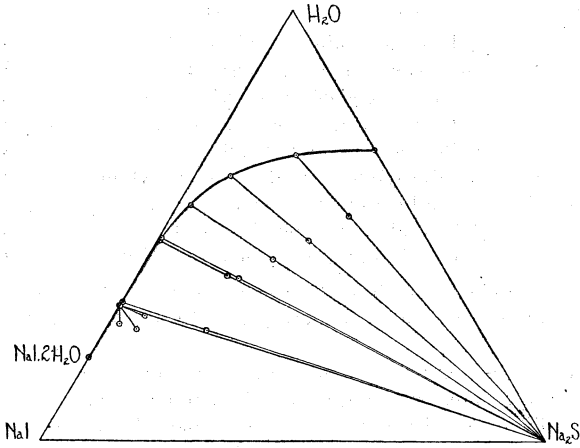

Fig. 4.—45° Isotherm: $NaI-Na_2SO_4-H_2O$.

Acknowledgment.—The author wishes to express his thanks to Dr. Nicholas S. Yanick, formerly of this Department, for his help in some of the experimental work of this paper.

Summary

Solubility measurements are given for the systems $KI-K_2SO_4-H_2O$ (at 25°) and $NaI-Na_2SO_4-H_2O$ (at 15, 25 and 45°); these salt pairs form neither double salts nor solid solutions at the temperatures reported.

Phenyl Urethan Anesthetics. II

BY E. S. COOK AND T. H. RIDER

The value of phenyl urethans as local anesthetics has been pointed out by Rider.[1] The present paper continues work in this field and deals largely with phenyl urethans of γ-dialkylaminopropanols ($R_2NCH_2CH_2CH_2OH$). Two esters of dialkylaminoisopropyl alcohols ($R_2NCH_2CHOHCH_3$) and the phenyl urethan of β-diethylaminoethanol are included.

These compounds are of particular interest because they are isomeric with the *p*-aminobenzoates, several of which have found considerable use as local anesthetics. The *p*-aminobenzoate homologs of compounds 4 and 9 (see Table I) are marketed as butyn and procaine, respectively, and the *p*-aminobenzoate homologs of compounds 2, 3,[2] and 6[3] have been prepared and found to possess local anesthetic activity.

Experimental Part

Amino Alcohols.—Beta-diethylaminoethanol, γ-diethylaminopropanol, and γ-di-*n*-butylaminopropanol were obtained from the Eastman Kodak Company and redistilled. The other γ-dialkylaminopropanols (dimethylamino-, di-*n*-propylamino-, piperidino- and methylphenethylamino-) were prepared by condensing the proper secondary amine with trimethylene bromohydrin in the absence of a solvent.

8	1-Piperidinopropanol-2-phenyl	$C_{15}H_{23}O_2N_2Cl$	11.87	11.23	11.17[b]	88–89.5
9	β-Diethylaminoethylphenyl[c]	$C_{13}H_{21}O_2N_2Cl$	13.00	13.04	13.05	142.5–143.5

[a] Previously prepared by Rider, ref. 1b. [b] Difficult completely to free from solvent. [c] Previously prepared by Rider[a] and reported by Fromherz [*Arch. Exptl. Path. Pharmakol.*, **76**, 257 (1914)]; m. p. given as 138–139°.

All were heated under reflux except dimethylamine (used as the 33% aqueous solution) which required a sealed tube. Usually no condensing agent was employed, but potassium carbonate was used successfully in several cases. The reaction mixtures were treated with potassium hydroxide solution, extracted repeatedly with ether, dried over potassium hydroxide, and the ether was removed. The alcohols were distilled either *in vacuo* or at atmospheric pressure. All of these alcohols are recorded in the literature with the exception of γ-(methylphenethyl)-aminopropanol. For this alcohol the methylphenethylamine was prepared from β-phenylethylamine, benzaldehyde, and methyl iodide by the method of Decker and Becker[4] with modifications suggested by Buck.[5] The amine was condensed with trimethylene bromohydrin as above. γ-(Methylphenethyl)-aminopropanol is a rather viscous, water-white liquid with a very slight violet fluorescence. It distils at 155–157° at 12 mm.

Anal. Calcd. for $C_{12}H_{19}ON$: N, 7.25. Found: N, 7.01.

1-Diethylamino- and 1-piperidinopropanol-2 were prepared by condensing the amines with propylene oxide. A sealed tube was necessary for the diethylamine but not for the piperidine. This method, which apparently has not been applied before to the preparation of these two compounds, gave 80% yields of amino alcohols, identical in all properties with those obtained from the corresponding chloro- or bromohydrin.

Phenyl Urethan Hydrochlorides.—Equimolar quantities of the amino alcohol and phenyl isocyanate were refluxed in absolute ether until disappearance of the odor of phenyl isocyanate. After cooling the reaction mixture, the hydrochloride was precipitated by adding a solution of hydrogen chloride in dry ether. The hydrochloride usually precipitated as a solid but 1-piperidinopropanol-2-phenyl urethan hydrochloride came down as an oil and considerable difficulty was encountered in crystallizing it. All the hydrochlorides were crystallized from a mixture of ethyl acetate and acetone except the γ-(methylphenethyl)-amino compound which was purified from absolute alcohol. The melting points and analyses of the compounds are given in Table I.

Pharmacological Properties.—In Table II data relative to the local anesthetic activity and toxicity of these compounds are given. All tests were made with 1% solutions of the hydrochlorides in distilled water. The third and fourth columns give the time in minutes required for the production of sensory and motor anesthesia in the exposed sciatic nerve of the frog.[6] The fifth column gives the duration of anesthesia after a one-minute application of the solution to the cornea of the rabbit.[6] Column six gives the approximate minimum lethal dose in milligrams per kilo by subcutaneous injection into guinea pigs.

TABLE II

PHARMACOLOGICAL PROPERTIES

Compound	*p*H, 1% Solution (quinhydrone electrode)	Time of onset of anesthesia, min. Sensory	Motor	Duration of anesthesia, min. Cornea	Toxicity mg./kg.
Cocaine	5.10	4	14	30	60
Procaine	5.50	6	18.5	Incomplete	400
1	5.82	6	36.5	Incomplete	..
2	5.98	3.5	27	14	150
3	6.46	2.75	21.75	24.5	150
4	5.93	2	10.5	65.5	150
5	5.88	3	16.5	17	150
6	5.40	3	28.75	91.5	75
7	6.48	3.25	16.5	16	150
8	5.47	3	25.5	35	200
9	6.25	3.75	14	11	150

It will be observed that the two derivatives of isopropyl alcohol (7 and 8) show some superiority over their primary alcohol isomers (2 and 5) in anesthetic activity and are less toxic as well. The one compound here reported with two dissimilar alkyl groups on nitrogen (6) has the highest anesthetic activity of the compounds tested but is extremely toxic. An increase in anesthetic power is found as the size of the nitrogen alkyls increases behavior which is duplicated in other series of anesthetics, but no progressive increase in toxicity is observed. The surprising similarity in toxici-

ties of these compounds is worthy of comment. The results were checked several times and are believed to be accurate within 30%. The diethylaminoethylphenyl urethan is less active than either of the propanol homologs, which, again, is in accord with previous observations on the influence of the length of the alcohol chain, but it is no less toxic. The propanol compounds are more effective on the exposed nerve, by the test which measures onset time rather than duration, than the corresponding mono- and diphenyl urethans of dialkylamino propanediols[1a] but the reverse is usually true with respect to corneal anesthesia. Other comparative tests indicate that the diphenyl urethans of propanediols (such as diothane) are more effective as topical anesthetics, and while giving a slower onset time likewise give considerably more prolonged duration of anesthesia following intradermal injection.

The phenyl urethans here reported are more active on the rabbit's cornea than such of the isomeric *p*-aminobenzoates as have been prepared and tested.[2,3] This same behavior has been observed for the corresponding esters of piperidinopropanediol[7] as well as for the phenyl urethan and *p*-aminobenzoate of 2-diethylamino-3-hydroxy-1,2,3,4-tetrahydronaphthalene.[8] These facts prompt the suggestion that the phenyl urethan configuration confers more topical anesthetic activity upon a molecule than does the isomeric *p*-aminobenzoate group.

Acknowledgment.—We wish to thank Dr. R. S. Shelton for assisting in the pharmacological work and Mr. Karl Bambach for the analyses.

Summary

The phenyl urethans of a number of dialkylaminopropanols have been prepared and shown to have local anesthetic properties. It is suggested that the phenyl urethan group is more active in causing anesthesia of the mucous surfaces than the isomeric *p*-aminobenzoate group.

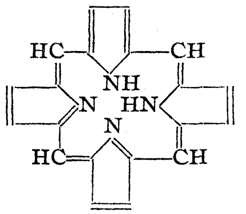
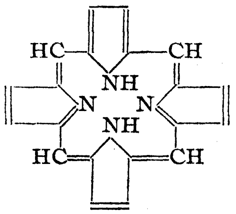
Studies in the Pyrrole Series. I. The Preparation of Certain N-Methyl Pyrroles[1]

BY ALSOPH H. CORWIN[2] AND WM. M. QUATTLEBAUM, JR.[3]

If we accept Küster's formulation of the porphyrin nucleus as proved and exclude "resonance isomers," the following isomeric forms should be possible





These will be referred to as N-isomers.

Fischer[4] has suggested the simpler possibility of N-isomerism in di-pyrryl methenes but has not demonstrated its existence. Since N-isomers of the salts of methenes with mineral acids would be "resonance isomers," a separation should be achieved only by fractionation of the free bases. Likewise with the porphyrins, the salts with acids would be "resonance isomers." As a result we should not expect to find examples of N-isomerism among the synthetic porphyrins made by acid melts unless the free bases had been fractionated subsequently by a procedure not involving the use of acid. Conant and Bailey[5] have pointed out that differences between N-isomers should be destroyed by conversion into metallic complexes but found no porphyrins which exhibited this phenomenon.

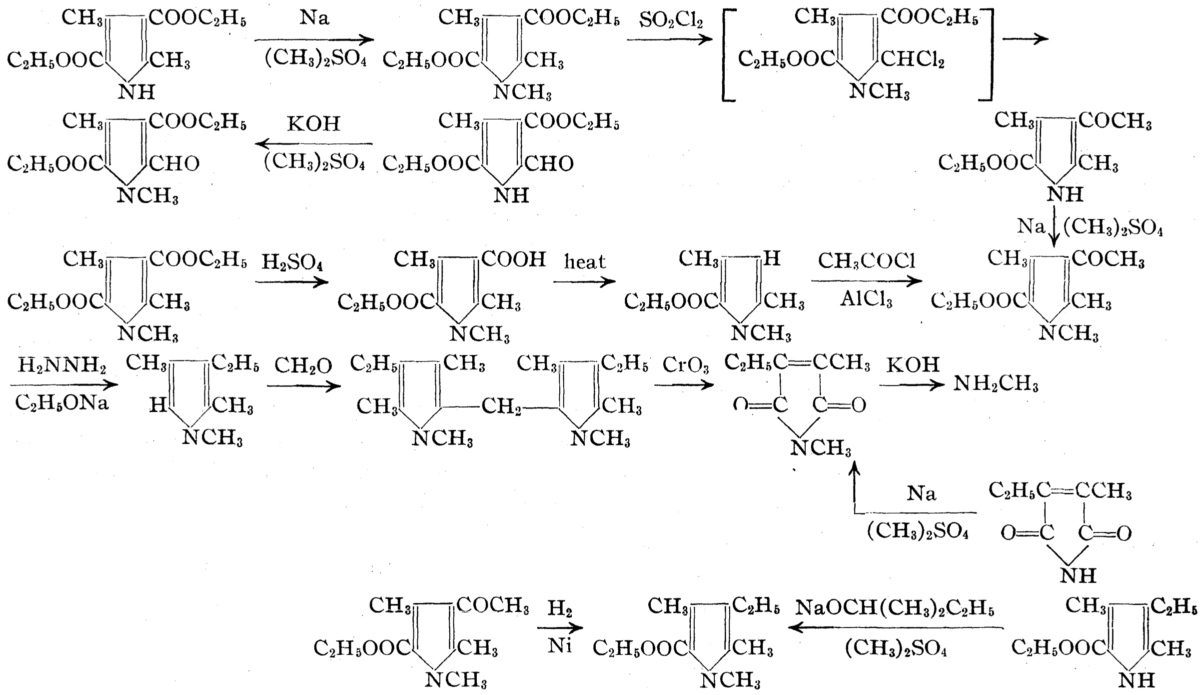
[5] Conant and Bailey, THIS JOURNAL, **55**, 796 (1933).

An examination of a space model of a porphyrin suggests the possibility that the adjacent secondary and tertiary nitrogens might be joined by a hydrogen bridge.

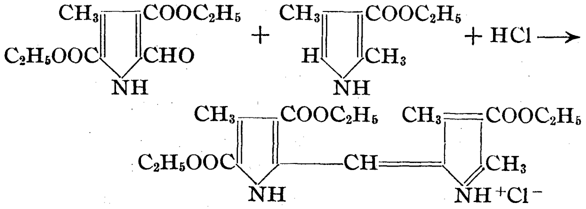
In such a case the predicated N-isomerism would not appear but might give way to another type in which the H bridges exchanged their partners.[6] Substitution of a functional group for hydrogen would destroy the latter isomerism and create the appearance that the original porphyrins were N-isomers.

To test the theoretical considerations presented, the question of N-isomerism is being submitted to experimental examination. It is proposed to synthesize porphyrins from compounds suited to the determination of the positions of the methylated nitrogens with reference to the unmethylated nitrogens. It is then proposed to N-methylate porphyrins and to compare the products with those prepared by synthesis. The first phase of this problem is the preparation and proofs of the structures of certain N-methyl pyrroles. Starting with Knorr's pyrrole (2,4-dimethyl-3,5-dicarbethoxypyrrole) the following interrelationships have been established



That the methyl group remains attached to nitrogen through all these reactions is shown by the fact that methylamine free from ammonia is obtained by the hydrolysis of N-methylmethylethylmaleic imide. The di-N-methyldipyrrylmethane indicated is the first completely alkylated dipyrrylmethane to be obtained by condensation with formaldehyde, despite many attempts.[7]

The second phase of the problem was the synthesis of N-methyl methenes. Since the simplest unsymmetrical methene containing carbethoxy groups rather than ethyl was unknown, it was prepared by the condensation



In this instance it was necessary to modify the usual methods for the preparation of methenes which failed due to the instability of this methene in solution.

The three possible combinations of the N-methyl homologs of the pyrroles in this condensation failed to yield methenes. That this failure

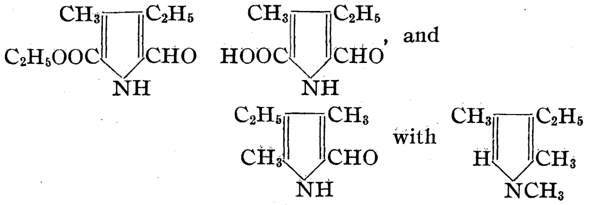
---

(6) The authors are indebted to Dr. Maurice L. Huggins for suggesting and critically examining the possibility of the existence of H bridges.

(7) Fischer and Bartholomäus, *Z. physiol. Chem.*, **83**, 50 (1913); Fischer and Eismayer, *Ber.*, **47**, 2021 (1914); Fischer and Nenitzescu, *Ann.*, **443**, 123 (1925); Fischer, Halbig and Walach, *ibid.*, **452**, 287 (1927).

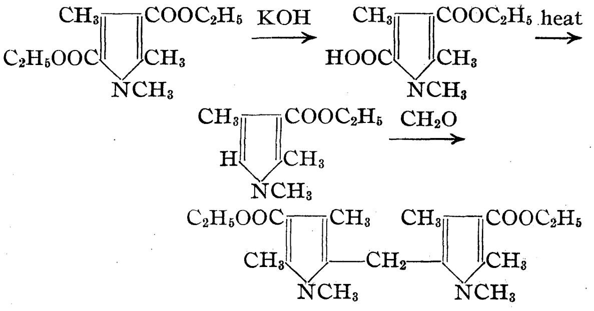
was due to a different type of reaction than that usually formulated will be shown in a separate communication.

To take advantage of the greater tendency toward methene formation exhibited by pyrroles containing only alkyl groups in the β-positions, the following combinations were tried



None of these yielded N-methyl methenes.

The failure of the aldehyde condensation led to an examination of the other general methods for methene synthesis. A di-N-methyldipyrrylmethane was prepared by the reactions



Neither the oxidation of this methane nor that of the hexamethyldiethylmethane mentioned earlier yielded a methene. The reactions of 1,2,4-trimethyl-3-carbethoxy and 1,2,4-trimethyl-3-ethylpyrroles with bromine and with formic acid again failed to yield methenes. Finally, attempts to methylate 3,5,3′,5′-tetramethyl-4,4′-dicarbethoxydipyrrylmethene were unsuccessful.

Our failure to obtain N-methylmethenes suggests the desirability of subjecting the various methene syntheses to careful scrutiny and commends to attention the possibilities of the synthesis of N-methylporphyrins by methods not involving the use of dipyrrylmethenes.

The authors are indebted to Mrs. G. Ware Wellwood for performing many of the microanalyses reported in this paper.

Experimental Part

2,4-Dimethyl-3,5-dicarbethoxypyrrole.[8]—The yield may be improved by adding sodium acetate to the zinc dust reduction to form a complex with zinc acetate and thus increase its solubility,[9] and by adding the solution of the nitroso compound to the mixture of zinc dust, sodium acetate, ethyl acetoacetate and glacial acetic acid instead of adding zinc dust to the other compounds; yield 75%.

1,2,4 - Trimethyl - 3,5 - dicarbethoxypyrrole.—Twenty-eight grams of sodium wire, 200 g. of 2,4-dimethyl-3,5-dicarbethoxypyrrole and two liters of toluene were heated with stirring for four hours on a steam-bath. The sodium salt of the pyrrole separated as a white curdy precipitate. Ninety cc. of freshly distilled dimethyl sulfate was then added dropwise and stirring and heating continued for another hour. The sodium methyl sulfate was filtered off and washed with toluene. The toluene was removed from the filtrate by steam distillation. On cooling the pyrrole crystallized out; yield 85–90%. The product may be recrystallized from methanol and water or from methanol alone by cooling with dry ice; m. p. 113–114°.

Anal. Calcd. for $C_{13}H_{19}O_4N$: C, 61.62; H, 7.56; N, 5.53. Found: C, 61.84; H, 7.95; N, 5.74.

As an alternative the sodium salt may be formed by the action of sodium tertiary amylate in tertiary amyl alcohol and subsequently methylated with dimethyl sulfate. The yield by this method was the same.

1,4 - Dimethyl - 2 - formyl - 3,5 - dicarbethoxypyrrole.—(a) Five grams of 2-formyl-3,5-dicarbethoxy-4-methylpyrrole was dissolved in a solution of 1.1 g. of potassium hydroxide in 11 cc. of methyl alcohol. Two and one-half cc. of dimethyl sulfate was added slowly below 50°. The mixture was allowed to stand for half an hour and cooled to crystallize the N-methyl aldehyde. The aldehyde was filtered off, washed with water and crystallized from methanol, m. p. 94°. This is the procedure of choice in quantity preparations.

(b) Twenty-five and three-tenths grams of 1,2,4-trimethyl-3,5-dicarbethoxypyrrole was dissolved in 127 g. of glacial acetic acid and 27 g. of sulfuryl chloride added slowly at 60°. The temperature was maintained for half an hour and the flask then cooled to 20° to permit crystallization of the aldehyde. Less pure product may be obtained by precipitating the mother liquor with water; m. p. 93°; mixed m. p. with aldehyde obtained in (a) 93°.

Anal. Calcd. for $C_{13}H_{17}O_5N$: C, 58.39; H, 6.41. Found: C, 58.34; H, 6.44.

1,2,4 - Trimethyl - 3 - carboxyl - 5 - carbethoxypyrrole.—The procedure was essentially that of Fischer and Walach[10] for the lower homolog. Twenty-five grams of 1,2,4-trimethyl-3,5-dicarbethoxypyrrole was added to 100 cc. of concd. sulfuric acid and the temperature kept below 30°: recovery 3 g.; yield 60% of the remainder; decomposition point 192°.

Anal. Calcd. for $C_{11}H_{15}O_4N$: C, 58.63; H, 6.71. Found: C, 58.99; H, 6.91.

1,2,4 - Trimethyl - 5 - carbethoxypyrrole.—The decarboxylation of the preceding compound was carried out as rapidly as possible in three times its weight of anhydrous glycerine;[11] yield 75%; m. p. 47°. The substance has a peculiar, sickening, sweetish odor.

Anal. Calcd. for $C_{10}H_{15}O_2N$: C, 66.25; H, 8.34. Found: C, 65.92; H, 8.34.

1,2,4 - Trimethyl - 3 - acetyl - 5 - carbethoxypyrrole.—(a) The best method for the preparation of this compound is the methylation of 2,4-dimethyl-3-acetyl-5-carbethoxypyrrole by the method given for 1,2,4-trimethyl-3,5-dicarbethoxypyrrole; yield 80%; m. p. 62° after recrystallization from ligroin.

(b) The preparation from 1,2,4-trimethyl-5-carbethoxypyrrole by the Friedel–Crafts reaction follows that of the lower homolog;[12] yield 25% after recrystallization; m. p. 60–61°; mixed m. p. with product from (a) 61°.

Anal. Calcd. for $C_{12}H_{17}O_3N$: C, 64.53; H, 7.67. Found: C, 64.46; H, 7.54.

1,2,4-Trimethyl-3-ethylpyrrole.—The procedure for preparing this from 1,2,4-trimethyl-3-acetyl-5-carbethoxypyrrole follows essentially that of Fischer, Baumann and Riedl.[13] The substance is sensitive to oxidation and should be protected by nitrogen; yield 55%; b. p. 93° at 23 mm.

Anal. Calcd. for $C_9H_{15}N$: C, 78.75; H, 11.02. Found: C, 77.85; H, 10.45.

(It appeared that this analytical discrepancy was due to the rapidity with which the substance oxidized during the weighing process.)

1,3,5,1′,3′,5′ - Hexamethyl - 4,4′ - diethyl - 2,2′ - dipyrrylmethane.—Success in preparing this compound depends upon the absence of mineral acid. The acid necessary for condensation was supplied by using old formalin which had accumulated enough formic acid to give an acid reaction to litmus.

One gram of N-methylcryptopyrrole, 2 cc. of 95% ethyl alcohol and 0.5 cc. of 40% formalin solution were stirred together without warming. The methane separated in colorless crystals. The precipitate was filtered off, washed and crystallized from methanol. It was very sensitive to air and was dried in a vacuum and stored under nitrogen; m. p. 106°.

Anal. Calcd. for $C_{19}H_{30}N_2$: C, 79.65; H, 10.56. Found: C, 79.80; H, 10.67.

N-Methylmethylethylmaleic Imide.—(a) Two grams of 1,2,4-trimethyl-3-ethylpyrrole was suspended in a saturated aqueous solution of 8 g. of CrO_3 and 50 cc. of 20% sulfuric acid added drop by drop at 60°. The flask was kept at 70° for several hours with occasional stirring and rubbing of the resinous precipitate. The solution was cooled, extracted five times with ether, the extract washed with water, dilute soda solution and again with water, dried and distilled. The imide was a colorless oil; b. p. 215–220°.

(b) 1,3,5,1′,3′,5′ - Hexamethyl - 4,4′ - diethyl - 2,2′ - dipyrrylmethane was oxidized according to the above procedure. N-methylmethylethylmaleic imide was isolated. When saponified according to the directions below and tested for ammonia the latter was found to be absent. CH_3NH_3Cl was isolated; m. p. 226–227°; mixed m. p. with CH_3NH_3Cl, 227°.

(c) One and four-tenths grams of methylethylmaleic imide was dissolved in 20 cc. of toluene and treated with 0.46 g. of sodium and then 2.52 g. of dimethyl sulfate according to the procedure for 1,2,4-trimethyl-3,5-dicarbethoxypyrrole. The toluene was removed by vacuum fractionation. The imide boiled at 215–221°.

Hydrolysis Procedure.—Two 50-cc. distilling flasks were connected through their side-arms with a small condenser. The first flask was provided with an ebullition tube, the second with a stopper containing a 12 in. length of 12 mm. glass tubing which dipped below a few cc. of distilled water in the flask. The imide was placed in the first flask with 20 cc. of normal sodium hydroxide solution and the apparatus tilted so that the condenser acted as a reflux during the hydrolysis. The solution was boiled for an hour, the apparatus tilted toward the second flask and the amine distilled slowly until most of the water had passed over. The liquid in the receiver was then tested for ammonia and methylamine by Thatcher's test.[14] No ammonia was found. A portion of the distillate was neutralized with hydrochloric acid and evaporated to dryness. A test portion of the residue was found to be completely soluble in absolute alcohol previously saturated with ammonium chloride. The residue was crystallized from hot absolute alcohol and ether; m. p. 227°; mixed m. p. with CH_3NH_3Cl, 227°.

1,2,4 - Trimethyl - 3 - ethyl - 5 - carbethoxypyrrole.—(a) This product may be prepared by the catalytic hydrogenation of 1,2,4-trimethyl-3-acetyl-5-carbethoxypyrrole in alcoholic solution with Raney's catalyst,[15] at 2500 pounds per sq. in. pressure and 150°. The pyrrole distilled at 124° at 2 mm. This is the method of choice in the preparation.

(b) The substance may be prepared by methylation of 2,4-dimethyl-3-ethyl-5-carbethoxypyrrole by the tertiary amylate method mentioned for 1,2,4-trimethyl-3,5-dicarbethoxypyrrole, b. p. 120–125° at 2 mm. Comparison of b. p. with product from (a) in the same apparatus shows them to be identical.

Anal. Calcd. for $C_{12}H_{19}O_2N$: C, 68.90; H, 9.09. Found: C, 68.65; H, 9.04.

3,5,4′ - Tricarbethoxy - 4,3′,5′ - trimethyl - 2,2′ - dipyrrylmethene.—Attempts to prepare this compound by any of the methods employed by Fischer for methene syntheses were unsuccessful. It was finally prepared by using cold ether as a solvent for the reaction and dry hydrogen chloride gas as a catalyst. The methene was so insoluble in ether that it crystallized out as rapidly as formed. It was then found that the earlier failures to obtain this methene were due to the fact that it decomposed when dissolved in alcohol or glacial acetic acid. In fact, this methene was not stable in any solvent which was investigated.

Two and five-tenths grams of 2-formyl-3,5-dicarbethoxy-4-methylpyrrole and 1.67 g. of 2,4-dimethyl-3-carbethoxypyrrole were dissolved with warming in 175 cc. of dry ether. The mixture was cooled to 10° and dry gaseous hydrogen chloride passed in for fifteen to twenty minutes. The solution was allowed to stand at 0° for several hours, the methene filtered off and washed with ether. Brilliant

[15] Raney, THIS JOURNAL, **54**, 4116 (1932); Signaigo and Adkins, *ibid.*, **58**, 710 (1936).

yellow needles were obtained. The crystals changed color at 120° and sintered gradually as the temperature was raised. The substance could not be recrystallized satisfactorily. When dissolved in cold toluene and plunged quickly into dry ice, crystals separated which were less pure than the starting product. When this methene was boiled in alcohol it decomposed to give 2-formyl-3,5-dicarbethoxy-4-methylpyrrole, m. p. 124°, and a residue which has not been identified.

Anal. Calcd. for $C_{21}H_{27}O_6N_2Cl$: C, 57.44; H, 6.20. Found: C, 58.01, 57.95; H, 6.20, 6.65.

The analytical discrepancy indicates an impurity which differs from the aldehyde used, because this has less C and H than the methene, and which probably is not 2,4-dimethyl-3-carbethoxypyrrole since this should have been removed by the ether wash used. Hence we feel that the discrepancy needs further investigation.

The attempted condensations of aldehydes and α-unsubstituted pyrroles to give N-methylmethenes followed the directions given above. The combinations tried were 2-formyl-3,5-dicarbethoxy-4-methylpyrrole with 1,2,4-trimethyl-3-carbethoxypyrrole; 1,4-dimethyl-2-formyl-3,5-dicarbethoxypyrrole with 2,4-dimethyl-3-carbethoxypyrrole and with 1,2,4-trimethyl-3-carbethoxypyrrole; 1,2,4-trimethyl-3-ethylpyrrole with 2-formyl-3-ethyl-4-methyl-5-carbethoxypyrrole, with 2-formyl-3-ethyl-4-methyl-5-carboxylpyrrole, and with 2-formyl-3,5-dimethyl-4-ethylpyrrole. These condensations led to reddish or purple oils.

1,2,4 - Trimethyl - 3 - carbethoxy - 5 - carboxylpyrrole.—Twenty-six grams of potassium hydroxide was dissolved in 300 cc. of 95% alcohol and 105 g. of 1,2,4-trimethyl-3,5-dicarbethoxypyrrole added and refluxed for two and one-half hours. The solution was poured into cold water, talc added and filtered. The pyrrole acid was precipitated with hydrochloric acid, filtered off and dried, yield 90%.

Anal. Calcd. for $C_{11}H_{15}O_4N$: C, 58.63; H, 6.71. Found: C, 58.93; H, 7.18.

1,2,4 - Trimethyl - 3 - carbethoxypyrrole.—The preparation was similar to that of 1,2,4-trimethyl-5-carbethoxypyrrole; yield 75%; m. p. 57°; mixed m. p. with the 5-carbethoxy isomer, 39°. The substance has nearly the same sickening sweet odor as its isomer. Repeated recrystallizations raised the m. p. to 62°.

Anal. Calcd. for $C_{10}H_{15}O_2N$: C, 66.25; H, 8.34. Found: C, 66.40; H, 8.59.

1,3,5,1′,3′,5′ - Hexamethyl - 4,4′ - dicarbethoxy - 2,2′ - dipyrrylmethane.—The procedure was similar to that of the corresponding 4,4′-diethylmethane except that hydrogen chloride catalyst was used and the mixture warmed. The yield was nearly quantitative, m. p. 151–152°.

Anal. Calcd. for $C_{21}H_{30}O_4N_2$: C, 67.33; H, 8.08. Found: C, 67.43; H, 8.45.

The preceding compound and its 4,4′-diethyl analog were treated with bromine in the usual manner for the preparation of methenes. Purple oils resulted from which no crystalline material could be isolated.

The method tried for the bromination of N-methyl pyrroles was essentially that of Fischer.[16] 1,2,4-Trimethyl-3-carbethoxypyrrole and 1,2,4-trimethyl-3-ethylpyrrole were tried and the products were purple oils.

The method tried for the condensation with formic acid was essentially that of Fischer and Zerweck.[17] The pyrroles used in the bromination were used in this condensation and again purple oils resulted.

3,5,3′,5′ - Tetramethyl - 4,4′ - dicarbethoxydipyrrylmethene, obtained by the formic acid condensation of Fischer and Zerweck was treated with sodium in the same manner as with Knorr's pyrrole. A bright red precipitate separated. When dimethyl sulfate was added to this the precipitate dissolved and the toluene solution turned green. When a toluene solution of the methene was treated with a small amount of mineral acid and warmed a similar green color appeared. This decomposition was even more marked in glacial acetic acid. Every attempt to recrystallize a mineral acid salt of this compound led to more or less extensive decomposition. A few minutes' boiling in glacial acetic acid was sufficient to complete this decomposition. We intend to submit this reaction to further investigation to determine whether or not this behavior is typical of dipyrrylmethenes.

Summary

1. The theoretical limits of a new type of isomerism have been discussed.

2. A program has been outlined which is designed to test the possibility of the existence of this type of isomerism.

3. The preparation of a group of N-methylpyrroles to fit into this program has been reported.

4. The formaldehyde synthesis of dipyrrylmethanes has been modified to permit the preparation of a completely alkylated dipyrrylmethane.

5. A method has been described for obtaining a dipyrrylmethene not available by older methods.

6. Attempts to prepare N-methyldipyrryl methenes have been described.

7. Certain decompositions of dipyrrylmethenes have been reported.

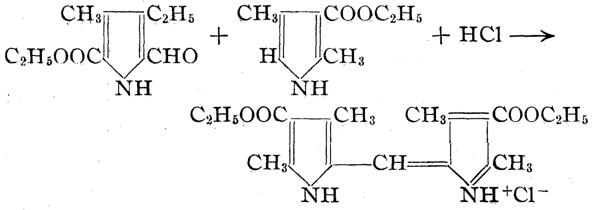
Studies in the Pyrrole Series. II. The Mechanism of the Aldehyde Synthesis of Dipyrrylmethenes[1]

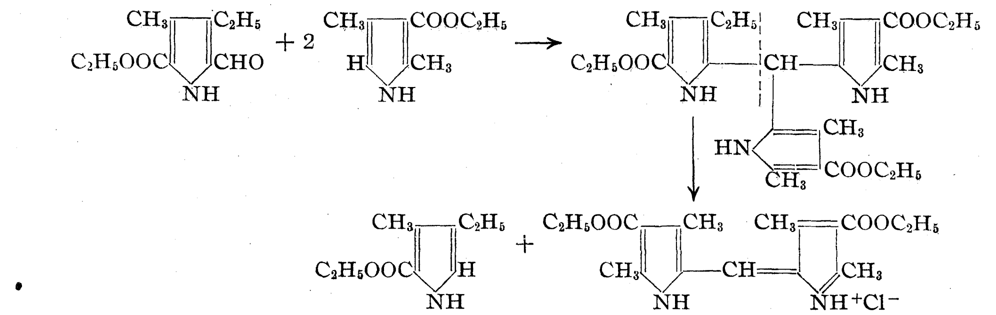
BY ALSOPH H. CORWIN AND JOHN S. ANDREWS

In the preceding paper[2] it was shown that the introduction of N-methyl groups into the pyrrole nucleus causes the aldehyde synthesis of methenes to follow a course different from that usually postulated. Fischer and Ernst[3] have also reported an anomalous aldehyde condensation



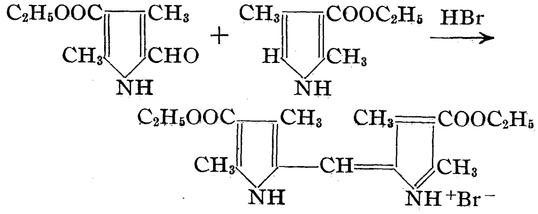
In order to account for the product obtained they assumed that the aldehyde was first hydrolyzed to yield formic acid which subsequently reacted with the 2,4-dimethyl-3-carbethoxypyrrole. This mechanism does not agree, however, with their observation that the best yield of methene resulted when two mols of the pyrrole were used for each mol of the aldehyde. These proportions suggest a tripyrrylmethane intermediate.

The suggestion of a tripyrrylmethane intermediate in the formation of methenes was unwittingly made by Piloty, Krannich and Will[4] who obtained a colorless compound as an intermediate in the synthesis of a methene and assigned to it the formula of a dipyrryl carbinol. Fischer and Ammann[5] proved this substance to be a tripyrrylmethane, substantiated Piloty's observation that hydrochloric acid would convert it into a methene but ignored his intuition that it was truly an intermediate in the reaction. If we assume a tripyrrylmethane as the intermediate in the reaction reported by Fischer and Ernst we have a complete explanation of the "abnormal" reaction by assuming cleavage at the bond which gives the symmetrical methene.

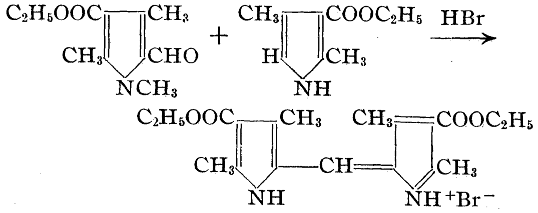


It becomes of interest, therefore, to determine whether or not tripyrryl methanes are actually intermediates in the methene syntheses. To this end we are reporting herewith a study of three reactions

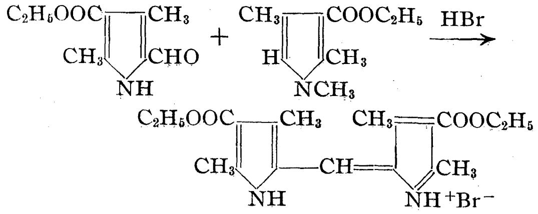
(1)



(2)



(3)



The first of these is well known. The latter two are new examples of anomalous aldehyde syntheses.

The possibility of the existence of a tripyrryl-

---

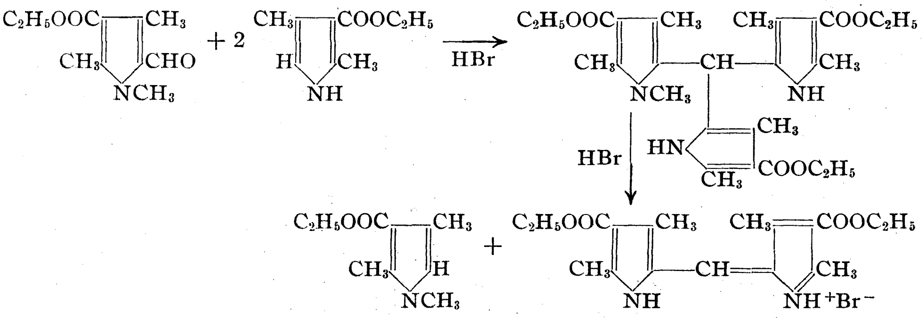
methane intermediate in the first reaction was tested by preparing the tripyrrylmethane and comparing its rate of cleavage with the rate of condensation of the aldehyde and the pyrrole. The fact that no appreciable difference in either velocity or yield could be found indicates that the tripyrrylmethane is a possible intermediate in the reaction.

In the second reaction a quantitative yield of methene was obtained when two mols of the pyrrole were used with one mol of the N-methyl aldehyde. In addition, 1,2,4-trimethyl-3-carbethoxypyrrole, predicted on the assumption of the tripyrrylmethane mechanism, was isolated in good yield. With equimolecular proportions the same products were formed but approximately half of the original aldehyde was recovered unchanged, indicating that it was not hydrolyzed to give formic acid under the conditions of the experiment. The tripyrrylmethane postulated as an intermediate was prepared and cleaved with acid under the conditions of the condensation. The same methene and N-methylpyrrole were obtained. We present these three facts as positive evidence of the existence of a tripyrrylmethane intermediate in this reaction as formulated in the following scheme



On the basis of this evidence we should predict that the condensation of the unmethylated aldehyde with the methylated pyrrole, the third reaction, should lead to an N-methyl methene. Actually, however, a new complication appears which upsets this prediction. The third reaction differs from the first two in that it is slow and does not give quantitative yields of the methene. That the postulated tripyrrylmethane is an intermediate in this reaction was proved by its actual isolation from the reaction mixture. Identification was made by comparison with a sample prepared by the Feist fusion method.[6] Cleavage of this material by acid led to the same yield of the methene as was produced in the same time by the condensation. We believe that these facts justify the formulation of the condensation given on the following page.

The three reactions which we have studied represent increasing degrees of complexity in the mechanism of the methene synthesis. They emphasize that the structures of the methenes obtained in the aldehyde condensation cannot in all cases be predicted from the starting products by the formulations previously used. The carbinol which is assumed to be formed first may undergo further condensation to give a tripyrrylmethane. This may cleave to form a second carbinol which may give either a methene or a second tripyrrylmethane. The latter may then yield a third carbinol and a third methene. The number of possible methenes resulting from the aldehyde condensation must be increased from one to three and we envisage the possibility that mixtures of these may occasionally result. The factors which influence the formation and cleavage of tripyrrylmethanes will be the subject of a later communication.

Experimental Part

Identification of 3,5,3′,5′-Tetramethyl-4,4′-dicarbethoxydipyrrylmethene (Piloty's Methene).—The recorded melting point of the hydrochloride[7] is not a true melting point but an irreversible decomposition point as noted by Fischer and Schubert.[8] Likewise the "melting point" of the free base, 190°, is the point of an irreversible decomposition. Thus the identification of the methene with unknown samples by the method of mixed melting points is theoretically unjustifiable. The method of mixed solubilities cannot be used on solutions of the methene hydrochloride for these darken and decompose on standing even at room temperature, thus precluding long contact of a solution with crystals to obtain a saturated solution. While a solution of the free base in methyl alcohol

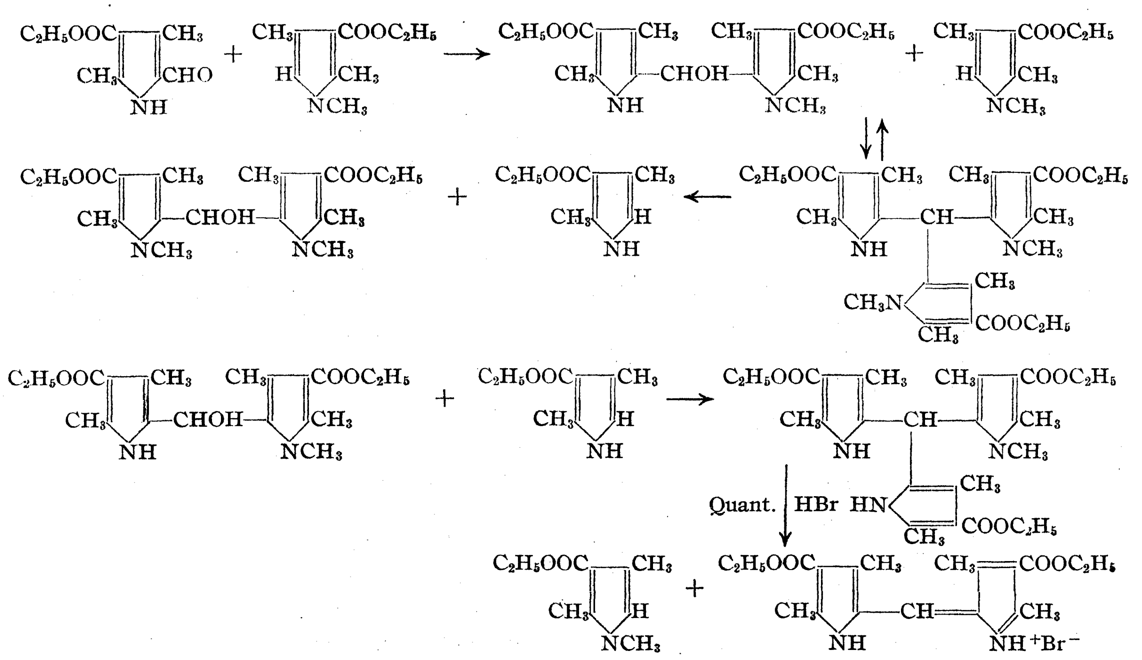
(8) Fischer and Schubert, *Ber.*, **56**, 1209–1210 (1923).



appears to be stable so that the method of mixed solubilities might be used for a comparison of the bases, it was found more convenient to resort to catalytic reduction to the methane. By this method a substance with a true melting point was obtained which was suitable for purposes of identification. The method of Fischer and Ammann[5] (p. 2324) was modified by the substitution of alcohol for glacial acetic acid as a solvent, under which conditions no green by-product was formed. Adams catalyst was used; yield of the methane, 85%; m. p. 230°.

3,5,3′,5′,3″,5″ - Hexamethyl - 4,4′,4″ - tricarbethoxytripyrrylmethane.—The method of Fischer and Heyse[7d] (p. 246) was used. Repeated recrystallizations from alcohol–water alternated with methanol increased the purity of the compound. The substance sintered at 195° and melted with decomposition at 220–225°.

Anal. Calcd. for $C_{28}H_{37}O_6N_3$: C, 65.71; H, 7.29. Found: C, 65.70; H, 7.28.

Parallel Cleavage of Tripyrrylmethane and Aldehyde Condensation.—0.197 g. of hexamethyltricarbethoxytripyrrylmethane and 0.075 g. of 2,4-dimethyl-3-carbethoxy-5-formylpyrrole were dissolved in 20 cc. of methanol. Another solution was prepared by dissolving 0.15 g. of the aldehyde and 0.13 g. of 2,4-dimethyl-3-carbethoxypyrrole in the same amount of methanol. One cc. of hydrobromic acid solution, prepared by adding 3 cc. of saturated aqueous hydrobromic acid to 10 cc. of methanol, was added to each solution. Almost simultaneously and in less than one minute precipitates of the methene were formed in each tube. Filtration and washing with methanol yielded 0.27 g. of the hydrobromide of Piloty's methene in each case.

2,4-Dimethyl-3-carbethoxy-5-formylpyrrole.—The modification of the Gattermann synthesis introduced by Adams[9] is advantageous in this preparation. Fifty grams of 2,4-dimethyl-3-carbethoxypyrrole was dissolved in 500 cc. of anhydrous ether. Seventy-five grams of zinc cyanide was added, the mixture cooled to 10° and dry hydrogen chloride passed in rapidly until the solution was saturated (about three hours). The solution was allowed to warm to room temperature and to remain at this temperature for at least three hours. The supernatant liquid should be only slightly yellow colored. The imide hydrochloride was filtered off and washed with dry ether. It was then dissolved in 3.5 liters of cold water and filtered. Upon heating to 40° the solution deposited 53–54 g. of crystalline aldehyde. This was recrystallized from ethanol; m. p. 164°. Repeated recrystallizations raised the m. p. to 167°.

1,2,4 - Trimethyl - 3 - carbethoxy - 5 - formylpyrrole.—Twenty grams of 2,4-dimethyl-3-carbethoxy-5-formylpyrrole was dissolved in 200 cc. of dry commercial benzene, 7 g. of sodium monoxide was added and the suspension refluxed for one hour. Twelve cc. of freshly distilled dimethyl sulfate was added dropwise with vigorous mechanical stirring. The gelatinous mixture was refluxed for one hour, the sodium sulfate filtered off and washed with benzene and the filtrate allowed to stand overnight. About 3 g. of starting product crystallized out. The filtrate was steam distilled and the residual oil cooled until it solidified, filtered off and recrystallized from 80 cc. of methanol; yield, first crop, 8.5 g.; m. p. 97°. The mother liquor was cooled in dry ice and 6 g. of additional yield obtained.

Anal. Calcd. for $C_{11}H_{15}O_3N$: C, 63.18; H, 7.23. Found: C, 63.19; H, 7.28.

Condensations of 1,2,4-Trimethyl-3-carbethoxy-5-formylpyrrole with 2,4-Dimethyl-3-carbethoxypyrrole.—First experiment, 1:2 ratio: 1 g. of the N-methyl aldehyde and 1.65 g. of 2,4-dimethyl-3-carbethoxypyrrole were dissolved in 100 cc. of warm hexane. After cooling to room temperature dry hydrogen chloride gas was passed in for fifteen seconds and the resulting methene hydrochloride filtered

---

[9] Adams and Levine, THIS JOURNAL, **45**, 2373 (1923); Adams and Montgomery, *ibid.*, **46**, 1518 (1924).

off and washed with a little hexane; yield, 1.90 g. or 100%; identified by reduction to the methane, m. p. 230°. The faintly yellow filtrate was evaporated on the steam-bath to about 20 cc. Chilling in dry ice–ethanol mixture yielded 0.6 g. of a nearly colorless crystalline solid, m. p. 57°. A mixed m. p. with 1,2,4-trimethyl-3-carbethoxypyrrole, m. p. 57°, gave no depression.

Second experiment, 1:1 ratio: 1 g. of the N-methyl aldehyde and 0.8 g. of the pyrrole were dissolved in 100 cc. of hexane and treated with dry hydrogen chloride for about thirty seconds. The methene was filtered off after five minutes and washed with hexane until the washings were nearly colorless; 0.9 g. of Piloty methene salt was obtained and identified by reduction to the methane. The filtrate was chilled in dry ice–ethanol mixture and 0.6 g. of colorless needles were obtained, m. p. 65–80°. This product was recrystallized by dissolving in ether at room temperature and cooling in dry ice mixture; 0.3 g. of colorless crystals was obtained, m. p. 94°, mixed m. p. with 1,2,-4-trimethyl-3-carbethoxy-5-formylpyrrole, no depression. By evaporation of the hexane filtrate from which the crude N-methyl aldehyde had been removed a nearly colorless residue was obtained. Recrystallization from 3–4 cc. of hexane by chilling in dry ice yielded 0.1 g. of material, m. p. 57°, mixed m. p. with 1,2,4-trimethyl-3-carbethoxypyrrole, no depression.

1,2,4,2′,4′,2″,4″ - Heptamethyl - 3,3′,3″ - tricarbethoxytripyrrylmethane.—The preparation was analogous to that of the hexamethyltricarbethoxytripyrrylmethane above. A preliminary purification was obtained by dissolving the product in chloroform and precipitating with petroleum ether. Crystallization from methanol yielded 1.6 g. of the methane and 0.3 g. additional was obtained from the mother liquor. Three recrystallizations from ethanol-water gave a colorless product, m. p. 177°.

Anal. Calcd. for $C_{29}H_{39}O_6N_3$: C, 66.24; H, 7.48. Found: C, 66.25, 66.29; H, 7.44, 7.44.

Cleavage.—Two-tenths gram of the heptamethyltricarbethoxytripyrrylmethane was dissolved in 50 cc. of hot methanol, cooled to 40°, and to it added 1 cc. of saturated aqueous hydrobromic acid. Within one minute the formation of a red precipitate was observed. This was filtered off after five minutes and washed with methanol; yield 0.16 g. or 95%. The product was identified by reduction to the methane, m. p. 230°.

Condensations of 2,4-Dimethyl-3-carbethoxy-5-formyl Pyrrole with 1,2,4-Trimethyl-3-carbethoxypyrrole.—Five grams of the aldehyde and 4.6 g. of the N-methylpyrrole were dissolved in 150 cc. of hot methanol and 0.5 cc. of saturated aqueous hydrobromic acid was added and the mixture allowed to stand at 70°. The precipitate which formed was reddish-purple even after washing with ether; yield 4.05 g. of methene hydrobromide, melting with decomposition at 213–215°. This was identified as Piloty methene by catalytic reduction to the methane, m. p. 230°, mixed m. p. with an authentic sample, 230°. The yield of methane from the discolored methene was identical with that from pure methene.

Parallel Test of Aldehyde with the N-Methylpyrrole and Aldehyde without the N-Methylpyrrole.—To test the possibility that the formation of Piloty's methene might be due to the cleavage of the aldehyde discovered by Fischer and Zerweck[7d] the course of the reaction of the aldehyde with and without the N-methylpyrrole was studied. Formation of the methene in the presence of the N-methylpyrrole takes place at a lower temperature than the cleavage of the aldehyde in the absence of the pyrrole. At a higher temperature, where both reactions proceed, the methene is formed more rapidly and in greater yield in the presence of the N-methylpyrrole than in its absence. A typical experiment follows.

Two-tenths gram of 2,4-dimethyl-3-carbethoxy-5-formylpyrrole and 10 cc. of methanol were mixed in each of two flasks. To the first, 0.185 g. of 1,2,4-trimethyl-3-carbethoxypyrrole was added. Both flasks were warmed until all the aldehyde dissolved and then held at about 50°; 0.1 cc. of 48% hydrobromic acid was added to each. The flask containing the N-methylpyrrole assumed a deep red color immediately. After about ten minutes it began to deposit colored crystals. A few minutes later the flask containing the aldehyde alone started to deposit similar crystals. After half an hour the crystals from both flasks were filtered off and weighed. From the flask containing aldehyde and pyrrole, 0.075 g. of the methene was obtained. From the flask containing the aldehyde alone, 0.040 g. of the methene was obtained.

Isolation of Tripyrrylmethane Intermediate in the Reaction.—If the flask containing the mixed aldehyde and N-methylpyrrole be cooled soon after the appearance of the deep red color mentioned above, tripyrrylmethane can be isolated as an intermediate. To favor this reaction, however, three mols of N-methylpyrrole was used to one mol of the aldehyde: 1 g. of the aldehyde and 2.75 g. of the N-methylpyrrole were dissolved in 35 cc. of hot methanol and 0.5 cc. of saturated aqueous hydrobromic acid added. The solution instantly became intensely red and, upon chilling in dry-ice and alcohol, deposited a large amount of a colorless precipitate. Upon warming to room temperature this deposit did not dissolve; yield, 2.5 g.; m. p. 146°. This was identified as 2,4,1′,2′,4′,1″,2″,4″-octamethyl-3,3′,3″-tricarbethoxytripyrrylmethane by a mixed m. p. with material made by the Feist fusion method given below. The yield was thus 88%.

2,4,1′,2′,4′,1″,2″,4″ - Octamethyl - 3,3′,3″ - tricarbethoxytripyrrylmethane.—One gram of 2,4-dimethyl-3-carbethoxy-5-formylpyrrole and 1.85 g. of 1,2,4-trimethyl-3-carbethoxypyrrole were fused at a temperature not exceeding 150° with about 0.1 g. of potassium bisulfate as a catalyst according to Feist's method. The product was purified by dissolving in methanol, adding ether and chilling in dry ice; yield, 1.5 g.; m. p. after several recrystallizations from C_2H_5OH–H_2O, 147–148°; mixed m. p. with substance from hydrobromic acid condensation above, no depression.

Anal. Calcd. for $C_{30}H_{41}O_6N_3$: C, 66.75; H, 7.66. Found: C, 66.67; H, 7.61.

Cleavage.—One and forty-five-hundredths grams of the di-N-methyltripyrrylmethane was dissolved in 25 cc. of hot methanol and when cool this solution was diluted with 50 cc. of ether. Five-tenths cc. of saturated aqueous hydrobromic acid was added and the solution allowed to stand at room temperature. A red coloration appeared very slowly and after one hour purple needles began to be deposited. After twenty hours these were filtered off and washed with ether yielding 0.3 g. of red-purple needles.

The material was identified as Piloty's methene salt by catalytic reduction to the methane, m. p. 230°. The yield was therefore 53%; mixed m. p. with 3,5,3',5'-tetramethyl-4,4'-dicarbethoxydipyrrylmethane, 230°. A parallel test using 1 g. of aldehyde and 1.85 g. of N-methylpyrrole under these conditions yielded 0.57 g. of methene or 52%.

Condensation of 1,2,4-Trimethyl-3-carbethoxy-5-formylpyrrole with 1,2,4-Trimethyl-3-carbethoxypyrrole.—When this condensation was carried out in acid media, highly colored tars resulted from which no crystalline compound could be isolated.

Summary

1. It has been demonstrated that tripyrrylmethanes can be and in two cases are intermediates in the formation of dipyrrylmethenes by Piloty's aldehyde synthesis.

2. As a result of the three possibilities for cleavage of a tripyrrylmethane of this type, the number of normally expected methenes from this reaction must be increased from one to three.

3. Experiments have been performed in which the substituent groups were so modified as to give each of the three possibilities.

Thiobarbiturates. II

BY ELLIS MILLER, JAMES C. MUNCH, FRANK S. CROSSLEY AND WALTER H. HARTUNG

In an earlier communication[1] it was pointed out that in spite of the unfavorable indications obtained with diethyl thiobarbituric acid,[2-4] the sulfur analogs of the well-known barbituric acids gave promise of therapeutic value and merited further investigation. This is confirmed by a subsequent report of Tabern and Volwiler.[5]

Prior to the publication of their paper, only a few thiobarbituric acid derivatives were described in the literature, namely, the unsubstituted acid itself,[6,7] 5-methyl,[9] 5-ethyl,[8,9] 5-trimethylene,[10] 5,5-diethyl,[11,12] and 5,5-dipropyl thiobarbituric acids.[13]

Twenty new thio analogs of known barbituric

acid derivatives have been prepared in our laboratories. Six of these (the ethyl isopropyl, ethyl allyl, ethyl *n*-butyl, ethyl isoamyl, ethyl phenyl and allyl *s*-butyl thiobarbituric acids) are included in the list given by Tabern and Volwiler, and since their properties agree substantially with those already described, they need not be repeated here.

The synthesis of these compounds follows a single pattern, and one example will illustrate the method.

Ethyl *n*-Propyl Thiobarbituric Acid.—In a 1-liter, 3-necked round-bottomed flask, equipped with a mechanical stirrer and reflux condenser, is placed 276 ml. of anhydrous ethanol, and in it is dissolved 13.8 g. (0.6 mole) of metallic sodium. 24 3 g. (0.32 mole) of thiourea is added, while stirring. With continued stirring, 46 g. (0.2 mole) of ethyl *n*-propyl malonic ester is added quickly. Stirring is continued and the mixture is gently heated to incipient refluxing over a period of six to seven hours. After standing overnight the reaction mixture is concentrated on a steam-bath to about 150 ml. and diluted with 75 ml. of water. Concentrated hydrochloric acid is now added until the mixture is strongly acid to litmus paper, whereupon the desired ethyl *n*-propyl thiobarbituric acid precipitates out. The crystals, after drying and recrystallizing from toluene, melt at 174–174.5° (uncorr.).

By substituting an equimolar amount of the appropriate malonic ester in the above reaction, other desired 5,5-disubstituted thiobarbituric acids have been obtained. In general the yield is somewhat higher than that obtained for the oxygen analogs.

The thiobarbituric acid derivatives are listed in Table I.

The intermediate dialkyl malonic esters have all been described in the literature. They were purchased where possible, or synthesized by well-known procedures. Of the esters synthesized, it may be said that in general the yields are satisfactory, except when a second alkyl group is being introduced into secondary-alkylmalonic ester.

Summary

Twenty 5,5-disubstituted thiobarbituric acids have been prepared and their chemical characteristics determined. Of these, six have recently been described by others. The method of preparation corresponds to that used for the oxygen analogs, but the yields are generally somewhat higher. A pharmacological study of these compounds has been completed and will be presented elsewhere.

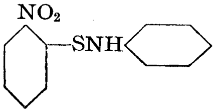
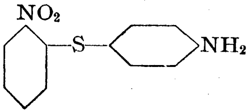
The Molecular Rearrangement of Sulfenanilides.[1] III

BY MAURICE L. MOORE[2] AND TREAT B. JOHNSON

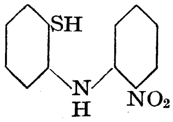
In previous communications[3] from this Laboratory, the authors have discussed the rearrangement of certain aromatic sulfenanilide compounds of Type I. They have shown that on heating these alone or in the presence of an excess of the corresponding amine, they undergo rearrangement to *p*-aminophenyl sulfides II, whereas by digestion in alcoholic sodium hydroxide solution they give the corresponding *o*-mercaptodiphenylamines III. We have now extended the study of these molecular rearrangements to other compounds of similar structure, and in this paper we shall discuss the results of some new experiments in which we have accomplished molecular rearrangements under the influence of heat.



I



II



III

In addition to the compounds of Type I, previously studied by the authors, many others examined give the same type of change upon heating. Thus, 2,4-nitrochlorobenzene-sulfenanilide, prepared by the action of 2,4-nitrochlorobenzenesulfenyl chloride upon aniline, gave 2,4-nitrochlorophenyl-4′-aminophenyl sulfide when heated at a temperature of 150–160° or when heated with an excess of aniline at a temperature of 180–190°. The corresponding *o*-toluidide underwent

---

[1] In our previous papers we have observed the nomenclature of the earlier workers in related fields in naming these sulfur compounds, but we have noticed that the abstractors for the *Chemical Abstracts* prefer and have applied another nomenclature. In order to be consistent and to maintain uniformity of spelling, in our Journals, we are, therefore, now following their system, as indicated in the Abstracts of our previous papers, and also in the last edition of "Organic Syntheses," Vol. XV, 1935, p. 45.

[2] A. Homer Smith Research Fellow in Organic Chemistry, 1935–1936.

[3] Moore and Johnson, THIS JOURNAL, **57**, 1517, 2234 (1935); see also *Science*, **81**, 643 (1935).

a similar rearrangement, giving the isomeric *p*-aminophenyl sulfide. 2-Nitrobenzene-sulfen-*o*-chloroanilide and 4-nitrobenzene-sulfen-*o*-chloroanilide were prepared by the action of the nitrobenzene-sulfenyl chloride on *o*-chloroaniline and both have been rearranged successfully to the corresponding sulfides by heating.

It is now quite apparent from our studies that the -S-NH- linkage between aromatic nuclei is very susceptible to a change of structure by application of heat, forming aminophenyl sulfides II and that the transformation involved is universal to compounds of Type I. Substituents in either benzene nucleus of the sulfenanilide I do not seem to have any influence in affecting a successful molecular rearrangement as long as there is at least a para or an ortho position open in the aromatic nucleus. Rearrangement, however, to the para position predominates. If this position is occupied then an ortho substituted sulfide is formed.

In the case of the methylene type of rearrangement studied by Cohn and Fischer[4] it has been shown that the anilide group in the molecule can be displaced by another aromatic amine which will then undergo rearrangement when digested in an acid solution of the amine hydrochloride. For example, when *p*-aminobenzyl-anilide IV is digested on the steam-bath with a hydrochloric acid solution of *o*-toluidine, diamino-phenyl-tolyl-methane V is formed in excellent yield. This displacement of amine and subsequent rearrangement is explained upon the basis of the following intermediate reactions

$$NH_2C_6H_4—CH_2—NHC_6H_5 \xrightarrow[\text{hydrolysis}]{\text{Acid}} \underset{\text{IV}}{NH_2C_6H_4CH_2OH} + C_6H_5NH_2$$

$$NH_2C_6H_4CH_2OH + NH_2C_6H_4CH_3(o) \xrightarrow{\text{Acid}} \underset{\text{V}}{NH_2C_6H_4CH_2C_6H_3(CH_3)NH_2}$$

In continuing the study of the rearrangement of sulfenanilides I, it was our prediction that these compounds would likewise suffer displacement of the anilide group in the molecule with subsequent rearrangement when heated in the presence of an excess of certain amines. This assumption has been confirmed. For example, when 2-nitrobenzene-sulfenanilide I was heated at a temperature of 180–190° with an excess of *o*-toluidine, 2-nitrophenyl-3′-methyl-4′-aminophenyl sulfide was formed. 2-Nitrobenzene-sulfen-*o*-toluidide and the corresponding *p*-toluidide also responded to similar reactions when treated with different aromatic amines. Aniline, *o*-toluidine and *p*-toluidine are able to displace each other from the respective sulfenanilide molecule.

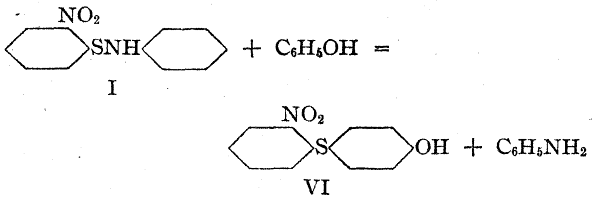
Notwithstanding this similarity in chemical behavior of the two different types of compounds when they interact with amines, it does not seem plausible to explain our sulfenanilide reactions upon the theoretical basis of the mechanism suggested above and involving first an hydrolysis. When compounds of Type I are heated in acid solution the amine radical is removed and a disulfide is formed smoothly. No rearrangement takes place in an acidic, aqueous or alcoholic medium. Heating with an amine alone leads to a normal rearrangement forming a sulfide in good yield. In an alkaline solution the sulfenanilide I is unstable and undergoes a diphenylamine rearrangement III. These results seem to preclude any initial hydrolysis of I taking place in the displacement and subsequent rearrangement reaction although there must be some dissociation of the sulfenanilide molecule I before an intramolecular change can take place.

We have also found that the amine, *o*-chloroaniline, will not displace the anilide group in sulfenanilide compounds I although a normal rearrangement does take place upon heating. Thus, if 2-nitrobenzene-sulfenanilide I is heated at 180–190° with an excess of *o*-chloroaniline rearrangement takes place with formation of the sulfide II. Under similar conditions the corresponding sulfen-*o*- and *p*-toluidides undergo a similar rearrangement without being displaced from the molecule by the *o*-chloroaniline. It was found, however, that the *o*-chloroanilide group, when present in the sulfenanilide molecule, is easily displaced by other amines. For example, 2-nitrobenzene-sulfen-*o*-chloroanilide gave the sulfide II when heated at a temperature of 180–190° in the presence of an excess of aniline. Similar transformations were accomplished by heating the *o*-chloroanilide with *o*- and *p*-toluidine. In all three cases the *o*-chloroaniline group was displaced smoothly. These results indicate that the reactivity of the aromatic amines used determines whether there is a displacement of the group already present in the sulfenanilide molecule before a rearrangement takes place.

---

(4) Cohn and Fischer, *Ber.*, **33**, 2586 (1900).

An attempt was made to prepare directly aromatic sulfide phenols VI by heating compounds of the sulfenanilide type I with an excess of a phenol



but without success. The phenol served merely as a solvent and the final result under such experimental conditions is a normal rearrangement of the sulfenanilide I to its isomeric aminophenyl sulfide II.

Experimental Part

2,4-Nitrochlorobenzene-sulfenanilide.—The 2,4-nitrochlorobenzene-sulfenyl chloride used here was prepared by allowing chlorine gas to react with di-(2,4-nitrochlorophenyl) disulfide[5] according to the method of Zincke.[6] 2,4-Nitrochlorobenzene-sulfenyl chloride (25 g.) dissolved in anhydrous ether (500 ml.) was allowed to react with aniline (23 g.) dissolved in ether (50 ml.). The aniline solution was added slowly through a reflux condenser to the 2,4-nitrochlorobenzene-sulfenyl chloride solution. A precipitate of aniline hydrochloride immediately formed and sufficient heat was evolved to boil the ether. After standing for one hour the aniline hydrochloride was then removed by filtration and the ether expelled by distillation when the sulfenanilide crystallized as an orange-yellow solid; yield 33 g. It crystallized from alcohol, m. p. 102° and was soluble in the ordinary organic solvents but insoluble in dilute hydrochloric acid.

Anal. Calcd. for $C_{12}H_9O_2N_2SCl$: N, 9.98; S, 11.41; Cl, 12.66. Found: N, 9.82, 9.97; S, 11.15, 11.25; Cl, 12.46, 12.63.

2,4-Nitrochlorobenzene-sulfen-*o*-toluidide.—From 2,4-nitrochlorobenzene-sulfenyl chloride (25 g.) and *o*-toluidine (24 g.); yield 28 g. It crystallized from alcohol as bright glistening orange-red platelets; m. p. 127°.

Anal. Calcd. for $C_{13}H_{11}O_2N_2SCl$: N, 9.51; S, 10.87; Cl, 12.06. Found: N, 9.54, 9.67; S, 10.47, 10.70; Cl, 12.02, 12.14.

2-Nitrobenzene-sulfen-*o*-chloroanilide.—From 2-nitrobenzene-sulfenyl chloride (25 g.) as previously prepared[7] and *o*-chloroaniline (32 g.). This reaction proceeded much slower than expected and the *o*-chloroaniline hydrochloride did not settle out completely until after the ether solution had stood for at least two hours; yield 33 g. It crystallized from alcohol in bright yellow crystals melting at 130°. The compound is only slightly soluble in alcohol but is easily soluble in the ordinary organic solvents.

Anal. Calcd. for $C_{12}H_9O_2N_2SCl$: N, 9.98; S, 11.41; Cl, 12.66. Found: N, 10.11, 10.14; S, 11.62, 11.48; Cl, 12.95, 12.80.

4-Nitrobenzene-sulfen-*o*-chloroanilide.—*p,p′*-Dinitrodiphenyl disulfide[8] (25 g.) was suspended in ice-cold anhydrous chloroform (250 ml.) and treated with chlorine gas until all the solid was dissolved. The excess of chlorine gas was then removed by distillation of the chloroform under reduced pressure to a volume of 150 ml. and then made up to a volume of 400 ml. with anhydrous ether. This solution of 2-nitrobenzene-sulfenyl chloride was subsequently treated with *o*-chloroaniline (32 g.) dissolved in ether (100 ml.) when the sulfenanilide above was obtained in a yield of 23 g. of crude material. This was contaminated with 4,4′-dinitrodiphenyl disulfide and after final purification by washing with ether the yield was reduced to 8 g. This was recrystallized from alcohol, m. p. 99–101°. It is immediately converted to 4,4′-dinitrodiphenyl disulfide by treatment with dilute hydrochloric acid.

Anal. Calcd. for $C_{12}H_9O_2N_2SCl$: N, 9.98; S, 11.41; Cl, 12.66. Found: N, 9.84, 10.06; S, 11.20, 11.31; Cl, 12.51, 12.40.

Rearrangements by Heating. 2,4-Nitrochlorophenyl-4′-aminophenyl Sulfide.—From 2,4-nitrochlorobenzene sulfenanilide (10 g.) when heated for six hours at 150–160°, according to our previous procedure.[6] Recrystallization from alcohol gave a product crystallizing as bright, glistening yellow plates, m. p. 127–129°. The sulfide was easily soluble in the ordinary organic solvents, and the hydrochloride was difficultly soluble in water. The hydrochloride was obtained in crystalline form by dissolving the free base in ether solution and slowly adding concentrated hydrochloric acid, m. p. 215–225°.

Anal. Calcd. for $C_{12}H_9O_2N_2SCl$: N, 9.98; S, 11.41; Cl, 12.66. Found: N, 9.96, 9.89; S, 11.30, 11.14; Cl, 12.90, 12.79.

The sulfide was obtained with better results by heating the sulfenanilide (10 g.) with an excess of aniline (20 ml.) at 180–190° for six hours. The mixture was worked up according to the previous procedure and 5 g. of material obtained. It was purified by crystallizing from alcohol after decolorizing with norite, m. p. 129°.

---

(5) This compound was prepared by the procedure given for *o,o′*-dinitrodiphenyl disulfide as described by Bogert and Stull, "Organic Syntheses," John Wiley & Sons, Inc., New York, 1928, Vol. VIII, p. 64.

(6) Zincke, *Ann.*, **416**, 111 (1918).

(7) Moore and Johnson, THIS JOURNAL, **57**, 1517 (1935).

(8) This compound was prepared by the procedure given for *o,o′*-dinitrodiphenyl disulfide[4] as used by Foss, Dunning and Jenkins [THIS JOURNAL, **56**, 1978 (1934)]. The results of this procedure are very unsatisfactory due to the formation of many by-products during the reaction. Fromm and Wittmann [*Ber.*, **41**, 2264 (1908)] have studied the conditions of this reaction in some detail. They have reported the isolation of 4,4′-dinitrodiphenyl sulfide, m. p. 154°, 4,4′-nitroaminodiphenyl sulfide, m. p. 142°, and the dinitrophenyl ether of azophenyl-*p*-dimercaptan, m. p. 164°, as well as the desired compound, 4,4′-dinitrodiphenyl disulfide, m. p. 181°. The Russian workers Voraghtzow and Krihov [*J. Gen. Chem.* (U. S. S. R.), 2939 (1932)] have isolated and identified two isomers of the disulfide present in the mixture, *i. e.*, $(NO_2C_6H_4)_2S{:}S$, m. p. 134° and the symmetrical compound, m. p. 181°. In our results following the above procedure we have isolated all of the above substances in varying quantities but have found the largest quantity present to be the dinitrodiphenyl sulfide. We have separated 60–75 g. of the desired disulfide, m. p. 181°, from 200 g. of the reaction product (m. p. 120–130°) by treatment with boiling benzene. All of the above materials will dissolve in the benzene except the symmetrical disulfide. This is obtained in fair purity, m. p. 172–179°, in this one step but the yield is relatively low. Further separation of the desired material from the soluble mixture involves considerable time and effort.

TABLE I

In these first eight experiments it is shown that the excess of amine present could displace the anilide group in the sulfenanilide molecule followed by rearrangement to give an "aminophenyl sulfide" when heated at 180–190°. In experiments 9, 10 and 11 it is shown that *o*-chloroaniline is not able to displace the anilide group in the sulfenanilide but that a normal rearrangement takes place without the *o*-chloroaniline taking part in the change.

	Sulfenanilide	Amine	Sulfide	M. p., °C.	Yield, %

2,4-Nitrochlorophenyl-3′-methyl-4′-aminophenyl Sulfide.—From 2,4-nitrochlorobenzene-sulfen-*o*-toluidide (10 g.) when heated with *o*-toluidine (15 ml.) in a yield of 6 g. Purification from alcohol after digesting with norite gave bright yellow prisms, m. p. 113–115°. A portion of the aminophenyl sulfide readily dissolved in ether and upon the addition of concentrated hydrochloric acid, gave a colorless precipitate of the hydrochloride, m. p. 216–220°.

Anal. Calcd. for $C_{13}H_{33}O_2N_2SCl$: N, 9.51; S, 10.87; Cl, 12.06. Found: N, 9.41, 9.36; S, 10.94, 10.80; Cl, 12.06, 12.20.

4-Nitrophenyl-3′-chloro-4′-aminophenyl Sulfide.—From the 4-nitrobenzene-sulfen-*o*-chloroanilide (m. p. 99–101°) when heated with boiling *o*-chloroaniline. The material was purified by dissolving in a mixture of ether–petroleum ether, boiling with norite and slowly evaporating. Yellow crystals were obtained, m. p. 127–129°. The free base was readily soluble in ether and gave a colorless crystalline hydrochloride.

Anal. Calcd. for $C_{12}H_9O_2N_2SCl$: N, 9.98. Found: N, 10.37, 10.11.

Rearrangement of Sulfenanilides by Heating in the Presence of an Excess of Aromatic Amines.—Our general procedure was to place 5 g. of the sulfenanilide in 10 ml. of the aromatic amine and heat on an oil-bath at a temperature of 180–190° for four hours. The reaction fluid was then poured into dilute hydrochloric acid solution with vigorous stirring and cooled in an ice-bath. The solid hydrochloride of the rearrangement product was filtered off and dissolved in alcohol. This solution was then neutralized with 5% sodium hydroxide solution, decolorized by boiling several times with norite, and the free aminophenyl sulfide separated by crystallization after cooling in an ice-bath. The reaction product in each case was identified by mixed melting points with the known amino sulfides. The results are tabulated in Table I.

Reaction in Acidic Alcoholic Solution.—2-Nitrobenzenesulfenanilide I (5 g.) was dissolved in alcohol (25 ml.) and gently refluxed after concentrated hydrochloric acid (3 ml.) was added. If the refluxing was discontinued at the end of fifteen minutes the sulfenanilide was recovered whereas if the refluxing was continued for some time, *o,o*′-dinitrodiphenyl disulfide began to be formed and at the end of about two hours all the sulfenanilide had been converted into the insoluble disulfide, m. p. 193–195°.

Summary

1. A study of the rearrangement of the sulfenanilide type of compounds to their isomeric aminophenyl sulfides has been continued, and several new applications have been made of the rearrangement.

2. These rearrangements are influenced by the presence of other aromatic amines. The anilide group is replaceable when the sulfenanilide is warmed with another amine giving the corresponding aminophenyl sulfide.

3. The amine, *o*-chloroaniline, fails to respond in this replacement reaction. On the other hand its rearrangement is possible when it occurs in sulfenanilide combinations.

4. All sulfenanilides are decomposed by action of acids with formation of organic disulfides and an amine.

The Effect of Oxygen on the Reaction between Bromine and Butadiene

BY G. B. HEISIG AND H. M. DAVIS

That oxygen influences the rate of the addition of bromine to unsaturated hydrocarbons was shown by the work of H. S. Davis[1] on the determination of acetylenes by titration with bromine. Schultze[2] also showed the disturbing influence of oxygen in the titration of cyclopentadiene with bromine. More recently, Bauer and Daniels[3] reported that the rate of the reaction between solutions of bromine and cinnamic acid in carbon tetrachloride was rapid, even in the dark, in the absence of oxygen, but slow in its presence. These observations, together with the remarkable effects produced by the presence of oxygen and peroxides noted by Kharasch and his collaborators,[4] serve to emphasize the importance of the presence of oxygen on the rates of reactions. That this effect may not be general is suggested in the note of Deanesly,[5] which states that oxygen fails to produce any inhibitory effect on the addition of chlorine to olefinic hydrocarbons such as beta-butylene, although he admits that the reaction may be so fast that a retardation by oxygen may be difficult to detect. Since there were no quantitative data available to show whether oxygen affects the rate of addition of a halogen to an unsaturated hydrocarbon in the gas phase, it seemed desirable to investigate the problem. The reaction between gaseous bromine and butadiene in the presence of nitrogen containing about 0.3% of oxygen, studied by Heisig and Wilson,[6] was chosen for the investigation. The reaction between equal numbers of molecules of bromine and butadiene is bimolecular and occurs largely on the surface of the reaction vessel. The product is 1,4-dibromobutene. This study is of more than usual interest since it involves the effect of oxygen on the addition of bromine to a conjugated system.

The apparatus used in the previous investigation was altered to permit the preparation of gaseous reaction mixtures with increased oxygen content or with oxygen completely absent. In the first runs of the present study, the oxygen content of the reaction mixtures was increased from a partial pressure of 2 mm. of mercury to 375 mm. by using purified, dry, tank oxygen instead of nitrogen as the diluting gas employed to bring the initial pressure in the reaction sphere up to that of the atmosphere. The product under these conditions had a melting point of 46–47° instead of the 51–52° found for the product obtained from mixtures containing 0.3% of oxygen or from mixtures from which oxygen was excluded. Also, the rate of the reaction was somewhat slower than that observed when the partial pressure of the oxygen was 0.3%, as can be seen in Tables I and II.

TABLE I

TYPICAL RUNS. REACTION BETWEEN BROMINE AND BUTADIENE WITH VARIOUS CONCENTRATIONS OF OXYGEN

30		27	28.6	30.8	24.4	25.7
∞		28.7	29.6	31.5	25.3	27.0

The apparatus was then modified so that the tank nitrogen was passed over hot, freshly reduced copper gauze. All parts of the apparatus were evacuated and then thoroughly flushed with the oxygen-free nitrogen. When nitrogen so treated was the only diluent used, the reaction rate was greater than that obtained when (untreated) tank nitrogen was the diluent. Moreover, the rate increased with subsequent runs, as would be expected with the progressive removal of the last traces of oxygen from the purifying

[a] Pressure given in mm. of mercury. [b] Pressure given in mm. of alpha-bromonaphthalene.

train. The product had the same appearance and melting point as that obtained when tank nitrogen (0.3% oxygen) was used.

The reaction was fast in all cases; in fact, somewhat more than half of the reaction took place in the twenty to thirty seconds required to mix the gases before the first reading could be made. The vapor pressure of the product is about 13 mm. of alpha-bromonaphthalene. When the first reading is made the gases in the reaction sphere are already saturated with product and a sufficient amount has been formed to cover the surface with a monomolecular layer.

It will be noted in Table II that the total observed pressure drop is somewhat smaller in the runs in which no oxygen was present, although the time required to make the first reading is less. This is in agreement with the other evidence that the reaction is faster in the absence of oxygen, since it indicates that a greater part of the reaction occurs before the first reading can be taken.

For ready comparison of the rates of the reactions, a curve for each experiment was prepared by plotting observed pressure drop against time. The slopes of the tangents to the curves when 80% of the calculated pressure drop has occurred, increase as the proportion of oxygen in the mixture decreases, as can be seen from column 7 in Table II. The greater the angle, the more rapidly is the reaction taking place. This is not a fortuitous coincidence, for the slopes determined when 66.7% of the reaction is completed increase in the same order. Furthermore, the time required for 80 and 66.7% of the reaction to take place decreases with the amount of oxygen present, as can be seen in columns 6 and 9 of Table II.

Since the rate of the reaction is sensitive to a small concentration of oxygen, and since the earlier work showed that the reaction occurred largely on the surface, a reasonable mechanism is that chains are initiated at the wall of the reaction vessel, and are broken by the oxygen. The data however do not exclude a mechanism in which the reaction occurs wholly on the surface and the rate of the reaction is decreased because of the occupation of the "active spots" on the surface by oxygen.

Experimental.—The apparatus was that described by Heisig and Wilson.[6] It was modified by the introduction of an electrically heated roll of copper screen to remove the 0.3% of oxygen in the tank nitrogen before it passed into the purifying and drying train. Before each run, the hot copper gauze was subjected to a long treatment with a stream of hydrogen under a pressure of one atmosphere, thus ensuring an active surface. A connection was also provided to permit purified oxygen to be mixed with the butadiene used in the experiment. This was a metal-to-glass connection. The oxygen was scrubbed by passage through three double wash bottles filled with a 40% solution of potassium hydroxide, and was dried by passage through calcium chloride and then through resublimed phosphorus pentoxide. The butadiene and bromine were portions of preparations of these substances used in the previous investigation. The reaction vessel had a volume of 53.8 cc. The slopes of the tangents to the curves were determined by a variation of the method described by Lipka.[7]

A grant was received from the Research Funds of the Graduate School to aid in carrying out this work.

Summary

The reaction between equimolar mixtures of bromine and butadiene has been studied in the presence of a partial pressure of oxygen at 375 mm., 2 mm. (Hg), and in the absence of oxygen, the total pressure of the reaction mixture being equal to that of the atmosphere.

The rate of the reaction as measured by the

---

(7) Joseph Lipka, "Graphical and Mechanical Computation," John Wiley and Sons, Inc., New York (*ca.* 1919): Part II, Article 110, page 255.

slopes of the tangents to the curves (of pressure-drop against time) when 80 and 67% of the gases have reacted, increases with the decrease of oxygen in the mixture. The increase in the rate is especially noticeable when the partial pressure of oxygen is well below 2 mm.

The sensitivity of the rate of the reaction to small amounts of oxygen, together with the evidence that the reaction occurs largely at the surface, suggests a chain mechanism with short chains initiated at the surface.

Organic Nitrogen Bases from Pyrolysis of Cottonseed Meal[1]

BY IVY PARKER, C. L. GUTZEIT, A. C. BRATTON AND J. R. BAILEY

Introduction

Research on the bases in petroleum distillates[2] has shown a preponderance of non-aromatic types, not previously obtained from any other natural source. On the assumption that petroleum is of vegetable or animal origin, it may be assumed that carbohydrates and fats, as well as proteins, contributed to the formation of nitrogen compounds; in any event an explanation of the genesis of non-aromatic petroleum bases, among which are probably compounds of cyclopentane structure, might have an important bearing on the origin of petroleum itself.

In an attempt to determine whether similar non-aromatic bases would result from pyrolysis of a material containing proteins, carbohydrates and fats, the present investigation was undertaken. The Union Oil Company of California contributed 337 pounds of crude bases obtained from the distillation of 23 tons of cottonseed meal with nitrogen-free lubricating oil as a liquid medium, through which low temperature pyrolysis could be controlled.[2a]

Previous work by other investigators on bases formed in protein pyrolysis are of little interest as concerns the present investigation, because in these studies pure proteins were employed.[3]

The complexity of the cottonseed meal bases is comparable with that of petroleum bases. An unexpected difference is that, unlike bases from other important natural products, those from protein material are at least 50% *petroleum ether insoluble* and, besides, the higher boiling fractions have a much greater nitrogen content than can be accounted for on the assumption of a single nitrogen in the molecule. Furthermore, there is no evidence of naphthenic structure, such as is highly probable for certain petroleum bases. From the lower boiling fractions there have been isolated pyridine, and a number of its homologs, identical with products from coal, shale or bones.

The coal tar bases, quinoline, isoquinoline, quinaldine and lepidine, along with the kero base, 2,3,8-trimethylquinoline[2b] (p. 1245), have been found. A beautifully crystallizing diazine, $C_{11}H_{14}N_2$, of undetermined structure is probably a dihydroquinazoline, as indicated by its amphoteric character.

Upon vacuum distillation of the high boiling protein bases in an atmosphere of nitrogen, colorless distillates are obtained which, unlike corresponding petroleum base cuts, soon darken and precipitate tar. This instability renders difficult the isolation of individual products. So far the petroleum ether insoluble bases have been only superficially studied.

In the boiling range of 135 to 172° a total of 876 cc. (14 fractions) of petroleum ether soluble material was available with $d^{25}{}_4$ values between 0.9418 and 0.9652 and $n^{25}{}_D$ values between 1.4947 and 1.4992. These physical constants clearly indicate a preponderance of pyridines. From the high nitrogen content of these fractions pyrazines and pyrimidines were suspected but a search for diazines was fruitless. The comparatively small volume of material in this range can be attributed

to the fact that no attempt was made at the Union Oil Company plant to isolate water soluble bases.

In the 172 to 215° range 2468 cc. of material (17 fractions) was available. Here there exists a progressive exaltation of the $d^{25}{}_4$ values from 0.9514 to 1.0189 and of the $n^{25}\text{D}$ values from 1.5010 to 1.5375. These constants, taken with an abnormally high nitrogen content, exclude the presence in quantity of pyridines, as well as quinolines.

The results of this investigation should not be accepted as proof that so-called petroleum bases are not of vegetable or animal origin. From the assumption that the complex nitrogen compounds in crude oil came from protein material, it does not follow that a high temperature was involved in their formation; it is more probable that they resulted from bacteriological decay at ordinary temperature;[4] at least, so far as California petroleum is concerned, the nitrogen does not exist in preformed *basic* compounds beyond a negligible amount and, therefore, the bases first encountered in distillates, are products of pyrolysis.[5,2a,b]

A recently developed practical method of indirect micro distillation, termed Amplified Distillation,[6] has proved of indispensable service in processing the cottonseed meal bases. In this process, which is even more effective than straight distillation, a fraction of bases is added to petroleum hydrocarbon oil boiling evenly over a somewhat broader range than the bases. After fractional distillation, the bases are withdrawn from the hydrocarbon fractions with sulfurous acid and then precipitated in the form of picrates or other suitable salts. In this way the components of a complex mixture, even where the total volume is only a fraction of a cubic centimeter, can be segregated in the order of their boiling points.

Another general method employed in resolving mixtures of protein bases, termed Cumulative Extraction,[2e] depends on the relative distribution ratio of base hydrochlorides between chloroform and water. This process enables a very satisfactory separation into aromatic and non-aromatic types.

The improved laboratory technique now available in this line of research, coupled with the advances made in our knowledge of the types and properties of the bases to be expected, should attract the attention of other investigators to the study of protein pyrolysis, especially the biochemist, whose interest in this practically unexplored domain of organic chemistry need not be emphasized.

To chemists who may become interested in protein pyrolysis as an attractive field for re-

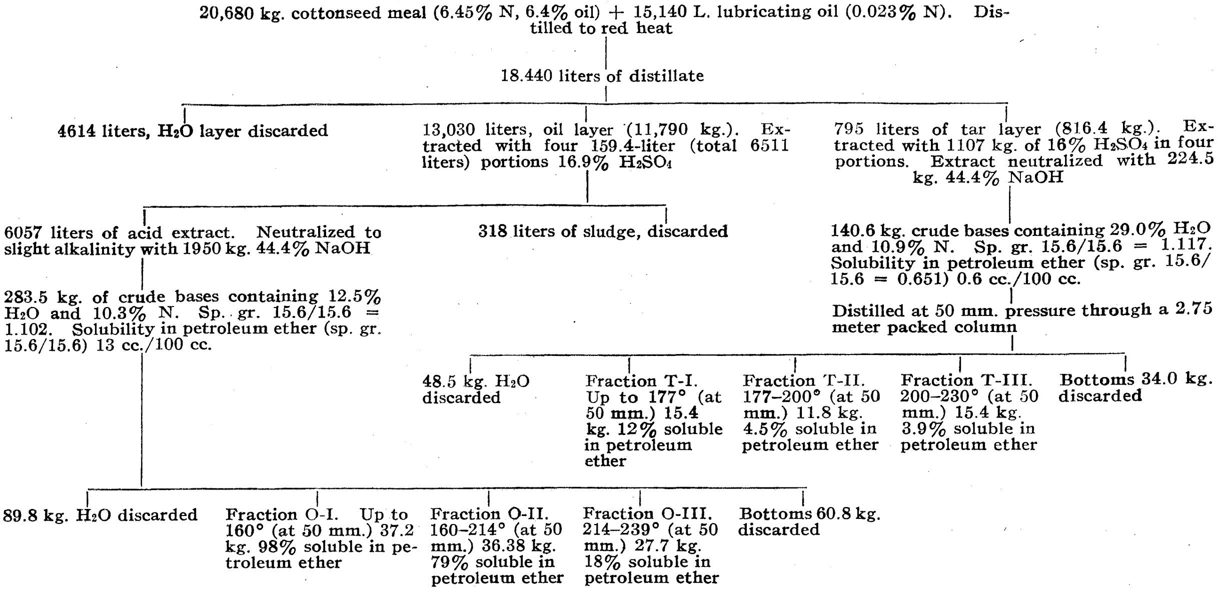

Fig. 2.

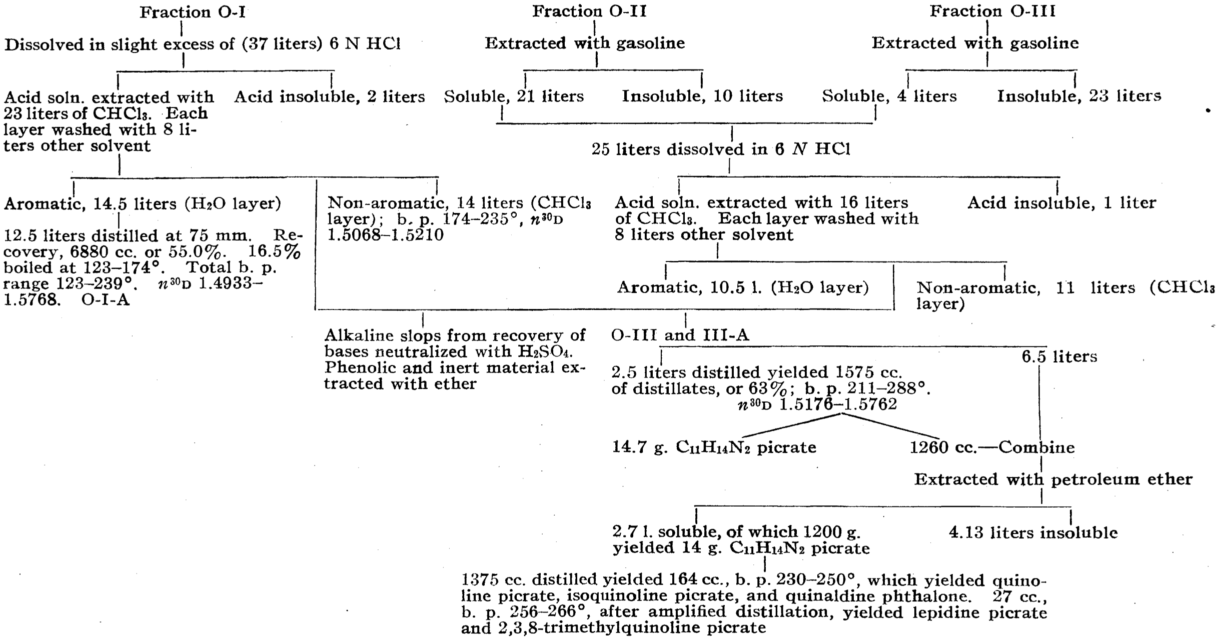

Fig. 3.

search, it may be emphasized that the cost of neither material nor equipment is prohibitive. In our preliminary investigation, an insulated iron still 3 feet (94 cm.) in height, 2 feet (61 cm.) in diameter and provided with a stirrer was used. For each of the six runs made, the charge consisted of 100 pounds (45 kg.) of cottonseed meal ($25–35 per ton (910 kg.)) and 8 gallons (30 liters) of lubricating oil. The distillates from 600 pounds (272 kg.) of meal processed in the usual way yielded a total of 5.5 liters of crude bases.

One of the most important considerations, especially where the distillation is carried out in the laboratory, is the obnoxious mercaptan odor developed. This nuisance can be suppressed conveniently by the use of two filter flasks connected separately with water pumps and serving interchangeably as receivers.

TABLE I

DISTILLATION OF O-I-A BASES

No.	Temp. range, °C.	Press., mm.	Vol., cc.	d^{25}_4	$n^{25}_{\rm D}$	N, %	Bases isolated

Experimental

In the production of nitrogen bases from cottonseed meal at the Oleum Plant of the Union Oil Company,[7] a shell still, 8 by 29 feet (2.5 × 8.8 meters) was used in distillation of the cottonseed meal–lubricating oil mixture, air from the spider of the still being used for agitation. The still run occupied seven days; however, most of the distillate was collected in four days. After completion of the distillation, the still was allowed to cool for four days and even then difficulty was experienced in handling the coke,[8] due to a tendency to spontaneous combustion. Distillation temperature and rate are summarized in Fig. 1. Acid extraction and distillation data, along with yields of base fractions are compiled in Fig. 2.

Fractions O-I, O-II and O-III, Fig. 2, were processed through petroleum ether extraction, cumulative extraction and fractional distillation, as shown in Fig. 3.[9] The material O-I-A, Fig. 3, boiling below 215° was carried through exhaustive fractionation by three separate distillations in a carbon dioxide atmosphere under reflux through a spirally indented column, 1 × 105 cm.

Volumes, boiling points, nitrogen content, d^{25}_4 values and $n^{25}_{\rm D}$ values of the 33 fractions obtained are collected in Table I.[10]

Investigation of O-I-A Forerun

BY A. C. BRATTON

The small volume of forerun (1 cc. of bases in 9 cc. of water) precluded direct fractional distillation under reflux. Amplified distillation was conceived to obviate the difficulty, and this first experiment in its use as an indirect method of microdistillation was carried out successfully as follows: to the 1 cc. of bases, 25 cc. of acid-and-caustic-washed hydrocarbon oil, b. p. 80–140°, was added and the mixture was distilled through a 0.5 × 100 cm. column packed with a copper spiral. The rate of distillation was

---

(7) The data in this connection were furnished by Mr. T. F. Ott, Assistant Manager of Research at Oleum, California.

(8) This proved a very effective decolorant.

(9) This work was carried out by Ivy Parker.

(10) This work was carried out by A. C. Bratton and C. L. Gutzeit.

0.6 cc. per hour, and nine 2.5-cc. cuts and a 3-cc. residue were collected in the ranges shown in Table II.

TABLE II

AMPLIFIED DISTILLATION OF THE BASES IN O-I-A FORERUN

Cut no.	B. p. base-hydrocarbon fractions, °C.	Products isolated, mg.	
1	55–85	30	Pyridine picrate
2	85–95		
3	95–100		
4	100–107	300	2-Methylpyridine picrate
5	107–109		
6	109–115	450	Mixed picrates
7	115–122		
8	122–124		
9	124–138	10	2,6-Dimethylpyridine picrate
Residue			

Each fraction was extracted twice with an equal volume of 6 *N* sulfuric acid, the bases were liberated from the extracts with sodium hydroxide and steam distilled, and finally precipitated with aqueous picric acid.

Pyridine.—The combined picrates from cuts 1 and 2 were recrystallized from water, ethyl acetate and isopropyl alcohol. The product, m. p. 167.7–168°, proved to be pyridine picrate through a mixed melting point with an authentic sample.

Anal. Calcd. for $C_{11}H_8O_7N_4$: N, 18.19. Found: N, 18.30.

2-Methylpyridine.—After similar treatment of the picrates from cuts 4 and 5, a salt melting at 166° was identified as 2-methylpyridine through a mixed melting point.

Anal. Calcd. for $C_{12}H_{10}O_7N_4$: N, 17.40. Found: N, 17.62.

2,6-Dimethylpyridine.—Fraction 9 yielded a picrate melting at 163° after recrystallization from water and isopropyl alcohol. It was identified as 2,6-dimethylpyridine by a mixed melting point.

Investigation of O-I-A Fractions 135–170°

BY C. L. GUTZEIT

3-Methyl-, 4-Methyl- and 2,6-Dimethylpyridine.—These bases boiling at 144, 145.3 and 144.6°, respectively, were suspected in the 140–145° fractions, and, after their separation through picrates proved tedious and unsatisfactory, the following procedure was employed: a solution of 10 cc. of crude bases in 500 cc. of saturated mercuric chloride and 10 cc. of concentrated hydrochloric acid was evaporated to 150 cc. The precipitate was recrystallized from alcohol and then dissolved in 1000 cc. of a hot saturated solution of mercuric chloride containing 100 cc. of concentrated hydrochloric acid. On cooling, the 2,6-dimethylpyridine double salt of the composition $C_7H_9N \cdot HCl \cdot 2HgCl_2$ separated in granular crystals melting at 167°.[11] The picrate prepared from this salt melted at 162° as reported by Eguchi. In final identification of these salts, they were prepared from 2,6-dimethylpyridine, synthesized from 2-methylpyridine methiodide according to the general method of Ladenburg.[12] Mixed melting points carried out in the usual way showed no depression.

Anal. of picrate. Calcd. for $C_{13}H_{12}O_7N_4$: C, 46.42; H, 3.57; N, 16.67. Found: C, 46.35; H, 3.58; N, 16.52.

Anal. of base. Calcd. for C_7H_9N: C, 78.50; H, 8.41; N, 13.08. Found: C, 78.42; H, 8.43; N, 13.29.

For the separation of 4-methylpyridine, the filtrate from the mercuric chloride salt of 2,6-dimethylpyridine was neutralized with sodium hydroxide and then made just acid to methyl orange. After twelve hours, a salt separated which was recrystallized from water in long slender needles melting at 128–129°, as found by Ladenburg for the mercuric chloride salt, $C_6H_7N \cdot HCl \cdot 2HgCl_2$, of 4-methylpyridine[12] (p. 13). Final identification was effected through a mixed melting point with a sample of picrate made from 4-methylpyridine synthesized from pyridine methiodide.[13]

Anal. Calcd. for $C_{12}H_{10}O_7N_4$: C, 44.72; H, 3.11; N, 17.39. Found: C, 44.66; H, 3.15; N, 17.49.

Anal. of base. Calcd. for C_6H_7N: C, 77.42; H, 7.53; N, 15.09. Found: C, 77.36; H, 7.51; N, 15.12.

In isolation of 3-methylpyridine, the low melting picrates from purification of 4-methyl- and 2,6-dimethylpyridine were used. After it was found impractical to segregate this picoline through the picrate, mercuric chloride salt[12] (p. 8) or the zinc chloride salt,[14] advantage was taken of the non-reactivity of 3-methylpyridine with benzaldehyde in contrast to the ease with which condensation takes place with the associated pyridine homologs.[15]

The bases recovered from the low melting picrates were mixed with twice their volume of benzaldehyde, a small piece of zinc chloride was added and the mixture was heated at 225° for six hours. The unchanged 3-methylpyridine was extracted with benzene from the reaction mixture made alkaline with sodium hydroxide. The dried extract was distilled and the 140–145° fraction was treated with a benzene solution of picric acid. The third recrystallization from alcohol gave a pure product in the form of long glistening needles melting at 149°, as reported for 3-methylpyridine picrate[11] (pp. 229, 241).

Anal. Calcd. for $C_{12}H_{10}O_7N_4$: C, 44.72; H, 3.11; N, 17.39. Found: C, 44.64; H, 2.93; N, 17.50.

Identification was further confirmed by a mixed melting point with the picrate prepared from the synthetic base.[16]

The 135–140° fraction of bases was investigated in a fruitless search for methylpyrazine. Since only 8 cc. of material was available, amplified distillation was resorted to in fractionation. A small amount of 3-methyl- and 2,6-dimethylpyridine was isolated, but none of the 4-methylpyridine.

3,5-Dimethylpyridine.—This base is easy to isolate and identify because of the difficult solubility and high melting point of its picrate. Three fractions of bases in the 165–170° range were picrated in two volumes of alcohol to one

[16] Ludwig Storch, *ibid.*, **19**, 2456 (1866).

volume of bases, picric acid solution being added to where no further separation of picrates resulted. The crude material melted at 234–236°. After two recrystallizations from acetone, the most satisfactory solvent for this salt, the melting point was raised to 242.5–243.5°.[17]

Anal. of picrate. Calcd. for $C_{13}H_{12}O_7N_4$: C, 46.43; H, 3.57; N, 16.67. Found: C, 46.61; H, 3.59; N, 16.54.

Anal. of base. Calcd. for C_7H_9N: C, 78.50; H, 8.41; N, 13.08. Found: C, 78.44; H, 8.36; N, 13.35.

The identity of the picrate was confirmed further by a mixed melting point with a sample made from synthetic 3,5-dimethylpyridine.[18]

3-Ethylpyridine.—From the 165–167.5° fraction of bases oily picrates admixed with crystalline 3,5-dimethylpyridine picrate were obtained. After removal of the latter, long yellow needles followed in about two weeks and, after several recrystallizations from alcohol, the melting point 129° agreed with that of 3-ethylpyridine picrate.[19]

Anal. Calcd. for $C_{13}H_{12}O_7N_4$: C, 46.43; H, 3.57; N, 16.67. Found: C, 46.32; H, 3.54; N, 16.56.

In further structural proof, 0.3 g. of the base in 100 cc. of water containing 2 g. of potassium permanganate was allowed to stand three days when the colorless solution was filtered hot and neutralized with acetic acid. On addition of copper acetate, followed by concentration of the solution to a small volume, a deep blue copper salt precipitated. After removal of the copper with hydrogen sulfide and evaporation of the filtered solution, the residue, recrystallized several times from alcohol, melted at 229° in agreement with nicotinic acid.[20]

2,4,6-Trimethylpyridine.—This pyridine was isolated from the 167.5–170° fraction of bases through the following procedure. The mixed bases (20 cc.) in 100 cc. of a saturated alcoholic solution of mercuric chloride containing 10 cc. of concentrated hydrochloric acid were allowed to stand for twelve hours, oily impurities were removed and the residue was dissolved in a small volume of hot alcohol. After twenty-four hours a dense crystalline precipitate separated. On one recrystallization from a saturated solution of mercuric chloride containing 5% hydrochloric acid,[21] and three recrystallizations from very dilute acid, the characteristic needles of the double salt of 2,4,6-trimethylpyridine, $C_8H_{11}N\cdot HCl\cdot 2HgCl$, melting at 156° were obtained.

The picrate melting at 155° was prepared and compared in the usual way with a sample made from the synthetic base.[22]

Anal. Calcd. for $C_{14}H_{14}O_7N_4$: N, 16.00. Found: N, 15.89.

2,4-Dimethylpyridine.—The 155–157.5° fraction of bases was treated with mercuric chloride in the way described under 2,4,6-trimethylpyridine. The more soluble mercuric chloride salts thus obtained were recrystallized three times from a mercuric chloride solution containing 5% hydrochloric acid. Since a pure product was not obtained, the bases were liberated in the usual way and converted to picrates. After four recrystallizations, a pure product melting at 182° in agreement with 2,4-dimethylpyridine picrate[11] (pp. 232, 241) was obtained. A mixed melting point with the picrate of the synthetic base[23,12] showed no depression.

Anal. Calcd. for $C_{13}H_{12}O_7N_4$: N, 16.67. Found: N, 16.56.

Investigation of Base Fractions in the 236–280° Boiling Range of O-II and III-A

By Ivy Parker

Quinoline and Isoquinoline.—The combined 236, 238 and 240° fractions (50 cc.) were dissolved in 75 cc. of 6 *N* hydrochloric acid and extracted with eight successive portions of chloroform. From the aqueous layer 27 cc. of bases was recovered. This material, extracted with 10 cc. of 3.5 *N* sulfuric acid, left undissolved 19 cc., which was treated with an excess of picric acid in alcoholic solution. The precipitate, after extraction with boiling benzene and next with boiling alcohol, was recrystallized from glacial acetic acid, yielding 2.5 g. of a picrate in the form of needles melting at 203°. Identification of this product was effected by a mixed melting point with an authentic sample of quinoline picrate.

Anal. Calcd. for $C_{15}H_{10}O_7N_4$: C, 50.28; H, 2.79; N, 15.64. Found: C, 50.21; H, 2.68; N, 15.74.

For the isolation of isoquinoline, 3 cc. of bases, recovered from the quinoline picrate washings above, was dissolved in 3 cc. of alcohol and fractionally precipitated in 11 stages with successive 3-cc. portions of a saturated solution of picric acid in alcohol. To induce crystallization, it was necessary to seed with a small crystal of isoquinoline picrate. The first eight isoquinoline picrate precipitates, leached out with boiling alcohol, yielded on recrystallization from glacial acetic acid 0.25 g. of light yellow needles melting at 221–222°. The identity of the product was established by a mixed melting point with an authentic sample of isoquinoline picrate.

Anal. Calcd. for $C_{15}H_{10}O_7N_4$: N, 15.64. Found: N, 15.92.

Quinaldine.—After it was found that the 246° fraction, unlike the lower boiling bases, showed phthalone formation, 5 cc. was heated for four hours at 200° with 2 g. of phthalic anhydride and the reaction mixture, after being dissolved in 17 cc. of concentrated sulfuric acid, was poured into 400 cc. of water. From the crude phthalone, admixed phthalic anhydride was sublimed at reduced pressure and the residue, after a leaching out with boiling alcohol, was dissolved in glacial acetic acid and poured into a large volume of water. From the impure product (0.22 g.) which precipitated, a pure phthalone was sublimed[24] in the form of

---

(17) This determination is in agreement with 244° reported by Eguchi, ref. 11, pp. 231, 241. Beilstein, 4th ed., Vol. XX, p. 246, gives 228–230°.

glistening yellow needles melting at 235°. A mixed melting point with an authentic sample of quinphthalone (m. p. 234–235°) showed no depression.

For hydrolysis of the phthalone a 0.5-g. sample was heated in a sealed tube for twenty-four hours with 2 cc. of concentrated hydrochloric acid and from the solution, made alkaline with caustic, an oil was distilled in steam. From the base a picrate was prepared which crystallized from alcohol in rosets of short slender needles melting at 189°. A mixed melting point of 190–191° was obtained with an authentic sample of quinaldine picrate (m. p. 190–192°).

Anal. Calcd. for $C_{16}H_{12}O_7N_4$: N, 15.05. Found: N, 15.18.

Lepidine.—Four fractions of bases (190 cc.) of b. p. 260–270° and with $n^{30}D$ 1.5770–1.5817, were separately fractionated through a Podbielniak column, 4-cc. cuts being collected. The fractions (50 cc.) of b. p. 257–262° and with $n^{25}D$ 1.5785–1.5806 were combined in 68 cc. of 6 *N* hydrochloric acid and carried through cumulative extraction by four successive extractions with 50-cc. portions of chloroform. The bases (32 cc.) from the acid layer were fractionated under reflux at 25 mm. pressure into nine 3-cc. cuts, with a 5-cc. residue. Cuts 1 and 2 were combined, as were also cuts 7, 8 and 9.

Amplified distillation of these fractions with 10 volumes of hydrocarbon oil was carried out under reflux at 20 mm. pressure, a total of 61 4-cc. fractions being collected. The bases were extracted from the hydrocarbon oil with sulfurous acid and directly converted to picrates. Where smears appeared, they were leached out with cold acetic ether. Then the crystalline material was recrystallized successively from alcohol, glacial acetic acid and 50% acetic acid. Nine of the 32 cuts from original fractions 1–2, 3 and 4 yielded a total of only 0.2 g. of a pure picrate melting at 212–213°. This product was identified as lepidine picrate in the usual way by a mixed melting point determination. Lepidine (b. p. 263°) appeared only in the 225–242° (atmospheric pressure) fractions of hydrocarbon fractions from amplified distillation.

Anal. Calcd. for $C_{16}H_{12}O_7N_4$: N, 15.05. Found: N, 15.25.

2,3,8-Trimethylquinoline.[25]—Here a procedure, involving cumulative extraction and amplified distillation, and similar to that employed in search of lepidine was employed on six fractions of bases (45 cc., b. p. 274–279°, $n^{30}D$ 1.5815). In the hydrocarbon fractions of b. p. 259–283°, 2,3,8-trimethylquinoline (b. p. 280°) was suspected. The mixture of picrates obtained was leached out with boiling alcohol and recrystallized from glacial acetic acid. In this way there resulted an apparently pure product crystallizing in characteristic short rods and melting with decomposition at 242–243°. A mixed melting point with an authentic sample of 2,3,8-trimethylquinoline picrate showed no depression.

Anal. Calcd. for $C_{18}H_{16}O_7N_4$: N, 14.00. Found: N, 13.81, 13.98.

Isolation of $C_{11}H_{14}N_2$ Base.—In processing Fractions O-II and O-III, there was encountered in very small amount among the aromatic, petroleum ether soluble bases a product easy to isolate through its difficultly soluble picrate. This picrate of the composition $C_{11}H_{14}N_2 \cdot C_9H_3O_7N_3$ (*cf.* Fig. 3) remained in the residue, after leaching out with benzene, alcohol and glacial acetic acid the complex mixture of picrates obtained in this boiling range. In final purification, it was recrystallized from diacetone alcohol in characteristic glistening plates which darkened at 259° and melted with decomposition at 261–263°.

Anal. Calcd. for $C_{17}H_{17}O_7N_5$: C, 50.62; H, 4.22; N, 17.37. Found: C, 50.38; H, 4.05; N, 17.60.

The base was liberated from the picrate with ammonium hydroxide and extracted with ether. For purification, it was distilled between 187–192° at 34 mm. pressure. It boils at 283° (750 mm.) and has an $n^{30}D$ value of 1.5790. The free base has an unpleasant odor, and on standing in contact with air is converted in part to a white solid which dissolves in potassium hydroxide but is insoluble in ether. Nitrous acid and both alkaline and acid permanganate react with the base in the cold. The analysis along with the decided amphoteric character of this substance is in agreement with an alkylated dihydroquinazoline. The small amount of material available precluded its further study.

Anal. Calcd. for $C_{11}H_{14}N_2$: C, 75.86; H, 8.05; N, 16.09; mol. wt., 174. Found: C, 75.5; H, 7.66; N, 16.33; mol. wt. 167.

Mercuric Chloride Salt.—The base in a slight excess of dilute hydrochloric acid gave with a saturated solution of mercuric chloride a precipitate which was recrystallized from water in rosets of needles. This salt sintered at 153° and melted at 173–174°.

Anal. Calcd. for $C_{11}H_{14}N_2 \cdot HCl \cdot HgCl_2$: N, 5.81. Found: N, 5.84.

Summary

The present investigation was undertaken in order to determine whether in low temperature pyrolysis of a natural product, containing proteins, carbohydrates and fats, products of the same structural types as the *non-aromatic* bases from petroleum distillates would be encountered. Although only negative results, so far as the main objective of this research is concerned, were obtained, it was found that cottonseed meal, in contrast to pure proteins, like egg albumin, casein and serine, yields on destructive distillation basic nitrogen compounds in preponderant amount which are different in three main respects from bases previously obtained from a natural source: *these properties are petroleum ether insolubility, an exceptional tendency to tar formation and an abnormally high nitrogen content.*

From the low boiling fractions pyridine, and seven pyridine homologs, identical with coal tar for shale oil bases, were isolated and in the higher fractions quinoline, isoquinoline, quinaldine, lepidine, the kero base, 2,3,8-trimethylquinoline and

a diazine, $C_{11}H_{14}N_2$, of undetermined structure were isolated.

This research will be concluded with an investigation now in progress on 18 fractions in the boiling range of 172.5–215°, in an effort to explain the abnormally high nitrogen content of these bases, coupled with a progressive exaltation of densities and refractivities from $d^{25}{}_4$ 0.9514 and $n^{25}{}_D$ 1.5025 to $d^{25}{}_4$ 1.0189 and $n^{25}{}_D$ 1.5375, respectively.

A Phase Rule Study of the Calcium Arsenates[1]

BY G. W. PEARCE AND L. B. NORTON

Calcium arsenate is a product of uncertain composition and variable properties, both in the form of the commercial insecticide and of the so-called pure salt. Although commercial preparations are generally assumed to consist essentially of tricalcium arsenate and an excess of hydrated lime, recent work[2,3,4] has shown that this assumption is inadequate to account for the variations in properties among products of similar gross composition. These variations suggest that other arsenates of calcium are probably present in the products prepared by the usual methods. Since data concerning the identity and the ranges of stability of the calcium arsenates are at present incomplete, a study of the equilibrium conditions in the system $CaO-As_2O_5-H_2O$ has been carried out.

A number of calcium arsenates have been reported in the literature. Smith,[5] in a study of the equilibrium conditions in the more soluble portion of the system, established the existence of two acid salts: monocalcium arsenate, $CaH_4(AsO_4)_2$, and dicalcium arsenate, $CaHAsO_4$. The dicalcium salt has also been prepared and studied by a number of other workers, and is known in the form of the minerals Haidingerite and Pharmacolite. Robinson[6] has reported the preparation of pure tricalcium arsenate, $Ca_3(AsO_4)_2$, from calcium chloride and sodium arsenate. Tartar *et al.*[7] obtained a basic product having the composition $[Ca_3(AsO_4)_2]_3 \cdot Ca(OH)_2$, by the repeated hydrolysis of calcium ammonium arsenate and of tricalcium arsenate prepared by Robinson's method.[6] Smith and Murray[8] concluded from complete analyses of a number of commercial preparations, that these products consist mostly of a compound more basic than tricalcium arsenate. Clifford and Cameron,[9] however, considered that some of the calcium arsenates reported were merely solid solutions of calcium oxide and arsenic oxide incidentally having the composition of possible compounds.

Experimental

The experiments were confined to the ranges of compounds more basic than dicalcium arsenate, since the work of Smith[5] on the acid compounds appears quite conclusive. Smith was unable to reach complete equilibrium in a reasonable time in the more basic region of the system at 35°, so a higher temperature was chosen for the present work. Preliminary experiments showed that changes in the system tend to occur more rapidly at higher temperatures, in spite of the decreased solubility of most of the compounds involved. Accordingly, a bath of petroleum oil maintained at 90 ± 0.1° was used for all of the work.

The calcium oxide was prepared by precipitating calcium carbonate from calcium chloride with ammonium carbonate, and igniting the product in an electric muffle furnace. It was found to be free from appreciable amounts of magnesium. Baker C. P. arsenic acid was used without further purification.

All analyses for calcium were made by the precipitation of calcium oxalate and titration with permanganate. Arsenic was determined by distillation as the trichloride and titration with bromate solution.[10] Application of these procedures to samples of pure calcite and of Bureau

of Standards arsenious oxide, respectively, showed that the maximum errors of the analysis were less than 0.1 mg. of calcium oxide and 0.05 mg. of arsenic oxide. In the analyses of the unknown samples, such quantities were taken that the analytical error was less than 1% except for the four most dilute solutions, in which it rose to about 3%.

Preliminary experiments, in which solid lime was shaken with arsenic acid of various concentrations, showed that equilibrium was not attained in six weeks, even at 90°. It appeared that penetration of the particles of lime by the dilute arsenic acid and the subsequent conversion to the proper compound is a process difficult to complete in a reasonable length of time. Further experiments in which the lime was added in solution showed more promise, but the solid in all cases showed a great reluctance to change, after once being precipitated, in contact with the extremely dilute solutions which characterize this portion of the system. These difficulties were finally avoided by precipitating the solid under such conditions that it had practically its final composition when it was first deposited. Both solution and solid then reached a constant and reproducible composition very quickly.

The procedure by which the final data were obtained was as follows. The solutions were made up in such proportions that small amounts of solid would precipitate at 90°, but the solutions would remain perfectly clear at room temperature. Such conditions were obtained when calculations from the preliminary data indicated that amounts of solid ranging from 50 mg. in the basic region to 500 mg. in the acid region should be deposited from 600 cc. of solution. Six hundred-cc. portions of the solutions were made up at room temperature in 1-liter wide-mouthed Pyrex Erlenmeyer flasks, using recently boiled distilled water and carefully standardized solutions of lime and of arsenic acid nearly saturated with lime. Each flask was closed with a rubber stopper through which extended a glass stirrer fitted with a mercury seal to protect the solution from evaporation and from contact with atmospheric carbon dioxide. The stopper also carried a small stoppered tube for withdrawal of samples for analysis during the course of the run. The flasks were immersed to the neck in the 90° bath, clamped in place, and the stirrers connected to a multiple stirring device which permitted the running of eight samples at one time. Most of the solids began to deposit only after the solutions had been held for some time at 90°. Under these conditions, equilibrium was established very quickly. Analyses of the solutions showed that no detectable changes occurred after the first few hours, but the samples were run for two to ten days before the final analysis. At the end of this period, most of the solids had begun to show a definite crystalline structure.

When the mixtures had reached a constant composition, they were removed from the bath and filtered rapidly by suction through a Büchner funnel. The filtration required about one minute, during which time the temperature of the solution dropped not more than 15–20°. No appreciable error was introduced by this procedure, since the composition of the filtered solutions checked within the

analytical error with samples of the same solutions previously pipetted directly from the flasks during the course of the run. Following the filtration, portions of the solution were cooled, weighed, and analyzed for calcium and arsenic. The solid was washed on the filter paper with small amounts of hot water, dissolved in 1:1 hydrochloric acid, made to volume, and suitable aliquots of this solution analyzed for calcium and arsenic. Because of the small quantity of the solid, no attempt was made to weigh it before analysis, but only the ratio of calcium oxide to arsenic oxide was determined.

Results and Discussion

The data obtained by the final procedure are presented in Table I, and plotted in Figs. 1 and 2.

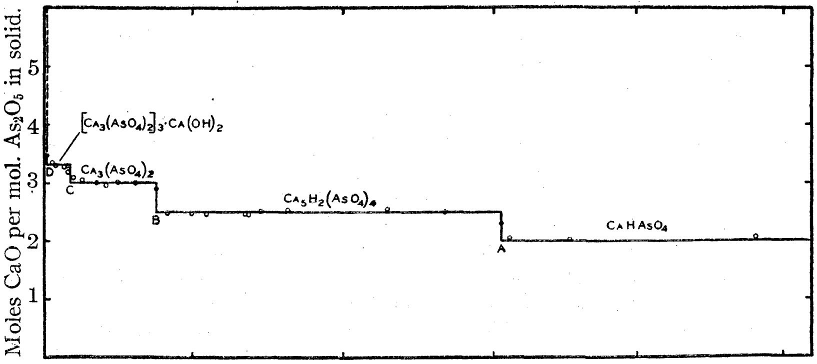

Fig. 1.

As shown in the table, the data are taken from the results of six different runs, only those samples being selected from each run which fulfilled the conditions of precipitating at 90° and not at room temperature. The reproducibility of the results is shown by the fact that the ranges of each of the three more basic compounds contain points from three different experiments.

The method of plotting used in Fig. 1 was employed for the identification of the compounds because the high dilution of all of the solutions made it impossible to plot the compositions of both solids and solutions to the same scale on a diagram such as that of Fig. 2.

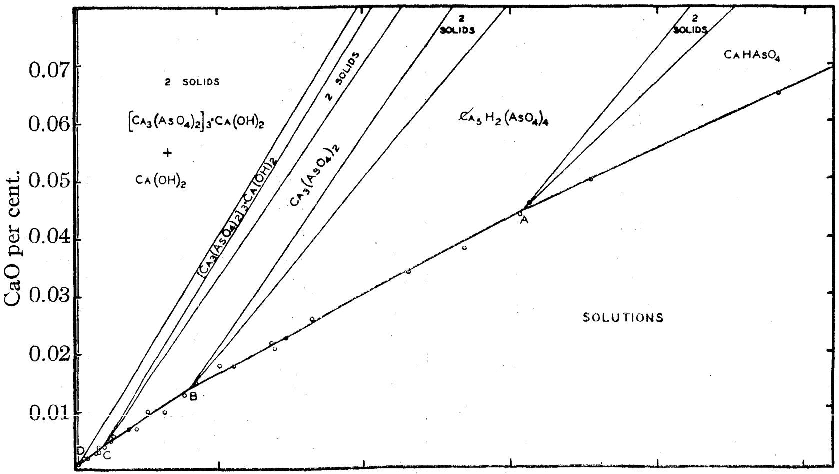

Fig. 2.

The flat portion of the curve in Fig. 1 from the extreme right to the point A shows the existence of a compound $2CaO:As_2O_5$. Although the data do not show the amount of water associated with any of the solid compounds, this composition corresponds to the dicalcium arsenate, $CaHAsO_4$. The curve as plotted shows only the extreme lower end of the range of this compound, which is stable in contact with solutions containing up to 27.5% arsenic oxide at 35°, according to Smith.[5] All of the solids in this group showed a definitely crystalline structure under the microscope.

The flat portion AB corresponds to a pentacalcium compound $5CaO:2As_2O_5$, which is another acid compound, the simplest empirical formula for which would be $Ca_5H_2(AsO_4)_4$. So far as the writers are aware, this compound has not previously been reported. An analogous compound is known among the calcium phosphates, however, in the form of the mineral Martinite, $Ca_5H_2(PO_4)_4$. The arsenate came out readily in the form of long, pointed needles, quite different in form from the crystals of dicalcium arsenate. The solid obtained in the sample, which falls on the vertical portion of the curve at A (Fig. 1), showed distinct crystals of both types.

The flat portion BC indicates the compound $3CaO:As_2O_5$, or tricalcium arsenate, $Ca_3(AsO_4)_2$. The very narrow range of this compound accounts for the difficulty experienced by other workers in preparing pure samples. The solids in this group were largely amorphous, although several showed a few crystals which were quite definitely not similar to those of either of the acid compounds.

The portion CD is somewhat more uncertain than the other three, being extremely short. There is very little question, however, from these results and from the results of preparations which are discussed later, that this portion represents a definite basic compound, $10CaO:3As_2O_5$, which is the same as the compound $[Ca_3(AsO_4)_2]_3 \cdot Ca(OH)_2$ reported by Tartar *et al.*[7] These solids appeared almost entirely amorphous, with a slight indication in one or two cases of the incipient formation of crystals.

The curve becomes vertical again at the point D, representing most probably a mixture of the basic compound with free lime. The points were not carried any farther up this curve, because the limitations of the analysis would not permit the identification of any further compounds if they existed, and because the etching of the flasks, which occurred in this region, would in any case make the results uncertain.

Figure 2 shows in more detail the general equilibrium conditions in the system. The curve ABCD represents the compositions of solutions in equilibrium with the various solid compounds. The letters A, B, C, and D represent the same points as in Fig. 1.

The diagram in Fig. 2 was used as the basis for a number of preparations of the different compounds, which were made in order to check the validity of the curve, and to furnish larger quantities of the pure compounds for a study of their properties. Small amounts of each of these preparations were made at 90°, but it was found more convenient for the larger amounts to be prepared at 100°, assuming that the curve would not be widely different at that temperature. Samples of two or three grams were prepared by making up solutions having a composition on the curve ABCD at about the center of the range of the compound sought, heating to boiling, and simultaneously adding lime and arsenic acid solutions in the proper proportions to form the compound, regulating the boiling and the rate of addition of the solutions so that the total volume of the mixture was kept constant. Little difficulty was experienced in obtaining products having the proper CaO/As_2O_5 ratios. Products were obtained having the following molecular ratios: basic, 3.30, 3.26; tri, 3.01, 3.00; penta, 2.49, 2.52; di, 2.00, 1.98. The actual percentages of the constituents varied somewhat, due to the fact that the products were rather amorphous in most cases, making it difficult to remove all of the mechanically combined water. Further attempts are being made to prepare completely crystalline samples of the compounds, on which accurate chemical and physical data can be obtained.

Figure 2 also furnishes an explanation of the fact that preparations made by adding concentrated arsenic acid to a suspension of lime are not consistent in properties. Even though the final composition of the mixture may lie in the region corresponding to a mixture of the basic compound with free lime, temporary local concentrations of the acid may make possible the formation of appreciable amounts of the other compounds. The conversion of these compounds being very slow, considerable amounts of them may be left unchanged in the final product. Thus commercial calcium arsenates probably contain a mixture of several compounds depending on the conditions of precipitation.

It is apparent from the fourth column in Table I that the basic compound is the only one which can dissolve in water at 90° without hydrolysis. All of the solutions in equilibrium with the other compounds have a lower ratio of lime to arsenic than the compounds themselves, as was noted by Smith[5] in the case of dicalcium arsenate. The data are in agreement with Tartar's[7] observation that the basic salt is formed by hydrolysis of the tricalcium salt, but is unchanged by further treatment with water. The di and penta salt should also be convertible to the basic by the same treatment.

Acknowledgment.—The authors wish to express their appreciation to Dr. A. W. Avens for his assistance in much of the analytical work.

Summary

1. A study of the system $CaO–As_2O_5–H_2O$ at 90° has been carried out.

2. A technique has been developed which permitted rapid attainment of equilibrium in the system.

3. Four compounds have been identified: dicalcium arsenate $CaHAsO_4$, pentacalcium arsenate $Ca_5H_2(AsO_4)_4$, tricalcium arsenate $Ca_3(AsO_4)_2$, basic calcium arsenate $[Ca_3(AsO_4)_2]_3 \cdot Ca(OH)_2$.

4. Application of the data to the preparation of pure and commercial calcium arsenates has been discussed.

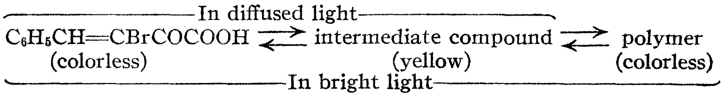
The Action of Light on Beta-Bromobenzalpyruvic Acid

BY MARIE REIMER

The action of sunlight on the methyl ester of benzalpyruvic acid results in polymerization of the ester to cyclobutane derivatives[1] as is the case with the cinnamic acids and many other ethylenic compounds. In a study of other unsaturated α-ketonic acids, in this Laboratory, it has been found[2] that benzalpyruvic acids in which methoxyl groups are substituted in the nucleus are less affected by light than the unsubstituted ester. The most active substance encountered is β-bromobenzalpyruvic acid which is extraordinarily sensitive to light. The present paper describes results so far obtained in the study of this light reaction.

When a colorless solution of β-bromobenzalpyruvic acid in benzene is allowed to stand in the diffused light of the laboratory it takes on a yellow color and, after two to three days, has become a brilliant lemon yellow. This color change does not take place in the dark.

On exposure of this yellow solution in thin layers to the direct sunlight the color fades quickly and the solution remains colorless for hours if kept in the direct rays of the sun. As soon as it is removed from the sunlight the yellow color reappears. The change from a yellow to a colorless solution in direct sunlight and from colorless to yellow in diffused light is rapid and can be repeated many times. The solution is so sensitive to the difference in intensity of the light that moving it a few cm. out of the direct rays is sufficient to bring back the yellow color and even the passing of a cloud over the sun has the same effect. After several hours of exposure a white crystalline substance begins to separate on the walls of the containing vessel. This is a dimeric form of β-bromobenzalpyruvic acid. The filtered solution, colorless after a day of exposure to the sunlight, becomes brilliantly yellow overnight. This yellow intermediate compound is, in all probability, a geometrical isomer of the original acid which forms an equilibrium mixture with that acid in diffused light. The effect of light on β-bromobenzalpyruvic acid is then, in part, as follows



$$\overbrace{\underbrace{\underset{\text{(colorless)}}{\mathrm{C_6H_5CH{=}CBrCOCOOH}} \rightleftarrows \underset{\text{(yellow)}}{\text{intermediate compound}} \rightleftarrows \underset{\text{(colorless)}}{\text{polymer}}}_{\text{In bright light}}}^{\text{In diffused light}}$$

The cause of the rapid change in color of the solution as it is moved into and out of the direct rays of the sun is evidently the difference in rate of polymerization in bright and in diffused light, the speed of polymerization outstripping that of isomerization in bright light but falling far behind it in diffused light, a sensitivity to difference of light intensity recalling that of lactoflavine, recently described.[3]

If the tubes used for exposure are tightly stoppered another effect of light becomes apparent in the formation of a volatile substance which, as soon as it has saturated the benzene solution, changes the course of the reaction. This substance was found to be hydrogen bromide formed evidently by photodecomposition of some of the bromine compounds present. In its presence there is no appearance of the yellow compound, the polymer is formed in but small quantity, much of the original acid being recovered unchanged. The solution slowly takes on a brown color due to formation of decomposition products. When the tubes are left open to the air, so that the hydrogen bromide escapes, there is no evidence of such products until the solution has been exposed for several weeks. The containers used were at first loosely stoppered to allow the escape of this gas but, as it was found that the solutions were sensitive to the oxygen of the air, later experiments were conducted in an atmosphere of nitrogen. The best yields of polymer were obtained in this way.

(3) Karrer, Köbner, Salomon and Zehender, *Helv. Chim. Acta*, **18**, 270 (1935).

The yellow solutions, saturated with nitrogen and exposed to bright sunlight with a stream of nitrogen running through, rapidly lost their yellow color. The polymeric compound was deposited in yields of 75 to 80%. The characteristics of this compound are like those of the substance formed from the unsubstituted benzalpyruvic ester in the sunlight[1] which has been proved to be a cyclobutane derivative. If these two reactions are, indeed, analogous, exposure to the light of the unsaturated bromo acid without a solvent would be expected to give directly a polymeric product, without the intermediate formation of an isomer, which should then be different from the polymer obtained from benzene solution. This has been found to be the case. On exposure of bromobenzalpyruvic acid to the sunlight without solvent, there is no change in color. The crystalline acid slowly crumbles to a fine powder from which there can be separated, in small quantity, a crystalline dimeric compound isomeric with the one obtained in benzene solution. The space relation of these isomeric polymers is still under investigation.

When freshly prepared, colorless solutions of β-bromobenzalpyruvic acid were exposed to bright sunlight with a stream of dry oxygen running through the solution, they took on a brownish-yellow color almost at once, a color which did not fade at all in the light, and a pale brownish solid was deposited slowly. This is a mixture, the chief components of which are the dimer, obtained previously from benzene solution, melting at 201°, and a bromo acid melting at 109°. This acid has the formula $C_{10}H_8O_4Br_2$, differing from the original unsaturated bromo acid, $C_{10}H_7O_3Br$, by the elements of hypobromous acid. It is evidently formed in the oxidizing mixture by the addition of hypobromous acid to the unsaturated acid as it can be readily obtained by suspending β-bromobenzalpyruvic acid in water and drawing bromine vapor through the liquid. It is the presence of this bromo acid (109°) that gives the brownish-yellow color to the solution.

The most interesting product of the action of light on β-bromobenzalpyruvic acid appeared after the experiments had been in progress for some time when the solvent was benzene from another source than that previously used. The yellow solutions, in tubes open to the air, began to deposit colorless crystals with a brilliant pearly luster almost immediately on exposure to the sunlight. After several hours the solution became slightly cloudy and the polymeric compound (201°) was slowly deposited. In many repetitions of this experiment the separation of the shining solid began within a few seconds of exposure to the sunlight and stopped abruptly after several hours. The fact that this compound had not been obtained when benzene from another source was used as a solvent and that its formation stopped completely after a limited time suggested that it was a product of reaction of the unsaturated acid with some foreign substance in the benzene. On investigation the benzene was found to contain moisture; after its removal the reaction proceeded as previously described. The new compound is, therefore, a hydrolytic product. It is a saturated acid free from bromine, fairly soluble in cold water, melting with vigorous decomposition at 134°. It has the formula $C_{10}H_{10}O_6$. Oxidation of a dilute solution of the sodium salt of the acid with hydrogen peroxide gave two soluble products which were proved to be mandelic and oxalic acids. The properties of the substance and these two products of oxidation suggest that the compound $C_{10}H_{10}O_6$ is an hydroxy acid, $C_6H_5CHOHCOCOCOOH \cdot H_2O$. The acid, however, is colorless and it does not lose water on standing for many weeks over sulfuric acid. Because of these facts and because the ketone groups in such a compound would be highly activated, more probable structures would be $C_6H_5CHOHCOC(OH)_2COOH$ or $C_6H_5CHOHC(OH)_2COCOOH$. That there are two hydroxyl groups attached to neighboring carbon atoms and the second of these formulas therefore correct is shown by the behavior of the acid toward the Criegee[4] reagent; when treated with lead tetraacetate, benzaldehyde is formed immediately.

It is to be expected that an acid of this constitution could be obtained from β-bromobenzalpyruvic acid by oxidation and hydrolysis at the double linkage and subsequent hydrolysis of the bromine atom and it has, in fact, been found possible to reproduce the light reaction by use of potassium permanganate under carefully controlled conditions. The products of this reaction were the bromo acid (109°), mandelic and oxalic acids and a 35 to 40% yield of the hydroxy acid. The possibility of preparing from this acid compounds with several highly activated groups makes it of more than usual interest. These experiments are now in progress.

---

(4) Criegee, *Ber.*, **64**, 260 (1931).

It is evident, from the foregoing account, that the products formed by action of light on β-bromobenzalpyruvic acid are determined by the conditions of the reaction. The acid, exposed to light in the solid condition, is very slowly polymerized to a dimeric form. In benzene solution it changes fairly rapidly to a yellow compound, probably a geometrical isomer, which in bright sunlight is transformed into a colorless, isomeric diamer. In the presence of oxygen the chief products obtained from the benzene solution are this same diamer and a bromo acid formed by addition of hypobromous acid to the original unsaturated acid. If moisture as well as oxygen is present, an hydroxy acid, $C_6H_5CHOHC(OH)_2$-COCOOH, separates rapidly from the benzene solution on exposure to the light. Such a light reaction, resulting in the addition of two hydroxyl groups to an ethylenic linkage, was postulated by Ciamician[5] to account for the final products obtained by him from the mixture of substances formed by action of light on methylheptenone but the compound was not isolated. A parallel behavior, "hydroxylation" at the double linkage, has recently been suggested[6] to account for the formation of azafrin in the escobedia plant and mentioned as a possible first step in the change of β-carotene to vitamin A. Certainly the compound here described is the result of photochemical "hydroxylation" in the presence of moisture and oxygen of the air.

Experimental Part

Beta-bromobenzalpyruvic acid was obtained as previously described[1] from benzalpyruvic acid prepared by a later method.[7] The pure bromo acid in saturated benzene solution was exposed to bright sunlight in quartz test-tubes or flasks fitted with grooved stoppers so that the hydrogen bromide, that had been found to block the reaction, could escape. The intermediate yellow compound, under these conditions, changed to the polymer as fast as it was formed. On moving the solution out of the direct rays of the sun, the yellow color became apparent. After several hours of exposure, fine crystals of the polymeric compound began to separate. These were filtered out at frequent intervals. After about two weeks of exposure there was no further separation of this compound. The benzene filtrates, now of a pale brownish color, contain a complex mixture of material from which benzoic and oxalic acids, an unidentified bromo acid and a tarry residue have been obtained. When dry nitrogen was passed through the solutions during exposure the yield of polymeric compound was increased from about 50 to nearly 80%.

The solid polymer, washed with benzene, separates slowly from methyl alcohol in large, brilliant, clear, rhombic crystals which rapidly become opaque on exposure to the air. The pure substance melts with vigorous decomposition at 201°. It is readily soluble in acetone, fairly soluble in ether and in boiling methyl alcohol, insoluble in benzene, chloroform and ligroin.

Anal. Clear crystals: Calcd. for $C_{20}H_{14}O_6Br_2 \cdot 2CH_3OH$: C, 45.99; H, 3.83. Found: C, 45.51; H, 3.66. Opaque crystals: Calcd. for $C_{20}H_{14}O_6Br_2$: C, 47.06; H, 2.74. Found: C, 47.03; H, 2.56.

The compound decomposes to give yellow solutions on long heating in organic solvents and, in the dry condition in the light, it takes on also a yellow color.

All attempts to replace the bromine atoms with hydrogen or to eliminate the bromine atoms so that the compound could then be reduced in the hope of obtaining one of the unsubstituted cyclobutane acids formerly prepared[1] have been unsuccessful. The acid is either not attacked at all by the reagents used or suffers deep-seated decomposition. It is interesting to find that Stoermer in his latest work on cyclobutane acids[8] has met with the same difficulty in the case of a brominated γ-truxillic acid.

The **methyl ester** of the acid could not be prepared by the action of methyl alcohol, saturated with hydrogen chloride, but was readily formed by action of diazomethane. The ester is very slightly soluble in ether and alcohols, more readily in acetone and benzene. It separates from boiling methyl alcohol in colorless prisms melting at 212° with slow decomposition above the melting point.

Anal. Calcd. for $C_{22}H_{18}O_6Br_2$: C, 49.07; H, 3.34; mol. wt., 538. Found: C, 49.08; H, 3.29; mol. wt. (Rast), 526.

The ester does not decompose on long boiling with methyl alcohol nor in the light but solutions in benzene turn yellow slowly on heating. It is extremely resistant to saponification. This same ester can be prepared by exposing methyl β-bromobenzalpyruvate to sunlight in benzene solution.[9]

When finely ground crystals of β-bromobenzalpyruvic acid were exposed to the sunlight without solvent they crumbled slowly to a fine powder, strongly triboelectric. After two to three months' exposure, the mass was extracted repeatedly with small quantities of boiling benzene from which the original unsaturated acid crystallized on cooling. The small amount of residue, not soluble in benzene, was a colorless acid which separated from boiling methyl alcohol in stocky needles melting with decomposition at 285°. The acid does not crystallize with methyl alcohol. It is readily soluble in boiling benzene and in ether.

Anal. Calcd. for $C_{20}H_{14}O_6Br_2$: C, 47.06; H, 2.74; mol. wt., 510. Found: C, 47.47; H, 3.17; mol. wt. (Rast), 468.

The *methyl ester* was prepared with diazomethane in the

α-Keto-β,β,γ-trihydroxy-γ-phenylbutyric Acid, $C_6H_5CHOHC(OH)_2COCOOH$.—This acid, obtained when benzene containing a trace of moisture was used as solvent in the light reactions, separated from solution in small platelike crystals which are conspicuous because of their brilliant pearly luster. It was purified by repeated extraction with boiling benzene, the residue then dissolved in the smallest possible quantity of dioxane, in which it is readily soluble, and double the volume of benzene added. The acid separates in fine needles melting with vigorous decomposition at 134°. It is readily soluble in alcohols and acetone, fairly soluble in water.

Anal. Calcd. for $C_{10}H_{10}O_6$: C, 53.09; H, 4.42; mol. wt., 226. Found: C, 53.26; 53.38; H, 4.47; 4.42; mol. wt., 232.

Proof of Structure.—To one-half gram of the acid in the calculated quantity of dilute sodium carbonate solution, 10 cc. of hydrogen peroxide (13 vol.) was added. After twenty-four hours the solution was acidified, extracted with ether, the ether evaporated and the residue crystallized repeatedly from boiling benzene. Clear needles separated which rapidly became opaque in the air and then melted at 118°. These properties indicated mandelic acid and this was confirmed by a mixed melting point with an authentic sample. The crystals left from evaporation of the residual aqueous solution were identified as oxalic acid.

These two products proved that the groups C_6H_5CHOHC— and —COCOOH were present in the molecule. The proof that there are two hydroxyl groups attached to neighboring carbon atoms and that the formula of the acid is, therefore, $C_6H_5CHOHC(OH)_2COCOOH$, was obtained by oxidation with lead tetraacetate prepared according to the directions of Dimroth.[11] After half an hour, steam was passed through the reaction mixture which smelled strongly of benzaldehyde. *p*-Nitrophenylhydrazine added to the distillate gave a brick red solid which, after crystallization from glacial acetic acid, melted at 192–194° alone and when mixed with a sample of the *p*-nitrophenylhydrazone prepared from pure benzaldehyde.

As the yields of the hydroxy acid were small, rarely more than 5%, attempts were made to obtain it in larger quantity. The obvious procedure of adding more water to the benzene before exposure was not satisfactory; if but a small excess of water was added, the hydrate of bromobenzalpyruvic acid crystallized out and the reaction stopped. By passing moist oxygen through the benzene solution, however, the yields of hydroxy acid were increased to 10 to 12%. After this acid had crystallized out, a mixture of solids slowly formed from which have been separated the dimeric compound (201°), unchanged β-bromobenzalpyruvic acid, mandelic acid and the bromo acid (109°).

Synthesis.—Four grams of β-bromobenzalpyruvic acid was dissolved in a mixture of 130 cc. of acetone and 30 cc. of water and a few drops of sulfuric acid. A solution of 1 g. of potassium permanganate in 200 cc. of acetone was added slowly, the mixture mechanically stirred, and kept at a temperature of 0 to −3°. Small amounts of dilute sulfuric acid were added as needed to keep the solution faintly acid. The oxidation required two and one-half hours. After spontaneous evaporation of the acetone there remained about 12 cc. of water and a mixture of crystalline solids, which were washed with a very little cold water and dried over sulfuric acid for forty-eight hours. The mixture, 3.5 g., was then repeatedly extracted with 5-cc. portions of hot benzene. The shining residue, not soluble in benzene, was the pure hydroxy acid (134°). A further small amount was deposited from the benzene extracts as they cooled. The yield in all was 1.3 g. (36%). On standing the yellow benzene solutions deposited slowly clear shining crystals of the bromo acid, melting at 109°, described below. From the aqueous filtrate 0.34 g. of mandelic acid and 0.2 g. of oxalic acid were obtained, showing that about one-half of the unsaturated acid was oxidized and hydrolyzed to the hydroxy acid and that about one-fourth of this product was oxidized further to mandelic and oxalic acids.

The hydrogen bromide formed by the hydrolysis was evidently oxidized in the permanganate solution to hypobromous acid which formed an addition product with part of the unsaturated acid.

Hydrated Dibromohydroxybenzylpyruvic Acid, $C_6H_5CHBrCBrOHCOCOOH \cdot H_2O$ or $C_6H_5CHOHCBr_2COCOOH \cdot H_2O$.—This acid was synthesized in quantitative yield as follows: 5 g. of β-bromobenzalpyruvic acid was suspended in 400 cc. of water, the mixture cooled with ice and 3 g. of bromine vapor drawn through slowly with a current of air. The bromine was at first rapidly decolorized, then more slowly, and a pure white granular solid separated. The compound can also be prepared by dropping bromine into a cooled, aqueous suspension of the unsaturated acid. The substance crystallizes from benzene in clear fine needles melting to an opaque liquid at about 107°, to a clear liquid at 109°. It is readily dehydrated over sulfuric acid.

Anal. Calcd. for $C_{10}H_8O_4Br_2 \cdot H_2O$: C, 32.43; H, 2.70. Found: C, 32.58, 32.73; H, 2.78, 2.63. Calcd. for $C_{10}H_8O_4Br_2$: C, 34.09; H, 2.27. Found: C, 34.18; H, 2.61.

When benzene solutions of the acid are heated or left standing in the air they take on the deep brownish-yellow color characteristic of benzene solutions of β-bromobenzalpyruvic acid exposed to light in the presence of oxygen.

Summary

The action of light on β-bromobenzalpyruvic acid results in products differing according to the conditions of the reaction. Two isomeric diamers, a hydrated bromo acid and a trihydroxy ketonic acid are here described.

[CONTRIBUTION NO. 42 FROM COAL RESEARCH LABORATORY, CARNEGIE INSTITUTE OF TECHNOLOGY]

Exhaustive Chlorination of a Bituminous Coal

BY J. F. WEILER

Further support of the concept that coal is essentially benzenoid[1] in character was sought by subjecting a bituminous coal from the Pittsburgh seam, Edenborn Mine, to exhaustive chlorination in antimony pentachloride, this reaction converting aliphatic substances to carbon tetrachloride and hexachloroethane while removing only the side chains of benzenoid substances, leaving the ring structures intact.[2]

The coal, suspended in carbon tetrachloride at 76°, in phosphorus oxychloride at 107°, stannic chloride at 114°, and antimony pentachloride at 100, 150, 200 and 400°, was treated with chlorine. The reaction in the first three media did not proceed so far as in the antimony pentachloride, and the data obtained are not reported herein. About 10% of the reaction product in antimony pentachloride at 200° was volatilized easily and consisted of carbon tetrachloride, hexachloroethane and hexachlorobenzene. The non-volatile residue was too complex for identification. Elementary balances were made of both the volatile and non-volatile products.

Experimental

A sample of 200 mesh coal, dried *in vacuo* at 105° to constant weight and weighing about 7 g., was placed in a reaction flask connected with a trap cooled with dry ice and 50 cc. of antimony pentachloride added. Chlorine was led through the apparatus at the rate of about 3 cc. per minute while the temperature was maintained at the desired point by a furnace with automatic temperature control. As the chlorination proceeded volatile products were condensed in the trap.

At the conclusion of the chlorination the apparatus was disconnected and the trap allowed to warm up to 10° so as to evaporate the chlorine that had condensed there. Water was then added slowly and with good cooling to hydrolyze the antimony pentachloride that had condensed in the trap.

The volatile contents of the trap were then swept through a combustion train by means of a current of oxygen. Cerium dioxide on silica gel served as the combustion catalyst; it was followed by a layer of silver wool to remove halogens.

The non-volatile portion of the reaction product was treated in a Soxhlet extractor with 20% hydrochloric acid for six days in order to remove antimony, and then dried *in vacuo* over phosphorus pentoxide at room temperature.

Microelementary analyses of these non-volatile residues were made. The samples still contained enough antimony to vitiate the carbon–hydrogen determinations when the usual combustion tube filling was used. It was found possible, however, to adapt the red lead filling used to retain arsenic in macrocombustions[3] so that correct analyses were obtained on organic compounds containing antimony.[4]

Results and Discussion

Data are summarized in Table I in the form of elementary balances for the various experiments performed.

The criteria for following the extent of chlorination with time and temperature were the values for non-volatile chlorinated residue, for the carbon content of the volatile products, and the chlorine and hydrogen contents of the residue. The amount of non-volatile residue showed no significant change in the various experiments but the carbon in the volatile products increased greatly as the temperature rose from 100 to 150 to 200°, then increased but slightly as the time at 200° increased from one to four to six days. The rate of increase of chlorine content and decrease of hydrogen content with time and temperature fell off abruptly at the four-day 200° chlorination. Apparently the coal was exhaustively chlorinated after four to six days' chlorination at 200°.

As a further test of the extent of the chlorination one-half of a sample of coal chlorinated for six days at 200° without driving off the volatile reaction products was reheated with antimony pentachloride in a sealed tube at 400° for four days. Both halves of the sample were then extracted for twelve hours each, successively, with ether, chloroform and chlorobenzene, in a Soxhlet. Both products showed practically the same solubility, indicating that the chlorination at 200° had been nearly complete. The ether removed 21%, the chloroform 22% and the chlorobenzene 18%, leaving an insoluble residue of 39%. Analyses and empirical formulas for the fractions from the material chlorinated at 200° only are given in Table II. The empirical formulas are calculated

arbitrarily on the basis of six carbon atoms and the oxygen is assumed to be hydroxyl oxygen.

The mean molecular weights of these fractions were determined cryoscopically in catechol by the method of Smith and Howard[5] but the results were not sufficiently reproducible to indicate more than the order of magnitude. The three soluble fractions gave values from 130 to 190; the insoluble residue gave values from 230 to 270. These values were too low to be consistent with the physical behavior of the substances and it may have been that the substances underwent a dissociation similar to that reported by the above authors for humic acids.

The ether soluble fraction was light brown in color. When heated considerable amounts of hexachlorobenzene sublimed off and then the material charred with evolution of hydrogen chloride. The ratio of carbon to attached substituents was nearly one to one, indicating the absence of appreciable amounts of condensed ring structure in this fraction.

The chloroform and chlorobenzene soluble fractions and the residue were black and infusible, losing hydrogen chloride on heating. The ratio of carbon to attached substituents was approximately 6 to 4 in each fraction, indicating the presence of a preponderance of condensed ring structure.

The fraction of each of the constituent elements of the coal which make up the stable ring structures as represented by the non-volatile residues from the 200° chlorinations may be obtained from the elementary balances in Table I.

The carbon balances show that the non-volatile residue accounted for 85% of the carbon of the original coal. Approximately 5% was accounted for in the volatile reaction products which consisted wholly of carbon tetrachloride, hexachloroethane and hexachlorobenzene, while 10% was unaccounted for. The 10% was probably lost as carbon dioxide. The results indicate that approximately 85% of the carbon of this coal is present in a large, condensed ring structure not destroyed by chlorination, the other 15% being present in side chains or ring structures broken by chlorination.

The values for hydrogen were erratic; the non-volatile residue contained approximately 35–50% of the hydrogen present in the original coal. Assuming that the increase in the oxygen content of the residue was due to replacement of chlorine by hydroxyl during the hydrochloric acid extraction and correcting for the hydrogen thus introduced, the hydrogen content of the residue before extraction was approximately 25–40% of that of the original coal. The 60–75% hydrogen not accounted for in the non-volatile residue is probably not entirely peripheral hydrogen[6] but includes such nuclear hydrogen as has undergone reaction.

The nitrogen balances show that the chlorinated residues contained more nitrogen than the original coal, the excess having increased with increased chlorination until it amounted to 50%.

---

(5) R. C. Smith and H. C. Howard, THIS JOURNAL, **57**, 512 (1935).

(6) A. Eccles, G. H. Kenyon and A. McCulloch, *Fuel*, **10**, 6 (1931).

The nitrogen could not be traced to the reagents or to the small amount (<0.5%) of antimony in the residue. It is possible that the chlorination alters the nature of the nitrogen bonds in the coal so that nitrogen, previously inert to the Kjeldahl reagents, becomes susceptible to conversion to ammonium sulfate. It was observed that the chlorinated residue went into solution during the Kjeldahl digestion much more readily than the original coal. The presence of the total original nitrogen of the coal in the non-volatile chlorinated residue is in agreement with the findings of Heathcoat and Wheeler[7] and would indicate that the nitrogen is an integral part of the stable ring structure of coal.

The sulfur balances, although the values are erratic, show a trend toward less sulfur in the more highly chlorinated residues. It is possible that the antimony in the residue caused some error in the microanalyses, which were done by combustion in oxygen.

The oxygen balances show that the residues from the mildest chlorinations contained threefold the amount of oxygen contained in the original coal. The oxygen content decreased uniformly as the time and temperature of chlorination increased, until it was only 1.5 times that of the original coal. The increase in oxygen is probably due to hydrolysis during the hydrochloric acid extraction. In the earlier stages of chlorination the amount of chlorine susceptible to hydrolysis would be greatest, diminishing with increased temperature and time of chlorination due to splitting out as hydrogen chloride.

The chlorine balances show that the non-volatile residues from the four- and six-day chlorinations at 200° contained approximately 50% chlorine.

The ash content of the coal has been lowered somewhat, probably as much the result of the hydrochloric acid extraction as of the chlorination.

Acknowledgments.—The author is indebted to F. C. Silbert and T. B. Smith for the microanalytical determinations, and to R. C. Smith for the molecular weight determinations.

Summary

Coal has been chlorinated exhaustively with chlorine and antimony pentachloride for six days at 200°. Additional chlorination at 400° for four days did not materially increase the breakdown of the coal substance. The volatile reaction products obtained at 200° consisted of carbon tetrachloride, hexachloroethane and hexachlorobenzene, and contained only about 5% of the carbon of the original coal. This 5% and an additional 10% unaccounted for were probably formed from the peripheral material of the coal substance.

The non-volatile residue is considered to originate from the stable nuclei of the coal substance. Elementary balances showed that the residue contained: (1) 85% of the carbon of the original coal, (2) 40% of the hydrogen of the original coal, (3) an excess of 50% nitrogen over that of the original coal, (4) approximately double the oxygen of the original coal due to hydrolysis of the more active chlorine atoms, and (5) a ratio of carbon to attached substituents that indicates a condensed ring structure.

The residue was separated into ether, chloroform and chlorobenzene soluble fractions; each showed a mean molecular weight (cryoscopic in catechol) of approximately 160; the insoluble residue which remained had a mean molecular weight of about 250.

From these data it may be concluded that approximately 85% of the carbon of a bituminous coal from the Pittsburgh seam is part of a large condensed ring system of which the nitrogen in the coal is probably an integral part.

The Catalytic Properties of Charcoal. I. "Peroxidase" Activity

BY CLAUDE SCHWOB

Active charcoal has been found to influence the oxidation of uracil by hydrogen peroxide in a peculiar way. In the absence of charcoal this pyrimidine is completely oxidized at 95°, in its presence the isolation of several intermediate products of biological importance is possible.[1] This action is not strictly analogous to the catalysis of some oxidative reactions by peroxidases, but it suggested an investigation of the behavior of active charcoal in some reactions commonly used to evaluate the activity of peroxidases.

The charcoal used in this investigation was one known to modify the uracil oxidation as above.[2] Although all charcoals tested in this Laboratory gave the usual qualitative tests for peroxidases, this one was chosen because of its neutrality, that is, it did not change the *p*H of buffer solutions in several hours, thus permitting work at constant *p*H.[2] However, there is no reason to suspect that, in other respects, the other charcoals would not behave very much as this one.

The first test used was the indophenol reaction, recently applied to peroxidases.[3] The indophenol produced was found to be strongly adsorbed by the charcoal, so that the latter and the filtrate were analyzed separately. Figure 1 shows the amount of indophenol formed in various times. For the present, we have no explanation to offer for the shape of the curves. The oxygen evolved during the reaction, due to the "catalase" action of the charcoal, was measured and gave a perfectly smooth curve when plotted against time. The behavior of the curve showing the amount of indophenol in the filtrate leads to interesting speculation. One of the hypotheses still under consideration, but still to receive experimental support, is that some of the charcoal had been reduced to colloidal size, and that, under the conditions of the experiments, this colloidal part underwent oxidation by the peroxide after one-half minute. We have observed the destruction of charcoal in colloidal solution at 60°, but not at room temperature with sufficient velocity to account for the rapidity of the disappearance of the indophenol from the filtrate. It may be, however, that the other components of the reaction mixture are a factor affecting this speed. The oxidation by hydrogen peroxide of indophenol adsorbed on charcoal has never been observed by us. It seems possible that the colloidal charcoal is destroyed and that the indophenol thus liberated by loss of its adsorbent is then adsorbed by the "massive" particles of charcoal. This transfer of indophenol would explain the fact that the additive curve shows no discontinuity at this point (curve 3, Fig. 1).

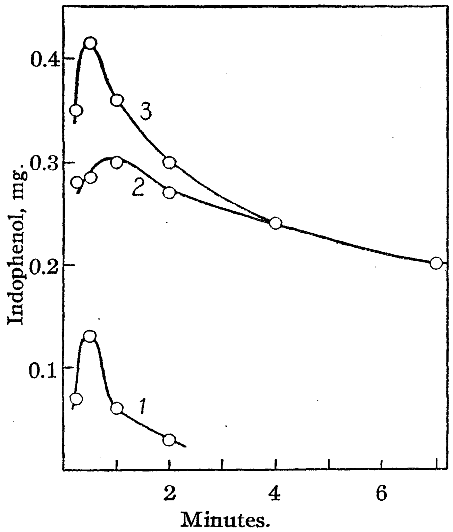

Fig. 1.—Curve 1, indophenol in the filtrate; curve 2, indophenol obtained from the charcoal. The amount remains constant at 0.20 ± 0.02 mg. from seven to at least forty minutes. Curve 3, total amount of indophenol obtained.

Colloidal charcoal was next tested by means of this same reaction. In the literature we were unable to find a method for the preparation of a colloidal solution of active charcoal. Von Weimarn's procedure[4] for obtaining sols of various substances by means of hand grinding with solid diluents was adapted to the problem in hand. We were aided in this preparation by the fact that charcoal sols, like some sulfur sols, seem to belong to the intermediate class of hydrosols, and are somewhat reversible. In fact, although the

colloidal properties of the charcoal sols so obtained have not as yet been fully ascertained, they are apparently similar to those of sulfur sols.

The behavior of this charcoal sol in catalyzing the formation of indophenol is shown in Fig. 2.

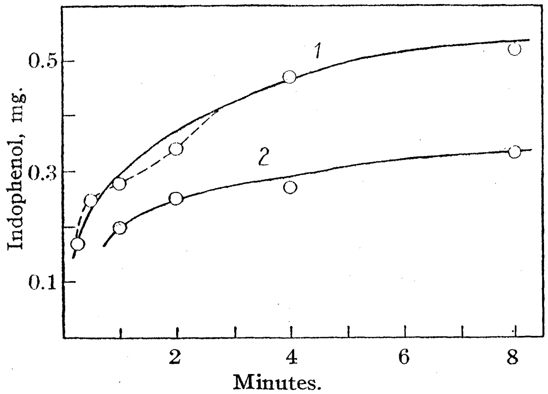

Fig. 2.—Curve 1, amount of indophenol obtained with charcoal hydrosol. For portion in dotted line see text. Curve 2, result obtained when the sol is replaced by distilled water.

No break in the curve, due perhaps to the destruction of the charcoal micelles, is apparent. A slight irregularity did show up in three of the five runs, the results of which have been averaged to give Fig. 2. These irregularities, however, were apt to cancel out in averaging, although if the average curve is redrawn as shown by the dotted line it assumes a form similar to, but less extreme than, each of the three "abnormal" curves. The point is still to be settled, however, since destruction of the charcoal would not necessarily lead to a great diminution in the indophenol yield.

An interesting fact observed was that the charcoal sol liberated no appreciable volume of oxygen from peroxide of the concentration used in these experiments over a period of several hours. Not only is this an added similarity of charcoal to natural purified peroxidase, since, until now, charcoal has been considered as having inherent "catalase" properties, but it tends to show that the suggested "peroxidase" activity is not due to a combined "catalase–oxidase" action. Accordingly, it seems untenable that the "catalase" activity serves to decompose the hydrogen peroxide to give oxygen which then forms indophenol under the influence of the "charcoal–oxidase."[5] Hence, it is probable that the charcoal activates the peroxide in some way. Ort and Bollman[6] have shown by electrometric means that some amino acids promote the oxidation of glucose by hydrogen peroxide. The effect of the charcoal sol on the voltage produced by hydrogen peroxide between a bright platinum electrode and an 0.1 *N* calomel electrode was therefore determined. While in the work of Ort and Bollman the activating effect of the amino acids may have been exercised on either the peroxide or the glucose, it seems that, in this case, it is the hydrogen peroxide that is activated. Figure 3 gives the curve obtained when there were added varying amounts of charcoal sol to peroxide solutions of fixed concentration (approximately 0.5%). By means of a blank run the effect of the small amount of gelatin used to stabilize the sol was found to be negligible for these rather qualitative results. It was thought interesting to find out whether a natural peroxidase gives a similar curve. The result for aqueous filtered potato extract (Fig. 3, curve 2) was found to have much in common with that obtained with charcoal, although the peroxide used in this case was not only from a different

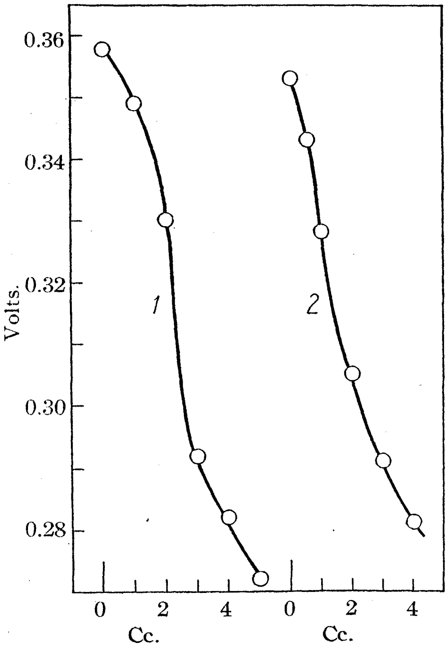

Fig. 3.—Curve 1, voltage obtained with hydrogen peroxide and varying amounts of charcoal hydrosol. Curve 2, result when diluted potato extract replaces the charcoal sol.

---

(5) In fact, we were unable to oxidize uracil in the presence of charcoal with either air or oxygen, although this pyrimidine is strongly adsorbed by charcoal.[2]

(6) Ort and Bollman, THIS JOURNAL, **49**, 805 (1927).

batch, but was not of the same strength (about 0.6%). No attempt was made to obtain any but relative values, and no corrections have been applied to the voltages as read on the potentiometer. It is projected to elaborate on this method in order to attempt applying it to the determination of peroxidase activity.

Experimental

The charcoal was a commercial animal charcoal purified by refluxing with four times its weight of constant boiling hydrochloric acid for twenty hours. It was then washed with distilled water until free of chlorides. Twice its weight of hot 95% alcohol was then used to extract further impurities (mostly consisting of a greenish gum), followed by treatment with the same amount of ether. This process reduced the ash content from 45 to 1.67%, although the ash still gave a positive test for iron with thioglycolic acid.

Peroxidase Activity of "Massive" Charcoal.—A combination of the methods of Guthrie and of Pack[3] was used. A 0.500-g. sample of the charcoal was suspended in 10 cc. of distilled water, and 5.75 cc. of a solution of *p*-phenylenediamine hydrochloride containing 0.5265 g. per 100 cc. was added. To 8.75 cc. of citrate buffer of *p*H 4.5 in a 10-cc. graduate, 0.6 cc. of 4% alpha-naphthol in 50% alcohol was added carefully so as to float on top of the buffer. The contents of this cylinder were added to the flask containing the charcoal simultaneously with 10 cc. of 1% hydrogen peroxide (commercial, containing acetanilide). All chemicals were at about 25°. The flask was then shaken by hand or machine and, at the end of the required time, 2 cc. of a 2% potassium cyanide solution was added to slow up the reaction. The suspension was then filtered through a fluted filter paper and the charcoal washed with three 10-cc. portions of water, the last portion being used to force the charcoal to the bottom part of the filter. The wash-water was added to the filtrate and it was immediately extracted with 25 cc. of toluene in a separatory funnel for thirty seconds. The toluene layer was then compared with a standard indophenol solution in a colorimeter. The charcoal was dried on the filter paper in the funnel at 100° (higher temperatures tended to destroy part of the indophenol). Four 6-cc. portions of toluene were poured over the charcoal. The last drops filtering through were quite colorless. This solution was also analyzed colorimetrically. A concordance of results of 5 to 8% was usually obtained. Figure 1 represents the average of six such trials.

Preparation of the Charcoal Hydrosol.—One gram of the charcoal was ground by hand in a glass mortar with 9 g. of pure sodium chloride for twenty minutes. Two grams of the resulting mixture was ground with 18 g. of sodium chloride for a further twenty minutes. This was then dissolved in 500 cc. of distilled water. The high salt concentration precipitated the charcoal. This suspension was then filtered through asbestos in a Gooch crucible and washed with one liter of distilled water. The entire contents of the Gooch were then suspended in 500 cc. of water and, for the sol used in this investigation, 4 cc. of a 1% gelatin sol was added. The suspension was then filtered through ordinary filter paper after "aging" six to ten days at room temperature. A fine deposit formed overnight and was filtered off, after which the sol is stable for more than three months. The resulting sol contained approximately 0.003 mg. of charcoal per cc. and was brownish by transmitted light and grayish-black by reflected light. A sol of lesser concentration may be obtained without the use of gelatin.

"Peroxidase" Activity of the Charcoal Hydrosol.—These experiments were performed as with the "massive" charcoal, except that 15 cc. of the sol was used instead of the charcoal suspension. Of course, the resulting solution was extracted with toluene directly. For the blank 15 cc. of distilled water was used instead of the sol.

Electrometric Measurements.—A 15-cc. weighing bottle was used as the cell. The voltage was measured between an uncoiled bright platinum wire immersed 2 cm. and an 0.1 *N* calomel electrode. In order to obtain reproducible results, the wire was heated in a Bunsen flame before each reading. Equilibrium seemed to be reached in five to ten minutes, the calomel electrode being negative. A total volume of 10 cc. was used in each case. Five cc. of 1% hydrogen peroxide was placed in the bottle and, if necessary, water so that when either the charcoal sol or the potato extract was added the resulting solution had a volume of 10 cc. The results were duplicable to 2–3 millivolts.

Summary

1. The "peroxidase" activity of charcoal in the indophenol reaction has been measured at room temperature and *p*H 4.5. The yield of indophenol is at a maximum at one-half minute.

2. A hydrosol of charcoal has been prepared.

3. This charcoal sol has been found to exhibit "peroxidase" activity in the formation of indophenol. No "catalase" activity has been observed.

4. The charcoal sol affects the voltage of the Pt, H_2O_2 || KCl (0.1 *N*), Hg_2Cl_2, Hg cell in a manner similar to that of potato peroxidase.

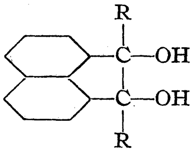
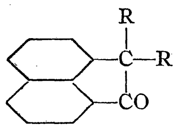
The Pinacol–Pinacolone Rearrangement. VIII. The Rearrangement of 7,8-Diarylacenaphthenediols

BY W. E. BACHMANN AND EDITH JU-HWA CHU[1]

Recently[2] we reported the results obtained on the rearrangement of a number of 9,10-diaryldihydrophenanthrenediols; in these compounds the simple aryl groups migrated exclusively and 9,9-diarylphenanthrones were formed. We have now turned our attention to the rearrangement of another class of cyclic pinacols, the 7,8-diarylacenaphthenediols (I).



I

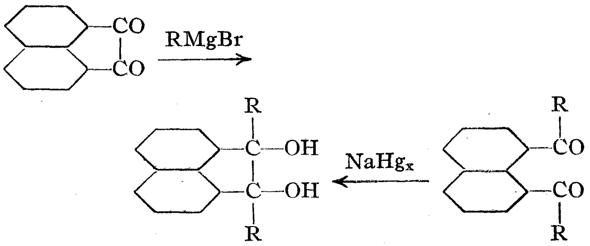


II

Acree[3] prepared 7,8-diphenylacenaphthenediol (I, R = phenyl) and reported that the compound remained unchanged when it was heated with acetyl chloride. Later, Beschke[4] obtained 7,7-diphenylacenaphthenone (II, R = phenyl) by heating the pinacol with acetic acid containing a small amount of hydrochloric acid.

We have now prepared seven new pinacols of this type in which the aryl groups, R, are *m*-tolyl, *p*-tolyl, *p*-biphenyl, *p*-anisyl, *p*-phenetyl, *p*-chlorophenyl and *p*-fluorophenyl. All of these pinacols were obtained from acenaphthenequinone through the Grignard reaction.

Since reduction of 2,2′-diacylbiphenyls by sodium amalgam gave 9,10-diaryldihydrophenanthrenediols which are diastereoisomers of the pinacols obtained by the Grignard reaction from phenanthrenequinone,[2] we have prepared several 7,8-diarylacenaphthenediols (I, R = phenyl, *p*-tolyl, *p*-chlorophenyl and *p*-fluorophenyl) by a similar reduction of 1,8-diacylnaphthalenes (III). Here, too, the pinacols prepared by reduction were diastereoisomers of those prepared by the Grignard reaction. It is of interest that solutions of the disodium salts of the diarylacenaphthenediols, like those of the diaryldihydrophenanthrenediols, are colorless, an indication that no appreciable dissociation into ketyl radicals takes place.[5]

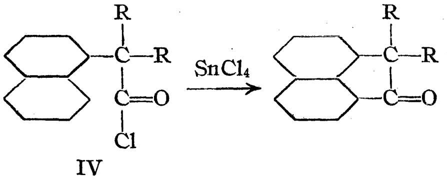


III

The yields and properties of the pinacols are shown in Table I.

Rearrangement of the Pinacols.—All of the pinacols were found to rearrange when they were heated with a solution of iodine in acetic acid. In every case the simple aryl group R was found to migrate exclusively with the formation of 7,7-diarylacenaphthenones (II). In the reaction the five-membered ring of the acenaphthene derivative was retained; no evidence of any tendency to form a four-membered ring was found. The stereoisomeric pinacols gave the same diarylacenaphthenone. The yields and the properties of the pinacolones are presented in Table II.

Two of the pinacolones, 7,7-diphenylacenaphthenone and 7,7-di-*p*-biphenylacenaphthenone, were synthesized by ring closure of diphenyl-α-naphthylacetyl chloride (IV, R = phenyl) and di-*p*-biphenyl-α-naphthylacetyl chloride (IV, R = *p*-biphenyl), respectively, by means of stannic chloride.



IV

7,8-Diarylacenaphthylenes.—The low yields of diarylacenaphthenones from the *p*-chlorophenyl and *p*-fluorophenyl pinacols were due to the formation of diarylacenaphthylenes (VI) through a side reaction. These compounds probably resulted through the action of hydrogen iodide present in the mixture of iodine and acetic acid; the pinacol is converted to the intermediate iodide (V) which yields the acenaphthylene (VI) by loss of a molecule of iodine.

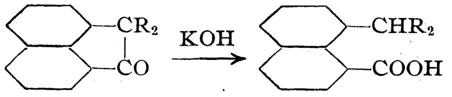
V VI

The structures of the acenaphthylenes were established by synthesis. The pinacols were converted to the corresponding dichlorides by reaction with hydrogen chloride; when the dichlorides were heated with an acetone solution of sodium iodide the diarylacenaphthylenes were formed. In this manner we prepared five diarylacenaphthylenes (R = phenyl, *p*-biphenyl, *p*-tolyl, *p*-chlorophenyl and *p*-fluorophenyl) as shown in Table III. Usually some pinacolone as well as the dichloride was formed by interaction of the pinacol with hydrogen chloride and in the case of dianisylacenaphthenediol and diphenetylacenaphthenediol the pinacolones were the sole products.

Scission of 7,7-Diarylacenaphthenones to 8-(Diarylmethyl)-1-naphthoic Acids.—The 7,7-diarylacenaphthenones were transformed into 8-(diarylmethyl)-1-naphthoic acids (VII) either by fusion with potassium hydroxide or by refluxing with 25% potassium hydroxide solution in methanol. Their yields and properties are listed in Table IV.



VII

Oxidation of 7,8-Diarylacenaphthenediols to 1,8 - Diacylnaphthalenes.—The 7,8 - diarylacenaphthenediols were oxidized to 1,8-diacylacenaphthalenes (III) by a hot solution of chromic acid in acetic acid. The yields and the properties of these diketones are presented in Table V.

Experimental

Preparation of 7,8-Diarylacenaphthenediols. (a) **Grignard Reaction.**—To the Grignard reagent prepared from 0.14 mole of aryl bromide (bromobenzene, *p*-bromobiphenyl, *p*-bromotoluene, etc.) in 50 cc. of anhydrous ether was added a benzene solution of 10 g. of acenaphthenequinone. The mixture was refluxed on a steam-bath for twenty-four hours except in the case of diphenylacenaphthenediol for which only four hours were allowed. By hydrolysis of the reaction mixture with dilute acetic acid and recrystallization of the product, the pinacols were obtained as colorless crystals.

(b) Reduction by Sodium Amalgam.—One gram of 1,8-diacylnaphthalene (obtained by oxidation of the pinacols prepared by the Grignard reaction) in a mixture of ether and benzene was shaken with 114 g. of 1% sodium amalgam at room temperature for twenty days, the mixture was filtered and the filtrate was treated with dilute acetic acid in order to hydrolyze the disodium salts of the pinacols. The product was a mixture of the pinacol and some unreacted diacylnaphthalene from which the pinacol was obtained by repeated recrystallization.

Rearrangement of the Pinacols.—A mixture of 0.0045 mole of pinacol, 1 g. of iodine and 100 cc. of acetic acid was refluxed for thirty minutes. The diarylacenaphthenones, which were precipitated by pouring the solution into an aqueous solution of sulfur dioxide, were purified by recrystallization, forming colorless crystals.

In order to detect if any of the isomeric pinacolone, $C_{10}H_6C(R)COR$ was formed, 1 g. of the crude pinacolone was refluxed with a solution of 25 g. of potassium hydroxide in 100 cc. of methanol for three days. After removal of the solvent by distillation under reduced pressure, the residue was stirred with cold water and filtered. In the filtrate no trace of acids (benzoic, *p*-toluic, etc.) could be detected. By washing with dilute hydrochloric acid, purification through the ammonium salts and then recrystallization the residue gave colorless crystals of 8-(diarylmethyl)-1-naphthoic acids.

Synthesis of 7,7-Diphenylacenaphthenone.—A mixture of 0.50 g. of diphenyl-α-naphthylacetic acid[6] and 1 g. of thionyl chloride was refluxed for an hour. After removal of the excess of thionyl chloride, the acid chloride was dissolved in carbon disulfide and treated with 5 cc. of stannic chloride and heated on a steam-bath. From the products of hydrolysis there was isolated a solid which after repeated recrystallization from benzene and acetone gave crystals of 7,7-diphenylacenaphthenone, which proved to be identical with the pinacolone obtained by rearrangement.

Di-*p*-biphenyl-α-naphthyl-acetic Acid.—A mixture of 1.5 g. of di-*p*-biphenyl-α-naphthylchloromethane[7] and 5.1 g. of 45% sodium amalgam was shaken in 20 cc. of ether and 30 cc. of benzene for two hours. A stream of dry carbon dioxide was passed through the intensely colored solution of the triarylmethylsodium compound until the color disappeared completely. The di-*p*-biphenyl-α-naphthylacetic acid crystallized from benzene in colorless prisms; yield, 66%; m. p. 216–217° with decomposition.

Anal. Calcd. for $C_{36}H_{26}O_2$: C, 88.2; H, 5.3. Found: C, 88.1; H, 5.0.

Synthesis of 7,7-Di-*p*-biphenylacenaphthenone.—This compound was obtained by cyclization of di-*p*-biphenyl-α-naphthylacetyl chloride (prepared by means of thionyl chloride) in the same method that was used for the phenyl analog. The 7,7-di-*p*-biphenylacenaphthenone was identical with the pinacolone obtained by rearrangement.

Scission of 7,7-Diarylacenaphthenones by Potassium Hydroxide.—One-tenth gram of pinacolone was fused with 1 g. of potassium hydroxide in a metal bath at the temperature shown in Table V. After the mass had been dissolved in acetone and water, the 8-(diarylmethyl)-1-naphthoic acid was precipitated by dilute hydrochloric acid. For purification the acid was dissolved in ammonium hydroxide, precipitated again by dilute hydrochloric acid and then recrystallized.

Oxidation of the Pinacols.—A mixture of 0.003 mole of pinacol, 0.25 g. of chromic acid anhydride in 12 cc. of acetic acid was heated on a steam-bath for thirty minutes. The 1,8-diacylnaphthalene was precipitated by addition of cold water and then purified by recrystallization.

Synthesis of 7,8-Diarylacenaphthylenes.—A stream of dry hydrogen chloride was passed through an ice-cold solution of 0.001 mole of pinacol in chloroform for thirty minutes. After the solvent had been removed, the dichloride crystallized when it was stirred with a little acetone and petroleum ether.

A mixture of 0.0003 mole of the dichloride and 0.12 g. of sodium iodide in a few cc. of acetone was refluxed for thirty minutes. The solution became yellow and then dark red due to the liberation of iodine during the reaction. The mixture was poured into an aqueous solution of sulfur dioxide and the orange-colored solid was refluxed with 25% potassium hydroxide solution in methanol for two days in order to destroy the pinacolone which was present. The product after this treatment was digested with dilute ammonium hydroxide in order to dissolve the diarylmethylnaphthoic acid and the residue of diarylacenaphthylene was filtered, washed with water and recrystallized.

By treating 7,8-di-*p*-chlorophenylacenaphthylene dichloride with sodium iodide, 1,8-di-*p*-chlorobenzoylnaphthalene was formed instead of 7,8-di-*p*-chlorophenylacenaphthylene. However, by refluxing a mixture of 0.001 mole of the dichloride, 10 cc. of hydrogen iodide (d. 1.7) and 20 cc. of acetic acid for two hours the acenaphthylene was obtained mixed with a small amount of pinacolone. The compound was also obtained in 27% yield by refluxing an ether solution of the dichloride with zinc dust.

Summary

Seven new 7,8-diarylacenaphthenediols have been synthesized and subjected to rearrangement. It was found that in each case the simple aryl group migrates exclusively with respect to the acenaphthyl group; the products of the rearrangement are 7,7-diarylacenaphthenones.

The 7,7-diarylacenaphthenones are cleaved into 8-(diarylmethyl)-1-naphthoic acids either by treatment with 25% potassium hydroxide solution in methanol or by fusion with potassium hydroxide.

The 7,8-diarylacenaphthenediols are oxidized to 1,8-diacylnaphthalenes by chromic acid.

Four new 7,8-diarylacenaphthylenes have been synthesized from the 7,8-diarylacenaphthenediols.

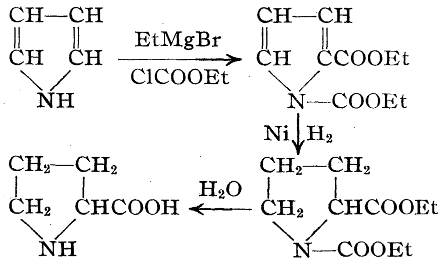
A Synthesis of *dl*-Proline from Pyrrole[1]

BY FRANK K. SIGNAIGO AND HOMER ADKINS

Several syntheses of *dl*-proline have been reported but none of them is very satisfactory from a preparational standpoint. The best methods are apparently those of Heymons,[2] who obtained the copper salt of *dl*-proline in three operations from piperidone-2, and that of Sørensen and Andersen,[3] who prepared the copper salt in five operations from malonic ester. The first method is said to give an over-all yield of 28%. The yield by the second method is not given, but is apparently somewhat greater. Several authors have suggested the desirability of developing a synthesis of proline from pyrrole through 2-carbethoxypyrrole as by Putokhin.[4] A difficulty in this process lies in the hydrogenation of the pyrrole ring in a carboxy- or carbethoxypyrrole. Putokhin used a high ratio of Adams platinum catalyst with 1 g. of pyrrole-2-carboxylic acid and as a result of repeated treatments with hydrogen and catalyst and change of solvent, obtained a 23% yield of the copper salt of *dl*-proline from the pyrrole acid.

While the hydrogenation of a 2-carboxy- or carbethoxypyrrole seems an impractical process with the catalysts now available, it appeared feasible to prepare *dl*-proline through the formation of 1,2-dicarbethoxypyrrole and the hydrogenation of the latter, *i. e.*



The hydrogenation may be carried out easily and almost quantitatively as a result of work recently reported.[5] The hydrolysis step is also a simple process but the preparation of the 1,2-dicarbethoxypyrrole in a good yield required study. However, by this process crystalline *dl*-proline has been obtained in an over-all yield of 57% from pyrrole.

Oddo[6] prepared 2-carbethoxypyrrole in over 90% yield from pyrrylmagnesium bromide and ethyl chlorocarbonate. In attempting to follow his method, but on a larger scale, we recovered 42% of the pyrrole and obtained 7% of 1-carbethoxypyrrole, 22% of 2-carbethoxypyrrole and 2% of 1,2-dicarbethoxypyrrole. When the conditions were modified by heating the reaction mixture for four hours at 35° before hydrolysis, instead of keeping it near 0°, then the yield of 1,2-dicarbethoxypyrrole was much greater, *i. e.*, 26%, accompanied by 13% of 1-carbethoxypyrrole and 3% of 2-carbethoxypyrrole. However, 50% of the pyrrole was recovered. These results suggested that pyrrylmagnesium bromide reacts with ethyl chlorocarbonate to give both 1- and 2-carbethoxypyrrole and that the latter but not the former reacts with pyrrylmagnesium bromide to give pyrrole and 2-carbethoxypyrrylmagnesium bromide. The last mentioned compound may then react, especially at higher temperatures, with ethyl chlorocarbonate to give 1,2-dicarbethoxypyrrole. These transformations are indicated below.

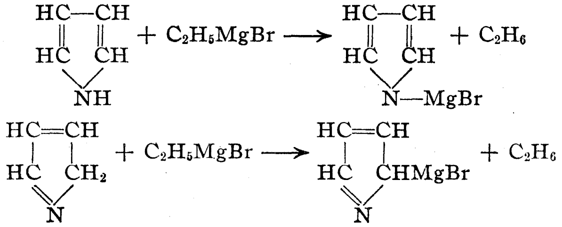
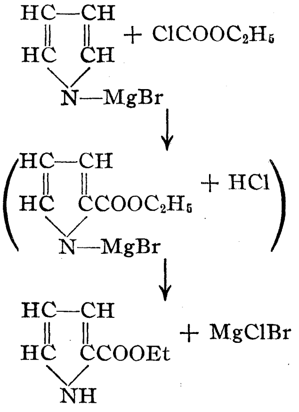
Upon the basis of this scheme it seemed desirable to treat one mole of ethylmagnesium bromide with one mole of pyrrole and then to add *alternately* in *portions*, one mole each of ethyl chlorocarbonate and ethylmagnesium bromide and finally a second mole of ethyl chlorocarbonate. By such a process the reaction of all of the pyrrole was brought about and at the same time excessive reaction between the ethyl chlorocarbonate and the ethylmagnesium bromide was avoided. Such a procedure as described in the experimental part gave a 65% yield of 1,2-dicarbethoxypyrrole.

There seem to be two rather reasonable explanations of the fact that 1- and 2-carbethoxypyrroles are formed simultaneously. Tschelinzew and Karmanov[7] suggested that the isomerism of the pyrrole nucleus makes possible the formation of two "pyrrylmagnesium bromides," *i. e.*



The formation of a Grignard reagent in the second case would be analogous to the behavior of a methylene group in cyclopentadiene, indene and fluorene. The formulation is in accord with the fact that only pyrroles which may tautomerize form Grignard reagents.[8] If the above is accepted then the relative proportions of 1- and 2-carbethoxypyrroles formed are a function of the proportion of the tautomers and (or) of the relative rates of reaction of ethyl chlorocarbonate with the two Grignard reagents.



However, it is not necessary to assume the existence of tautomeric pyrroles in order to explain the formation of 2-carbethoxypyrrole, for the ethyl chlorocarbonate may condense with the hydrogen on the 2-carbon atom.

Such a scheme finds support in the fact that 1-methylpyrrole does not form a Grignard reagent yet condenses with acid chlorides in the presence of an alkylmagnesium halide to yield 1-methyl-2-acylpyrroles.[8] However 1-carbethoxypyrrole apparently did not react with ethyl chlorocarbonate in the presence of a Grignard reagent.

Experimental Part

The apparatus for the preparation of 1,2-dicarbethoxypyrrole consisted of a 1-liter, 4-necked flask fitted with a mercury-sealed stirrer, a reflux condenser, the upper end of which was connected to a drying tube containing calcium chloride, and two dropping funnels. One of these dropping funnels was of the usual type, and the other was a 500-cc. flask with a stopcock sealed on the bottom and so fitted that a Grignard reagent could be prepared in it. Both of the funnels were graduated.

Ethylmagnesium bromide (approximately 0.25 mole) was prepared in the reaction flask from 32.7 g. (0.30 mole) of ethyl bromide, 7.2 g. (0.30 mole) of magnesium turnings and 150 cc. of ether. A like amount also was prepared in the 500-cc. dropping funnel. The reaction flask was cooled with a mixture of ice and salt to below 0° and 17 g. (0.25 mole) of pyrrole in 35 cc. of ether was added dropwise through the smaller dropping funnel. The reaction mixture was stirred during this and subsequent operations.

Into the smaller dropping funnel was placed 75 cc. of an ether solution containing 28 g. (0.25 mole) of ethyl chlorocarbonate. The Grignard reagent in the larger dropping funnel was diluted with ether to a volume of 200 cc. These two reagents were then added to the reaction flask drop by drop in the following fashion. One-half of the ethyl chlorocarbonate solution (37 cc.) was first added. This was followed by one-half of the Grignard solution (100 cc.). Again half of the remaining ethyl chlorocarbonate solution (19 cc.) was added and followed by half of the remaining Grignard solution (50 cc.). This process was repeated, each time adding one-half of the solution remaining in the dropping funnel until only 5–10 cc. of each reagent remained. This last small amount of each solution was then added and 37 g. (0.35 mole) of ethyl chlorocarbonate was poured into the reaction mixture through the smaller dropping funnel. These addition processes were completed in two hours. The reaction mixture was allowed to warm up to room temperature and then refluxed on a steam-bath for four hours. The contents of the reaction flask were then poured onto ice and the mixture made slightly acid by the addition of dilute sulfuric acid. The ether layer was separated and the aqueous layer was extracted twice with ether. The combined ether solutions were then washed once with a small quantity of sodium bicarbonate solution and dried for eight hours over anhydrous sodium sulfate. The ether was distilled off and the liquid residue was fractionated at reduced pressure as indi-

cated in the table. The recovery of ethyl chlorocarbonate as well as the amount of 1-carbethoxypyrrole obtained, indicate that 1.75 mole each of the Grignard reagent and the ethyl chlorocarbonate per mole of pyrrole would give as good a yield as did the proportion of reactants used above.

Table I

Products of Reaction

Fraction	Compound	Boiling range, °C.	Weight, g.	Yield, %
1	Ethyl chlorocarbonate	Up to 55° (65 mm.)	10	..
2	1-Carbethoxypyrrole	60– 65° (7 mm.)	9.2	26.4
3	2-Carbethoxypyrrole	100–110° (7 mm.)	0.5	1.5
4	1,2-Dicarbethoxypyrrole	125–135° (7 mm.)	34.2	65.0
	Residue		1.8	
			Total	92.9

The fourth fraction was found to be nearly pure 1,2-dicarbethoxypyrrole[5] since on refractionation 98% of the material distilled at 132–134° at 8 mm. The 1-carbethoxypyrrole had a b. p. of 57–58° at 7 mm., and 178–180° at 740 mm., and d^{25} 1.037, n^{25}_{D} 1.4698. The boiling point of this compound checks with that reported by other investigators. Only one author has reported the density and refractive index of this compound and these values do not check with those given above. However, the compound seems to be sufficiently characterized by the fact that it takes up 4 atoms of hydrogen to give a non-basic compound having the correct analysis for a carbethoxypyrrolidine, indicating that the carbethoxy group is on the nitrogen atom. The 1-carbethoxypyrrole is better prepared from potassium pyrrole and ethyl chlorocarbonate.[7a,9]

The 2-carbethoxypyrrole had a m. p. of 41–42° when crystallized from low-boiling petroleum ether and a b. p. of 102–104° at 7 mm.

The 1,2-dicarbethoxypyrrole so obtained was hydrogenated rapidly and quantitatively over Raney nickel.[5] In a typical experiment 1,2-dicarbethoxypyrrolidine b. p. 133–134° (8 mm.) was obtained in 98% yield by the hydrogenation of 0.2 mole of the pyrrole ester over 5 g. of Raney nickel under 100 to 200 atm. of hydrogen at 50 to 85° in less than one hour.

The 1,2-dicarbethoxypyrrolidine (10.6 g. or 0.05 mole), was refluxed with 25 cc. of concentrated hydrochloric acid for three hours; 10 cc. more of hydrochloric acid was then added and the refluxing continued for two hours. The mixture was then evaporated on a steam-bath. The partially crystallized residue was dissolved in 100 cc. of water and treated with 0.10 mole of freshly precipitated silver carbonate. After filtration, the filtrate was treated with hydrogen sulfide. The solution was heated with 1 g. of activated charcoal and this together with the silver sulfide was removed by filtration. Upon evaporation of the filtrate on a steam-bath, there was obtained 5.7 g. of a gummy crystalline mass. This was dissolved in 25 cc. of hot ethanol and 50 cc. of hot dioxane was added. After cooling the solution with ice, the crystalline proline was filtered off and dried in a desiccator. The yield was 5.2 g. (90%), m. p. 204°. The picrate was prepared by dissolving 1 g. of proline and 2 g. of picric acid in 2 cc. of hot acetic acid, followed by addition of 7 cc. of ether and cooling. The picrate was recrystallized from ethanol and showed a m. p. of 136°.

Summary

Crystalline *dl*-proline may be prepared in yields of 55 to 60% from pyrrole through the intermediate formation of 1,2-dicarbethoxypyrrole and 1,2-dicarbethoxypyrrolidine. A method for the synthesis of 1,2-dicarbethoxypyrrole has been devised and developed.

A Further Study of Extremely Weak Acids

By W. K. McEwen

The purpose of this paper is to report the new methods used and the results obtained in the study of extremely weak acids.

It has been shown by Conant and Wheland[1] that reactions of the type

$$R_1H + R_2^- \rightleftarrows R_1^- + R_2H$$

may be used to determine the relative acid strength of very weak acids such as the aromatic and aliphatic derivatives of water, ammonia and methane. The determination of the relative amounts of the different substances present at the point of equilibrium is a measure of the relative strength of the two acids. This can be determined in either of two ways.

The first method used was to observe the change in color. Since many compounds of the type R^- are colored, it is only necessary to mix the reactants and observe whether or not a change in color results. As a check the products of the reaction are also mixed. From such observations the compounds can be arranged in a series of de-

---

[1] Conant and Wheland, This Journal, **54**, 1212 (1932).

creasing acid strength. Using equivalent quantities, and assuming that apparent complete reaction corresponds to at least 90% reaction, a minimum difference in *pK* for the acids may be taken as 2 *pK* units.

A second method used by Conant and Wheland was to introduce carbon dioxide into the equilibrium mixture, isolate the acids and from their analysis draw similar conclusions regarding the equilibrium and the relative strengths of the acids.

Three methods have been used in the present paper to extend the series of weak acids.

I. Colorimetric Method

Essentially the same method as devised by Conant and Wheland was used to measure acids having colored sodium or potassium salts. Twenty-five acids were investigated by this method. These results, with the results of the two following methods, are summarized in Table II.

Each compound that has a colorless metallic salt was measured against the nearest colored compound appearing in the table, and was found to differ from it in acidity by at least 2 *pK* units. Every compound having a colored metallic salt was measured against as many compounds as necessary to determine its position in the table. However, alpha-naphthylfluorene could not be measured against phenylfluorene as the metallic salts of both compounds have approximately the same color. For this same reason, phenylxanthane could not be measured against xanthane. The last four compounds in Table II had been measured by Conant and Wheland using a five-fold quantity of the hydrocarbon, so that they were found to differ by only a minimum of 0.4 *pK* unit. By using equivalent quantities, the minimum difference was extended. It was found that etioporphyrin I[2] had an acidity approximately that of the alcohols. The formation of the sodium salt of the porphyrin is accompanied by a striking spectroscopic change. Etioporphyrin I forms a disodium salt[3,4] but no difference in acidity could be found between its first and second dissociation constant.

Other compounds were measured colorimetrically but the data obtained were insufficient to warrant placing them definitely in Table II. Diethylcarbinol, diphenyl-alpha-naphthylcarbinol, phenylxanthydrol, acetanilide, tricarbomethoxymethane, 2,4-dimethylpyrrole and pyrrole were found to be 2 *pK* units stronger than phenylfluorene, while tertiary butylfluorene seemed to be weaker than triphenylmethane.

II. Spectroscopic Method

This method is strictly analogous to the ordinary water system of acid–base titration. That is, the acid to be measured is titrated with sodium triphenylmethyl, a strong base, in the presence of a minute amount of etioporphyrin I as an indicator, in an inert atmosphere. The change in the indicator is apparent when the shift in the absorption bands is observed with a small hand spectroscope. If the porphyrin is at least 2 *pK* units stronger than the acid, it will take the sodium from the first few drops of sodium triphenylmethyl. Likewise, if both the acid and the porphyrin are the same strength, the porphyrin will be partially converted into its basic form at the start, but will not be completely converted until the end of the titration. The results of this method are also summarized in Table II. This method was useful in showing that of the alcohols measured, all were at least 2 *pK* units weaker than etioporphyrin except methyl alcohol which has an acidity very close to that of etioporphyrin. Standard pyrrole (2,4-dimethyl-3,5-dicarbethoxypyrrole) was only slightly weaker. Experiments with other porphyrins and porphyrin-like compounds showed that they were at least 2 *pK* units stronger than etioporphyrin I. However, N-methyletioporphyrin I[4] is only about 1 *pK* unit stronger than etioporphyrin itself. This compound is interesting in that one of the imino hydrogens of the porphyrin ring is replaced with a methyl group, making the compound a monobasic acid. According to Hammett and Deyrup,[5] it is thus better suited for an indicator.

III. Polarimetric Method

The third method is useful in dealing with colorless compounds and permits in some cases more exact values for the relative acid strength of the compounds studied. In this method an optically active acid is used and the position of equilibrium determined with the aid of a polarimeter. The optical activity of the equilibrium mixture together with the values for the optical activity of the acid and salt allow one to calculate

$[\alpha]^{23}_D$ sodium *l*-menthylate −12.2°. $[\alpha]^{23}_D$ *l*-menthol −45.6°.

the extent to which the reaction has gone. Thus, if a weak acid is allowed to react with sodium menthylate,[6,7] the amount of free menthol produced can be measured and the strength of the weak acid, relative to menthol, can be calculated. This was done with six alcohols, one enol and one hydrocarbon. The data are shown in Table I.

It should be noted that the *pK* values, given in the table above, are relative to menthol, a negative value indicating that an acid is stronger than menthol. A precipitate formed in the reaction with those acids whose value is followed by the abbreviation "max." The consequent shift in the point of equilibrium results in a maximum value. That is, the acid is no stronger than the value given, and may be weaker. In attempting to measure the acidity of methyl alcohol, it was found that the reaction went substantially to completion with the formation of a precipitate. It was then necessary to determine the solubility of sodium methylate in benzene in order to obtain the minimum value given in the table above. The order of magnitude of the solubility was necessary, rather than its precise value.

There are too few alcohols from which to draw definite conclusions, but it is apparent that the acidities fall into three groups corresponding to the primary, secondary and tertiary structures of the alcohols, with the acidity decreasing in that order. Evidently the determining factor in the acid strength of the alcohols resides in the functional group being of primary, secondary or tertiary character, and the substituents whether aliphatic or aromatic are of secondary influence.

From the position of acetophenone in the table, one can make a rough calculation of the fraction of the material which is present as enol. This is so small as not to be measurable by analytical means. The structure of the enolic form (a double bond alpha-beta to an hydroxyl group) is similar to phenol, and should have an approximate *pK* value of 10. This is probably fairly close, as the value for ethylacetoacetic ester has been found to be 12. Assuming the *pK* value of the pure enolic form of acetophenone is 10, the equilib-

(7) Professor E. P. Kohler suggested optically active menthol.

rium constant for the reaction keto $\rightleftharpoons$ enol would have to be 10^{-9}.

IV. Summary

In order to relate all the acids, it is necessary to choose some arbitrary standard to which to relate them. The standard chosen in this work is methyl alcohol whose acidic dissociation constant has been measured accurately by A. Unmack[8] and found to be 10^{-16}, giving it therefore a pK value of 16.

Since the values obtained by the three methods are transferred directly to Table II with no correction for solvent effects, or for changes of solvent or of concentration, the values should be considered as accurate to about one power of ten.

Compounds italicized appeared in the table of Conant and Wheland.

(C) = compounds having colored metallic salts
s = measured spectroscopically, using etioporphyrin as an indicator
c = measured colorimetrically
p = measured polarimetrically
1 = work to be published concerning this compound
2 = measured spectroscopically against methyl alcohol
3 = pK values 18–37 are minimum pK values
4 = equilibrium approached from both ends when measuring against fluorene and phenylfluorene
5 = acidity determined by Conant and Wheland, but not included in their table

Where feasible compounds were measured by two or more methods in order to check their positions in the table.

The author wishes to express his gratitude and appreciation to both former Professor James Bryant Conant who directed the research on the colorimetric and spectroscopic methods and Professor Henry Edward Bent who directed the research on the polarimetric method.

Experimental Part

Treatment of Compounds.—All liquid alcohols were carefully fractionated from their sodium salts and kept in sealed bottles in a desiccator over phosphorus pentoxide. Different samples of the same alcohol were used in various runs to guard against any one sample being contaminated.

The liquid amines were distilled from potassium hydroxide and kept in sealed bottles in a desiccator over potassium hydroxide.

All solids were recrystallized until pure by melting point and other tests, and dried in a drying pistol.

The nitrogen was passed through Fieser's solution, lead acetate solution, sulfuric acid, phosphorus pentoxide towers and finally through a xylene solution of sodium benzophenone ketyl. When a piece of apparatus is filled with nitrogen, it is done so by evacuating with an oil pump and then filling with nitrogen, the apparatus being flamed over with a micro-burner during the process. This procedure is carried out three times. The apparatus is of course allowed to cool before a solution is added so as not to evaporate any solvent. When the apparatus is cleaned, cleaning solution, soap and water, distilled water, alcohol, ether and dry, distilled ether are used in the order named.

Colorimetric Method.—The storage flask for the metal-alkyl solution was similar to that used by Conant and Wheland[1] for the storage of their metal-alkyl solutions, except that a calibrated Pyrex buret of 25-cc. capacity was used in place of the roughly calibrated side-arm, and two slant-bore stopcocks in series were used instead of the mercury seal stopcock. The lower stopcock bears the brunt of the frequent evacuations and fillings of the reaction flask, and thus protects the upper stopcock. As there is little or no difference in pressure on either side of it, there is no tendency for the ether to make channelings in the ether-soluble grease. The lower stopcock can be regreased, without danger of changing the titer of the solution, if the key is only taken from the socket when there is a strong positive pressure of nitrogen so as to prevent back diffusion. The upper stopcock need only be regreased at very infrequent intervals, and this is done in the same manner as the lower stopcock, except that the solution is again standardized to be sure that there has been no change.

A different reaction flask was developed. This was a small flask of 100 cc. capacity which was joined to the

---

(8) A. Unmack, *Z. physik. Chem.*, **133**, 45 (1928).

lower terminal of the stopcocks on the storage flask by means of a ground glass joint. The nitrogen train was also attached to this flask with a ground glass joint. The substance to be measured, if a solid, is weighed into a short length of glass tubing which is then capped on each end with two pieces of glass tubing sealed at one end and fitting smoothly over the tube, forming a capsule. This capsule is then placed in a short length of 15-mm. tubing bent at an angle of 45°, sealed off at one end and carrying at the other end a 15-mm. male standard taper ground glass joint, which in turn fits into the female joint attached to the reaction flask. The tube containing the capsule is turned downward while the system is being filled with nitrogen. To introduce the compound, the tube is rotated, allowing the capsule to descend. Usually the capsule slips apart on hitting the bottom of the flask, but if this does not happen the apparatus is either gently shaken to break it open, or the capsule is covered with a layer of solution, and a vacuum is applied. The gas inside the capsule bursts it apart on expanding. The compound may then be measured directly against the metal-alkyl solution in the reservoir, by adding an equivalent amount and observing the color change. When the solution is standardized against benzoic acid, this method is used.

If the substance to be measured is a liquid, a somewhat different procedure is used. The entire apparatus is connected using, however, a little longer crooked tube. The system is evacuated and filled with nitrogen several times. The liquid is pipetted into one of the caps of the capsule, the crooked tube is disconnected from the apparatus, the cap is placed in it and it is filled with benzene, and reconnected to the reaction flask. The benzene is then frozen with a salt and ice mixture placed around the outside of the tube. When the benzene has frozen, the system is evacuated and again filled with nitrogen in order to get rid of any air that may have entered the apparatus when the crooked tube was temporarily removed. When it is desired to introduce the sample, the benzene is melted, the tube rotated and the contents run into the flask.

There was a certain amount of difficulty involved in the handling of volatile amines like *n*-butylamine and di-*n*-butylamine. For this reason, an attempt was made to use the amine hydrochlorides, and to treat them with one equivalent of sodium triphenylmethyl in order to liberate the free amine directly in the reaction flask. The amine hydrochlorides were so insoluble in ether that the reaction took place too slowly and did not seem to go to completion within a reasonable length of time. Although aniline hydrochloride worked fairly satisfactorily, and gave the same results as with aniline itself, the method was abandoned as it was too slow with the other amines.

Tertiary Butylfluorene.—2.38 grams (0.01 mole) of tertiary butylfluorenol,[9] 10 cc. of glacial acetic acid, 2 cc. of hydrogen iodide (sp. gr. 1.7) and 1. g. of red phosphorus were refluxed for four hours in a 50-cc. Erlenmeyer flask under a return condenser. The solution was filtered while hot and water added to precipitate the hydrocarbon, which was slightly pinkish. It was recrystallized from methyl alcohol to a melting point of 98–99° and a yield of 1.6 g. (73%) of fine white needles that gave no color in sulfuric acid. This product was further dried in a drying pistol at 61°.

Anal. Calcd. for $C_{17}H_{18}$: C, 91.89; H, 8.11. Found: C, 91.68; H, 8.11.

Spectroscopic Method.—When using this method, the same apparatus is used as in the colorimetric method. The acid to be measured and a few specks of etioporphyrin were frozen in benzene in the long crooked tube of the apparatus. When the flask is ready, the benzene is melted, providing a homogeneous solution on which the effect of the sodium triphenylmethyl readily may be determined by viewing the solution through a small hand spectroscope. As to the efficiency of the indicator, dilution experiments showed that the basic form in the presence of the acidic form could be detected if 50% or greater. The acidic form could be detected in the presence of its basic form in as low an amount as 10%. This range, 50–90%, compares favorably with the range of the usual color indicators.

Polarimetric Method.—The storage flask for the sodium menthylate solutions was the same as used in the other methods for the storage of metal-alkyl solutions. The polarimeter cell was made from approximately 21-mm. Pyrex tubing with Pyrex windows sealed on the ends, and a slant-bore stopcock sealed to the middle of the tube. The length of the cell was 1.995 dec., and it had a capacity of about 43 cc. There was little or no strain noticeable in the windows. This cell was connected to the storage flask by a ground glass joint. The nitrogen train was attached between the junction of the cell and the storage flask. All the ground glass joints were standard taper.

Experiments were tried with fusel oil as a possible alcohol for the polarimetric method, but the difficulty of separating the active component and the inadvisability of using a mixture made its usefulness doubtful.

Difficulties arose in the preparation of pure sodium menthylate. It had been found in previous work on the preparation of alcoholates that they often turned yellow This yellow coloration was thought to be due to side reactions caused by the relatively high reaction temperatures. To prevent this, 40% sodium amalgam was used instead of sodium wire, and the mixture of amalgam, alcohol and benzene was shaken at room temperature under nitrogen until no more hydrogen was given off. This procedure formed a colorless solution of sodium *l*-menthylate. However, if air is present, the yellow color develops. Benzene was used as a solvent because it would dissolve sodium *l*-menthylate at least up to concentrations of 0.1 mole per liter. The sodium *l*-menthylate appeared very insoluble in ether. All polarimetric reactions were carried out using benzene (dried over sodium) as the solvent, under an atmosphere of dry, oxygen-free nitrogen. The polarimeter was readable to 0.01°. The light source was a General Electric sodium vapor lamp. The light from this lamp was about 99% monochromatic, by spectroscopic examination.

In order to obtain the specific rotation of pure sodium *l*-menthylate, the solution of menthylate, obtained by shaking with 40% sodium amalgam, was titrated with sodium triphenylmethyl just until the formation of a permanent end-point. The reaction between *l*-menthol and 40% sodium amalgam did not go to completion, so to be sure that all the *l*-menthol was finally converted to sodium

---

[9] H. W. Scherp, "Rate of Autoxidation of Di-aryl-di-fluoryls," Thesis, Harvard University, 1931, p. 105.

l-menthylate, it was titrated with sodium triphenylmethyl. This solution was then measured in the polarimeter and the specific rotation for sodium *l*-menthylate was found to be $[\alpha]^{23}\mathrm{D}$ -12.2 ± 0.6. Patterson and Taylor[10] give the specific rotation of menthol as $[\alpha]^{23}\mathrm{D}$ -45.57.

An ethereal solution of menthol was successively diluted from 1 to 0.0125 *M*, and no change was observable in the specific rotation.

Patterson and Taylor[10] have shown that *l*-menthol in benzene is "practically insensitive to temperature change." With the menthylate solution, a 0.003° change in rotation was observed for every degree change in temperature. In the same way, the temperature effect on the equilibrium of a reaction is from 0.001 to 0.003° change in rotation per degree temperature change. Since the polarimetric room was thermostatted to 24.5 ± 1.5°, the maximum change in rotation due to temperature change is less than the experimental error.

Since the specific rotation of both pure menthylate and menthol is known, it is only necessary to know, in a given solution, the total concentration of menthol, either as menthol or menthylate, and a measurement of the rotation gives the concentrations of both. The total concentration was found by weighing the amount of pure menthol used and measuring the benzene volumetrically.

The rates of these metathetical reactions were all practically instantaneous. In the measurement of benzhydrol, three to five minutes after adding the benzhydrol, the reaction had reached a value that did not change after one and one-half hours. A second reading after at least one-half hour had elapsed was taken on tertiary amyl alcohol, tertiary butyl alcohol, isopropyl alcohol and acetophenone, and no change was observed. Of the remaining compounds, precipitates appeared with methyl alcohol and phenylfluorene which took quite a while to settle (one to two hours) and only on benzyl alcohol was no second reading taken after some time had elapsed. So with no alcohol was a shift in the rotation observed. The rate of the reaction was faster than could be detected.

Since most of the sodium salts of the alcohols are fairly insoluble in benzene, it was necessary to prevent their formation as much as possible. This was done by using smaller and smaller amounts of alcohol and menthylate and larger and larger quantities of menthol, until no precipitate formed. This was not always successful, and the accuracy of the readings was reduced. When the menthol was used in solution to partially block the reaction, a small amount of menthylate was also present in the solution in order to be sure that there was no contaminating substance present.

Solubility of Sodium Methylate in Benzene.—A 100-cc. flask was filled with benzene under nitrogen and a large amount of sodium wire was added. One-half cc. of methyl alcohol was added against a current of nitrogen. A rapid reaction occurred. The flask was left for two days, after which three samples were removed and titrated with 0.01 *N* hydrochloric acid, using phenolphthalein as an indicator. The value for the solubility was found to be 0.3 to 0.9 of a millimole per liter. A correction was then made for the dissolved sodium hydroxide. The solubility was determined by sealing sodium hydroxide, sodium and benzene in a small flask and shaking overnight. The solution was titrated and found to contain 0.1 millimole of sodium hydroxide per liter of benzene.

Summary

1. Fifteen weak acids have been measured colorimetrically and inserted in a table of acids of decreasing strength. Eight other weak acids have been investigated by this method.

2. Ten weak acids have been measured spectroscopically by an indicator method that is described.

3. The acidity of six alcohols, one enol and one hydrocarbon have been determined by a polarimetric method that is described.

The Diffraction of X-Rays by the Higher Polyethylene Glycols and by Polymerized Ethylene Oxides[1]

BY W. H. BARNES AND SYDNEY ROSS

In recent studies[2] Hibbert, Perry and Pullman have obtained very strong evidence in support of the suggestion[3] that polymerized ethylene oxides probably have the same composition as the polyethylene glycols (*i. e.*, $HOCH_2CH_2(OCH_2CH_2)_xOCH_2CH_2OH$). Since the former already have been subjected to x-ray examination,[4] and since specimens of polymerized ethylene oxides and polyethylene glycols of comparable molecular weights[5] were available, an opportunity was presented for a comparison of the diffraction

of x-rays by the polymerized ethylene oxides and polyethylene glycols prepared by Pullman and Hibbert[2] and a comparison of these data with those for the polymerized ethylene oxides examined by Sauter.[4]

Sauter[4,6] has studied polymerized ethylene oxides of molecular weights 2400, 3100, 8000, 13,000, 16,000, 33,000, 55,000 and 100,000, respectively. The last, which is reported[4] to be a rubber-like substance, enabled him to obtain fiber diagrams by stretching the specimen, so that most of his work was confined to this polymer. Powder diagrams of all specimens, however, were identical (at least without photometric or ionization measurements) both as to positions of haloes and relative intensities.

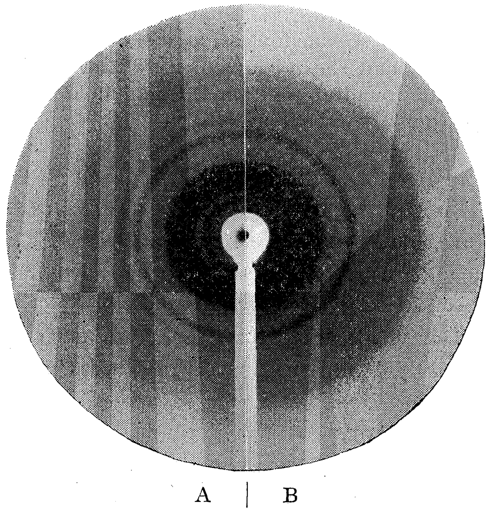

Fig. 1.—A, Polymerized ethylene oxide; B, polyethylene glycol.

As none of the polymers available for the present investigation were high enough to possess any appreciable elasticity the present paper is concerned solely with powder diagrams. Copper radiation (λ = 1.54 Å.), filtered through nickel foil to remove the K_β line, was employed with a crystal-to-plate distance of 2.25 cm.

The specimens of Pullman and Hibbert[2] selected for study were the 54 and 162-membered polyethylene glycols and the corresponding polymerized ethylene oxides (mol. wts. 3000 and 6500). Preliminary photographs having given essentially identical diagrams for all four specimens, and shown that very long exposure times would be necessary for accurate identification and measurement of the weaker haloes, a detailed examination of the 162-membered polyethylene glycol and the polymerized ethylene oxide of molecular weight 3000 (corresponding to the 54-membered polyethylene glycol) was undertaken.

A typical composite negative for these two specimens is reproduced in Fig. 1. Due to the pronounced background fogging (particularly in the case of the glycol) and to the excessive range of densities in the original negatives some difficulty was experienced in obtaining reproducible prints. The authors are indebted to Mr. H. Rudoff, graduate student in the Department of Chemistry, McGill University, for technical assistance in this connection.

The detailed results of the x-ray examination are summarized in Table I. The first and second columns give the numbers of the diffraction effects and the corresponding values of sin θ, respectively, from Table I of Sauter's paper.[4] Corresponding values of sin θ for the polymerized ethylene oxide of molecular weight 3000 and for

(6) See Staudinger,[3c] p. 294.

the 162-membered polyethylene glycol are shown in columns three and four, respectively. Visually estimated intensities[7] are recorded in columns five (from Sauter's paper[4]), six (for the oxide), and seven (for the glycol), respectively.

In connection with the foregoing table the following remarks may be noted. Sauter's lines 1 and 2 apparently are present in traces on the best negatives for the oxide and glycol obtained in the present study but are too weak in intensity for measurement. Lines 3 and 5 would fall within about 0.2 mm. of the inner and outer edges of line 4 so that they would practically be unresolvable for the crystal-to-plate distance employed. The remainder of the data, however, appeared to be conclusive enough not to warrant the long exposure times necessary to bring out lines 1, 2, 3 and 5 at a longer crystal-to-plate distance. Certain groups of diffraction effects in Sauter's table appear as bands in the powder diagrams. In Table I these have been bracketed and the mean position of the observed band is given in columns 3 and 4. For example, Sauter's numbers 11, 12, 13, 14, 15 have sin θ values which would result in haloes falling within the inner and outer edges of the band on the present oxide negative whose mean position is given by a sin θ value of 0.231. Finally the very weak halo at sin $\theta = 0.482$ (Sauter's No. 32) is present in the best negative for the glycol but is not included in Table I because it is too weak in intensity for accurate measurement.

The general agreement among Sauter's data for polymerized ethylene oxides, and the present data for the polymerized ethylene oxides and polyethylene glycols prepared by Pullman and Hibbert is very satisfactory. The only anomalous features are the absence of line 23 from the present polymerized ethylene oxide negatives, and the definitely stronger relative intensity of line 22 in the oxide compared with the glycol photographs. In this connection, however, it should be noted that line 23 is of weak intensity and is, moreover, clearly present on the glycol negatives. These features may be purely fortuitous or may have something to do with the relative physical characteristics of the samples. In general the glycols are more hygroscopic than the corresponding oxides, probably because the former comprise only one polymeric species while the latter probably contain appreciable fractions of higher (less hygroscopic) polymers. In comparing the relative intensities of Sauter with those observed in the present investigation it must also be borne in mind that the former were estimated on fiber diagrams whereas the latter were obtained from powder diagrams.

A consideration of the data presented in Table I, and a comparison between Fig. 1 of this paper and Fig. 2 of that of Sauter,[4] leads to the conclusion that, in so far as the diffraction of x-rays is concerned, there is no essential difference either between the polymerized ethylene oxides and the polyethylene glycols prepared by Pullman and Hibbert or between these and the polymerized ethylene oxides prepared by Lohmann for Sauter's investigation.

A New Reagent for Structure Determination

By Ralph Connor[1] and John H. Van Campen

In the identification of organic compounds those tests are especially valuable which can be carried out quickly on small amounts of material and which show, by the production of a color or precipitate, the presence of a specific group or structure. In work with active methylene compounds it has often been desirable to have a reliable *general* test for such substances. The production of colors with ferric chloride solution is limited in usefulness because many active methylene compounds (for example, the malonic esters) do not react with this reagent. The present paper describes a test which has frequently been of value and which, under the conditions specified later, is general for substances which contain hydrogen on a carbon atom bearing at least *one* acyl group or *two* other activating groups.

The test consists of the addition of an alcoholic solution of mercuric chloride to a solution of the unknown in alcohol containing sodium ethoxide.

---

[1] Present address, John Harrison Laboratory of Chemistry, University of Pennsylvania, Philadelphia, Pa.

The formation of a *white* (or occasionally, cream-colored) precipitate is a *positive* test. The negative test is the formation of a deep yellow precipitate similar to that obtained when the sodium ethoxide and mercuric chloride solutions are mixed in the absence of an additional reactant.

Over two hundred organic compounds have been tested with this reagent and *it seems advisable to limit the test to neutral compounds which do not contain elements other than carbon, hydrogen and oxygen.* Considering this limitation, the classes of compounds with which the test will be concerned include ketones, aldehydes, esters, hydrocarbons, ethers, acetals, alcohols, quinones and anhydrides. Of these, the last five types fail to give a positive test. Aldehydes and ketones with hydrogen on the carbon atom bearing the carbonyl group give a positive test. The only esters which give a positive test are those which have both hydrogen and a labilizing group on the carbon bearing the carboxyl group. While acetylenes have not been investigated thoroughly, they apparently give a positive test and are certainly the only hydrocarbons to do so.

A few substances (such as anthrone) give colors with sodium ethoxide solution and others (such as ethyl formate) give white precipitates with sodium ethoxide; in such cases the results of the test are not significant. Likewise, the formation of reduction products of mercuric chloride should not be considered as either positive or negative, but merely as indicating the presence of a structure susceptible to oxidation.

The limitation of this test to neutral compounds containing no elements other than carbon, hydrogen and oxygen is imposed because the results of the test are anomalous when it is applied to other compounds. This is not a serious limitation, however, since many tests are available for acidic and basic compounds and for those containing elements in addition to carbon, hydrogen and oxygen. The test in its present form is specific for the structures  $\mathrm{H}\overset{|}{\underset{|}{\mathrm{C}}}-\overset{\overset{\mathrm{O}}{\|}}{\mathrm{C}}-\mathrm{R}$ and  $\mathrm{Y}-\overset{\overset{\mathrm{R}}{|}}{\mathrm{C}}\mathrm{H}\overset{\overset{\mathrm{O}}{\|}}{\mathrm{C}}-\mathrm{OR'}$ (where Y is a labilizing group and R may be hydrogen, alkyl or aryl); few tests are available for such structures. This is a quick and satisfactory method, for example, of distinguishing between mono- and di-substituted malonic esters and for detecting the presence of a monosubstituted product in a disubstituted malonic ester.

From the types of compounds which undergo the reaction and from the efficiency of sodium ethoxide as a catalyst, it seems probable that the reaction is one of the enol form. The mechanism of the mercuration may then involve addition to the double bond of the enol[2] or the formation of intramolecular chelation products similar to those proposed by Johnson[3] and by Carothers[4] for other reactions of similar systems.

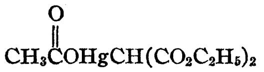
The reaction upon which this test is based is probably similar to that obtained by other workers[5] with mercuric compounds, but apparently sodium ethoxide is a more efficient catalyst and permits the omission of the periods of reflux previously used. As applied in this test, the reaction usually occurs instantly and always within a few minutes.

The compounds obtained from these reactions have been assigned various structures.[5] With malonic ester and mercuric chloride or mercuric acetate the possibilities suggested include the following

$\mathrm{Hg{=}C(CO_2C_2H_5)_2}$ $\mathrm{HOHgCH(CO_2C_2H_5)_2}$

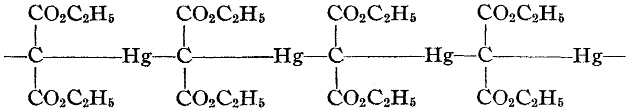
$\mathrm{(C_2H_5O_2C)_2CHHgCH(CO_2C_2H_5)_2}$

$\mathrm{(ClHg)_2C(CO_2C_2H_5)_2}$



$\mathrm{CH_3}\overset{\overset{\mathrm{O}}{\|}}{\mathrm{C}}\mathrm{OHgCH(CO_2C_2H_5)_2}$

For the present purpose a discussion of the structures of the products is not pertinent. However, the possibility of the formation of structures similar to the following should be pointed out



$$-\underset{\underset{\mathrm{CO_2C_2H_5}}{|}}{\overset{\overset{\mathrm{CO_2C_2H_5}}{|}}{\mathrm{C}}}-\mathrm{Hg}-\underset{\underset{\mathrm{CO_2C_2H_5}}{|}}{\overset{\overset{\mathrm{CO_2C_2H_5}}{|}}{\mathrm{C}}}-\mathrm{Hg}-\underset{\underset{\mathrm{CO_2C_2H_5}}{|}}{\overset{\overset{\mathrm{CO_2C_2H_5}}{|}}{\mathrm{C}}}-\mathrm{Hg}-\underset{\underset{\mathrm{CO_2C_2H_5}}{|}}{\overset{\overset{\mathrm{CO_2C_2H_5}}{|}}{\mathrm{C}}}-\mathrm{Hg}-$$

Although we have no definite evidence for such structures, the intractable nature of the products leads us to believe that linear polymers of this type may be formed.

Experimental Part

Procedure.—The mercuric chloride solution was prepared by dissolving 10 g. of mercuric chloride in 100 ml. of commercial absolute ethanol. The sodium ethoxide solution was prepared by dissolving 1.0 g. of sodium in 100 ml. of commercial absolute ethanol. For use by students it has been convenient to keep these solutions in indicator

bottles fitted with medicine droppers. To 1 ml. of sodium ethoxide solution was added 2 drops of the unknown, followed by 5 drops of the mercuric chloride solution. The mixture was shaken vigorously and the result observed after one minute.

Influence of Conditions upon the Reaction.—The relative amounts of reactants indicated above were selected after a series of tests with acetophenone, using varying amounts of the mercuric chloride and sodium ethoxide solutions. An excess of mercuric chloride over that necessary for reaction with acetophenone gave a yellow-orange precipitate which masked the white. Mercuric acetate seemed to be fully as satisfactory as the chloride and gave the same type of products. Mercuric nitrate, however, was reduced by sodium ethoxide and was unsatisfactory. Mercuric sulfate was too insoluble for use in alcohol solution. Dilute aqueous potassium hydroxide solution could be used to replace the sodium ethoxide but the formation of the white product was very slow and it was necessary to allow the test to stand for some time before judging the results.

The results are summarized below. In the lists of compounds tested, compounds with more than one functional group are given with the last-discussed series; thus, ketonic esters are given with the esters, cyano esters with the nitriles, etc. In each series the compounds giving a white precipitate are listed under "positive," those giving a yellow or orange precipitate under "negative," and compounds which give other results are listed under "special reactions."

Neutral Compounds Containing no Elements Other than Carbon, Hydrogen and Oxygen

HYDROCARBONS

Positive—Phenylacetylene.

Negative—Benzene, 2-pentene.

ALCOHOLS

Negative—Allyl alcohol, ethyl alcohol, ethylene glycol, isoamyl alcohol, triphenylcarbinol.

ETHERS

Negative—Acetal, anisole, *n*-butyl ether, ethyl ether.

ALDEHYDES

Positive—Acetaldehyde, heptaldehyde.

Negative—Anisaldehyde, benzaldehyde, piperonal, *p*-tolualdehyde.

Special Reactions—Formaldehyde reduced the mercuric chloride and paraldehyde first gave a yellow precipitate which turned lighter on standing.

ANHYDRIDES

Negative—Acetic, benzoic, *n*-butyric, cinnamic and isobutyric anhydrides.

KETONES

Positive—Acetone, acetophenone, benzalacetophenone, benzylacetophenone, 2-butanone, *n*-butyrophenone, desoxybenzoin, dibenzoylmethane, 2-heptanone, *p*-methylacetophenone, 2-octanone, α,γ-dibenzoyl-β-phenylpropane, pinacolone, propiophenone, 2-undecanone.

Negative—Benzalpinacolone, benzophenone, xanthone.

Special Reactions—Anthrone, benzoin, furfuralacetophenone, mesityl oxide and phenanthraquinone gave such deep colors with sodium ethoxide solution that the color of the precipitate was obscured. Some of these also apparently caused reduction of the mercuric chloride. Carvone, cyclohexanone and 1,1-dibenzoylethane also gave slight colors with the sodium ethoxide solution but the precipitate formed when the mercuric chloride was added was distinctly white.

ESTERS

Positive—Ethyl acetoacetate, ethyl α-benzoylisovalerate, ethyl α-benzylacetoacetate, ethyl benzylmalonate, ethyl *n*-butylmalonate, ethyl α,γ-dibenzoyl-β-phenylbutyrate, ethyl α-ethylacetoacetate, ethyl ethylmalonate, ethyl malonate, ethyl α-methylacetoacetate, ethyl methylmalonate, ethyl phenylacetate, ethyl phenylmalonate, methyl phenylacetate.

Negative—Benzyl acetate, benzyl propionate, *n*-butyl acetate, ethyl acetate, ethyl benzoate, ethyl α-benzoylcinnamate, ethyl *n*-butyrate, ethyl cinnamate, ethyl crotonate, ethyl diethylmalonate, ethyl α-ethyl-β-hydroxybutyrate, ethyl isobutyrate, ethyl isovalerate, ethyl myristate, ethyl β-phenylpropionate, ethyl propionate, ethyl sebacate, ethyl succinate, isoamyl acetate, isoamyl benzoate, methyl benzoate, methyl cinnamate, methyl oxalate, phenyl acetate, triacetin.

Special Reactions—Ethyl α-acetyl-β-phenyl-γ-benzoylbutyrate and ethyl α-benzalacetoacetate gave colors with sodium ethoxide solution and the color of the precipitate formed when mercuric chloride was added could not be determined. Ethyl benzalmalonate and ethyl formate gave white precipitates with sodium ethoxide solution; however, the final reaction products were yellow.

Compounds Acidic or Basic or/and Containing Elements Other than Carbon, Hydrogen and Oxygen

Many *phenols* gave bright colors with sodium ethoxide solution and some reduced the mercuric chloride; only guaiacol gave a positive test. *Nitro compounds* gave negative tests in which the colors varied, depending upon the influence of sodium ethoxide on the nitro compound. Nitromethane, the only aliphatic nitro compound tested, gave a white precipitate with sodium ethoxide solution, but this became yellow when the mercuric chloride solution was added. No generalizations can be made concerning the behavior of *amines*—some gave positive tests, some negative tests and some reduced the mercuric chloride. The test may prove of some value with *amides*. It was found that the grouping  $—C\begin{smallmatrix}\nearrow O\\ \searrow NH_2\end{smallmatrix}$ gave a positive test. The only exceptions were *o*-acetotoluide, which gave a positive test, and thiourea, which gave a black precipitate (mercuric sulfide). *Sulfonamides* ($—SO_2NH_2$), gave a negative test. All the *nitriles* tested (except ethyl cyanoacetate) gave a negative test. *Acids, salts of acids* and *quaternary ammonium salts* formed the yellow precipitate only. The specific compounds tested are listed below.

PHENOLS

Positive—Guaiacol.

Negative—*o*-Chlorophenol, *m*-cresol, *o*-cresol, *p*-cresol, β-

naphthol, phenol, phenyl salicylate, phloroglucinol, vanillin.

Special Reactions—Catechol, hydroquinone, orcinol and resorcinol monomethyl ether all gave colored solutions with sodium ethoxide. The first three of these also reduced the mercuric chloride. A color was also formed with sodium ethoxide and α-naphthol, but the precipitate formed with mercuric chloride was distinctly yellow. Resorcinol gave a negative test but the precipitate darkened on standing. Salicylaldehyde gave a white precipitate with sodium ethoxide; the addition of mercuric chloride solution gave a yellow solution but the white precipitate apparently remained.

AMINES

Positive—*n*-Butylethylamine, diethylamine, isoamylamine, methyl anthranilate, *o*-toluidine.

Negative—1-Amino-2,4-dimethylaniline, aniline, *o*-anisidine, *m*-bromoaniline, *o*-bromoaniline, *p*-bromoaniline, di-*n*-butylamine, tri-*n*-butylamine, *p*-chloroaniline, N,N-diethylaniline, diphenylamine, N-ethylaniline, ethyl *p*-aminobenzoate, ethyl anthranilate, α-naphthylamine, nicotine, *m*-toluidine, *p*-toluidine.

Special Reactions—β-Naphthylamine and benzidine reduced the mercuric chloride. *p*-Aminoazobenzene, *p*-aminophenol and *p*-anisidine gave colors with sodium ethoxide solution and apparently reduced the mercuric chloride as well.

NITRILES

Positive—Ethyl cyanoacetate.

Negative—Acetonitrile, benzonitrile, isocapronitrile, phenylacetonitrile, *o*-tolunitrile, *p*-tolunitrile, *n*-valeronitrile.

ACIDS

Negative—Acetic acid, *m*-aminobenzoic acid, anthranilic acid, *p*-hydroxybenzoic acid, salicylic acid.

Special Reactions—Malonic acid formed a white precipitate when treated with the sodium ethoxide solution. Acids will give only a clear solution when the test is applied to them, unless an excess of sodium ethoxide is present. In the case of acetic acid, for example, it was necessary to add an additional portion of sodium ethoxide in order to obtain a precipitate.

NITRO COMPOUNDS

Negative—*o*-Bromonitrobenzene, *p*-bromonitrobenzene, *p*-chloronitrobenzene, *m*-dinitrobenzene, *o*-dinitrobenzene, methyl *m*-nitrobenzoate, *m*-nitroaniline, *p*-nitroaniline, *o*-nitroanisole, *p*-nitroanisole, *m*-nitrobenzaldehyde, *o*-nitrobenzaldehyde, nitrobenzene, *m*-nitrobenzoic acid, *o*-nitrobenzoic acid, *p*-nitrobenzoic acid, *p*-nitrobenzyl acetate, *p*-nitrophenol, *m*-nitrotoluene, *o*-nitrotoluene, *p*-nitrotoluene.

Special Reactions—2,4-Dinitrobenzaldehyde, *o*-nitroaniline, *o*-nitrophenol, picric acid and 1,3,5-trinitrobenzene gave colors with sodium ethoxide solution. Nitromethane gave a white precipitate with the sodium ethoxide solution but when a mercuric chloride solution was added, a yellow precipitate, characteristic of the negative test, was obtained.

AMIDES

Positive—Acetamide, *o*-acetotoluide, benzamide, α-bromopropionamide, urethan.

Negative—Acetanilide, β-acetonaphthalide, *p*-acetotoluide, benzanilide, N-methylacetanilide, phenacetin, phthalimide.

Special Reactions—*p*-Nitroacetanilide gave a colored solution with sodium ethoxide solution, but a typical negative test was obtained when the mercuric chloride solution was added. Succinamide was apparently quite insoluble in the sodium ethoxide solution and the addition of mercuric chloride solution gave a yellow precipitate; upon standing, however, a white precipitate was formed. Thiourea gave a negative test but the precipitate quickly became dark.

SALTS

Negative—Ammonium benzoate, tetraethylammonium bromide, tetramethylammonium chloride, tetramethylammonium iodide.

MISCELLANEOUS

Positive—Benzal-*p*-bromoacetophenone.

Negative—Benzenesulfonamide, *p*-bromobenzaldehyde, carbazole, *o*-chlorobenzaldehyde, *p*-chlorobenzyl acetate, dicresyl-*o*-sulfobenzoate.

Summary

A mercuric chloride test for structure determination has been described. It is recommended for use with neutral compounds which contain no elements other than carbon, hydrogen and oxygen; it gives a positive test with ketones and aldehydes which have hydrogen on the alpha carbon atom and with esters having at least one hydrogen and one labilizing group on the alpha carbon atom. The behaviors of over two hundred organic compounds with this reagent have been described.

The Nature of the Hydrogen Bond. I. Association in Carboxylic Acids

BY R. H. GILLETTE AND ALBERT SHERMAN

Introduction

It has long been known that many organic compounds, especially those containing hydroxyl groups, are associated at ordinary temperatures, both in the gaseous state and in solution in nonpolar solvents.[1] The equilibrium was investigated by Auwers,[2] who was able to distinguish two classes of associating substances, those in which the molecular weight increases in proportion to the concentration and those in which the molecular weight approaches a limiting value corresponding to dimer formation. Examples of the former class are alcohols, phenols and amides; of the latter class the carboxylic acids constitute the best example. Much later work using many different methods has yielded discordant results but has largely verified the above conclusions. The present work is concerned with assuming a structure for the dimeric carboxylic acid, and calculating its energy with respect to unassociated molecules. It is mainly for these substances that experimental values for the heat of the association reaction are available. For formic acid Coolidge[3a] obtained the value 14,125 cal., and Fenton and Garner[3b] found 13,790 cal. for acetic acids. The fact that consistent values for the heat of association over a considerable range of temperature and pressure were obtained lends considerable credence to the view that these acids are associated only to dimers, as does also the work of Smyth and Rogers,[4] who showed that associated molecules of acetic acid and butyric acid have an electric moment of zero in benzene solution.

Several mechanisms have been postulated to explain this association, the simplest being that the interaction between two juxtaposed dipoles is responsible for the reaction. This, however, is unimportant in this case, and in general this interaction is insufficient to deal with polar molecules, as has been pointed out by Hildebrand.[5] Williams[6] remarks that the presence of a dipole movement may be a necessary condition for association in general, but it is not sufficient. Phenol and benzoic acid are generally regarded as associated, yet over a considerable range of concentration (benzene solution) these substances show no change in their molar polarizations.

Moore and Winmill[7] were probably the first to postulate a hydrogen bond, *i. e.*, two atoms or groups held together by a hydrogen atom or nucleus between them. Pfeiffer[8] used the idea to explain the weakness of *o*-hydroxyanthraquinone and Huggins[9] used the concept as a theory in regard to certain organic compounds. Latimer and Rodebush[10] were the first to recognize the hydrogen bond as a general phenomenon.

Pauling[11] has considered a hydrogen bond to be polar in nature while Sidgwick[12] as a result of his theory of the coördinate covalent link, postulated that organic acids would associate since an inner coördination would lead to a four-membered ring, which is unstable, whereas two molecules could join together, forming a stable configuration, with carboxyl groups facing one another, the hydroxyl hydrogens acting as acceptors for the formation of coördinate links. This view is, however, untenable, as Sidgwick himself has since stated,[13] since hydrogen cannot be divalent unless some of the electrons are promoted to the 2s state, which is unstable. This argument for the instability of divalent hydrogen assumes that the atomic quantum numbers for hydrogen essentially retain their significance in the molecule.

Sidgwick now regards the hydrogen as first attached to one atom and then to the other, this electronic resonance on a time average amounting to making hydrogen divalent, *i. e.*, the resonance phenomena of wave mechanics. Bell and Arnold[14] come to the same conclusion for dimer formation in the case of trichloroacetic acid molecules.

W. D. Kumler[14a] discusses the hydrogen bond in relation to dielectric constants and boiling points of organic liquids.

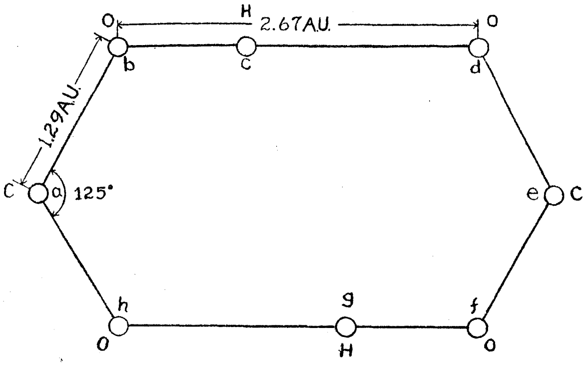

Fig. 1.—The model obtained from electron diffraction experiments for associated dimeric formic acid. The two carboxyl groups form an eight-membered plane ring.

In view of the above facts it is of interest to calculate the energy of the carboxylic acid complex with the aid of wave mechanics in order to throw some light upon the nature of the hydrogen bond, *i. e.*, to determine whether it is polar, homopolar or both.

We shall restrict our considerations for the present to formic acid, partly because it is the simplest acid and partly because accurate experimental data for the substance are available. In order to calculate the energy of the dimer we must assume some particular spacial configuration. The one chosen was that suggested by Latimer and Rodebush[10] and verified experimentally by Pauling and Brockway[15] by electron diffraction measurements. This structure places all the atoms in a plane with carboxyl groups opposite one another, as shown in Fig. 1. Zahn[16] has suggested an alternative model as a result of electric moment investigations, and based on the results of electron diffraction measurements by Hengstenberg and Brú.[17] However, Pauling and Brockway state the model postulated by the latter authors is not in agreement with their electron diffraction pattern and hence can be definitely excluded.

Procedure

All the electrons are considered uniquely paired except those in the ring and the problem is treated in the ordinary way as one of 8 electrons with spin degeneracy. There are in general 14 linearly independent bond wave functions for 8 electrons, a convenient set being the so-called canonical set[18] given below.

The energy of the complex is calculated as a function of the distance between carboxyl groups, *i. e.*, between atoms b and d. For every distance r_{bd} two cases were considered. In one case the hydrogen atoms are placed midway between the oxygen atoms, as shown in Fig. 1. In the other case the hydrogen atoms are at the normal O–H distance (0.97 Å.) from diagonally opposite oxygen atoms. It is of course immaterial where the hydrogen atoms are located as far as the 14 bond wave functions in Fig. 2 are concerned.

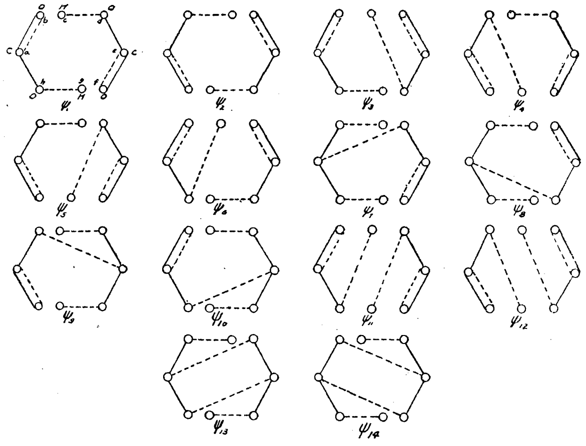

Fig. 2.—Fourteen linearly independent bond wave functions for eight electrons in the ring of dimeric acetic acid.

For the second case we give ψ_3 and ψ_4 the same coefficient in the wave function for the system, and similarly for ψ_5 and ψ_6 and ψ_7, ψ_8, ψ_9 and ψ_{10}. The functions ψ_{11}, ψ_{12}, ψ_{13} and ψ_{14} are neglected. They are what Pauling and Wheland[19] have called second excited structures, and it is evident that they will contribute little to the energy of the system and may be neglected in an approximate calculation. Thus, we define

$$\phi_1 = \psi_1,\ \phi_2 = \psi_2,\ \phi_3 = \psi_3 + \psi_4,\ \phi_4 = \psi_5 + \psi_6,$$
$$\phi_5 = \psi_7 + \psi_8 + \psi_9 + \psi_{10}$$

The matrix components between the ϕ's were computed by first calculating the components in terms of the ψ's, by either Pauling's[18] or Eyring and Kimball's method,[20] and then using the definition of the ϕ's.

In this case $ab = ah = de = ef$; $ac = eg$; $ad = af = be = eh$; $ag = ce$; $bc = fg$; $bd = fh$; $bf = dh$; $bg = df$; $cd = gh$; $dg = ch$ and $bh = df$.

(20) Eyring and Kimball, *ibid.*, **1**, 626 (1933).

The components in terms of the ϕ's are given below.

$$H_{11} = Q + (ab - ac - ag - bc - bd - bf - bg - bh - dg) + 2(cd - ad) - {}^1/_2(ac + cg)$$
$$H_{22} = Q + (ab - ac - ag - bd - bf - cd - bg - bh - dg) + 2(bc - ad) - {}^1/_2(ac + ag)$$
$$H_{33} = 2{}^1/_2Q + 4(ab - ag - bh) - 2{}^1/_2(ac + bc + bd + bf + dg) + 2(bg + cd) - 1{}^1/_4(ac + cg) - 5ad$$
$$H_{44} = 7{}^1/_2Q + 3(ab + ad) + 6(cd + bc - bg - dg) - 4{}^1/_2cg - 7{}^1/_2ac - 10{}^1/_2(ac + ag) - 12(bd + bh) - 9bf$$
$$H_{55} = 2{}^1/_2Q + 4(ab - ac - bh) - 2{}^1/_2(ag + bd + bf + bg + cd) + 2(bc + dg) - 1{}^1/_4(ae + cg) - 5ad$$
$$H_{12} = {}^1/_8Q + {}^1/_2(ab + ad - ac - bd - ag - bh - bf) + {}^1/_4(bc + cd + bg + dg - ae - cg)$$
$$H_{13} = Q + 2{}^1/_2(ab - ag - bh) + 2(cd - ad) - (ac + bc + bd + bf + dg) + {}^1/_2(bg - ae - cg)$$
$$H_{14} = 1{}^1/_2Q + 2{}^1/_4(ab - ag - bf - bh) + {}^3/_4(ad + bc - cg - bg) + 3cd - 1\,{}^1/_2(ae + dg) - {}^{15}/_4(ac + bd)$$
$$H_{15} = {}^1/_2Q + 1{}^1/_4(ab - ac - bd - bf - bh - ag) + {}^1/_4(bc + bg - ad - ac) + cd + dg - cg$$
$$H_{23} = {}^1/_2Q + 1{}^1/_4(ab - ac - bd - bf - bh - ag) + {}^1/_4(cd + dg - ad - ae) + bc + bg - cg$$
$$H_{24} = 1{}^1/_2Q + 2{}^1/_4(ab - ac - bf - bh) + {}^3/_4(ad + cd - dg - cg) - {}^{15}/_4(bd + ag) + 3bc - 1{}^1/_2(ae + bg)$$
$$H_{25} = Q + 2{}^1/_2(ab - bh - ac) + 2(bc - ad) + {}^1/_2(dg - ae - cg) - ag - bd - bf - bg - cd$$
$$H_{34} = 2{}^1/_4Q + 4{}^1/_2(ab - bd - ag - bh) + 1{}^1/_2(ad + bc + bg) - 6(bf + ac) + 3cd - 2{}^1/_4(ae + cg)$$
$$H_{35} = 1{}^1/_4Q + 2(ab - ac - ag - bh - bf) - ad + bc + cd + bg + dg - ae - 2{}^1/_2cg - 3{}^1/_2bd$$
$$H_{45} = 2{}^1/_4Q + 4{}^1/_2(ab - ac - bd - bh) + 1{}^1/_2(ad + cd + dg) - 6(bf + ag) + 3bc - 2{}^1/_4(ae + cg)$$

Here Q is the Coulombic energy of the system, ab the exchange energy between electrons a and b, and similarly for ac, ad, etc.

The Coulombic and exchange energies were evaluated from the various Morse potential energy curves in question, and an approximate formula was used for correcting the Morse values for directed valence. It was assumed that $K'_{ab} = K'_{ab}\cos^2\alpha$ holds for a bond formed from one s and one p electron, where K_{ab} is the exchange energy of a bond determined from a Morse curve, α the angle through which the bond is distorted from its normal value (*i. e.*, from the angle for which the bond energy is a maximum), and K'_{ab} the directed valence exchange energy. The carbon wave functions were considered to be tetrahedral and orthogonal. The Coulombic energy was assumed to be 14% of the total bond value.[21]

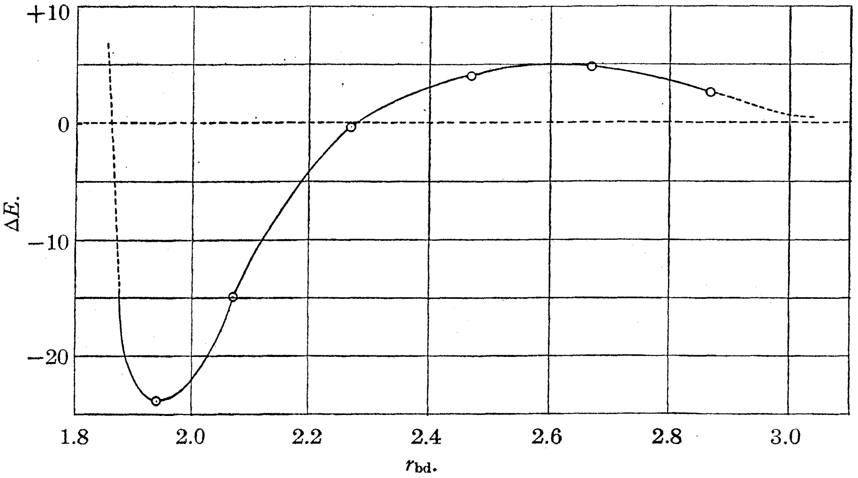

Fig. 3.—The heat of the association reaction of two carboxyl groups as a function of the distance between them. The minimum corresponds to the formation of a stable dimer.

The constants used for constructing Morse curves are given in Table I.

TABLE I

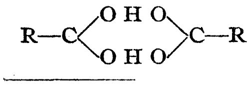
Bond	r_0(Å.)	ω(cm.$^{-1}$)	D(kcal.)
O–O	1.32	1304	34.3
C–H	1.12	2930	92.3
C–O	1.43	1030	81.8
H–H	0.74	4375	102.4
C–C	1.54	990	83.0
O–H	0.97	3660	113.1

Results

For every distance between oxygen atoms b and c or h and f the configuration where the hydrogen atoms are placed at the normal distance from diagonally opposite oxygen atoms turned out to be more stable than when they were placed midway between the oxygens. Hence only the matrix component for the more stable configuration was given in the preceding section, since it is the only one of interest for our present problem.[22]

The results of the calculation are shown in Fig. 3.

ΔE is the heat of the association reaction 2R—COOH ⟶



$$R{-}C\begin{matrix}\diagup O\ H\ O \diagdown \\ \diagdown O\ H\ O \diagup\end{matrix}C{-}R$$

, *i. e.*, $\Delta E = E_{\text{dimer}} - 2E_{\text{monomer}}$

---

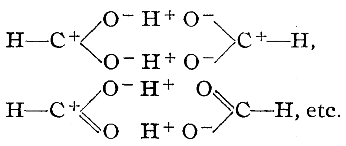
[21] This percentage is taken over from activation energy calculations. See Van Vleck and Sherman, *Rev. Modern Phys.*, **1**, 168 (1935).

(22) The secular equation for the more unstable configuration was taken as a cubic, defined by the wave functions $\theta_1 = \psi_1 + \psi_2$, $\theta_2 = \psi_3 + \psi_4 + \psi_5 + \psi_6$, $\theta_3 = \psi_7 + \psi_8 + \psi_9 + \psi_{10}$.

Discussion

It is seen from Fig. 2 that the curve has the form to be expected and that for the reaction 2HCOOH $\longrightarrow$ $(HCOOH)_2$ we calculate an activation energy of 4.8 kcal., a minimum at $r_{bd} = 1.94$ Å., and a heat of reaction of 23.8 kcal. This is to be compared with the experimental values $r = 2.67$ Å., and ΔE at the minimum equal to 14.1 kcal.

From theoretical considerations we know that a complete wave function for a system should include terms to allow for both polar and homopolar states. It is exceedingly difficult, however, to include polar states in the calculation in any practical way, but it was considered of interest to see to what extent homopolar states alone could account for the results in order to determine, if possible, the relative importance of each. The existence of such states as



are possible, and the most important cause of the discrepancy between calculated and experimental quantities is undoubtedly to be sought in the neglect of them. Pauling and J. Sherman[23] calculate from thermochemical data that the resonance energy of a carboxyl group is 1.2 v. e. relative to the structure . We have made additional calculations and find the resonance energy to be 0.8 v. e. if it arises from the two states  and . Accordingly other states must be involved, such as ,  and .

To the extent that polar states are important directed valence is unimportant. Since we neglected polar terms we consequently over-corrected for directed valence. This is the main reason why the calculated ΔE was not in numerical agreement with experiment.

Polar terms will come in to the energy expression in an additive way. Although it is not quite correct to infer that they will therefore effectively increase the Coulombic percentage above 14, nevertheless it is interesting to remark that if the importance of directed valence is decreased and the percentage of Coulombic energy slightly increased agreement with experiment is obtained. Thus if directed valence be decreased by 25% and the Coulombic percentage increased from 14 to 17.5 the calculated value of ΔE agrees with experiment.

Resonance between bond wave functions ψ_1 and ψ_2 may be considered to be the resonating hydrogen bond of Sidgwick, mentioned in the introduction. It is to be noticed, however, that if the functions ψ_1 and ψ_2 alone were involved ΔE would be $+5$ kcal. rather than -23.8 kcal. Thus we see that states ψ_3 through ψ_{10}, although not as important as ψ_1, and ψ_2, must also be considered since they contribute considerable energy to the complex. If all excited states[19] be neglected, both for the dimer and the monomers, the heat of the association reaction turns out to be approximately equal to that found by taking all states into account.[24] Hence it turns out that the ordinary chemical formulation of the reaction  happens to be fortuitously correct if the bonds drawn in the complex are interpreted to represent the functions ψ_1 and ψ_2.

Various assumptions concerning the value of a in the expression $K' = aK \cos^2 \alpha$, together with various choices of the Coulombic percentage all affect the value of ΔE and the activation energy of the association, but many detailed calculations show that the position of maximum stability always occurs at $r_{bd} = 1.94$ Å. The fact that r_{bd} (exptl.) $= 2.67$ Å. indicates polar states are important, but the discussion above indicates that homopolar states are also important.

Pauling,[11] after remarking that the hydrogen bond in HF_2^- is polar, *i. e.*, $F^-H^+F^-$, says the polar concept of the hydrogen bond explains why only atoms of high electron affinity such as fluorine, oxygen and nitrogen form such bonds. It is not clear, however, why from this viewpoint chlorine which is at least as electronegative as nitrogen[25] forms at best only very weak hydrogen bonds.[26]

We wish to thank Professor Farrington Daniels for his constant interest in this problem. One of us (A. S.) also acknowledges a profitable talk with Professor L. Pauling. He also wishes to thank

the Wisconsin Alumni Research Foundation for financial support.

Conclusions

From the preceding discussion we conclude that the wave function for a hydrogen bond should include both polar and homopolar terms.

Although we are not able to decide quantitatively the relative importance of each it seems safe to conclude that both are important. Most simply, therefore, the hydrogen bond must be considered as consisting of at least the three states $X^-H^+X^-$, X—H X and X H—X.

Madison, Wisconsin Received April 14, 1936

[Contribution from the Laboratory of Physical Chemistry, University of Wisconsin]

The Effect of Association on the Infra-red Absorption Spectrum of Acetic Acid

By R. H. Gillette and Farrington Daniels

The effect of interactions between various groups on the infra-red absorption of organic molecules has been investigated recently by a number of workers.[1] The work, however, has been confined chiefly to the study of the intensities of overtones of vibrations involving hydrogen linked to carbon, nitrogen or oxygen. Acetic acid is particularly interesting in this connection because one can observe the effect of association on the spectrum of the carboxyl group. It has, in fact, proved possible to measure a considerable portion of the spectrum of both the monomeric and dimeric acid and to interpret it so as to bring it into accord with the results of electron diffraction measurements and, perhaps less certainly, of electric moment measurements.

Several investigators have used Raman data to obtain such information.[2] Dadieu and Kohlrausch[3] have determined the Raman spectra of several binary liquid mixtures of acetic acid in different solvents and have found that only the lines associated with the C═O group are affected by the solvent. Leitman and Ukholin[4] have shown that the Raman line at 623 cm.$^{-1}$ in acetic acid becomes much weaker when the acid is dissolved in water, and finally, as the concentration is decreased, fades out entirely. They interpret this to mean that the association of acetic acid leads to molecules of quite definite configuration.

Experimental

The spectrometer of the Wadsworth type using a rock salt prism, Nerst glow lamp, and Paschen galvanometer has been described before.[5] The absorption cells were made by cementing polished rock salt windows onto both ends of Pyrex tubes 8 cm. long. Glyptol cement was found to be excellent for attaching the windows to the glass—much better than fish glue. The cells were heated electrically with a constancy of ±1°.

The acetic acid, obtained from the Niacet Chemical Company, was carefully purified by distillation *in vacuo*. Different samples always gave the same absorption spectrum.

Results

The vapor of acetic acid was studied at room temperature and at 172° from 1100 to 10,000 cm.$^{-1}$, the results being shown in Table I and Fig. 1 (to conserve space the high frequency region containing only the band ν_1 was omitted in Fig. 1). In both cases the acid was present at a partial pressure of 19 mm. in an atmosphere of air.

Table I

Band	25° C.	172° C.
ν_1	2985 cm.$^{-1}$	2985 cm.$^{-1}$
ν_2	1740 cm.$^{-1}$	1786 cm.$^{-1}$
ν_3	1435 cm.$^{-1}$	1398 cm.$^{-1}$
ν_4	1296 cm.$^{-1}$	1288 cm.$^{-1}$
ν_5	1190 cm.$^{-1}$	1185 cm.$^{-1}$

Five sharply defined bands occur in the region studied, their shape suggesting that the rotational fine structure is completely blotted out, as might be expected at the high pressure of foreign gas. Of these, three are not shifted by the increase in temperature although the band at 1190 cm.$^{-1}$ (ν_5) is greatly intensified. The remaining two bands, at 1740 cm.$^{-1}$ (ν_2) and 1435 cm.$^{-1}$ (ν_3) at room temperature, are shifted considerably fur-

ther apart at 172°—occuring at this temperature at 1786 and 1398 cm.$^{-1}$, respectively.

Since the temperature shifts are appreciably larger than the shifts produced by substitutions in the acetic acid molecule itself,[6] it was felt that some type of chemical reaction must be involved which changes bonds between atoms. It is well known from the work of Ramsay and Young[7] and Fenton and Garner[8] that acetic acid is almost completely associated into double molecules even at the boiling point, and at 183° and 400 mm. pressure is still 9% associated. If this association is responsible for the observed shifts, it would be expected that at intermediate temperatures where both monomeric and dimeric forms are present both bands should appear. This is strikingly borne out in Fig. 2 where the absorption of the C=O group is shown at various temperatures. As is to be expected the weaker band drifts toward the stronger one due to the fact that the width of the spectrometer slit is finite and some overlapping occurs.

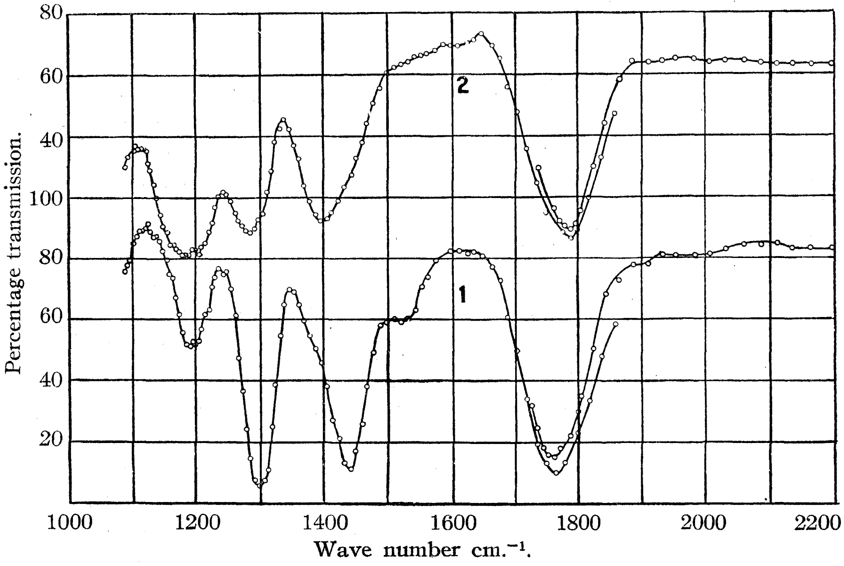

Fig. 1.—The infra-red absorption spectrum of acetic acid vapor. Curve 1 at 25°; Curve 2 at 172°.

Discussion

In order to assign the bands to definite vibrations within the molecule, it is necessary first to consider the nature of the single and double molecules. The former cannot vary greatly from the planar model assumed by Mecke[9] for formaldehyde. There is some arbitrariness in the choice of fundamental modes of vibration for this molecule, but since the molecule is completely unsymmetrical a possible set is shown in Fig. 3, where ω's are used to indicate modes of vibration of the model to be associated with the fundamental frequencies in the absorption spectrum (ν's) having the same subscript. The usual assumptions that interactions between bonds can be neglected and that only the valence vibrations will lie in this region are made.[10] It is apparent that these modes correspond essentially to the vibration of a C=O, a –C–O–, and a C–C bond. At 172° under the conditions of our experiments acetic acid is almost completely dissociated into single molecules and hence the spectrum at this temperature should correspond to that of the model of Fig. 3.

One of the most firmly established frequencies in infra-red spectroscopy is that of the C=O group which occurs in the same region in aldehydes, ketones, acyl halides, amides, esters and acids and has been investigated extensively[11] by both Raman and infra-red measurements. This is clearly to be associated with the ν_2 and ω_2 described here.

Bands occurring in the vicinity of 2960 cm.$^{-1}$ are well known to be produced principally by a valence vibration of the C–H bond.[12] In this region occur also bands due to overtone and combination vibrations of the carboxyl group as well as the fundamental of the O–H vibration. It is also well established that a deformation vibration of the C–H group occurs in the vicinity of 1300 cm.$^{-1}$. To these two vibrations we assign our ν_1 and ν_4, respectively.

The remaining two vibrations are assigned as shown in Fig. 3. This assignment is in qualitative agreement with the fact that the frequency of a C–O vibration is in general higher than that of a C–C frequency, and will be further justified by a consideration of the double molecule.

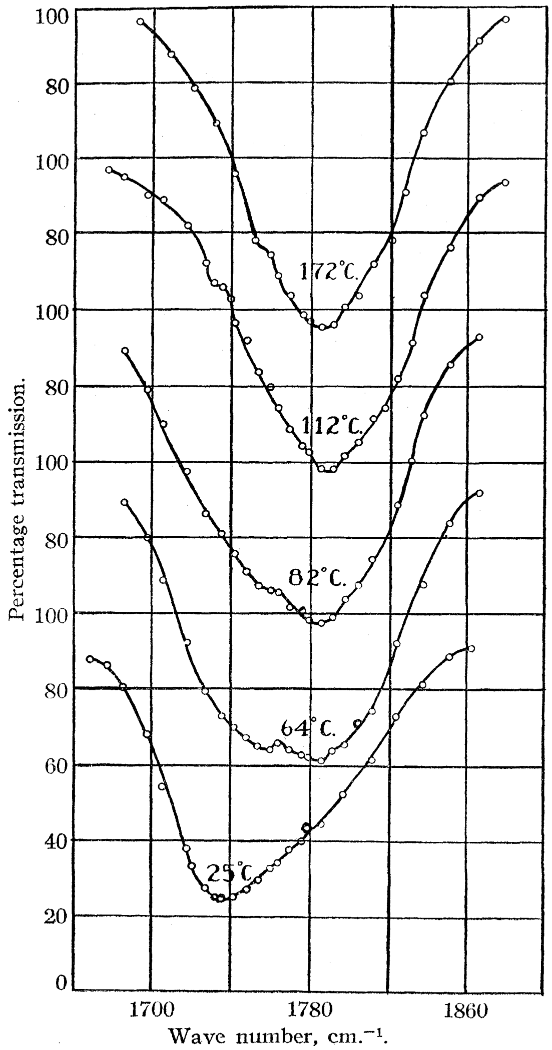

Fig. 2.—The infra-red absorption spectrum of the carbonyl group of acetic acid.

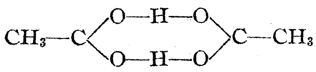
That the association of acetic acid involves hydrogen bonds was first suggested by Latimer and Rodebush.[13] This view was later verified by Pauling and Brockway[14] who determined the configuration of the double molecule of formic acid by electron diffraction measurements. It was found to be a monoplanar ring, the two molecules being joined by two hydrogen bonds



We shall assume that this same structure is also found in acetic acid.

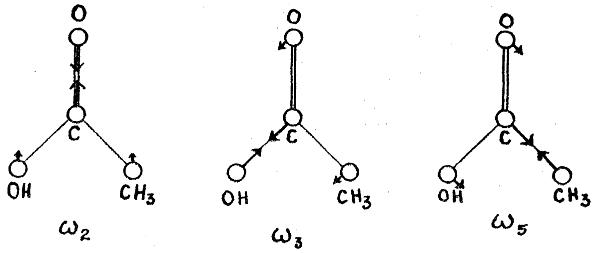


Fig. 3.—Fundamental modes of vibration of the single molecule of acetic acid. (The deformation vibrations have been omitted.)

In formulating the fundamental modes of vibration the hydrogen in the ring is neglected since the electric moment changes associated with its vibration are undoubtedly small as shown by the fact that the formation of hydrogen bonds blots out the characteristic O–H absorption. Again making the assumption that interaction between bonds is negligible we are able to separate the two vibrations of the methyl groups against the ring from vibrations of atoms in the ring itself.

The usual requirement that vibrations be symmetric or antisymmetric with respect to the symmetry elements present leads to the formulation for the double molecule shown in Fig. 4, where the primes are used to distinguish the vibrations of the dimer from those of the monomer. It may be seen that the frequencies in the first column are

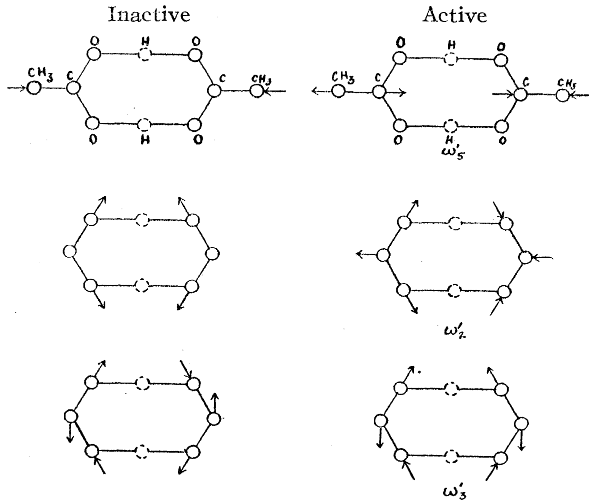

Fig. 4.—The fundamental valence vibrations of dimeric acetic acid.

(14) Pauling and Brockway, *Proc. Nat. Acad. Sci.*, **20**, 336 (1934).

inactive since they produce no change in the electric moment of the molecule.

It will now be shown that the active frequency ω_5' of the dimer should be the same as ω_5 of the single molecule. Denote by M the mass of the ring exclusive of the methyl groups and by m the mass of a methyl group. Then the reduced mass for the vibration ω_5' is

$$\mu = \frac{2m_1M}{2m + M} = \frac{2m}{1 + (2m/M)}$$

while that for ω_5 is

$$\mu_5 = \frac{m(M/2)}{m + (M/2)} = \frac{m}{1 + (2m/M)}$$

But since there are two methyl groups involved in the vibration ω_5' the force constant f_5' will be twice as large as f_5. Thus the frequency of vibration calculated from the relation $\nu = {}^1/_{2\pi} \sqrt{f/\mu}$ will be the same in both cases. This indicates that it is justifiable to assign the frequency at 1190 cm.$^{-1}$ to this vibration. The greater intensity of absorption in the single molecule may be correlated with the splitting of the band upon association into an active and an inactive vibration.

The frequencies ν_1 and ν_4 associated with carbon to hydrogen vibrations should not, of course, be affected by the increase in temperature. This is, in fact, found to be the case, although the band ν_4 is slightly displaced at 172°, probably because of overlapping with ν_5 which becomes much more intense.

The remaining two frequencies ν_2 and ν_3 are more difficult to attribute to the definite modes of vibration of the associated molecule. Qualitatively they should be closer together in this case than in the single molecules since their separation is merely the result of similar modes of vibration of the ring which cannot have greatly different force constants. Since it appears plausible that a greater electric moment change is to be associated with the active vibration ω_2' than with ω_3' (Fig. 4) it may be tentatively assigned to the more intense band at 1740 cm.$^{-1}$ (ν_2).

The Raman spectrum of acetic acid has been examined most accurately by Kohlrausch, Köppl and Pongratz.[15] The Raman lines occurring in this region are 1275, 1363, 1429, 1663 ± 7.5 cm.$^{-1}$. These are to be compared with the maxima of the infra-red absorption bands recorded here at room temperature: 1205, 1296, 1435, 1740 cm.$^{-1}$.

The findings of this investigation suggest that in the single molecule it is safe, at least as a good approximation, to assign a definite band in the spectrum to a definite bond in the molecule. In the double molecule, on the other hand, because of the highly symmetrical structure this approximation fails completely. A similar case is discussed by Cross and Van Vleck,[16] who show that because of mass symmetry in ethyl alcohol it is no longer possible to apply the approximation which was found to hold well for the ethyl halides.

In all the above reasoning it has been assumed that the association of acetic acid, and undoubtedly of carboxylic acids in general, takes place through the formation of hydrogen bonds. The fact that it has been possible to interpret the spectra on this assumption yields additional evidence that this is the actual mechanism of association. The fundamental nature of this hydrogen bond is discussed by Gillette and A. Sherman.[17]

Summary

1. The infra-red absorption spectrum of acetic acid has been obtained at 25 and at 172°—corresponding to the single and the associated molecule. At intermediate temperatures both spectra appear.

2. Three of the fundamental frequencies are the same in both molecules and two are shifted. These two must be intimately connected with the association process.

3. Modes of vibration of the two molecules are suggested, corresponding to the fundamental frequencies.

4. The results of this investigation suggest that the association of carboxylic acids to give dimers occurs through the formation of hydrogen bonds leading to ring structure which gives rise to different absorption frequencies.

The Effect of Substitution on the Infra-red Absorption Spectrum of Acetic Acid

BY R. H. GILLETTE

In an earlier publication[1] from this Laboratory it was shown that the substitution of hydrogen atoms by chlorine in acetic acid giving progressively stronger acids is reflected also in a corresponding shift of the infra-red absorption band at 1721 cm.$^{-1}$. A more recent interpretation[2] of the infra-red absorption spectrum of the single and double molecules of acetic acid made it seem useful to investigate this substitution more thoroughly.

Experimental

The apparatus and method were the same as used in the investigation reported in the preceding paper.[2] The absorption cells were made by cementing rock salt windows onto both sides of holes drilled in plate glass about 4 mm. thick. They were filled through narrow grooves sawed in the window and sealed with partially dried Glyptal cement. One cell was filled with the pure solvent and the others with solutions of the acids being investigated.

The absorption spectra of acetic acid and eight substituted acids are shown in Fig. 1 and Table I. In all cases the acids were dissolved in carbon tetrachloride to give 0.025 *M* solutions and the measurements were taken at 25°. It had been found previously that the change in the position of absorption bands with concentration was very small. In the last column of Table I are recorded the dissociation constants of the acids at 25° when dissolved in water.

TABLE I

SHIFTS IN THE ABSORPTION BANDS OF THE SUBSTITUTED ACETIC ACIDS IN 0.025 MOLAR SOLUTIONS OF CARBON TETRACHLORIDE

No. in Fig. 1	Acid	ν_1, cm.$^{-1}$	ν_2, cm.$^{-1}$	ν_3, cm.$^{-1}$	Dissociation constant
4	Acetic	2941	1721	1435	1.86×10^{-5}
9	Monochloroacetic	2950	1736	1433	155×10^{-5}
8	Dichloroacetic	3049	1751	1428	5000×10^{-5}
7	Trichloroacetic	3030	1764	1416	$30{,}000 \times 10^{-5}$
6	Monobromoacetic	2976	1730	1447	138×10^{-5}
5	Monoiodoacetic	2992	1721	1441	74×10^{-5}
3	Dimethylacetic	2907	1715	1433	1.4×10^{-5}
2	Trimethylacetic	2907	1704	1433	0.98×10^{-5}
1	Diethylacetic	2910	1706	1433	1.89×10^{-5}

Discussion

Before it is possible to make any interpretation of these results it is necessary to investigate the degree of association of the acids under the conditions of measurement. A search of cryoscopic measurements in the older literature[3] suggested that down to small concentrations (about 0.01 *M*) all carboxylic acids are nearly completely associated in non-polar solvents. This is confirmed by the recent accurate measurements of Bury and

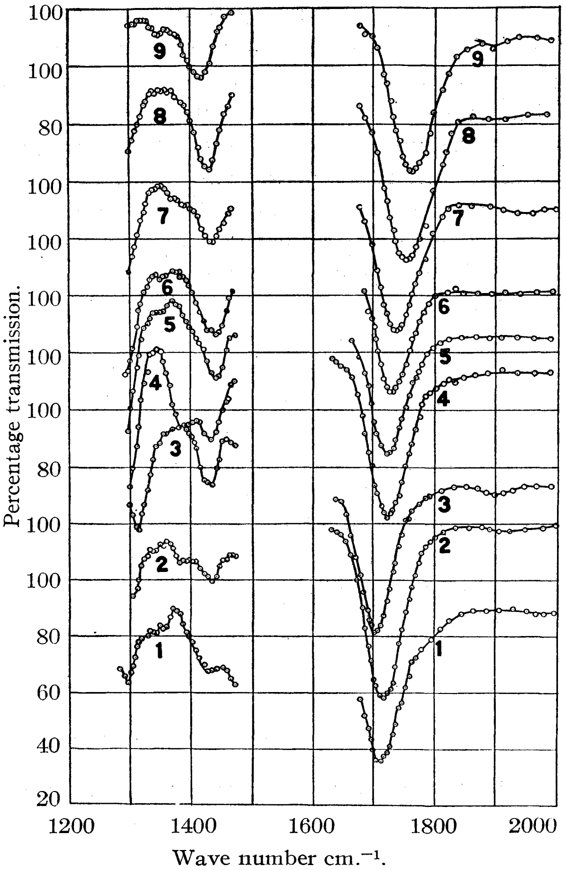

Fig. 1.—Displacements in the infra-red absorption spectrum produced by substituting various groups for hydrogen in acetic acid: 1, diethylacetic acid; 2, trimethylacetic acid; 3, isobutyric acid (dimethyl); 4, acetic acid; 5, iodoacetic acid; 6, bromoacetic acid; 7, chloroacetic acid; 8, dichloroacetic acid; 9, trichloroacetic acid.

Jenkins[4] and Bell and Arnold.[5] The latter authors have shown in benzene solutions of concentrations from $M = 0.01$ to $M = 1.5$ trichloroacetic acid is completely associated. We assume, therefore, that under the conditions of our measurements all the acids were entirely present as dimers.

The three infra-red absorption bands which can be investigated in this solvent correspond to the frequencies ν_1, ν_2 and ν_3 of the previous paper. The first of these (ν_1) (which has been omitted in Fig. 1 to conserve space) is mainly due to the C–H valence vibration, but is also in part made up of overtone and combination vibrations from other parts of the molecule. Thus it occurs even in trichloroacetic acid, but considerably displaced and much weaker. The remaining two bands are to be attributed to vibrations within the ring formed by the union of the two single molecules. Attempts to measure some of these bands in the single molecules at high temperatures were unsuccessful on account of decomposition.

It may be seen by reference to Table I that the band ν_2 is shifted toward higher frequencies by groups recognized by the organic chemist as electronegative, while it is shifted to lower frequencies by groups electropositive in the same sense. The uniform shift in the chloroacetic acids discovered by Bennett and Daniels is confirmed. The effect of the weight of the groups may be seen by considering the monohalogen acids. Here the shift in the band decreases as the weight of the halogen increases until in iodoacetic acid it occurs in the same position as acetic. This suggests that there may be two opposing factors operative, one a weight factor and the other perhaps connected with the electron affinity or polarizability of the substituted group. It is noticeable that there is a correlation between the strength of the acid in aqueous solution and the position of this band. This is perhaps to be associated with changes in the contribution of ionic states to the energy of the molecule.

The remaining band, ν_3, is shifted in each case in the opposite direction, but the displacement is smaller. This behavior was observed also in the investigation on the effect of association.[2] It does not seem possible in the light of our present knowledge to give an exact interpretation of these band shifts although they seem too uniform to be fortuitous.

The author is grateful to Dr. Farrington Daniels for helpful suggestions and for continued interest in this problem.

Summary

1. The infra-red absorption spectra of acetic acid and eight substituted acetic acids have been measured in carbon tetrachloride solution. Certain uniform shifts in the absorption bands have been observed and correlated with other measurements.

The Entropy of Water and the Third Law of Thermodynamics. The Heat Capacity of Ice from 15 to 273°K.

BY W. F. GIAUQUE AND J. W. STOUT

It has long been known to those interested in the accurate application of the third law of thermodynamics that measured entropy changes in reactions involving water did not agree with those calculated from low temperature heat capacity data. In early comparisons the inaccuracy of the available data seemed sufficient to explain the disagreement, but even after more accurate experiments were performed discrepancies still remained. The investigations of Wiebe, Johnston, Overstreet, and one of us[1] on the entropies of hydrogen chloride, hydrogen, oxygen and chlorine, combined with very accurate determinations of the heats of reactions

$$H_2 + {}^1/_2O_2 = H_2O$$
$$\text{and } 2HCl + {}^1/_2O_2 = H_2O + Cl_2$$

---

[1] (a) Giauque and Wiebe, (HCl), THIS JOURNAL, **50**, 101 (1928); (b) Giauque and Johnston, (H_2), *ibid.*, **50**, 3221 (1928); (c) Giauque and Johnston, (O_2), *ibid.*, **51**, 2300 (1929); (d) Giauque, (H_2), *ibid.*, **52**, 4816 (1930); (e) Giauque and Overstreet, (HCl, Cl_2), *ibid.*, **54**, 1731 (1932).

made by Rossini[2] and various equilibrium data, including those relating to the reactions[3]

$$HgO + H_2 = Hg + H_2O$$
$$Hg + {}^1/_2O_2 = HgO$$

indicated that the $\int_0^T C_p d \ln T$ for water did not give the correct entropy. That this was so became a certainty when Giauque and Ashley[4] calculated the entropy of gaseous water from its band spectrum and showed that an entropy discrepancy of about one calorie per degree per mole existed. They presumed this to be due to false equilibrium in ice at low temperatures.

Water is a substance of such importance that we considered further experimental investigation to be desirable not only to check the above discrepancy but especially to see whether slow cooling or other conditions favorable to the attainment of equilibrium could alter the experimental result.

Apparatus.—In order to prevent strains in the resistance thermometer when the water was frozen a double-walled calorimeter, Fig. 1, was constructed. The outside wall was of copper, 0.5 mm. thick, 4.4 cm. o. d., and 9 cm. long. The inside copper wall, 0.5 mm. thick, was tapered, being 3.8 cm. o. d. at the bottom and 4.0 cm. o. d. at the upper end. The top of the inner container was made from a thin copper sheet, 0.2 mm. thick, which prevented the transmission of strains to the resistance thermometer. The neck for filling the calorimeter was in the center of this sheet. A series of thin circular slotted vanes of copper were soldered to the inner container, and the assembly forced inside the outer tube. A heavy copper plate, 1 mm. thick inside the inner wall, and 2 mm. thick between the walls, served as the bottom of both tubes. The thermocouple was soldered into tube D by means of Rose's metal.

A resistance thermometer-heater of No. 40 double silk covered gold wire containing about 0.1% silver was wound on the outside of the calorimeter. The resistance was 310 ohms at 290°K. and dropped to about 17 ohms at 15°K. The resistance thermometer was calibrated during the measurements by means of copper–constantan thermocouple No. 16 which had been compared with a hydrogen gas thermometer.[5] However one of the five parallel constantan wires in the thermocouple had accidentally been broken since the original calibration. This wire was discarded and after the completion of the measurements the thermocouple was compared with the oxygen and hydrogen vapor pressure thermometers.[5b] The thermocouple was also checked against the melting point, 54.39°K. and higher transition point, 43.76°K., of oxygen.[1c] On the basis of these comparisons a small correction to the original calibration was readily made.

Helium gas was introduced into the space between the two walls by means of a German silver tube, A. A similar German silver tube was soldered by means of Wood's metal into the cap, B. The sample, C, was transferred through this tube into the calorimeter, and helium gas at one atmosphere pressure admitted. The German silver tube was then heated and removed from the cap, leaving the hole sealed with Wood's metal. After the measurements on the full calorimeter had been completed, the calorimeter was heated to the melting point of the Wood's metal (72°C.) and the water completely pumped out without dismantling the apparatus. The heat capacity of the empty calorimeter was then measured.

The remainder of the heat capacity apparatus, the method of making the measurements and calculations, and accuracy considerations were similar to those previously described.[1a,c]

Purification of Water.—Distilled water from the laboratory still was transferred into the vacuum-tight purification apparatus constructed from Pyrex glass. The apparatus was evacuated to remove dissolved gases, and flushed out several times with helium gas. The water was distilled into a receiving bulb, the first fraction being discarded. The calorimeter had previously been attached to the purification system and evacuated. When sufficient water had collected in the receiving bulb, it was transferred into the calorimeter. Helium gas at one atmosphere pressure was admitted to the calorimeter which was then sealed off as described above.

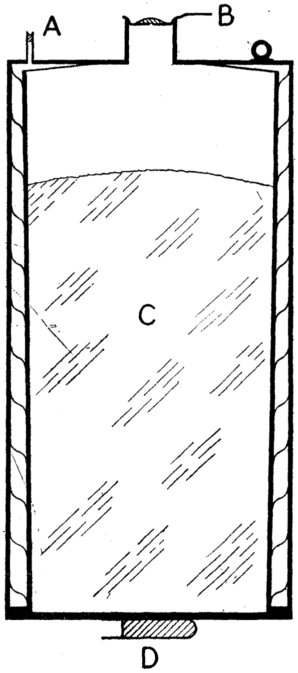

Fig. 1.—Calorimeter.

A series of short heat capacity measurements were made in the temperature region immediately below the melting point in order to determine the pre-melting effect due to liquid-soluble solid-insoluble impurity. From these measurements it was calculated that the mole fraction of impurity was three parts in a million.

The Heat Capacity of Ice.—The results of the heat capacity measurements are given in Table I. The data are shown in Fig. 2.

In the calculations one 15° calorie was taken as equal to 4.1832 international joules. The calorimeter contained 72.348 g. of ice.

In order to allow time for the establishment of an equilibrium state in the solid, the ice was cooled

---

very slowly. The following are temperatures reached at various times after the ice was frozen: 0 hours, 273.1°; 12 hours, 246°; 37 hours, 203°; 60 hours, 180°; 84 hours, 168°; 92 hours, 156°; 108 hours, 105°; 120 hours, 91°; 156 hours, 90°. The sample was then cooled from 90 to 68° in about three hours and the heat capacity measurements of series I taken. Next the calorimeter was cooled to the temperatures of liquid hydrogen at the following rate: 0 hours, 85°; 1.5 hours, 72°; 2 hours, 60°; 2.5 hours, 56°; 7 hours, 39°; (liquid hydrogen evaporated) 17.5 hours, 49°; 22 hours, 50° (more liquid hydrogen added); 23 hours, 41°; 27 hours, 13°. The measurements of series II were then made.

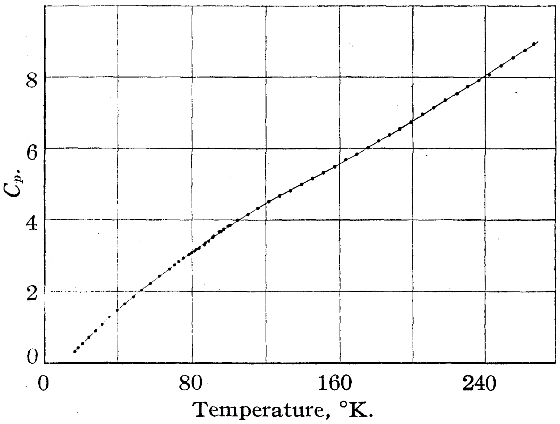

Fig. 2.—Heat capacity in calories per degree per mole of ice.

During this series of measurements which extended from 15°K. to the melting point, and covered a period of eighty hours, the calorimeter was under constant observation. To make certain that no unusual thermal situation was present in the solid near the melting point, the heat of fusion was determined at the end of the above series of measurements. The value obtained, 1436 cal./mole, agrees well with that which has been chosen for the entropy calculation.

In the heat capacity measurements between 85 and 100°K., the attainment of temperature equilibrium in the solid was much less rapid than at other temperatures. This observation is of considerable interest and some of its implications will be discussed below.

To study possible effects due to rapid cooling the sample was cooled from 273.1 to 90° in four hours. The heat capacities in series III were then measured. Slow equilibrium was again encountered, and the heat capacities were not significantly different from those previously obtained.

To determine whether the ice was being transformed from an unstable to an equilibrium condition at an appreciable rate, measurements extending over several hours each were made of the rate of temperature drift at 60, 72, 78 and 85°K. After correcting for the known heat interchange with the surroundings, the rate of evolution of heat due to internal changes was zero within the limits of experimental error. An amount of 0.0008 calorie per mole per minute could have been detected.

The calorimeter was allowed to stand for four days at temperatures between 60 and 80° before taking the measurements in series IV. Again the measurements were not significantly different from those previously obtained.

In Table II are listed the values of the heat capacity at even temperatures as read off a smooth curve through the observations. These values are compared with those of previous investigators. A review of the measurements prior to 1913 has been given by Dickinson and Osborne.[6] Of these the measurements of Nernst and co-workers are most important. The values used for comparison in Table II are calculated from an equation proposed by Nernst, Koref and Lindemann[7] as representing these data. Pollitzer[8] made measurements between 20 and 90°K. His measurements were plotted and a smooth curve drawn through them to give the values compared in Table II. The very accurate work of Dickinson and Osborne[6] between 0 and −40°C. has been calculated from an equation proposed by these authors. Maass and Waldbauer[9] and Barnes and Maass[10] have measured the total change in heat content from various low temperatures to 25°C., and from the results have proposed equations for the specific heat of ice. Simon[11] lists values for the heat capacity of ice from 10°K. to the melting point.

Professor Simon[12] informs us that, of the values listed in the "Handbuch der Physik," only the one at 10°K. is based on the results of his own measurements. The heat capacities at higher temperatures were calculated from the work of earlier observers. The experimental results of Simon[12] are in excellent agreement with the continuation of the curve drawn through our measurements. We have included in Table II a value for the heat capacity of ice at 10°K. picked from a smooth curve through Simon's data.

vaporization of water are so accurately known that further investigation was unnecessary.

The heat of fusion of ice has been accurately determined by a number of workers. The measurements prior to 1913 have been critically summarized by Dickinson, Harper and Osborne,[14] who also made a number of measurements of the heat of fusion both by an electrical method and by the method of mixtures. Dickinson and Osborne[6] measured the heat of fusion in an aneroid calorimeter, using electrical heating. The measurements in which energy was introduced electrically were recalculated by us on the basis of 1 int. joule = 4.1832 calories (15°). A weighted average of all the reported values yields 1435.7 cal./mole with an estimated accuracy of ±0.9 cal./mole, for the heat of fusion.

Fiock[15] has reviewed the measurements of the heat of vaporization of water and compared them with the results of determinations at the Bureau of Standards[16] extending down to 50°. All measurements were converted into international joules. Of the data considered by Fiock, those of Griffiths, of Smith and of Henning contained measurements in the neighborhood of 25°C. Giving equal weight to the result of each of the above three observers and to the value extrapolated from the Bureau of Standards measurements, and taking 1 calorie (15°) = 4.1832 int. joules, we obtained an average value of 10,499 ± 3 (av. dev.) calories/mole for the heat of vaporization of water at 25°.

The "I.C.T." values for the heat capacity of liquid water[17] were plotted against the logarithm of the absolute temperature and integrated graphically to obtain the entropy between 0 and 25°. The value for the vapor pressure at 25° was also obtained from the "I.C.T."[18] Using Berthelot's equation of state and thermodynamics it can be shown that the entropy correction[1a] to the ideal gas state is almost negligible in this case The critical constants[19] used were $T_c = 647.1$°K. and $P_c = 217.7$ atm.

The entropy between 10 and 273.10°K. was obtained by graphical integration of the measured heat capacities. The entropy between 0 and 10°K. was calculated by means of the Debye equation, using $h\nu/k = 192$. A summary of the entropy calculation is given in Table III.

TABLE III

CALCULATION OF ENTROPY OF WATER

0–10°K., Debye function $h\nu/k = 192$	0.022
10–273.10°K., graphical	9.081
Fusion 1435.7/273.10	5.257
273.10–298.10°K., graphical	1.580
Vaporization 10499/298.10	35.220
Correction for gas imperfection	0.002
Compression $R \ln 2.3756/760$	−6.886
Cal./deg./mole	44.28±0.05

The value of the entropy given in Table III may be compared with that calculated from spectroscopic data. Giauque and Ashley[4] utilized the preliminary molecular constants of water as given by Mecke and Baumann[20] to determine the entropy of water. Later Gordon[21] recalculated the thermodynamic quantities for water using the revised moments of inertia of Freudenberg and Mecke.[22] He obtained $S°_{298\cdot1} = 45.10$ cal./deg./mole. The difference between the spectroscopic and calorimetric values is 0.82 cal./deg./mole.

The Problem of the False Equilibrium in Ice.—To account for the discrepancy between the calorimetric and spectroscopic values for the entropy of water Giauque and Ashley[4] offered an explanation based on the assumption that the ortho and para molecular states, which are known to exist in gaseous water, had persisted in the crystalline state at low temperatures. The situation was assumed to be similar to that which accounts for the entropy discrepancy in the case of solid hydrogen.[1b,d] The ortho water was assumed to have non-polar clockwise and counter clockwise rotations in ice, since the dielectric constant of ice at low temperatures corresponds to that of non-polar substances. This leads to a calculated discrepancy of $^3/_4 R \ln 2 = 1.03$ cal./deg./mole.

We have had many interesting private discussions with Professor Linus Pauling who has consistently objected to the ortho-para explanation. During the course of the present investigation Pauling[23] offered an alternative explanation based

on the random orientation of hydrogen bonds in ice. Crystal structure investigations have shown that each oxygen atom is surrounded by four equivalent oxygen atoms. Although the positions of the hydrogen atoms have not been determined experimentally it seems reasonable to assume that they are located on lines joining adjacent oxygens. Since the oxygen–oxygen distance is considerably greater than twice the separation which is characteristic of an oxygen–hydrogen linkage, it has been assumed by Bernal and Fowler[24] that each oxygen is joined to two close and two distant hydrogen atoms. At higher temperatures the bond directions of the close or distant hydrogen atoms of a given oxygen are a matter of chance. We quote from the paper of Bernal and Fowler. "Therefore it is quite conceivable and even likely that at temperatures just below the melting point the molecular arrangement is still partially or even largely irregular, though preserving at every point tetrahedral coördination and balanced dipoles. In that case ice would be crystalline only in the position of its molecules but glass-like in their orientation. Such a hypothesis may be still necessary to explain the dielectric constant and the absence of pyroelectricity."

Pauling assumes further that when ice is cooled to low temperatures, it fails to attain the ordered arrangement which would correspond to zero entropy. He shows that the discrepancy corresponding to the above lack of order would be $R \ln 6/4 = 0.806$ cal./deg./mole. This is in very close agreement with the experimentally determined discrepancy of 0.82 ± 0.05 cal./deg./mole.

However, it should be pointed out that in two previous cases, carbon monoxide[25] and NNO[26] where random molecular orientations led to entropy discrepancies, the experimental discrepancy was a few tenths of a unit lower than the calculated value due to partial attainment of an ordered state. If this were the case in ice, the ortho-para explanation might be correct. However, we consider that the explanation advanced by Pauling is the more plausible as well as being in better agreement with the experimental results.

It is of interest to note that MacDougall and Giauque[27] investigated ice from 0.2 to 4°K. and found no appreciable heat capacity in this region.

One of the purposes of the present work was to investigate the possibility of more complete attainment of equilibrium. We have mentioned above that various experiments, in which ice was cooled slowly or rapidly to low temperatures, or was allowed to stand for long periods of time at low temperatures, resulted in heat capacities which were not appreciably different in the various series of measurements. At temperatures between 85 and 100°K. the attainment of thermal equilibrium in the solid was very much less rapid than at other temperatures. For this reason the heat capacity measurements in this region are somewhat less accurate than the others. This slow equilibrium presumably is due to the initial stages of excitation of some new degrees of freedom. From the value of the heat capacity this evidently is connected with motion of the hydrogen atoms. At temperatures below the region of slow equilibrium the dielectric constant[28] is of the order of magnitude characteristic of a nonpolar substance. At higher temperatures the dielectric constant rises rapidly and the orientation time of the dipole decreases. From this it would appear that the new degrees of freedom referred to above are associated with the dipole orientation mechanism.

From the temperature drift experiments at 60, 72, 78 and 85°K. it appears that no great change in the heat content would be expected if ice were kept at these temperatures for a considerable period of time.

We may mention in passing that low temperature heat capacity measurements on some of the high pressure forms of ice would undoubtedly lead to correct values for the entropy of water.

It is perhaps worth noting that while the theory of random bond orientation would lead to the same discrepancy, $R \ln 3/2 = 0.806$ cal./deg./mole in both hydrogen and deuterium oxides, the theory of molecular rotation in ortho states of water would lead to different values for the calculated discrepancy. For hydrogen oxide the value is $3/4\, R \ln 2 = 1.033$, for deuterium oxide, $1/3\, R \ln 2 = 0.459$ cal./deg./mole. Although we believe the latter theory to be less plausible it will be of interest to make the comparison when measurements on deuterium oxide become available.

Summary

The heat capacity of ice has been measured between 15 and 273°K.

It has previously been shown by Giauque and Ashley that a discrepancy exists between the spectroscopic value of the entropy and the $\int_0^T C_p\, d \ln T$ for water.

The purpose of the present investigation was to make an accurate determination of the discrepancy.

With the assistance of the well-known values for the heats of fusion and vaporization of water we find that the $\int_0^T C_p\, d \ln T = 44.28 \pm 0.05$ cal./deg./mole for H_2O (g.) at one atmosphere and 298.1°K. The spectroscopic value is 45.10 leading to a discrepancy of 0.82 cal./deg./mole. This is in excellent agreement with the theoretical discrepancy 0.806 calculated by Pauling on the assumption of random orientation of hydrogen bond directions in ice.

Experiments have been described in which ice was cooled slowly or rapidly to low temperatures or was allowed to stand for long periods of time at low temperatures. No difference in the thermal properties of ice was observed in these experiments.

Pyrimidine Research. Synthesis of 4-Methyl-5-*n*-butylcytosine

BY YUOH-FONG CHI

In this paper is described a method of synthesizing 4-methyl-5-*n*-butylcytosine (VII), which is prepared as its hydrobromide from 2-ethylmercapto-4-methyl-5-*n*-butylcytosine (VI) by hydrolysis with concentrated hydrobromic acid. The free base (VII) is liberated from its hydrobromide by neutralizing with ammonia. For the preparation of 2-ethylmercapto-4-methyl-5-*n*-butylcytosine (VI), the starting point is the corresponding 6-oxypyrimidine, 2-ethylmercapto-4-methyl-5-*n*-butyl-6-oxypyrimidine (II). This is treated with phosphorus oxychloride to form the corresponding 6-chloropyrimidine (V), and the latter then heated with alcoholic ammonia at 170–180° to give the desired 2-mercapto-6-amino derivative (VI).

2 - Ethylmercapto - 4 - methyl - 5 - *n* - butyl-6-oxypyrimidine was prepared according to the general method of Wheeler and Liddle.[1] Ethyl *n*-butylacetoacetate is first condensed with thiourea in the presence of sodium ethylate to give 2-thio-4-methyl-5-*n*-butyl-6-oxypyrimidine (I), which is then treated in the presence of sodium ethylate with ethyl bromide to give 2-ethylmercaptopyrimidine (II). Alkylation of the latter with methyl iodide gives the corresponding 2-methylmercapto compound (III), and with ethyl chloroacetate to give ethyl 4-methyl-5-*n*-butyl-6-oxypyrimidine-2-thioglycolate (IV).

Experimental Part

2 - Thio - 4 - methyl - 5 - *n* - butyl - 6 - oxypyrimidine I.—Twenty-six grams of sodium was dissolved in 500 cc. of absolute alcohol and 210 g. of ethyl *n*-butylacetoacetate and 94 g. of thiourea added to the solution. This was then heated on a water-bath for ten hours and the excess of alcohol removed by heating under diminished pressure. The crude sodium salt of the desired pyrimidine was dissolved in water and the solution acidified with acetic acid, when the thiopyrimidine separated. It crystallized from hot water in needles, melting at 197–198°. The yield was 144 g.

Anal. Calcd. for $C_9H_{14}ON_2S$: N, 14.14. Found: N, 14.03, 13.98, 14.00.

---

[1] Wheeler and Liddle, *Am. Chem. J.*, **40**, 547 (1908).

2 - Ethylmercapto - 4 - methyl - 5 - *n* - butyl - 6 - oxypyrimidine II.—Eight and one-tenth grams of sodium was dissolved in 200 cc. of absolute alcohol and 70 g. of the above thiopyrimidine and 42.5 g. of ethyl bromide were added to the solution. This was then heated on a water-bath until the solution became neutral. The excess alcohol was then distilled off under diminished pressure, and the mercaptopyrimidine washed with water and recrystallized from dilute alcohol. It separated in long needles, melting at 92–93° to a clear oil.

Anal. Calcd. for $C_{11}H_{18}ON_2S$: N, 12.39. Found: N, 12.8, 12.6, 12.5.

4-Methyl-5-*n*-butyluracil. A.—This is easily prepared by digestion of the above 2-thiopyrimidine with chloroacetic acid in aqueous solution. This pyrimidine separated in the form of needles and was purified by recrystallization from hot water. It melted at 245°.

Anal. Calcd. for $C_9H_{14}O_2N_2$: N, 15.38. Found: N, 15.22, 15.10.

B.—This same pyrimidine is also formed from 2-ethylmercapto-4-methyl-5-*n*-butyl-6-oxypyrimidine by digestion with concentrated hydrobromic acid for several hours. It melted at 245°.

2 - Methylmercapto - 4 - methyl - 5 - *n* - butyl - 6 - oxypyrimidine III.—This is formed by alkylation of the 2-thiopyrimidine with methyl iodide. It was purified by crystallization from alcohol and it separated as needles, melting at 158–159° to a clear oil.

Anal. Calcd. for $C_{10}H_{16}ON_2S$: C, 56.55; H, 7.60; N, 13.20. Found: C, 56.33; H, 7.94; N, 13.0, 13.1.

Ethyl - 4 - methyl - 5 - *n* - butyl - 6 - oxypyrimidine - 2 - thioglycolate IV.—This was prepared by the action of ethyl chloroacetate on the sodium salt of the 2-thiopyrimidine. The ester was purified by crystallization from dilute alcohol, whereupon it separated in needles, melting at 110–111°.

Anal. Calcd. for $C_{13}H_{20}O_3N_2S$: N, 9.86. Found: N, 9.94, 10.00.

4 - Methyl - 5 - *n* - butyluracil - 2 - thioglycolic Acid.—Two grams of the thioglycolate was warmed with aqueous potassium hydroxide on a water-bath for half an hour. After cooling, the solution was acidified with dilute hydrochloric acid, when the thioglycolic acid separated in a crystalline condition. The yield was nearly quantitative. It was purified by recrystallizing from dilute alcohol, and melted at 117–118°.

Anal. Calcd. for $C_{11}H_{16}O_3N_2S$: C, 51.52; H, 6.29; N, 10.94. Found: C, 51.55; H, 6.63; N, 11.3, 11.5.

2 - Ethylmercapto - 4 - methyl - 5 - *n* - butyl - 6 - chloropyrimidine V.—Twenty-two and six-tenths grams of the oxypyrimidine was dissolved in 80 cc. of cold phosphorus oxychloride and the solution heated on an oil-bath at 110–120° for seven hours. The excess of phosphorus oxychloride was then removed under diminished pressure. A sirup was obtained which was treated with cold water to decompose phosphorus compounds and then extracted with ether. The ethereal solution was separated and dried, and the solvent removed, leaving behind the desired pyrimidine as an oil. It was distilled under diminished pressure and boiled at 160° at 2 mm. The yield was 19 g.

Anal. Calcd. for $C_{11}H_{17}N_2ClS$: C, 53.95; H, 7.00. Found: C, 54.11; H, 7.33.

2 - Ethylmercapto - 4 - methyl - 5 - *n* - butyl - 6 - aminopyrimidine. VI.—The corresponding 6-chloropyrimidine was heated with alcoholic ammonia under pressure for three hours at 170–180°. The solution was filtered from the insoluble ammonium chloride, and then evaporated to dryness on a water-bath, yielding the desired compound. The aminopyridine crystallized from a benzene–petroleum ether mixture and melted at 104–105°. The yield was 1.7 g. from 5 g. of the chloropyrimidine.

Anal. Calcd. for $C_{11}H_{19}N_3S$: C, 58.60; H, 8.50. Found: C, 59.06, 59.15; H, 8.87, 8.90.

4-Methyl-5-*n*-butylcytosine Hydrobromide.—The above 2 - ethylmercapto - 4 - methyl - 5 - *n* - butyl - 6 - aminopyrimidine was boiled with concentrated hydrobromic acid (48%) for sixteen hours. On evaporating this solution to dryness, cytosine hydrobromide was obtained and crystallized in prisms from hot water, melting at 222° with decomposition.

Anal. Calcd. for $C_9H_{15}ON_3{\cdot}HBr$: C, 41.21; H, 6.15. Found: C, 41.15; H, 6.06.

4-Methyl-5-*n*-butylcytosine VII.—An aqueous solution of the above cytosine hydrobromide was treated with ammonia. The free base separated and after purification by recrystallizing from very dilute alcohol (about 10%) it separated in prisms, melting at 299–300° with decomposition.

Anal. Calcd. for $C_9H_{15}ON_3{\cdot}{}^3/_4(H_2O)$: C, 55.48; H, 8.55; N, 21.59. Found: C, 55.97, 55.88; H, 8.03, 8.37; N, 21.20, 21.42.

Hydrochloride.—The cytosine was treated with a small quantity of hydrochloric acid, when the cytosine hydrochloride separated in prisms, melting at 235° to a clear oil. It was purified by recrystallizing from hot water.

Anal. Calcd. for $C_9H_{15}ON_3{\cdot}HCl$: C, 49.63; H, 7.41. Found: C, 49.41; H, 7.36.

Summary

1. Ethyl *n*-butylacetoacetate condenses with thiourea in the presence of sodium ethylate to form 2-thio-4-methyl-5-*n*-butyl-6-oxypyrimidine.

2. This 2-thiopyrimidine reacts in presence of sodium ethylate with ethyl bromide and methyl iodide to give 2-ethylmercapto-4-methyl-5-*n*-butyl-6-oxypyrimidine and 2-methylmercapto-4-methyl-5-*n*-butyl-6-oxypyrimidine, respectively.

3. Ethylmercapto - 4 - methyl - 5 - *n* - butyl - 6-oxypyrimidine when treated with phosphorus oxychloride gives the corresponding chloropyrimidine which reacts with ammonia to form 2-ethylmercapto - 4 - methyl - 5 - *n* - butyl - 6 - aminopyrimidine. This pyrimidine is converted by boiling with concentrated hydrobromic acid into 4 - methyl - 5 - *n*-butylcytosine.

Synthesis of 1-Phenyl-2-methyl-4-ethylpyrazol-5-one

BY YUOH-FONG CHI[1] AND MARGARET CHUN-HWA YANG

This short paper describes a method for synthesizing 1-phenyl-2-methyl-4-ethylpyrazol-5-one, a compound similar in constitution to the well-known antipyretic, antipyrine, and which may prove to have similar physiological action. Starting with ethyl formylbutyrate, the sodium salt of which was prepared by Johnson and Menge[2] and Chi and Tien,[3] the writers were able to synthesize this pyrazolone in a good yield by reaction of the aldo-ester with phenylhydrazine to form 1-phenyl-4-ethylpyrazol-5-one, followed by treatment of the latter with methyl iodide in methyl alcoholic solution.

Experimental Part

Ethyl Formylbutyrate.—Twenty-three grams of sodium (1 mole) in wire form was suspended in anhydrous ether, and a mixture of 127.6 g. of ethyl butyrate (1.1 mole) and 81.4 g. of ethyl formate (1.1 mole) dissolved in anhydrous ether were added slowly. For the completion of the reaction, it required about forty hours at ordinary temperature. The mixture was then shaken with ice water, to dissolve the sodium salt of ethyl formylbutyrate. The ethereal solution containing the unreacted esters assumed a red color, and was separated from the aqueous solution containing the sodium salt of the required aldo-ester. This aqueous solution, cooled in ice mixture, was acidified with the calculated amount of acetic acid, whereupon the free aldo-ester separated as a brownish-yellow oil. It was then extracted with ether, washed with sodium carbonate solution, and with water and lastly dried over sodium sulfate. After the solvent had been removed, it was fractionated under vacuum several times. The ester boiled at 37–38° at 2 mm. pressure, and the yield was 16 g.

Anal. Calcd. for $C_7H_{12}O_3$: C, 58.29; H, 8.39. Found: C, 57.90, 58.01; H, 8.35, 8.55.

Semicarbazone.—The aldo-ester and semicarbazide interacted normally in alcohol solution at ordinary temperature to give the semicarbazone. This was recrystallized from boiling water and melted at 108–108.5°.

Anal. Calcd. for $C_8H_{15}O_3N_3$: C, 47.73; H, 7.52; N 20.89. Found: C, 47.75; H, 7.63; N, 21.22, 21.08.

4-Ethylisoxazol-5-one.—Five grams of ethyl formylbutyrate was added to an aqueous solution of hydroxylamine prepared by treating 7.4 g. of hydroxylamine hydrochloride dissolved in water with 3.25 g. of aniline. After heating on a water-bath for two hours water was added and the isoxazol extracted with ether and the solution dried with sodium sulfate. The isoxazol boiled at 113–114° at 2 mm. pressure. The yield was 2.1 g.

Anal. Calcd. for $C_5H_7O_2N$: N, 12.39. Found: N, 12.1, 12.11.

1-Phenyl-4-ethylpyrazol-5-one. Method A.—One gram of the aldo-ester was treated with 0.75 g. of phenylhydrazine, and the mixture heated on a water-bath for about two hours. After cooling, the reaction mixture solidified to a crystalline mass of the required pyrazol. This crystallized from 95% alcohol or from benzene–petroleum ether in colorless prisms, melting at 99–99.5°. The yield was 70%.

Anal. Calcd. for $C_{11}H_{12}ON_2$: C, 70.17; H, 6.43; N, 14.90. Found: C, 69.76; H, 6.52; N, 15.3, 15.07.

Method B.—Ethyl formylbutyrate was treated with an aqueous solution of the required amount of phenylhydrazine hydrochloride, and then acidified with a few drops of concentrated hydrochloric acid. The mixture was shaken occasionally, and allowed to stand for about eight to nine days. The ester gradually dissolved and finally a yellowish oil appeared suspended in the solution. This was separated and the filtrate was exactly neutralized with 25% ammonia, when the pyrazolone separated. On account of its amphoteric character an excess of ammonia was avoided. It was recrystallized from benzene–petroleum ether in prisms and melted at 99.5°. The yield was poor.

Anal. Calcd. for $C_{11}H_{12}ON_2$: N, 14.90. Found: N, 14.94, 15.13.

1-*p*-Nitrophenyl-4-ethylpyrazol-5-one.—One gram of the aldo-ester interacted at water-bath temperature with *p*-nitrophenylhydrazine to form this pyrazole compound. It was purified by recrystallization from 95% alcohol, and melted at 212–214° with slight decomposition.

Anal. Calcd. for $C_{11}H_{11}O_3N_3$: N, 18.03. Found: N, 18.15, 18.33.

1-*p*-Bromophenyl-4-ethylpyrazol-5-one.—By action of the aldo-ester on *p*-bromophenylhydrazine for one and one-half hours. After purification by recrystallization from benzene–petroleum ether, it melted at 170–171°.

Anal. Calcd. for $C_{11}H_{11}ON_2Br$: Br, 29.93. Found: Br, 29.81.

1-Phenyl-2-methyl-4-ethylpyrazol-5-one.—Five-tenths gram of 1-phenyl-4-ethylpyrazol-5-one and 0.38 g. of methyl iodide were dissolved in a small quantity of methyl alcohol and heated at 100–110° in a bomb tube for about eight hours. After the completion of the reaction the solvent was removed and the residue, after decolorizing with sulfurous acid, was treated with dilute sodium hydroxide solution to dissolve unchanged pyrazolone. The fraction insoluble in alkali solution was extracted with benzene. From the benzene solution the above pyrazole separated in crystalline form. The yield was 0.2 g. It was purified by recrystallization from benzene–petroleum ether, and melted at 121–121.5°.

Summary

1. The preparation of pure ethyl formylbutyrate is described.
2. This aldo-ester reacted with phenylhydrazine, nitrophenylhydrazine and bromophenylhydrazine to give the corresponding pyrazolone compounds.
3. The aldo-ester reacted with hydroxylamine to give 4-ethylisoxazol-5-one.
4. The methylation of 1-phenyl-4-ethylpyrazol-5-one gave 1-phenyl-2-methyl-4-ethylpyrazol-5-one.

Kinetics of the Trivalent Vanadium–Iodine Reaction

By J. B. Ramsey and M. J. Heldman

In oxidations by iodine in aqueous solutions, usually containing iodide, several possible oxidizing molecular species exist: namely, iodine molecules, triiodide ions, hypoiodite ions and hypoiodous acid molecules. That iodine atoms may be involved under ordinary conditions in the dark seems improbable, although such an interpretation is warranted in the photochemical oxidation of oxalate.[1] Iodine molecules have been shown to be a reacting species in several oxidations, among them, that of phosphorous acid,[2] of trivalent titanium[3] and of ferrous iron.[4] The oxidation of arsenious acid by iodine[5] is an outstanding historical example of those reactions in which hypoiodous acid molecules are involved in the rate determining step. Triiodide ion is at least one of the reacting molecular species in the oxidations of phosphorous acid,[2] of ferrous iron,[4] and of hypophosphorous acid.[6] It seems probable that some relation may be found between the molecular species of iodine involved and the nature of the reducing species or of its transformation, after a larger number of kinetic studies has been made.

The more immediate interest in this reaction is due to its possible importance in the interpretation of the induced catalysis of the autoxidation of hydriodic acid by vanadic acid.[7] In a general qualitative survey of the reactions of vanadium in its different valence states Rutter[8] observed that the trivalent vanadium–iodine reaction proceeded at a moderate rate. The stoichiometry of the reaction may be represented by the following equation.

$$2V^{+++} + I_3^- + 2H_2O = 2VO^{++} + 3I^- + 4H^+$$

Preparation and Standardization of Stock Solutions.—All chemicals were of c. p. grade. The sodium perchlorate and sodium iodide were shown free from possible impurities by methods recommended by Murray.[9] Sodium oxalate from the Bureau of Standards was the primary standard. Known solutions of each of the following substances were obtained as indicated: potassium permanganate, with sodium oxalate; sodium thiosulfate, by the Volhard method, under conditions recommended by Bray and Miller;[10] sodium triiodide and potassium iodate, with the sodium thiosulfate; perchloric acid, with potassium iodate by the method of Kolthoff;[11] sodium iodide and sodium perchlorate, from accurately weighed quantities which had been dried carefully (the former checked by the method of Andrews[12]); ammonium vanadate, iodometrically.[13]

The stock solutions of vanadic perchlorate, $V(ClO_4)_3$, were prepared by electrolytic reduction of vanadyl perchlorate, VO_2ClO_4. The latter was formed by mixing vanadium pentoxide, from thermal decomposition of pure ammonium vanadate, with perchloric acid. The oxide dissolved as the reduction progressed. A platinized platinum cathode and a platinum anode were used. The reduction was followed analytically (by a method

to be described later) and stopped with a small quantity of vanadium still remaining in the tetravalent state. Washed carbon dioxide from a cylinder passed through the solution during the electrolysis and was kept over it during use. The resulting solutions were usually about 0.5 normal in perchloric acid.

The combined equivalent concentration of the tri- and tetravalent vanadium in this solution was obtained by adding a pipetted aliquot to an ammonium vanadate solution containing slightly more than enough vanadate to oxidize the trivalent vanadium, heating almost to boiling, and titrating with permanganate, thus oxidizing the tetravalent vanadium to the pentavalent state. That no oxygen error was involved during the oxidation of trivalent vanadium by the vanadate (which occurred instantaneously in these solutions) was shown by previously freeing the vanadate solution from air before adding the aliquot.

The concentration of the trivalent vanadium alone was found by adding a known volume of the solution to a measured quantity of known vanadate in excess, then determining the vanadate remaining by the iodometric method.[13]

Finally the concentration of the perchloric acid was found by adding a standard base in slight excess to a measured volume of the solution, filtering off the two hydroxides formed, and titrating with standard acid. The perchloric acid concentration may be calculated knowing that the trivalent and tetravalent vanadium are present as V^{+++} and VO^{++}, respectively.

These stock solutions of vanadic perchlorate were quite stable. Over a period of some three weeks the trivalent vanadium was converted to the tetravalent state to a slight extent, both by oxygen and by perchlorate. The extreme slowness of the latter oxidation was shown by tests for chloride during the period of use.

Rate Measurements.—The reaction was followed by determining the iodine present in measured aliquots (10 to 25 ml.), removed from the reacting mixture at suitable intervals. The following possible sources of error were considered: (1) loss of iodine by volatilization; (2) oxidation of trivalent vanadium by oxygen and perchlorate; and (3) oxidation of iodide by oxygen. Also the possibility of induction of one of these reactions by another or by the reaction being considered was not overlooked.

Experiments were carried out in the same manner and under the same conditions as those finally adopted in the rate measurements but with vanadium absent. With the concentrations of iodine and iodide such as to give the maximum volatility existing in any experiment, the loss of iodine was found negligible. That none of the reactions listed under (2) and (3) above occurred to a measurable extent under the conditions adopted was proven by the fact that during several of the experiments the equivalents of trivalent vanadium oxidized were determined at intervals and found at all times to be precisely equivalent to the iodine reduced.

Prior to the addition of the triiodide solution, the last reagent added, the solution of the other reagents was freed from oxygen with carbon dioxide. In those runs requiring more than two or three hours, it was found necessary to maintain an atmosphere of carbon dioxide in the reaction flask. This was accomplished by providing that carbon dioxide passed through the flask above the solution only during the removal of aliquots, since a continuous stream of carbon dioxide caused an appreciable loss of iodine. In experiments requiring less time the maintenance of an atmosphere of carbon dioxide was found unnecessary. The initial time was taken as that at which one-half of the triiodide solution had been added.

Preliminary experiments had shown that the reaction rate decreased with increasing concentration of acid. It was found that adequate quenching was provided if the 10- to 25-ml. aliquots were added to approximately 100 ml. of ice-cooled 0.5 *N* sulfuric acid. The 0.01 *N* sodium thiosulfate was freshly prepared from the stock 0.1 *N* solution. A 10-ml. buret was used for the titrations; the end-point was determinable within 0.02 ml.

Order of the Reaction.—The ionic strength of the reaction mixture was maintained substantially constant at 1.00 by means of sodium perchlorate. At the same initial total iodide and iodine concentrations, variation in the quantity of the stock vanadic perchlorate–perchloric acid solution in a given volume of the reacting mixture caused no variation in the initial rate as determined by slopes. This shows the net order with respect to trivalent vanadium and acid to be zero. Other experiments in which the initial concentration of the acid alone was varied showed definitely that the rate was inversely proportional to the acid concentration. From these preliminary results it followed that the reaction is first order with respect to trivalent vanadium. These conclusions were confirmed throughout the range of concentrations of vanadium and acid used. It is apparent from these results that the hydrolysis of both tri- and tetravalent vanadium must be negligible.

Results obtained by varying the triiodide and iodide concentrations indicated that iodine molecules might be the only oxidizing species; if this were the case, the rate equation would be

$$\frac{-\mathrm{d}[\Sigma(\mathrm{I}_2)]}{\mathrm{d}t} = k\,\frac{(\mathrm{V}^{+++})}{(\mathrm{H}^+)}\,(\mathrm{I}_2) \qquad (1)$$

in which $\Sigma(I_2)$ represents the total iodine concentration. On account of the known equilibrium between triiodide, iodine and iodide this equation may be written

$$\frac{-\mathrm{d}[\Sigma(\mathrm{I}_2)]}{\mathrm{d}t} = k'\,\frac{(\mathrm{V}^{+++})(\mathrm{I}_3^-)}{(\mathrm{H}^+)(\mathrm{I}^-)} \qquad (2)$$

The results obtained by use of equation (2) are given in Table I. In experiments 1–9 and 16–17, inclusive, the iodine and vanadic ion were the only substances involved whose concentrations changed appreciably during the experiment. Also the (I_2) was negligible relative to the (I_3^-), which in turn was negligible relative to the (I^-). In these experiments it was therefore convenient to determine k' from an integrated expression. In these cases equation (2) can be written

$$\frac{-\mathrm{d}[\Sigma(\mathrm{I}_2)]}{\mathrm{d}t} = k'\,\frac{(\mathrm{I}_3^-)}{(\mathrm{H}^+)(\mathrm{I}^-)}\,[(\mathrm{V}^{+++})_0 - 2\{(\mathrm{I}_3^-)_0 - (\mathrm{I}_3^-)\}] \qquad (3)$$

[a] Numbered chronologically.

in which the subscript 0 indicates initial concentration. Letting $c = (I_3^-) \doteqdot (I_3^-) + (I_2)$, and $b = (V^{+++})_0 - 2(I_3^-)_0$, equation (3) becomes

$$\frac{-\mathrm{d}c}{\mathrm{d}t} = \frac{k'}{(\mathrm{H}^+)(\mathrm{I}^-)} \times c(2c + b) \qquad (4)$$

which on integration gives

$$k' = \frac{2.303(\mathrm{H}^+)(\mathrm{I}^-)}{b(t - t_0)}\,\log_{10}\frac{(2c + b)(c_0)}{(2c_0 + b)(c)} \qquad (5)$$

The values of k' given for each of these experiments are averages of those determined from at least five well distributed points on the best concentration–time curve.

Since in experiments 10–15 inclusive the concentrations of the acid and/or iodide, as well as those of the vanadium and iodine, were so low that their concentrations changed appreciably during a run, the graphical slope method was employed to evaluate k' from equation (2). In each experiment slopes were obtained at not less than five well distributed points by use of both the Latshaw tangentimeter[14] and the Richards–Roope Tangent Meter.[15] Application of this method to a few of the experiments in which the "integration" method had been used, gave in each case satisfactory agreement in the values of k'. The value 0.00140 for the triiodide equilibrium constant at 25° was considered sufficiently accurate for the purpose of calculating the ratios of $(I_3^-)/(I^-)$.[16]

In none of the experiments was the average deviation of the values of k' from that given greater than 5%, and in most, less than 3%. Also there was no trend in the values of k' in any particular experiment. Several of the experiments were run in duplicate, and such pairs gave values of k' agreeing within these limits. The small variation in the values of k' over the wide range of concentrations used establishes equation (2) as the rate law.

Among the factors which may be effective in producing the small variation in the values of k' obtained are (1) the possibility of formation of vanadic–iodide complexes, and (2) the inadequacy of "ionic strength" alone as a criterion of constant ionic environment in solutions of such high concentrations of mixed electrolytes.

That the presence of tetravalent vanadium had no effect on the rate is shown by the results of experiment 5, in which the vanadyl perchlorate

was purposely made initially greater than that finally produced in any other experiment.

The Salt Effect.—Several experiments were carried out at various ionic strengths between 0.31 and 1.76, and at a constant iodide concentration of 0.108 molal. The large negative non-linear salt effect is shown in Fig. 1.

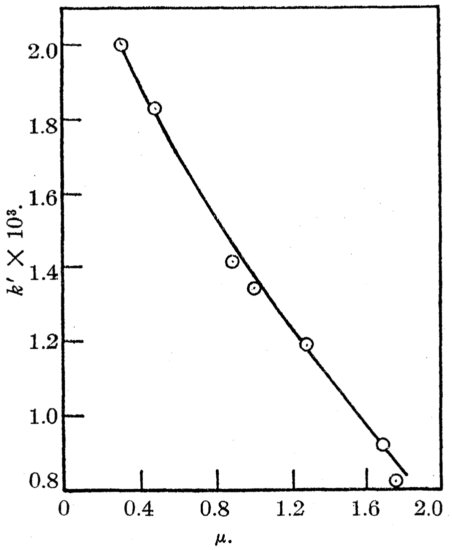

Fig. 1.—The salt effect.

Discussion.—The rate law established at constant ionic strength may be interpreted as meaning that the sole rate-determining step is a bimolecular one between iodine molecules and hydrolyzed vanadium ions, VOH^{++}. $(VOH^{++}) = K_2(V^{+++})/(H^+) = K_2$(total trivalent vanadium)$/(H^+)$, since the (VOH^{++}) is negligible compared to the (V^{+++}).

If a slow reaction between HIO and V^{+++} occurs to any measurable extent, a second term, $k''(V^{+++})(I_3^-)/(H^+)(I^-)^2$ (considering the mass-action expression for the small hydrolysis of iodine, $I_2 + H_2O = H^+ + I^- + HIO$), would have appeared in the rate equation. The constancy of k' over the eighty-fold range of iodide concentration is conclusive evidence that this reaction is not measurably involved.

Several rapid follow-up reaction mechanisms are possible. (1) The $VOH{\cdot}I_2^{++}$ critical complex[17] may break down directly to vanadyl vanadium and I_2^-, the latter immediately oxidizing trivalent vanadium or reacting with another of its own kind to form iodine and iodide ions. Diiodide ion has been previously assumed as an intermediate by Wagner.[18] (2) The complex may decompose into iodide and pentavalent vanadium, the latter immediately reacting with trivalent vanadium. (3) VOH^{++} may react rapidly with the complex to form vanadyl vanadium and iodide. This last mechanism is similar to that proposed by Yost and Zabaro[3] in their kinetic study of the entirely analogous trivalent titanium–iodine reaction.

Application of Brönsted's theory[17] to this reaction results in the expression

$$\text{rate} = k_B K_1 \frac{(I_3^-)}{(I^-)} K_2 \frac{(V^{+++})}{(H^+)} \frac{\gamma_{VOH^{++}} \cdot \gamma_{I_2}}{\gamma_{VOH \cdot I_2^{++}}} \qquad (6)$$

in which k_B is the Brönsted specific reaction rate, K_1 and K_2 are the mass action "constants" for the triiodide equilibrium and the vanadium hydrolysis, respectively, and the γ's are activity coefficients. It is evident that at constant ionic strength the above equation reduces to the experimentally found rate law.

It is possible to draw certain rather qualitative conclusions regarding K_2 if the assumption is made that the large negative salt effect found is principally due to changes in the activity coefficients of the chemical species as the ionic strength is varied, rather than to a solvent effect brought about by this variation. The ratio $\gamma_{VOH^{++}}/\gamma_{VOH \cdot I_2^{++}}$ may be assumed not to change to any great extent over the range of salt concentrations considered; both K_1 and γ_{I_2} are known to be substantially constant over the range of ionic strength of 0.0 to 2.0.[16b] According to this theory, the assumptions made, and the facts stated, it follows that this large negative salt effect is due to a rapid decrease of K_2 as the salt concentration is increased. This is equivalent to stating that the quotient, $\gamma_{V^{+++}}/\gamma_{H^+}\gamma_{VOH^{++}}$, decreases rapidly as the ionic strength increases. That this be so does not require that these ion activity coefficients individually decrease over the range of ionic strength used. In fact, from the well known variation in the activity coefficients of the uni-univalent strong acids over this range of ionic strength, it seems probable that the activity coefficient of the hydrogen ion does pass through a minimum at some ionic strength between 0.3 and 1.8.

Summary

The rate of the reaction at 24.95° between iodine and trivalent vanadium in perchloric acid solutions has been measured, and found to be, at constant ionic strength, directly proportional to

---

(17) Brönsted, *Z. physik. Chem.*, **102**, 169 (1922).

(18) Wagner, *ibid.*, **113**, 261 (1924).

the concentrations of triiodide and vanadic ions, and inversely proportional to the concentrations of the hydrogen and iodide ions. This result is in agreement with the postulation that the single rate determining step is one between hydrolyzed vanadic ions, VOH^{++}, and iodine molecules. Several possible rapid follow-up mechanisms have been suggested. The salt effect has been measured over the range of ionic strengths from 0.31 to 1.76, and a possible explanation for its large negative magnitude has been advanced.

The Mechanism of Substitution Reactions. Substitution of Bromine and Chlorine in Phenylbromo and Phenylchloroacetic Acids by Chloride and Bromide Ions in Aqueous Solution

BY M. J. YOUNG AND A. R. OLSON

When an optically active bromo compound is treated with chloride ion, a whole system of reactions is initiated. By making a kinetic study of the system of reactions which occurs when *l*-bromosuccinic acid is treated with chloride ion in aqueous solution, Olson and Long[1] were able to prove the correctness of the theory of the mechanism of substitution reactions advanced by Olson,[2] and by Bergmann, Polanyi and Szabo,[3] according to which configurational inversion accompanies every single-step substitution.

The present study deals with the kinetics of the corresponding system of reactions produced by treating *l*-phenylbromoacetic acid with chloride ion in aqueous solution. The results provide additional confirmation of the above-mentioned theory.

The relations between the heats of activation of the various reactions in the succinic system, studied by Olson and Long,[4] are again apparent in this system. The same is true of the temperature independent factors.

Preparation of Materials

Phenylbromoacetic acid and phenylchloroacetic acid were prepared from mandelic acid (phenylhydroxyacetic acid) by treatment with the corresponding phosphorus pentahalides, following the procedure given by Walden and Bischoff.[5] The acids were resolved by fractional crystallization of their morphine salts from methyl alcohol, following the procedure of McKenzie and Clough.[6] The products were shown to be chemically pure by the usual analyses. Complete resolution was not obtained in all cases but as is shown by the rate laws, optical purity is in no way essential. It is essential that the assumption that *l*-phenylchloroacetic acid and *l*-phenylbromoacetic acid have the same configuration be correct. This assumption is in accord with the opinion of those who have worked with such compounds.

Apparatus

For all measurements of optical activity a laboratory constructed polarimeter of the Lippich type was used, with monochromatic light (λ 5461) obtained from a mercury arc and suitable filters. The angle of rotation was determined from the deflection of the image of an illuminated scale, four meters distant, produced in a small plane mirror mounted nearly on the axis of the analyser, and reflected into a telescope parallel to the optic axis by means of a periscope arrangement. This device enabled rotations to be read directly to 0.007° (1 mm. of scale) and estimated to 0.001°. A given setting can be duplicated to 0.005°. A thermostat provided with glass windows was mounted directly on the polarimeter so that tubes did not have to be removed for observation.

Experimental Procedure

Due to the slowness with which the phenylhalogenoacetic acids dissolve in water, the following procedure was adopted. A weighed amount of the active acid was dissolved in 0.4 cc. of methyl alcohol. To this solution was added the required amount of 2.00 N perchloric acid (about 10 cc.) followed, after re-solution had occurred, by the required amount of 2.00 N halogen acid (about 10 cc.). The addition of so small an amount of methyl alcohol has no observable effect on the reaction rates. All solutions were prepared at the temperature of the experiment. After the solution process, the material was transferred rapidly to a 30-cm. polarimeter tube and placed in the thermostat. Zero time was taken as the moment of addition of halide ion. The time interval between this addition and the first reading was never more than four minutes. In all experiments the concentrations are: active acid 0.015 M, halide ion 1.00 M, hydrogen ion 2.00 M, unless otherwise specified.

The Formation of Mandelic Acid from Phenylhalogenoacetic Acids.—The detailed mechanism

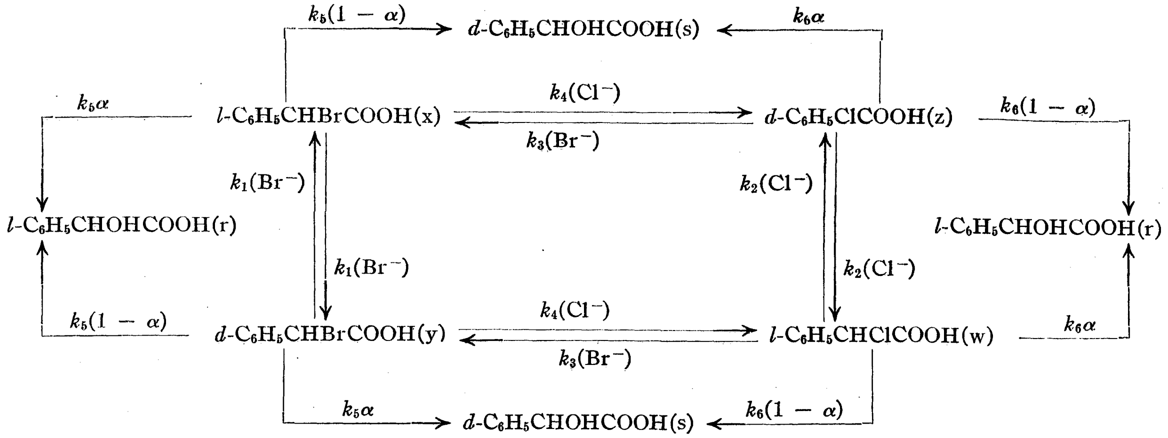

Fig. 1.—System of reactions occurring when *l*-phenylbromoacetic acid is treated with chloride ion in aqueous solution, assuming complete inversion accompanies each single-step substitution.

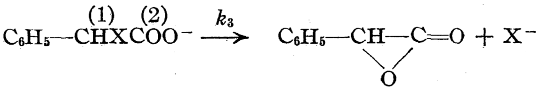
of the reactions between phenylbromoacetic acid or phenylchloroacetic acid and water, by which mandelic acid, hydrogen ion and halide ion are produced, is not completely understood in spite of the amount of investigation to which it has been subjected.[7,8,9] The specific rate, measured by the rate of formation of hydrogen ion, is in accord with the assumption that the undissociated acid reacts more slowly than its ion. Measurement of the decrease of optical activity with time makes it necessary to suppose that the ion can react with water in either of two different ways, one reaction producing a *d*-mandelic acid, and the other an *l*-mandelic acid. The following mechanism can account for this effect and is at the same time in accord with the theory that inversion in configuration accompanies each single-step substitution.

$$\text{(1)}\quad C_6H_5\text{—}\overset{(1)}{CHX}\text{—}\overset{(2)}{COOH} + H_2O \xrightarrow{k_1} C_6H_5CHOHCOOH + H^+ + X^- \ \text{(inversion at C(1))}$$

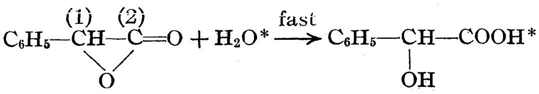
$$\text{(2)}\quad C_6H_5\text{—}\overset{(1)}{CHX}\text{—}\overset{(2)}{COO^-} + H_2O \xrightarrow{k_2} C_6H_5CHOHCOOH + X^- \ \text{(inversion at C(1))}$$

(3)



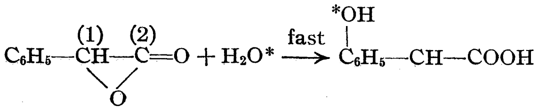
(inversion at C(1))

(4)



(inversion at C(2))

(5)



(inversion at C(1))

Reactions (1), (2) and the sequence (3), (4) lead to a mandelic acid of configuration opposite to that of the $C_6H_5CHXCOOH$. The sequence (3), (5), involving a double inversion at C(1), leads to a mandelic acid of the same configuration as that of the $C_6H_5CHXCOOH$. The relative amounts of levo and dextro mandelic acids depend on the relation between the specific rates of the various reactions under the conditions of the experiment.

Although we failed to isolate the postulated lactone, a similar compound is known to be formed in the hydrolysis of bromosuccinic acid.

When the hydrogen-ion concentration is large, this mechanism predicts that *l*-$C_6H_5CHXCOOH$ will disappear at a specific rate $k_1 + \{(k_2 + k_3) k_a/(H^+)\}$, where k_a is the dissociation constant of $C_6H_5CHXCOOH$, and that *d* and *l* mandelic acids will appear at specific rates $k_1 + \{(k_2 + k_3\beta)k_a/(H^+)\}$ and $k_3(1 - \beta)k_a/(H^+)$, respectively, where β is the fraction of the lactone hydrolyzing by reaction (4) and $(1 - \beta)$ the fraction hydrolyzing by reaction (5). If the specific rate of disappearance of *l*-$C_6H_5CHXCOOH$ is represented by K, the specific rates of production of *l* and *d* mandelic acid can be represented by $K(\alpha)$, and $K(1-\alpha)$, respectively, where $\alpha = 1-\{k_3\beta k_a/[k_1(H^+) + k_2k_a + k_3k_a]\}$.

Rate Laws

Following the system of reactions and the notation shown in Fig. 1, we can write the differen-

(4) $dz/dt = -k_2(\mathrm{Cl}^-)z + k_2(\mathrm{Cl}^-)w - k_3(\mathrm{Br}^-)z + k_4(\mathrm{Cl}^-)x - k_6z$

(5) $dr/dt = k_5\alpha x + k_5(1-\alpha)y + k_6\alpha w + k_6(1-\alpha)z$

(6) $ds/dt = k_5\alpha y + k_5(1-\alpha)x + k_6\alpha z + k_6(1-\alpha)w$

(7) $d(\mathrm{Br}^-)/dt = k_4(\mathrm{Cl}^-)(x+y) - k_3(\mathrm{Br}^-)(w+z) + k_5(x+y)$

(8) $d(\mathrm{Cl}^-)/dt = -k_4(\mathrm{Cl}^-)(x+y) + k_3(\mathrm{Br}^-)(w+z) + k_6(w+z)$

For the determination of the angle of rotation only the quantities $(x - y)$, $(w - z)$ and $(r - s)$ need be calculated, for $\theta = C_1(x - y) + C_2(w - z) + C_3(r - s)$. For the evaluation of the six specific rates, a series of experiments was devised each involving only one unknown specific rate. This series, and the corresponding integrated rate laws, are shown in Table I.

TABLE I

(1) Initial conditions: $(x - y) = (x - y)_0$, $(w - z) = 0$, $(r - s) = 0$, $(\mathrm{Cl}^-) = 0$, $(\mathrm{Br}^-) = 1\ M$, $(\mathrm{H}^+) = 2\ M$

Additional assumption: $k_1 >> k_5$ so that k_5 can be neglected. (Br^-) = constant

Rate law: $\Theta/\Theta_0 = e^{-2k_1(\mathrm{Br}^-)t}$

(2) Initial conditions: $(x - y) = 0$, $(w - z) = (w - z)_0$, $(r - s) = 0$, $(\mathrm{Cl}^-) = 0$, $(\mathrm{Br}^-) = 0$, $(\mathrm{H}^+) = 2\ M$

Additional assumption: Since (Cl^-) remains small, $k_2(\mathrm{Cl}^-)$ can be neglected compared to k_6

Rate law: $(\Theta - \Theta_\infty)/(\Theta_0 - \Theta_\infty) = e^{-k_6t}$, $\Theta_\infty = C_3(w - z)_0(2\alpha - 1)$

(3) Initial conditions: $(x - y) = 0$, $(w - z) = (w - z)_0$, $(r - s) = 0$, $(\mathrm{Cl}^-) = 1\ M$, $(\mathrm{Br}^-) = 0$, $(\mathrm{H}^+) = 2\ M$

Additional assumption: (Cl^-) = constant

Rate law: $(\Theta - \Theta_\infty)/(\Theta_0 - \Theta_\infty) = e^{-[2k_2(\mathrm{Cl}^-)+k_6]t}$, $\Theta_\infty = C_3(w - z)_0k_6(2\alpha - 1)/\{2k_2(\mathrm{Cl}^-) + k_6\}$

(4) Initial conditions: $A = (x - y) = (x - y)_0$, $(w - z) = 0$, $(r - s) = 0$, $(\mathrm{Cl}^-) = 0$, $(\mathrm{Br}^-) = 0$, $(\mathrm{H}^+) = 2\ M$

Additional assumptions: none

Rate law: $(\Theta - \Theta_\infty)/(\Theta_0 - \Theta_\infty) = e^{-(2k_1A+k_5)t+\{2k_1A(1-e^{-k_5t})/k_5\}}$ $\Theta_\infty = C_3(x - y)_0(2\alpha - 1)k_5/(2k_1A + k_5)$

(5) Initial conditions: $(x - y) = 0$, $(w - z) = (w - z)_0$, $(r - s) = 0$, $(\mathrm{Cl}^-) = 0$, $(\mathrm{Br}^-) = 1\ M$, $(\mathrm{H}^+) = 2\ M$

Additional assumptions: (1) $k_1 >> k_3$ so that ϕCHBr-COOH is racemized as fast as it is formed; *i. e.*, $(x - y) = 0$; k_5 makes no contribution to $(r - s)$.
(2) (Cl^-) is so small that $k_2(\mathrm{Cl}^-)$ and $k_4(\mathrm{Cl}^-)$ are negligible.
(3) (Br^-) = constant

Rate law: $(\Theta - \Theta_\infty)/(\Theta_0 - \Theta_\infty) = e^{-[k_3(\mathrm{Br}^-)+k_6]t}$, $\Theta_\infty = k_6(w - z)_0C_3(2\alpha - 1)/(k_3(\mathrm{Br}^-) + k_6)$

(6) Initial conditions: $(x - y) = (x - y)_0 = A$, $(w - z) = 0$, $(r - s) = 0$, $(\mathrm{Cl}^-) = 1\ M$, $(\mathrm{Br}^-) = 0$, $(\mathrm{H}^+) = 2\ M$

Additional assumptions: (1) $k_3(\mathrm{Br}^-)$ can be neglected,
(2) $k_6 << k_5$,
(3) (Cl^-) = constant,
(4) $\Theta_\infty = 0$ (experimentally true)

Rate law: $\theta/\theta_0 = (1 + R)e^{-Q(t)} - Re^{-[2k_2(\mathrm{Cl}^-)+k_6]t}$
$R = [C_2/C_1]k_4(\mathrm{Cl}^-)/[2k_1A + k_4(\mathrm{Cl}^-) + k_5 - 2k_2(\mathrm{Cl}^-) - k_6]$
$Q(t) = [2k_1A + k_4(\mathrm{Cl}^-) + k_5]t - 2k_1A[(1 - e^{-[k_4(\mathrm{Cl}^-)+k_5]t})/(k_4(\mathrm{Cl}^-) + k_5)]$.

The rate laws for experiment series (1), (2), (3) and (5) follow in a perfectly straightforward manner from the differential equations; those for experiment series (4) and (6) involve an integral of the form

$$I = \int_0^t e^{-(a+b)t+[a(1-e^{-bt})/b]}dt$$

We have been unable to evaluate this integral exactly in terms of elementary functions. Olson and Long handled it by means of a series expansion and term by term integration. We have found the following procedure more convenient in this case. Integration by parts gives

$$I = \left\{ (1 - e^{-(a+b)t+[a(1-e^{-bt})/b]} \right\} \Big/ (a+b) + \left\{ a\int_0^t e^{-(a+2b)t+[a(1-e^{-bt})/b]}\,dt \right\} \Big/ (a+b)$$

The second integral can be neglected for two reasons. The integrand is smaller by a factor e^{bt}, and the coefficient a is small compared to 1, in the time units employed. The error introduced by this neglect is never more than 0.3%.

The constants appearing in expressions (1), (2), (3) and (5) can be evaluated by calculating one value from each observation and averaging the results in the usual manner, or by obtaining a value of the slope of the line

$$\ln (\Theta - \Theta_\infty)/(\Theta_0 - \Theta_\infty) = -kt$$

using the method of least squares. The expressions (4) and (6) cannot be solved explicitly for the unknown specific rates k_5 and k_4, respectively. In these cases a value of the specific rate was determined by a trial and error process to fit one observation; the remaining observations were plotted on a curve calculated using this constant, and agreement was found satisfactory in all cases. The results obtained are given in Tables II–VIII. The values of k(calcd.) are those obtained from the activation energies and temperature independent factors shown in Table VIII. All times are in minutes unless otherwise specified.

l-$C_6H_5CHClCOOH + Br^-$	20,016 ± 87	1.90
l-$C_6H_5CHBrCOOH + Cl^-$	19,805 ± 100	6.93

No values of E and A for the hydrolysis reactions (Tables III and VI) were calculated for they would be of doubtful significance since the specific rates are complex averages over several reactions. The listed probable errors are mean deviations from the average of the values of E calculated for each temperature interval.

It can be shown that the introduction of the assumption of incomplete inversion in configuration, giving rise to the system of reactions appearing in Fig. 2, where the Greek letters represent in each case the fraction of the reaction occurring without inversion, results in an alteration of the rate laws which is not detectable except in the case of expression 6. In this case the new rate law is

$$\Theta/\Theta_0 = (1 + R)e^{-Q(t)} - Re^{-[2k_2(\text{Cl}^-)+k_6]t}$$

$$\text{where } R = C_2k_4(\text{Cl}^-)(1 - 2\epsilon)/C_1[2k_1A + k_4(\text{Cl}^-)(1 - 2\epsilon) + k_5 - 2k_2(\text{Cl}^-) - k_6]$$

$$Q(t) = [2k_1A + k_4(\text{Cl}^-)(1 - 2\epsilon) + k_5]t - \{2k_1A(1 - e^{-[k_4(\text{Cl}^-)+k_5]t})/[k_4(\text{Cl}^-) + k_5]\}$$

The effect which this modification has on the calculated value of θ for various times and for various values of ϵ is shown in Table IX for the

TABLE IX

Time min.	Θ cm. $\epsilon = 0$	ΔΘ $\epsilon = 0.03$	ΔΘ $\epsilon = 0.05$	ΔΘ $\epsilon = 0.07$

200	9.72	− .01	− .01	− .01

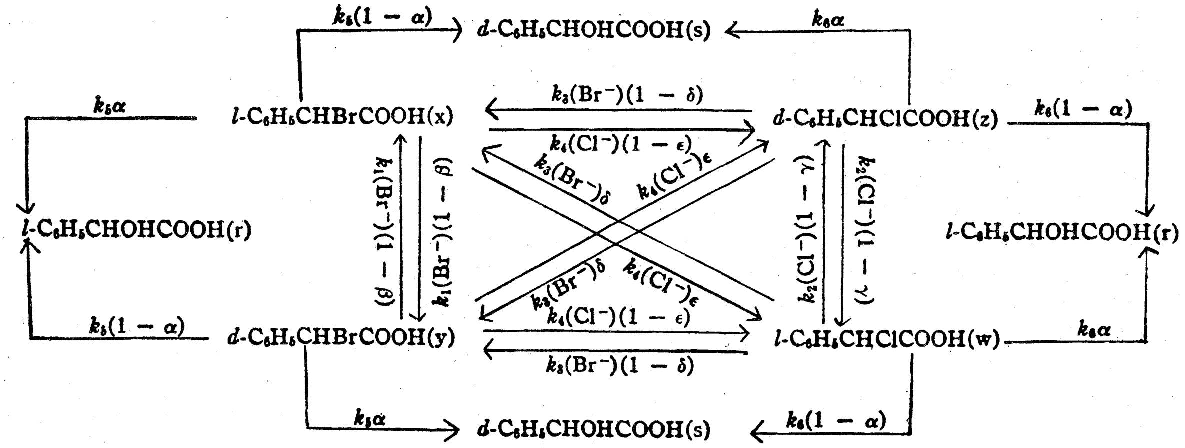

Fig. 2.—System of reactions occurring when *l*-phenylbromoacetic acid is treated with chloride ion in aqueous solution, assuming some substitution without inversion can occur.

experiments at 322.54°K. The curve calculated for $\epsilon = 0$ on which the experimental points have been superimposed is shown in Fig. 3. ($\Delta\theta$ is taken positive when the value for $\epsilon = 0$ is larger in absolute magnitude than that for $\epsilon \neq 0$.)

Since the average deviation of the experimental points from the calculated curve is 0.06 cm. with no trend, one can conclude that inversion is complete within the limits of detectability (5%). The rather large limits on ϵ are a result of the small value of A, the initial concentration of bromo acid, made necessary by its slow solubility. $\Delta\theta$ is directly proportional to A.

Discussion of Results

The results obtained are compared with those of Olson and Long[4] in Table X.

TABLE X

Reaction	Activation energy cal./mole Phenyl-acetic system	Succinic system	Δ	Collision number × 10^{-9} sec.$^{-1}$ moles^{-1} liters Phenyl-acetic system	Succinic system	Ratio
1 BrA + Br⁻	17,971	21,800	3829	3.13	14.9	4.76
2 ClA + Cl⁻	21,683	24,770	3087	4.74	8.42	1.78
3 ClA + Br⁻	20,016	23,540	3524	1.90	6.24	3.28
4 BrA + Cl⁻	19,805	23,650	3845	6.93	39.5	5.71

(1) The difference between the activation energies of the two series is nearly the same for all reactions, although it is somewhat larger for the bromo acids than for the chloro acids. This 3600 calories is a composite of the alterations in bond strength and resistance to inversion brought about by substituting $-CH_2COOH$ for C_6H_5 in the reacting molecule. Nothing quantitative can be said about the relative contributions of the two factors.

(2) The fact that the activation energy of the exchange reactions (the same for both within experimental error) is closer to that of ClA + Cl⁻ than to that of BrA + Br⁻ may mean that the unstable intermediate $(BrACl)^-$, where A is the rest of the molecule resembles $(ClACl)^-$ more closely than $(BrABr)^-$.

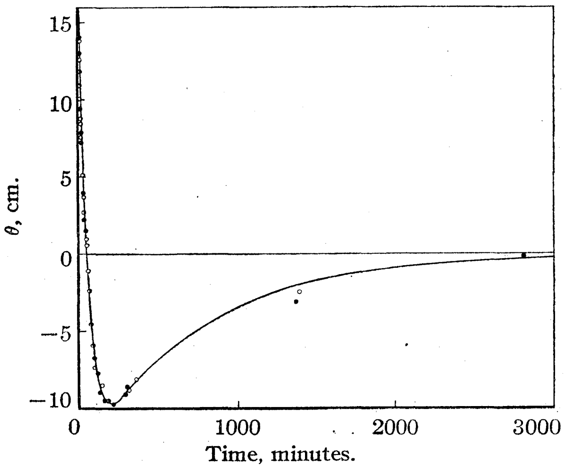

Fig. 3.—Angle of rotation plotted against time for the reaction between *l*-phenylbromoacetic acid and chloride ion in aqueous solution at 322.54°K.

(3) The collision numbers of reactions involving Cl⁻ are larger than those involving Br⁻, while those involving bromo acids are larger than those involving chloro acids, and the collision number of the exchange reaction BrA + Cl⁻ is larger than that of ClA + Br⁻ in the ratio one would expect from the two tendencies in combination.

A calculation of the total number of collisions for comparison with the observed collision number is somewhat arbitrary because of the uncertainty in collision diameter. The arbitrary selection of a value 1.75 times the length of the bond to be formed, leads to a steric factor of from $^1/_{40}$ to $^1/_{10}$. The face centered addition of X^- at C_6H_5CHY-COOH leads to an orientation factor of less than $^1/_2$ for $C_6H_5CHYCOOH$; solvation of X^- may introduce an additional orientation factor. Furthermore, one must take into account the efficiency of transfer between translational and vibrational energy which Rice[10] has found to vary widely from case to case. The most that one can say is, that there is nothing in the collision numbers to invalidate the given picture of the reaction.

The correlation between the kinetic and thermodynamic interpretations of a chemical equilibrium leads to a relation between the ratio of the collision numbers of the forward and reverse reaction and the standard entropy change. For reactions (3) and (4) this relation is

$$R \ln (A_4/A_3) = S^0(\mathrm{Br}^-) + S^0(\mathrm{Cl}A) - S^0(\mathrm{Cl}^-) - S^0(\mathrm{Br}A)$$

where S^0 is the molal entropy of the given substance when its concentration is 1 M in an ideal aqueous solution, based on $S^0(\mathrm{H}^+) = 0$ for comparison. Latimer, Schutz and Hicks[11] give 5.9 e. u. as the difference between $S^0(\mathrm{Br}^-)$ and $S^0(\mathrm{Cl}^-)$. Using this value, and the experimental values of A_4 and A_3 we calculate that the difference in entropy between solutions of l-BrA and l-ClA is 2.7 ± 1 e. u., a not unreasonable result.

Rice and Gershinowitz[12] have made use of the relation between entropy and collision number to develop a method for calculating the collision numbers of bimolecular associations. The reactions studied can be looked upon as being of this type followed by the almost instantaneous decomposition of the associated pentavalent carbon "complex." We have applied this method in calculating the collision numbers of the four reactions, omitting consideration of vibrational entropy, and calculating moments of inertia from rough geometrical models of the reactants. The results are shown in Table XI.

TABLE XI

	Reaction	$A \times 10^{-9}$ calcd.	$A \times 10^{-9}$ obsd.
(1)	l-$C_6H_5CHBrCOOH + Br^-$	3.22	3.13
(2)	l-$C_6H_5CHClCOOH + Cl^-$	6.43	4.74
(3)	l-$C_6H_5CHClCOOH + Br^-$	3.54	1.90
(4)	l-$C_6H_5CHBrCOOH + Cl^-$	6.33	6.93

Considering the nature of the calculation the agreement is striking. All of the features of the general reaction picture (inversion, face centered addition) have been included in the calculation and no additional ones.

Summary

The specific rates in aqueous solution of the following four reactions, at several temperatures in the interval 15–50°, have been determined.

(1) l-$C_6H_5CHBrCOOH + Br^- = d$-$C_6H_5CHBrCOOH + Br^-$

(2) l-$C_6H_5CHClCOOH + Cl^- = d$-$C_6H_5CHClCOOH + Cl^-$

(3) l-$C_6H_5CHClCOOH + Br^- \longrightarrow d$-$C_6H_5CHBrCOOH + Cl^-$

(4) l-$C_6H_5CHBrCOOH + Cl^- \longrightarrow d$-$C_6H_5CHClCOOH + Br^-$

It was shown that reaction 4, which alone provides information on this point, is accompanied by complete inversion in configuration, in accord with the theory.

The activation energies of the four reactions bear relations to each other similar to those in the corresponding reactions of the halogenosuccinic acids.

The collision numbers of the four reactions, considered from a kinetic viewpoint, are not in disagreement with what might have been predicted from the theory. They are in close agreement with values calculated by a statistical mechanical method embodying the essential features of the theory.

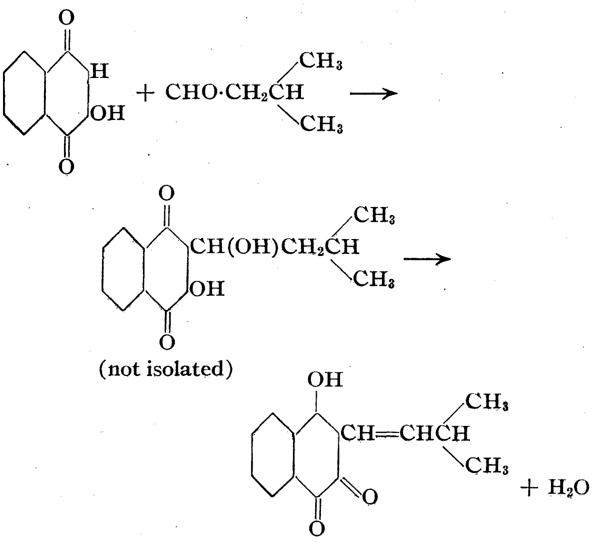
Condensation of Aldehydes with β-Hydroxy-α-naphthoquinone. Synthesis of Hydrolapachol[1,2]

BY SAMUEL C. HOOKER

In the course of my researches on the constitution of lapachol and in hope of synthesizing this substance I studied in 1896 the interaction of isovaleraldehyde and 2-hydroxy-1,4-naphthoquinone,[3] and was thus led to a compound isomeric with lapachol which I was able to convert into several substances which I had previously obtained from lapachol itself, and which contained the full complement of carbon atoms. With these facts in mind the condensation was interpreted as follows:



(not isolated)

Iso-β-lapachol

It was originally thought that this condensation compound owing to its *red* color must be considered a derivative of β-naphthoquinone and it was referred to as iso-β-lapachol in consequence. Fieser,[4] who has examined many of the compounds obtained in my laboratory, has shown however that the reduction potential of iso-β-lapachol agrees very closely with that of derivatives of 2-hydroxy-1,4-naphthoquinone having

---

(1) This is the first of a group of eleven papers reporting the results of investigations carried out by the late Dr. Samuel Cox Hooker (1864–1935) in continuation of his studies of lapachol, lomatiol, and related compounds as described for the most part in papers published in 1889–1896 in the *Journal of the Chemical Society*. The early investigations were resumed shortly after Dr. Hooker's retirement from the board of directors of the American Sugar Refining Company in 1915 and the work was continued to the time of his death on October 12, 1935 (see obituary sketch by Dr. C. A. Browne, *J. Chem. Soc.*, 550 (1936)). The papers have been assembled and prepared for purification by Dr. L. F. Fieser, of Harvard University, in whose care Dr. Hooker left the samples from all of his investigations. Dr. Fieser states that the collection includes a large supply of lapachol and a moderate amount of lomatiol, and that it was Dr. Hooker's intention that these be made available to other interested investigators.—THE EDITOR.

(2) Dr. Hooker had no intention of withholding the results accumulating in the course of twenty years of research, but he was reluctant to publish work on any one of the closely related problems until quite satisfied that all phases of the different investigations had been adequately explored. With one or two minor exceptions, this point had been reached at the time of his death and he had already prepared the manuscript for the theoretical part of several of the papers. Frequent periods of ill health and eventually death prevented him from completing the writing, but fortunately his observations had been recorded with such fluent expression and his records kept with such meticulous care that the experiments can be reported with complete accuracy, if not always in Dr. Hooker's own clear style.

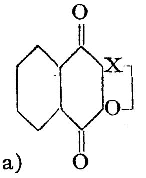
The theoretical part of the present paper, with the exception of the last paragraph, is taken from an original draft written by Dr. Hooker in 1934 and the second section of the experimental part, excepting the last paragraph, is likewise compiled almost entirely from original summaries. Dr. Hooker was assisted in the experiments by Dr. G. H. Connitt (1926–1927), Dr. C. A. Lear (1932–1933), and Dr. A. Steyermark (1934–1935). Four of the analyses were carried out by Dr. Connitt and the remainder were done by Dr. D. Price of Columbia University. Dr. Steyermark has been very helpful in collecting the notes.

Certain statements in these papers cannot be properly appreciated without some explanation of the special and perhaps unique methods of identification and characterization which Dr. Hooker developed and on which he placed great reliance. Most of these involved the microscopic examination of crystals obtained in different ways, using merely a simple, low-powered instrument. In his "fusion test" a few granules of material are spread on a cover glass and barely fused over a small flame, giving characteristic crystalline patterns. An acidic substance is dissolved in 1% sodium hydroxide or other alkali and a drop of the solution allowed to evaporate on a slide and deposit crystals of the salt, or acidified under microscopic observation. A drop of a solution of the substance in concentrated sulfuric acid on being exposed on a slide absorbs moisture and deposits characteristic crystals, at first at the edges and then in the body of the solution. In Dr. Hooker's skilled hands these tests provided a means of making a positive identification which he felt was at least as reliable as a mixed melting point determination. Such microscopic examination proved to be of invaluable service in working with substances which when heated decompose rather than melt. The tests were also employed to advantage in following the progress of a reaction and in working out methods of purification and separation. In purifying small amounts of material, Dr. Hooker made much use of the "dry crystallization method." A dilute solution of the substance is allowed to go to dryness in an Erlenmeyer flask set in an inclined position with the liquid covering less than half of the bottom. Often the impurities are deposited in an outer ring while uncontaminated crystals of the substance appear at the lowest part of the vessel and can be detached and caught on the clean part of the flask after this has been rotated to the proper position. Very sensitive substances frequently can be crystallized satisfactorily by this method, the solution being prepared at room temperature. The homogeneity of a colored, acidic substance was tested to advantage by dusting a small amount of the powdered material onto the surface of 1% sodium hydroxide, when the presence of more than one compound often could be detected by a differential coloration of the solution. Dr. Hooker took full advantage of the beautiful color phenomena peculiar to the group of compounds under investigation, but many of his methods of experimentation can be applied quite generally. Of considerable importance in paving the way to discoveries was his habit of looking for any changes which might occur in solutions of his compounds or even in the solid state, often over long periods of time, and his practice of conducting reactions under the mildest conditions sufficient to effect a change.—L. F. FIESER.

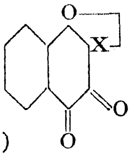
(3) Hooker, *J. Chem. Soc.*, **69**, 1356 (1896).

(4) Fieser, THIS JOURNAL, **50**, 439 (1928).

similarly located side chains, and further that it agrees almost exactly with the values of lapachol and hydrolapachol, both of which are *yellow*. The reduction potential of iso-β-lapachol also agrees far better with the values determined for compounds of the general formula (a) derived from lapachol than it does with those obtained for substances of the general formula (b), having the ortho quinone group.



(a) Yellow

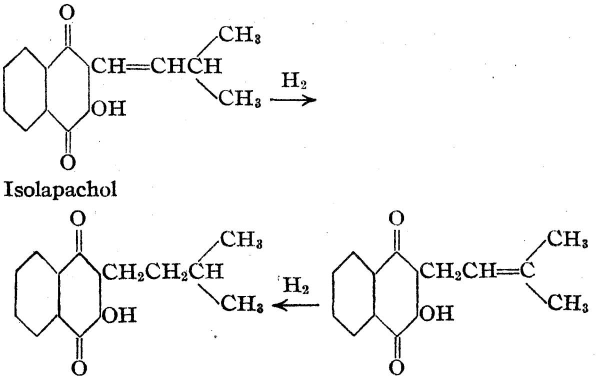


(b) Red

It would seem necessary therefore to accept for iso-β-lapachol the paraquinone structure as suggested by Fieser and the compound will in future be referred to as isolapachol. The *red* color of isolapachol, however, is not without significance and I shall return to its consideration later in another paper.

The study of the above condensation has been extended to a number of other aldehydes as the resulting compounds were required for an investigation on the oxidation of derivatives of 2-hydroxy-1,4-naphthoquinone. In most cases fairly uniform results have been obtained and the reaction has thus proved to be a general one.

Hydrocinnamaldehyde, phenylacetaldehyde, oenanthol, *n*-valeraldehyde, *n*-butyraldehyde, and propionaldehyde have all yielded compounds corresponding to isolapachol, which like it are much deeper in color than the previously known derivatives of 2-hydroxy-1,4-naphthoquinone. They vary from a deep orange or orange-red to a deep red in color, and all give intensely violet solutions with 1% alkali from which the sodium salts can be readily obtained in crystalline form. Hydrogen addition is easily effected by Roger Adams' method with platinum oxide–platinum black, the resulting substances affording ample proof of the structure assigned to the condensation products, as the latter are thus converted into compounds identical with the hydrogenation products of similar substances of known structure differing only from the condensation products in having the double bond in the chain located other than in the α,β-position. Thus isolapachol and lapachol yield the same compound, namely, hydrolapachol. Incidentally it may be noted that this step completes the synthesis of hydrolapachol.

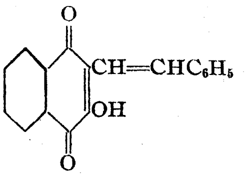


The other 2-hydroxy-1,4-naphthoquinone derivatives examined which have yielded identical compounds on hydrogenation are shown side by side in the following columns, the chains only being given.

$—CH{=}CHCH_2CH_3$	$—CH_2CH{=}CHCH_3$
$—CH{=}CHCH_3$	$—CH_2CH{=}CH_2$
$—CH{=}CHCH_2C_6H_5$	$—CH_2CH{=}CHC_6H_5$

The first column contains the chains of the aldehyde condensation compounds; the second those of compounds obtained by Fieser[5] in part by the Claisen rearrangement and in part by direct carbon alkylation. The identity of the hydrogenation products of the two sets of compounds leaves no doubt, therefore, as to the correctness of the interpretation of the aldehyde condensation. I am greatly indebted to Dr. Fieser for the substances represented in the second column which were hydrogenated in my laboratory.

In the earlier work[3] attention was called to the striking difference in color between the orange-red isolapachol and its yellow acetyl derivative. It was suggested at the time that acetylation may be attended with a change from a β- to an α-quinone group, but it is now recognized that both compounds very probably are α-quinones and that the difference in color is attributable to the effect of masking the free hydroxyl group. In order to extend the observations two additional acetyl derivatives were prepared. The first of these, 2-α-butenyl-3-acetoxy-1,4-naphthoquinone,



---

[5] Fieser, THIS JOURNAL, **48**, 3201 (1926); **49**, 857 (1927).

is similarly yellow, in comparison with the red hydroxy compound from which it is derived. 2-β-Phenylvinyl-3-hydroxy-1,4-naphthoquinone is deeper in color (deep red) than the condensation products having completely aliphatic side chains (orange-red) or the chain $-CH{=}CHCH_2C_6H_5$ (orange), an effect doubtless attributable to the conjugation of the phenyl group with the chromophoric system. Acetylation in this case also was found to lighten the color, and the interesting observation was made that the acetyl derivative is capable of existing in two distinct modifications. The two forms are orange-yellow and bright red and they separate from the same solvents under similar conditions. The latter substance changes to the former on heating, and only one melting point is observed.

Experimental Part

1. Condensation of Aldehydes with 2-Hydroxy-1,4-naphthoquinone

Following a number of trials, 2-α-butenyl-3-hydroxy-1,4-naphthoquinone was most satisfactorily obtained by the following procedure, which served with minor changes for the other condensations investigated. Two grams of 2-hydroxy-1,4-naphthoquinone was dissolved in 35 cc. of hot glacial acetic acid, the temperature was brought to 80° and concentrated hydrochloric acid (2 cc.) was added, followed at once by *n*-butyraldehyde (5 cc.). The mixture was digested at 75–80° for one and one-half hours and poured into 200–300 cc. of water. After allowing several hours for the dark, resinous, partly crystalline material to collect, the aqueous solution was decanted through a filter, the oily residue was dissolved in 100 cc. of ether (or in benzene or ether–benzene) and the solution was extracted with 200 cc. of aqueous 1% sodium hydroxide solution. On acidifying the intensely violet alkaline extract a deep orange oil precipitated and gradually became crystalline. After washing and drying, the crude material (1.5 g.) was extracted with petroleum ether (b. p. 35–55°) in the Soxhlet apparatus. This left a brown, earthy residue and gave 1.1 g. of purified material as orange-red plates. The sample for analysis was recrystallized from alcohol.

In the condensation of hydroxynaphthoquinone with other aldehydes some variations in the proportions of the reagents and in the time of heating were found advisable, as indicated in Table I. The reaction can be followed readily by removing from the mixture during digestion a fraction of a drop, evaporating this to dryness, dissolving the residue in a drop of alcohol, and adding a drop of 1% alkali. As the condensation progresses the test solution becomes increasingly violet, and when the color ceases to increase in intensity the reaction may be assumed to be reasonably complete. The digestion is then stopped. The time varies with the different aldehydes from about fifteen minutes to one and one-half hours, and can be shortened and the yield slightly increased by using larger quantities of the aldehyde. As a general rule about five molecules of the aldehyde to one of the hydroxynaphthoquinone give satisfactory results.

Attempts to prepare condensation products under similar conditions from acetaldehyde and from isobutyraldehyde were unsuccessful. In the case of the latter aldehyde the reaction mixture was heated for a total of five hours, but

[a] By concentrating the benzene solution after extraction with alkali, brown, sword-shaped crystals of a by-product (0.2 g.) were obtained. Recrystallized from alcohol, the substance formed light yellow, arrowhead-shaped crystals, m. p. 160–160.5°. (Found: C, 84.87; H, 5.24; mol. wt., 241.4.)

[b] Best crystallized from petroleum ether; the material decomposes badly when crystallized in large lots from alcohol.

[c] The substance undergoes far-reaching changes when the crude material is crystallized from alcohol or benzene. Acetic acid gave better results but the recovery was less than 50%.

color tests made throughout this period failed to give any indication of the formation of a compound of the desired type. With acetaldehyde it appeared that a condensation product if formed is rapidly destroyed in the acid mixture.

The condensation products having aliphatic side chains are very soluble in benzene or acetone and somewhat less soluble in alcohol. A phenyl group decreases the solubility. Characteristic of all of the compounds is the intense violet color of their sodium salts, and distinctive patterns often can be observed by allowing a drop of the alkaline solution to evaporate under the microscope. Some decomposition usually occurs at the melting point.

The crystallization of the crude condensation products presents some difficulties for the quinones are subject to decomposition in solution, particularly in the presence of impurities. The crude materials may suffer extensive destruction when crystallized directly from alcohol or benzene, and it is best first to extract the products with petroleum ether. The purified substances then can be crystallized successfully from alcohol or benzene if care is taken to avoid undue heating or prolonged exposure of the solutions to the air. Even the most highly purified samples in time undergo far-reaching changes in contact with these solvents, and in a preliminary study of these changes carried out in conjunction with Dr. Steyermark it was found possible in some cases to isolate crystalline transformation products. Thus a solution of 1 g. of 2-γ-phenyl-α-propenyl-3-hydroxy-1,4-naphthoquinone in 45 cc. of benzene after standing with free access to the air for about four days deposited 0.04 g. of yellow needles which after recrystallization from benzene (sparingly soluble) melted at 227–228°, dec. The analyses are suggestive of a formula having one atom of oxygen more than the starting material (calcd. for $C_{19}H_{14}O_4$: C, 74.51; H, 4.57. Found: C, 73.95, 74.10; H, 4.61, 4.51) and it is perhaps safe to conclude that in this case an oxidation is involved. The substance is neutral, but it dissolves in boiling alkali and the yellow material is precipitated unchanged on acidifying the red, alkaline solution.

Yellow, neutral decomposition products were obtained from some of the unsaturated quinones in alcoholic solution but the substances have not been characterized. The propenyl compound, refluxed in alcoholic solution for about ten hours in the course of three days, gave in 10% yield a substance forming yellow prisms from benzene, m. p. 197–198°, dec., insoluble in cold alkali (found: C, 73.16, 73.20; H, 4.69, 4.81; mol. wt., 364). A solution of the butenyl compound in alcohol on standing for four months at room temperature deposited in 11% yield a yellow substance which formed yellow plates from dilute acetic acid, m. p. 207–208°, dec. (found: C, 70.63; H, 5.05). Like the other substances it is insoluble in cold alkali and dissolves on boiling to give a crimson solution.

2-α-Butenyl-3-acetoxy-1,4-naphthoquinone.—A mixture of 1 g. of 2-α-butenyl-3-hydroxy-1,4-naphthoquinone, 2 g. of fused sodium acetate and 20 cc. of acetic anhydride was boiled for three minutes, when the initially red solution had become brownish-yellow in color. The mixture was poured into water and the green oil which separated crystallized on standing overnight. The yield was quantitative. On crystallization from alcohol the substance formed bright yellow needles, m. p. 83.5–84.0°. The compound is insoluble in dilute alkali in the cold but it dissolves readily on boiling and the original hydroxyquinone is obtained on acidifying the solution.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.08; H, 5.22. Found: C, 71.28; H, 5.55.

2-β-Phenylvinyl-3-acetoxy-1,4-naphthoquinone.—This compound was prepared in good yield by the above procedure and crystallized from alcohol or from acetic acid. The substance crystallizes from these solvents either as orange-yellow needles or as bright red needles, the orange-yellow form being the more common. Both forms melt sharply at 138.7–139.2°, and it appears that the red form changes into the other modification before this temperature is reached, for on gentle heating the red needles become coated with small yellowish needles, making them appear opaque. Neither form contains solvent of crystallization, for a mixture of the two lost no weight on being heated at 130° for one-half hour. Both forms yield the original hydroxy quinone on alkaline hydrolysis and they impart a purple coloration to concentrated sulfuric acid. Both varieties become resinous on rubbing.

Anal. Calcd. for $C_{20}H_{14}O_4$: C, 75.45; H, 4.44. Found: C, 75.60; H, 4.56.

2. Hydrogenations

The condensation products are of the type $C_{10}H_4\left\{\begin{matrix}O_2\\ CH{=}\\ OH\end{matrix}\right.$ $CHCH_2X$ are deep orange in color and they dissolve in dilute alkalies to intensely violet solutions varying but little in tone. In these respects they differ materially from the compounds of the general type $C_{10}H_4\left\{\begin{matrix}O_2\\ CH_2CH_2CH_2X\\ OH\end{matrix}\right.$ into which they are readily converted by hydrogenation. These are yellow (occasionally golden brown when in fair sized crystals) and give solutions with alkalies of a claret red shade. These differences between the two classes of compounds enable the hydrogenation of very small quantities to be satisfactorily followed. The catalyst was prepared in accordance with the directions of Roger Adams and the hydrogenations were carried out in the cold, mostly in alcoholic solution at a pressure of 38–40 lb. (2.53–2.66 atm.). The time necessary varies from a few minutes to several hours, depending on the quantity and condition of the catalyst. To ascertain when the hydrogenation is complete, it is simply necessary to remove a trace of the solution from the pressure flask, allow it to evaporate to dryness, and redissolve the residue in a drop of 1% sodium hydroxide solution. If the oxidation of the hydroquinone group resulting from the action of the hydrogen has not already taken place by atmospheric oxygen during evaporation, it will be almost instantly effected in contact with the alkali. The hydrogenation may be considered complete as soon as the alkaline solution obtained is red without any trace of violet. A drop of dilute hydrochloric acid added to the alkaline solution also should yield a yellow precipitate instead of the orange one given by the substance before hydrogenation.

Hydrolapachol was first prepared by Monti[6] by the action of hydrogen in the presence of palladium black on the acetyl derivative of lapachol, followed by hydrolysis

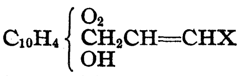
and exposure of the solution to the oxidizing action of the air. Fieser and Brodie[7] obtained hydrolapachol from lapachol itself by employing the method of hydrogenation of Roger Adams. A more detailed study of hydrolapachol has been undertaken here in order that the identity of the substance obtained by the hydrogenation of isolapachol might be established without doubt. Several lots of hydrolapachol have been prepared in my laboratory from lapachol with very satisfactory results by Adams' method, a yield of fully 97% being obtained. The reaction was carried out at room temperature, using 6 g. of lapachol in 100 cc. of alcohol and 0.2 g. of catalyst. The progress of the absorption may be followed and its end determined by removing a drop of the solution from time to time and allowing it to evaporate completely on a watch glass. As evaporation proceeds the hydroquinone is again oxidized and the residue on solution in concentrated sulfuric acid and subsequent dilution gives a *yellow* suspension when the hydrogenation is complete, in place of the *orange* β-lapachone which would be obtained from lapachol under like circumstances.

In preparing moderately large lots of hydrolapachol the oxidation of the hydroquinone may be advantageously hastened by drawing air through the alcoholic solution. After oxidation the solution was evaporated to about 50 cc. and cautiously diluted with water, the dilution being increased from time to time as crystallization proceeded. The fine, silky needles obtained were washed with 50% alcohol. Recrystallized, the substance melted constantly at 93.5–94.5°, a temperature considerably higher than that reported by Monti (87–89°) and by Fieser and Brodie (88–89°). Isolapachol, hydrogenated in the same manner, gave a substance identified by melting point, mixed melting point and all other properties, as hydrolapachol. In hydrogenating the synthetic compounds of the type



$C_{10}H_4\left\{\begin{array}{l}O_2\\ CH_2CH{=}CHX\\ OH\end{array}\right.$

the progress of the reaction was followed by the color test with sulfuric acid, as in the case of lapachol.

The yields in the hydrogenation experiments were uniformly good and the quinones with reduced side chains were easily obtained in a pure condition, usually by crystallization from alcohol. 2-*n*-Propyl-3-hydroxy-1,4-naphthoquinone crystallized well from petroleum ether. The properties and analyses of the compounds are recorded in Table II. In those cases in which it is indicated that the same hydrogenation product was obtained from two different quinones, the identity was established by melting point and mixed melting point determinations and by a careful comparison of the crystalline forms and color reactions of the two substances.

Summary

1. The condensation of aldehydes with 2-hydroxy-1,4-naphthoquinone, which in the case of isovaleraldehyde resulted in the formation of isolapachol, is shown to be generally applicable to the preparation of corresponding alkenyl derivatives of hydroxynaphthoquinone, the alkenyl group being situated in the quinone ring adjoining the hydroxyl, and the double bond occupying the α,β-position in the chain.

2. It is shown that by the addition of hydrogen to the synthetic isolapachol the same product, namely, hydrolapachol, is formed as is obtained from the natural product, lapachol, under similar circumstances.

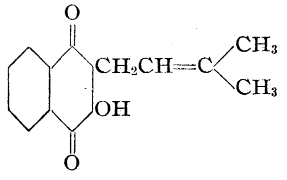
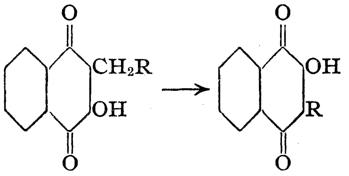
The Constitution of Lapachol and its Derivatives. Part IV.[1] Oxidation with Potassium Permanganate[2,3]

BY SAMUEL C. HOOKER

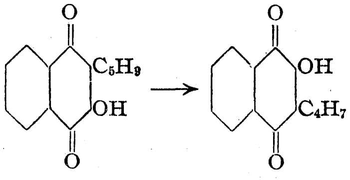
In the course of my researches on the constitution of lapachol, oxidation with alkaline permanganate was studied in anticipation of additional confirmation regarding the structure of the amylene chain in this compound. The results obtained were, however, entirely unexpected. Instead of helping substantiate in a simple way the conclusions I had reached, they themselves gave rise to a major problem, the solution of which has led to the discovery of a most interesting general reaction by means of which substances of the general formula (a) can be readily converted in good yield into others of the formula (b) with the elimination of CH_2 from the body of the chain, a conclusion which would be difficult to accept but for the very conclusive evidence I shall give in this and succeeding papers. In this way as a result of the action of alkaline permanganate on lapachol one carbon and two hydrogen atoms are removed, as indicated in the formulas:



Lapachol

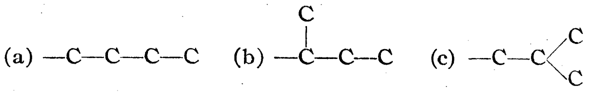


(a) (b)



I II

That the oxidation product is still a derivative of hydroxynaphthoquinone can be demonstrated by the formation of hydroxynaphthoquinone itself therefrom by further oxidation. Moreover, in many of its reactions it parallels lapachol itself, including its ability to add on hydrogen. This unmistakably demonstrates the presence of a double bond in the side chain, as the resulting hydrogenated compound still shows the essential characteristics of a hydroxynaphthoquinone derivative. Now a chain C_4H_7 must have one of the following skeleton structures:



and I shall show that the last of these (c) is that present in the oxidation product.

Of eight possible derivatives of hydroxynaphthoquinone having the unsaturated chain C_4H_7 in the β-position of the ring, three are known in addition to the lapachol oxidation product, namely, III, IV and V. Of these III has been prepared by the condensation of *n*-butyraldehyde with hydroxynaphthoquinone,[4] and IV and V were obtained by Dr. Louis F. Fieser in the course of his researches on the alkylation of hydroxynaphthoquinone,[5] to whom I am greatly indebted for samples of these substances which have considerably facilitated my work. By the hydrogenation of the above hydroxynaphthoquinone derivatives it is possible to determine the structure of the lapachol oxidation product. Thus, as I have

[1] Previous papers: Hooker, (a) *J. Chem. Soc.*, **61**, 611 (1892); (b) **63**, 1376 (1893); (c) **69**, 1356 (1896).

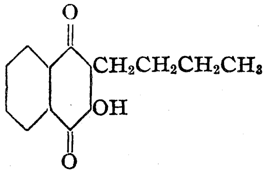
[2] See Editor's note (1) to the preceding paper.

[3] The theoretical part of this paper was written by Dr. Hooker in 1934 and only one or two minor changes have been made. The experimental part has been constructed from notes assembled by Dr. A. Steyermark. In the experimental work Dr. Hooker was in part assisted by Mr. J. G. Walsh, Jun., in the period 1893–1894, and by Dr. G. H. Connitt in 1927–1928. Isolated experiments were made by Mr. L. D. Gibson and Dr. A. Steyermark and certain of the analyses are by Dr. D. Price.—L. F. FIESER.

[4] Hooker, THIS JOURNAL, **58**, 1163 (1936).

[5] Fieser, *ibid.*, **49**, 458 (1927).

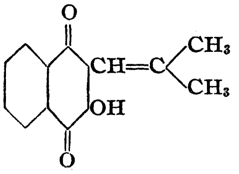
previously shown,[4] III and IV give the same compound, namely, VI, and as this differs from that



VI

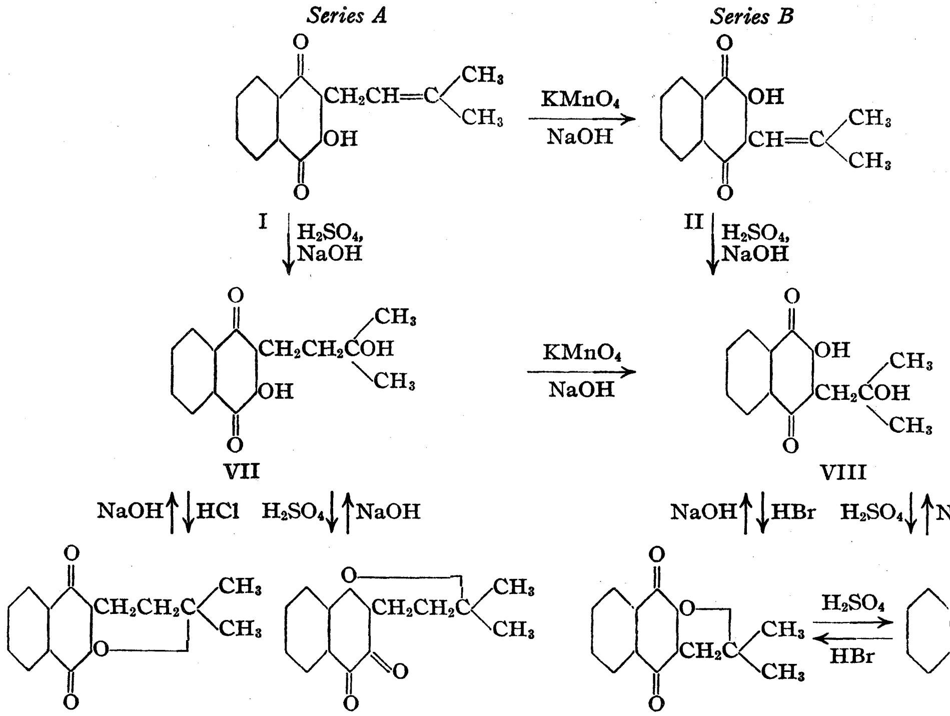
obtained by the addition of hydrogen to the lapachol oxidation product the latter cannot have the chain —$CH_2CH_2CH{=}CH_2$.

To V, I have likewise added hydrogen and the product also differs from that arising from the lapachol compound. There remains therefore for the chain of the latter only one possible skeleton, namely $\text{—C—C}\!\left\langle\begin{smallmatrix}C\\C\end{smallmatrix}\right.$, and as the double bond has taken no part in the oxidation it may be most reasonably assumed that no change has occurred in its position relative to the methyl groups. The oxidation product must therefore have the formula:



The position of the double bond is confirmed by the red color of the substance, as I have recently shown[4] that all 2-alkenyl derivatives of hydroxynaphthoquinone having the double bond in the α,β-position are deep orange to red, and that if the double bond is otherwise situated they are yellow. The formula thus assigned to the oxidation product necessitates the conclusion that CH_2 has disappeared from the body of the chain and has not been removed by oxidation from its extremity.

The following series of changes show the relations existing between lapachol (I) and its oxidation product (II). Substances can be produced from II having their exact counterpart in substances obtained under similar circumstances from I. The preparation, constitution and relationship to each other of the compounds in Series A were discussed by me many years ago;[1a,c] the compounds of Series B are now described for the first time.[6] (Among other transformations re-



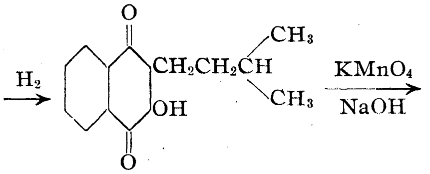
IX X XI XII

---

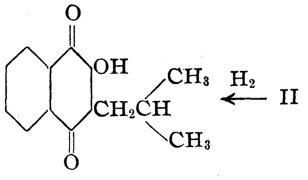
[6] Dr. Hooker did not assign names to compounds XI and XII or to a host of other ring compounds to be described in subsequent papers. On considering all of the various types of side rings, including variously substituted 5- and 6-membered saturated and unsaturated structures, and taking account of the desirability of correlating both α- and β-quinones with open-chain compounds such as VIII, I have decided to adopt the following nomenclature, which I believe would conform with Dr. Hooker's taste for simplicity and clarity (see next page).

ported in the experimental part is the formation from the substance II of a condensation product with *o*-phenylenediamine. The yield is not as good as in the case of lapachol,[1b] but it is of interest that some reaction occurs for under the same conditions the similarly constituted aldehyde condensation products[4] do not form azines.—L. F. F.)

Inasmuch as the attack of alkaline permanganate might be expected to occur at the double bond of the side chain of lapachol, it should again be emphasized that this bond takes no part whatever in the change. By reference to the above diagrammatic table it will be seen that VIII, which is formed by the action of alkali on XI and XII, also results from VII by oxidation with alkaline permanganate. Another example of this remarkable change is thus afforded and, as there is no double bond in the chain of VII, this is further evidence that the oxidation of I also occurs without reference to the double bond. Still another example is shown below.



XIII



XIV

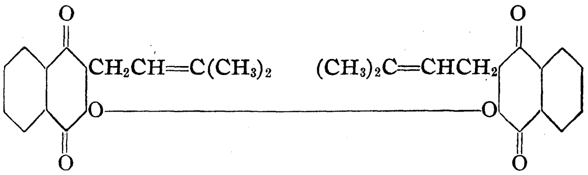
The above considerations and a study of the tables seem to leave no doubt as to the correctness of the formulas attributed to the alkaline permanganate oxidation products of lapachol and its derivatives. It remains therefore to attempt to explain how these compounds have been formed and to show how the carbon and hydrogen have been removed. I believe the following theory satisfactorily explains these changes.

Briefly, it may be assumed that in the course of the oxidation the first step is the splitting of the quinone ring, following which the ring is again formed. In the process of the new ring formation the carbon atom of the original ring attached to hydroxyl is eliminated as carbon dioxide, a carbon atom of the side chain takes its place and a new hydroxynaphthoquinone derivative is generated with the relative positions of hydroxyl and side chain reversed.

In a paper I hope to publish shortly I shall fully discuss the theory of this change and show that the reaction is applicable generally to derivatives of hydroxynaphthoquinone.

Addendum[7]

Lapachol Peroxide.—In connection with the above observations some study was made of the action of other oxidizing agents on lapachol. It was found that in acetic acid solution the hydroxyquinone is converted by lead peroxide into a neutral, sparingly soluble, yellow compound having the composition and molecular weight of a peroxide, XV. The peroxide is slowly attacked by boiling alkali and is in large part reconverted by the reagent into lapachol. 2-*n*-Amyl-3-hydroxy-1,4-naphthoquinone forms a peroxide on similar treatment with lead peroxide, while hydroxynaphthoquinone is converted only into a lead salt.

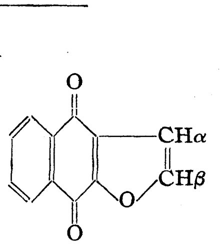


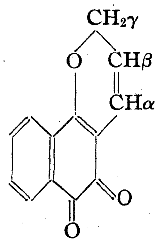
XV

Experimental Part

The lapachol required for this and other investigations was obtained largely from logs of Surinam Greenheart apparently very rich in the pigment and known in the trade as Bethabarra wood. The wood was reduced by various mills in turn to planks, to chips, and to a powder, but, as the fine sawdust did not allow the free passage of extracting solution, a mixture of 1140 lb. (518 kg.) of the ground wood with 614 lb. (279 kg.) of coarser planings of similar wood was used. This was charged in portions into a stoneware percolator and extracted with warm 1% sodium carbonate solution. The crude material which precipitated on acidification was collected and washed in a filter

---





Furano-1,4-naphthoquinone Pyrano-1,2-naphthoquinone

Compound XI is thus β,β-dimethyldihydrofurano-1,4-naphthoquinone; β-lapachone (X) is γ,γ-dimethyldihydropyrano-1,2-naphthoquinone.—L. F. F.

(7) Dr. Hooker left no instructions regarding the publication of this material. The work was carried out with the experimental assistance of Dr. A. Steyermark.—L. F. F.

press. The dried solid contained 60–70% of lapachol, which was easily extracted with benzene from an insoluble resin.

Permanganate Oxidations[8]

(a) **Lapachol.**—Ten grams of lapachol was dissolved in 1 liter of 1% sodium hydroxide solution and the red solution was cooled to about 0°. A solution of 10 g. of potassium permanganate in 1 liter of water was cooled to about 0° and added quickly in one portion to the lapachol solution. The mixture immediately became green and then changed to olive-green and to brown, and finally manganese dioxide separated leaving the solution almost colorless. The faintly pink supernatant solution became more strongly red on standing. After three to four hours the solution was filtered from the manganese dioxide and the now red solution was acidified. Orange-red needles separated slowly and after several hours the collected material amounted to 4–4.5 g. This material was found to consist largely of 2-β,β-dimethylvinyl-3-hydroxy-1,4-naphthoquinone, contaminated with some unchanged lapachol and with small amounts of other oxidation products. A separation was accomplished by fractional precipitation from 0.25–1% alkali. The lapachol was precipitated first, followed by the main reaction product. The mother liquor, after further acidification, yielded a small amount of an orange substance, and on concentrating the solution a colorless compound and some phthalic acid were obtained. The by-products were not further investigated.

2 - β,β - Dimethylvinyl - 3 - hydroxy - 1,4 - naphthoquinone (II) was obtained in yield of about 3.3 g. Crystallized from alcohol, in which it is readily soluble, the substance forms red needles melting at 119–120°. The quinone also dissolves readily in benzene or glacial acetic acid. It dissolves in cold dilute alkali to form a reddish-purple solution from which the material may be recovered unchanged on acidification.

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.26. Found (Hooker): C, 73.60; H, 5.28.

The acetyl derivative was prepared by boiling for one to two minutes a mixture of the hydroxyquinone (10 g.), fused sodium acetate (10 g.), and acetic anhydride (25 cc.) and pouring it into 700 cc. of cold water. The crude product was digested for a few minutes with cold 0.25% alkali in order to extract some unacetylated material (0.92 g.) and the residue was dried and crystallized from benzene–petroleum ether and finally from alcohol. The substance forms yellow prisms, m. p. 85.5–86°. It can be hydrolyzed with boiling alkali and yields the original quinone. The solution in concentrated sulfuric acid is at first crimson, but changes almost instantly to purple, violet and finally a rich blue.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.11; H, 5.18. Found (Walsh, Hooker): C, 70.67, 71.15; H, 5.35, 5.23.

The eurhodol (eurhodone?) derivative of II was prepared as follows. A mixture of 1 g. of the oxidation product, 0.86 g. of *o*-phenylenediamine hydrochloride, 3 g. of crystalline sodium acetate, and 20 cc. of glacial acetic acid was heated on the steam-bath for one and one-quarter hours, during which time the color of the solution changed from red to brown and orange-brown prisms were deposited. After cooling, the solid was collected and washed with 50% acetic acid, with water, with cold 0.25% alkali to remove unchanged material, and with water; yield, 0.6 g. Dilution of the mother liquor gave chiefly the starting material, mixed with some condensation product. The reaction product crystallized from alcohol (200 cc. per g.) in the form of amber prisms melting at 226–227° with decomposition.

Anal. Calcd. for $C_{20}H_{16}ON_2$: C, 79.96; H, 5.37. Found (Price): C, 80.39; H, 5.16.

The experiment was repeated several times using up to 25% excess of the diamine, but without material increase in the yield. In the case of lapachol the condensation product is formed in practically quantitative yield. On the other hand 2-α-butenyl- and 2-β-phenylvinyl-3-hydroxy-1,4-naphthoquinone[4] did not condense with *o*-phenylenediamine after several hours of heating. It would seem that a double bond in the α,β-position of the side chain inhibits or even prevents this type of reaction. Another difference is that the azine derivative of lapachol is dark red, and perhaps is to be regarded as a eurhodone;[1b] the condensation product from the oxidation product II is amber-yellow, a possible indication that it has the alternate structure of a eurhodol.

(b) **Hydroxyhydrolapachol (VII).**—A solution of 1 g. of hydroxyhydrolapachol[1a,c] in 100 cc. of 15% sodium hydroxide solution was cooled under the tap and treated as quickly as possible in one operation with a solution of 1 g. of potassium permanganate in 100 cc. of water. The color changes were as described above, and after three hours the filtered, red solution was acidified. The material first formed an emulsion and then became crystalline. The yield of nearly pure material was 0.71–0.73 g. **2-β-Hydroxyisobutyl-3-hydroxy-1,4-naphthoquinone (VIII)** dissolves readily in alcohol or benzene and crystallizes from these solvents in the form of silky, yellow needles, m. p. 121–122°.

Anal. Calcd. for $C_{14}H_{14}O_4$: C, 68.29; H, 5.69; mol. wt., 246.1. Found (Hooker, Connitt): C, 68.24; H, 5.70; mol. wt., 257.6 (av. of 6 determinations).

(c) **Hydrolapachol (XIII).**—One-half gram of hydrolapachol[4] was immersed in 50 cc. of 10% alkali, stirred, broken up and shaken until the whole appeared to be converted into the sodium salt which however did not all dissolve. The solution containing suspended matter was cooled in ice and 0.5 g. of potassium permanganate dissolved in 50 cc. of water, also ice cold, was quickly added. After standing about half an hour the manganese dioxide was filtered off and the deep claret red solution was rendered slightly acidic. This caused the separation of a bright yellow emulsion which soon gave way to microscopic needles; yield 0.34 g.

By one crystallization from alcohol the **2-isobutyl-3-hydroxy-1,4-naphthoquinone (XIV)** was obtained in bright yellow needles melting at 132–133°.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.04; H, 6.08. Found (Connitt): C, 72.73; H, 5.98.

In another experiment hydrolapachol was dissolved in 1% alkali and oxidized under conditions otherwise similar

---

[8] Quinones having saturated side chains are best oxidized in a strongly alkaline solution, while dilute alkali gives better results with the unsaturated compounds. Further observations regarding the optimum conditions are given in later papers.—L. F. F.

to those above. Only a very small yield of isobutylhydroxynaphthoquinone was obtained and an odor strongly suggestive of butyric acid was noticed.

It was afterward found that in oxidations of this type necessitating the use of strongly alkaline solutions it is best to dissolve the substance to be oxidized in dilute alkali, adding the remaining alkali required to the permanganate solution. In this way substances usually are readily dissolved.

Structure of the Lapachol Oxidation Product (II)

Hydrogenation.—The oxidation product, 2-β,β-dimethylvinyl-3-hydroxy-1,4-naphthoquinone (5 g.) was hydrogenated in alcoholic solution (100 cc.) in the presence of Adams catalyst (0.2 g.). The filtered solution was allowed to stand overnight with access of air and on concentration it yielded yellow needles of 2-isobutyl-3-hydroxy-1,4-naphthoquinone (XIV); total yield, 4.25 g. Recrystallized from alcohol it formed yellow needles, m. p. 132.5–133.5°.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.04; H, 6.08; mol. wt., 230.1. Found (Connitt): C, 72.72; H, 6.07; mol. wt., 226.2, 227.4, 226.1.

The substance gave no depression in melting point when mixed with the oxidation product obtained from hydrolapachol, but a considerable depression of the melting points of 2-*n*-butyl-3-hydroxy-1,4-naphthoquinone[4] and of 2-*s*-butyl-3-hydroxy-1,4-naphthoquinone (see below) was noted.

2-*s*-Butyl-3-hydroxy-1,4-naphthoquinone.— 2-α-Methylallyl-3-hydroxy-1,4-naphthoquinone[5] on hydrogenation as above gave in good yield a substance which crystallized from dilute alcohol in the form of yellow needles melting at 92.5–93°.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.04; H, 6.08. Found (Connitt): C, 72.93; H, 6.06.

Oxidation.—A solution of 2 g. of 2-β,β-dimethylvinyl-3-hydroxy-1,4-naphthoquinone in 200 cc. of 1% sodium hydroxide solution was cooled to 3° and treated quickly with 2 g. of potassium permanganate in 200 cc. of cold water (1°). After one and one-half hours the filtered, red-brown solution was acidified to faint turbidity, when 0.1 g. of unchanged starting material separated. On adding an excess of hydrochloric acid the filtrate soon became cloudy and after standing deposited a dark brown precipitate which was discarded. The filtrate was made faintly alkaline with sodium carbonate and evaporated to a volume of 212 cc. A brown scum, which increased in amount on standing, was removed after two days and the solution on being acidified then yielded 0.42 g. of 2-hydroxy-1,4-naphthoquinone. On further evaporation as before an additional amount (0.16 g.) was obtained. Recrystallized from alcohol the product was obtained in the form of light brownish-yellow plates melting at 189.5–190.5°, dec. The substance showed no depression when mixed with an authentic sample of the quinone, m. p. 190–191°, dec.

Ring Compounds from 2-β,β-Dimethylvinyl-3-hydroxy-1,4-naphthoquinone (II)

The following is an account of the transformations summarized in part by the formulas in Series B in the above chart. The correctness of the 5-membered ring formulas, as in XII, is established by observations which will be presented in a later paper. A substance of the same carbon skeleton as XII but having a 6-membered oxide ring has been prepared in my laboratory and it is not identical with XII but is an isomer of this substance.

β,β - Dimethyldihydrofurano - 1,2 - naphthoquinone (XII).—Five grams of the unsaturated oxidation product (II) was dissolved in 25 cc. of cold, concentrated sulfuric acid, and after standing for a few minutes the brownish-red solution was poured into 600 cc. of cold water. The cyclic compound separated as a red, crystalline precipitate in quantitative yield. Crystallized from alcohol the compound formed deep red needles melting at 186.5–187°. An identical product was obtained from 2-β-hydroxyisobutyl-3-hydroxy-1,4-naphthoquinone (VIII) by allowing a solution of 10 g. of the quinone in 25 cc. of concentrated sulfuric acid to stand at room temperature for one-half hour and pouring the solution into water; yield, 9.3 g. (deep red needles from benzene, m. p. 187–188°).

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.26. Found (Walsh, Hooker): C, 73.12, 73.55; H, 5.39, 5.28.

The oxide ring of the ortho quinone is easily cleaved by alkali. On boiling a mixture of 0.24 g. of the substance XII with 18 cc. of 1% sodium hydroxide solution the material nearly all dissolved. The red solution was cooled, filtered, and acidified with acetic acid, giving a yellow oil which soon gave rise to yellow crystals. After reprecipitation from dilute alkali the material melted at 118.5–120° and proved to be identical with the dihydroxyisobutylnaphthoquinone (VIII) obtained by other methods.

The azine of XII was prepared (a) by heating the components in glacial acetic acid for one and one-quarter hours on the steam-bath (0.1 g. yielded the same weight of product), and (b) by dissolving 0.3 g. of the eurhodol of II in concentrated sulfuric acid and pouring the yellow-green solution into water. In the latter case the azine precipitated in the form of an orange-red sulfate, from which the free base was recovered by rendering the suspension alkaline and warming it on the steam-bath (yield, 0.3 g.). The azine dissolves in alcohol to give an orange solution with a green fluorescence, and the compound crystallizes as golden yellow needles, m. p. 154–155°.

Anal. Calcd. for $C_{20}H_{16}ON_2$: C, 79.96; H, 5.37. Found (Price): C, 79.88; H, 5.42.

2-β-Chloroisobutyl-3-hydroxy-1,4-naphthoquinone.—The oxide ring of the red ortho quinone XII can be opened by the action of hydrochloric acid in such a way as to give the chloro compound. Thus 1.4 g. of the compound was dissolved in 42 cc. of a mixture of equal volumes of concentrated hydrochloric acid and water and the deep red solution was heated at 50–55° for one hour and then at 60–65° for an additional half-hour. Yellow crystals were deposited during the heating, and after cooling the mixture these were collected on glass wool and washed with dilute hydrochloric acid followed by water. The chloro compound was crystallized from alcohol, forming bright yellow scales melting at 147–148° with decomposition. Prolonged heating of the alcoholic solution decomposes the substance. The compound dissolves readily in cold dilute alkali, giving a red solution. With concentrated sulfuric acid it slowly evolves hydrogen chloride.

Anal. Calcd. for $C_{14}H_{13}O_3Cl$: C, 63.51; H, 4.91; Cl, 13.42. Found (Walsh): C, 63.00; H, 4.79; Cl, 12.83.

β,β - Dimethyldihydrofurano - 1,4 - naphthoquinone (XI).—By the action of hydrogen bromide the red ortho quinone XII can be isomerized to the yellow para quinone XI. Probably the oxide ring first opens to give the hydroxy compound VIII, with subsequent ring closure in a different direction. To bring about the transformation 1.87 g. of β,β-dimethyldihydrofurano-1,2-naphthoquinone (XII) was dissolved in 18.7 cc. of hydrobromic acid (sp. gr. 1.49) and the red solution was heated at 65–69° for thirty-five minutes. On cooling, the reaction product was deposited in the form of greenish-yellow crystals which, when washed with concentrated hydrochloric acid and with water and dried, weighed 1.38 g. An additional 0.21 g. was obtained on diluting the mother liquor with water after it had stood for two weeks. The compound formed light yellow scales from alcohol, m. p. 183–184°.

The yellow quinone was also obtained as follows from 2 - β - hydroxyisobutyl - 3 - hydroxy - 1,4 - naphthoquinone (VIII). One gram of the material was made into a paste with a mixture of 15 cc. of concentrated sulfuric acid and 85 cc. of water and this was refluxed for one-half hour. The substance was first converted into red crystals of the ortho quinone (XII), which were slowly converted into yellow masses of the para quinone (XI). The yield was 0.88–0.89 g. and on crystallization from benzene the substance formed heavy yellow crystalline masses, m. p. 183–184°.

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.26. Found (Walsh, Hooker): C, 73.17, 73.69; H, 5.42, 5.31.

The substance was also prepared by refluxing the dihydroxy compound VIII with equal volumes of concentrated hydrochloric acid and water.

β,β-Dimethyldihydrofurano-1,4-naphthoquinone (XI) can be converted into the dihydroxy compound VIII by short boiling with 1% alkali, followed by acidification with acetic acid. The yield of reprecipitated material, m. p. 118.5–120° was 0.72 g. from 0.75 g. A conversion of the para quinone into the ortho quinone XII was accomplished by allowing a solution of the material in concentrated sulfuric acid to stand for one hour at room temperature and pouring the solution into water. The product, obtained in quantitative yield, melted at 186–187°.

Lapachol Peroxide

A solution of 10 g. of lapachol in 100 cc. of glacial acetic acid was heated to boiling, the source of heat was removed, and 10 g. of lead peroxide was added. The hot mixture was shaken for a minute or two and filtered to remove oxides of lead, and the filtrate on cooling very slowly deposited large yellow crystals of the peroxide. Collected after six days this amounted to 2.7 g., and an additional 0.6 g. of crystalline material separated after diluting the mother liquor with 40 cc. of water. Lapachol peroxide crystallizes from glacial acetic acid as heavy, orange-yellow prisms melting at 154–155°. Some decomposition occurs on crystallization from alcohol or benzene.

Anal. Calcd. for $C_{30}H_{26}O_6$: C, 74.68; H, 5.39; mol. wt., 482.0. Found (Price): C, 74.33; H, 5.38; mol. wt., 467.0, 470.6.

When a suspension of 0.5 g. of the finely powdered peroxide was boiled with 50–60 cc. of 1% sodium hydroxide solution the material dissolved completely in about five minutes. On acidifying the red solution a crystalline yellow precipitate consisting of nearly pure lapachol (0.4 g.) was obtained. Extraction of the mother liquor with ether gave only resinous material.

Treated with lead peroxide in the same manner, 2-*n*-amyl-3-hydroxy-1,4-naphthoquinone (1 g.) gave a crystalline yellow product (0.6 g.) closely resembling lapachol peroxide. The crude material melted at 113–114° and one crystallization from dilute acetic acid gave crystals melting at 117–118°. The substance partially decomposed on further crystallization and it was not analyzed.

Summary

Lapachol has been found to undergo a remarkable change when submitted to reaction with cold alkaline permanganate. The double bond in the side chain —$CH_2CH{=}C(CH_3)_2$ remains undisturbed and a hydroxyquinone is formed which differs from the starting material only in that CH_2 has been removed from the body of the side chain, which has become —$CH{=}C(CH_3)_2$. The structure of the oxidation product is fully established by comparison of its hydro derivative with known compounds and by a number of transformations parallel to those of lapachol. The observation that hydrolapachol and hydroxyhydrolapachol similarly lose CH_2 from the side chain on oxidation shows that the double bond plays no part in the transformation and indicates that the reaction is a general one. It is suggested that the quinone ring opens in the course of the reaction and closes in a different position.

On the Oxidation of 2-Hydroxy-1,4-naphthoquinone Derivatives with Alkaline Potassium Permanganate[1,2]

BY SAMUEL C. HOOKER

I have shown in a recent paper[3] on the constitution of lapachol that the following extraordinary changes are brought about by oxidation with alkaline potassium permanganate:

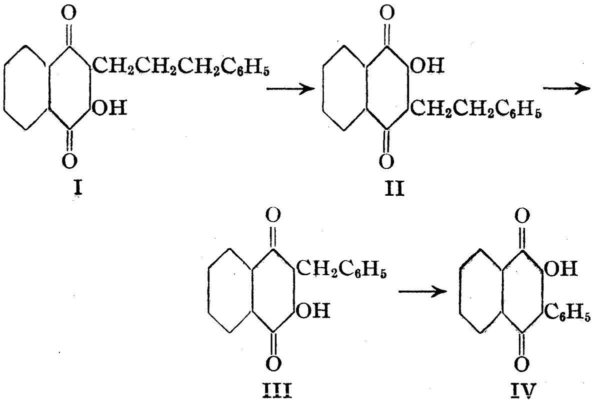
$$(1)\quad C_{10}H_4O_2\left\{\begin{array}{l}CH_2CH_2CH(CH_3)_2\\ OH\end{array}\right.\ \text{becomes}\ C_{10}H_4O_2\left\{\begin{array}{l}OH\\ CH_2CH(CH_3)_2\end{array}\right.$$

$$(2)\quad C_{10}H_4O_2\left\{\begin{array}{l}CH_2CH{=}C(CH_3)_2\\ OH\end{array}\right.\ \text{becomes}\ C_{10}H_4O_2\left\{\begin{array}{l}OH\\ CH{=}C(CH_3)_2\end{array}\right.$$

$$(3)\quad C_{10}H_4O_2\left\{\begin{array}{l}CH_2CH_2COH(CH_3)_2\\ OH\end{array}\right.\ \text{becomes}\ C_{10}H_4O_2\left\{\begin{array}{l}OH\\ CH_2COH(CH_3)_2\end{array}\right.$$

The full discussion of the mechanism involved I have reserved for the present paper.

In view of the varied chains from which CH_2 was eliminated as shown in the above examples, the conclusion seemed inevitable that the reaction would prove to be a general one, and further study has fully confirmed this anticipation. Thus through successive oxidations the following compounds have been prepared from 2-γ-phenylpropyl-3-hydroxy-1,4-naphthoquinone:



I II III IV

The starting material (I) was prepared by the hydrogenation of the condensation product of hydrocinnamaldehyde with hydroxynaphthoquinone, and the first oxidation product (II) proved to be identical with the quinone similarly obtained[4] from the condensation product from phenylacetaldehyde. The product of the second oxidation (III) was compared directly and found to be identical with 2-benzyl-3-hydroxy-1,4-naphthoquinone,[5] kindly sent to me by Dr. L. F. Fieser. The final product (IV) is undoubtedly identical with "β-phenylhydroxynaphthoquinone" of Zincke.[6]

In another series of experiments starting with *n*-heptylhydroxynaphthoquinone (V) CH_2 has been removed step by step passing through hexyl-, pentyl-, butyl-, propyl-, ethyl-, and methyl-hydroxynaphthoquinone until finally hydroxynaphthoquinone itself has been reached. This series of oxidations has yielded substances which with the exception of the hexyl and ethyl compounds have been compared with those having the same number of carbon atoms, prepared[4] by the aldehyde synthesis and hydrogenation. They proved to be identical in every instance. Comparison was not made in the case of the hexyl compound because hexyl aldehyde was not commercially available, and, as it was not possible to obtain a condensation product of the required type with acetaldehyde, comparison was made with the ethyl product prepared by the hydrogenation of

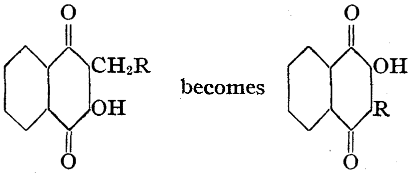
the vinyl compound[7] resulting from the oxidation of 2-allyl-3-hydroxy-1,4-naphthoquinone. The next to last oxidation product, 2-methyl-3-hydroxy-1,4-naphthoquinone (VI), was compared directly and found to be identical with synthetic phthiocol,[8] kindly sent to me by Professor R. J. Anderson. The final product of the reaction was fully identified as 2-hydroxy-1,4-naphthoquinone, a result which shows clearly that the new reaction can be extended for the purpose of eliminating completely a saturated radical attached to the quinone group.

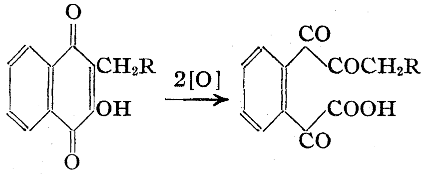
Stated generally, by suitable oxidation with alkaline potassium permanganate



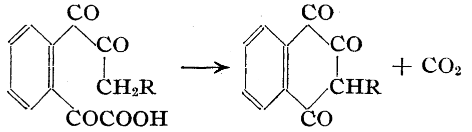
The conditions most suitable for bringing about the transformation are more clearly defined in the experimental part of the present paper. For the oxidation of quinones having saturated side chains a rather strongly alkaline solution is required and the reaction is conducted at 0–5°. The quantity of permanganate used is sufficient to supply two atoms of oxygen to the molecule of the hydroxyquinone plus 5%. In carrying out the reaction, solutions of the hydroxyquinone in 1% alkali and of the permanganate in 10% alkali are cooled in ice and quickly mixed. In the course of the reaction the crimson solution of the sodium salt of the hydroxynaphthoquinone derivative becomes *almost colorless* as manganese dioxide is being deposited. In a short time, varying somewhat with the substance oxidized, sometimes very rapidly, *the solution again becomes more or less intensely crimson.* On acidification of the filtered solution the oxidation product is obtained in a crystalline, usually yellow condition. The purity of the oxidation product is excellent and the yield generally ranges from 70 to over 80% of the weight of the material taken. It has been found in some cases that still better yields may be obtained by increasing the concentration of alkali, and conversely a decrease in the alkalinity may result in diminished yields.

The above remarks and method of procedure apply to derivatives with saturated chains. In oxidizing those with a double bond in the chain it has proved desirable to use a much less strongly alkaline medium. In this case the permanganate is dissolved in water containing no alkali and in other respects the procedure is the same. The yields are considerably less, ranging from 35–40% of the material oxidized as a maximum in the substances examined, and may be much smaller. If the double bond now occupies the α,β-position the substance obtained varies in color from deep orange to red instead of being yellow.

The oxidation appears to take place in at least three stages, as follows: (1) The hydroxyquinone ring probably is split thus:

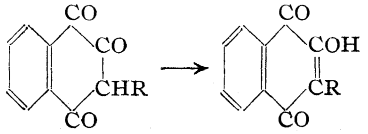


(2) A six-membered ring is again formed, the carbon originally attached to hydroxyl, however, being eliminated as carbon dioxide and the carbon in the α-position in the chain entering into the ring:



The ring as first formed probably has no double bonds, as the compound appears to be colorless, or nearly so. Whether the carbon dioxide is eliminated at the time of the formation of the ring or before or subsequent to its formation can only be surmised, as it has not yet been possible to isolate the intermediate compound or compounds.

(3) By tautomeric change the colorless compound becomes a hydroxynaphthoquinone derivative:



As the oxygen supplied by the permanganate up to the formation of manganese dioxide is sufficient only for the opening of the ring, it was originally thought that the oxidation is effected first by the oxygen derived from the permanganate and then, corresponding to the reddening of the

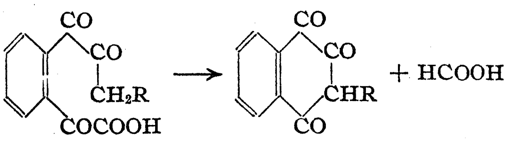
---

[7] Details of experiments conducted in conjunction with Dr. Al Steyermark will be recorded in another paper describing the formation of this compound by permanganate oxidation of the allyl derivative.

[8] Anderson and Newman, *J. Biol. Chem.*, **103**, 197, 405 (1933); Anderson, Crowder and Newman, *ibid.*, **105**, 279 (1934).

colorless solution, by oxygen of the air. This view was found to be incorrect, as the same changes occurred in an atmosphere of nitrogen. It was also shown that the reddening of the solution takes place equally readily after removal of the manganese dioxide by filtration, and oxidation by the dioxide at this stage was thus eliminated as a possibility.

Ring closure without oxidation was also considered for the second stage, but a careful search for formic acid failed to yield any evidence of its presence, both when reddening of the solution occurred in contact with the precipitated manganese dioxide and also after filtration from it.



In view of all the above considerations it became evident that the final change probably is a tautomeric one only, since it involves no oxidation, as the ring formation does. Further, as the oxygen derived from the permanganate up to the formation of the manganese dioxide is sufficient for only about two-thirds of that required for the complete change, the remaining oxygen most probably is supplied by the manganese dioxide itself previous to the reddening of the solution.

In the attempts to isolate the intermediate compound previous to the reddening of the solution, it was found that the final change could be arrested by the addition of acid. The substance in acid solution gave evidence of only partial change after a number of days, for the reddening was resumed on the addition of alkali, but not to the same extent as if the change had been allowed to proceed uninterruptedly. It was also found that by using weaker alkali for the oxidation the reddening was retarded, and thus it was possible to filter off the manganese dioxide and acidify the solution before the final change had proceeded too far; but this did not facilitate obtaining the intermediate compound, as a much smaller yield of the desired substance and an increased quantity of other products probably made its isolation more difficult.

It is seen that while the hydroxynaphthoquinone ring is broken and then regenerated in the course of such oxidations, an essential change has occurred which however may be masked by the symmetry of the compounds involved. The hydroxyl and the side chain no longer occupy the same positions as formerly. They are reversed as the result of the oxidation. The experiments recorded in this paper offer sufficient evidence of this fact, but still more positive proof could be furnished by oxidizing derivatives in which one hydrogen atom has been replaced by some other group or element in the ring adjoining the quinone ring and in this way breaking the symmetry. As owing to advancing age and uncertain health the work I am able to do is unfortunately quite limited, I am glad that Dr. Louis F. Fieser, who has been much interested in ring formation and to whom I have from time to time communicated my results, has undertaken at his own suggestion some experiments in this direction. The results obtained, Dr. Fieser has kindly informed me, support the theoretical conclusions I have reached.

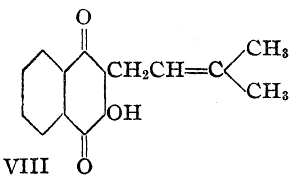
As the oxidation generally is easily effected and the resulting product is obtained in excellent yield and high purity, it will undoubtedly prove valuable not only in the preparation of substances which might be otherwise difficult to make, but also as an aid in determining the structure of the side chain in the quinone ring of 2-hydroxy-1,4-naphthoquinone derivatives. For instance, let us suppose it is necessary to determine the structure of a chain $-C_3H_7$, which could be either (1) $-CH_2CH_2CH_3$ or (2)  $-CH(CH_3)_2$. If on oxidation CH_2 were removed and the resulting compound remained a hydroxynaphthoquinone derivative the chain would have the structure (1); if no hydroxynaphthoquinone resulted with loss of CH_2 the structure (2) would be probable. Similarly the reaction undoubtedly could at times be used for the determination of the position of a double bond in the chain. I have shown that in 2-hydroxy-1,4-naphthoquinone derivatives a double bond between the α and β carbon atoms of the chain invariably results in a much more highly colored compound than if located elsewhere. This may be brick red, deep red or deep orange, but it is always very different from the yellow or orange-yellow of the compounds with the double bond elsewhere in the chain.

Lapachol may be taken as an example. As the result of many experiments I showed in 1896 that lapachol had probably the structure VIII[9] instead of IX, that assigned to it by Paternò. This

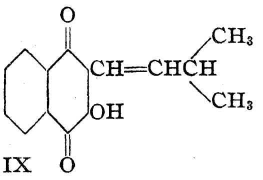
---

[9] Hooker, *J. Chem. Soc.*, **69**, 1355 (1896).

formula (VIII) was confirmed by Fieser by synthesis many years later.[10] Now in view of my



VIII



IX

more recent experiments, as lapachol is *yellow* it could not have the formula IX for the position of the double bond in this case would require the substance to be *red* or *orange-red*. Synthesis of IX has substantiated this; it is red.[9] On oxidation lapachol loses CH_2 and the resulting hydroxynaphthoquinone derivative is *red*. The bond therefore has moved one step to the left as the result of the removal of CH_2 and lapachol therefore has the side chain  $-CH_2CH{=}C(CH_3)_2$ and not  $-CH_2CH_2C({=}CH_2)CH_3$. I have proved independently[3] that the substance resulting from the oxidation actually has the chain $-CH{=}C(CH_3)_2$ which the above considerations would require.

As Fieser has shown[11] that the chemistry of polycyclic β-hydroxy-α-quinones closely follows in a number of respects that of 2-hydroxy-1,4-naphthoquinone, it is not unreasonable to expect that they too would be subject to the aldehyde synthesis and their derivatives to the permanganate oxidation described in this and preceding papers.

Experimental Part

Potassium Permanganate Oxidations

The amounts of materials oxidized in the different experiments and the quantities of potassium permanganate and of alkali employed are indicated in Table I, which records also the yields, properties and analyses of the oxidation products. It is evident from the results that the yield is improved by using a rather strongly alkaline solution. The alkali is added to the permanganate solution rather than to the solution containing the hydroxynaphthoquinone because the troublesome separation of the sodium salt is in this way avoided. Generally very satisfactory results are obtained by operating in the following manner.

General Procedure.—For the oxidation of an alkylhydroxynaphthoquinone, for example of the molecular weight 230, 1 g. of the material is dissolved in 100 cc. of 0.5% sodium hydroxide solution and the crimson solution is cooled in ice water. The second solution is prepared by dissolving 0.96 g. of potassium permanganate, an amount sufficient to furnish two atoms of oxygen plus 5% in excess, in 100 cc. of 10% sodium hydroxide, and this is likewise cooled in ice water. The two solutions are mixed rapidly in one operation and kept in ice water until manganese dioxide separates, the crimson solution of the hydroxynaphthoquinone derivative on the addition of the permanganate usually becoming successively bright green, olive green, brown, and as the manganese dioxide separates almost colorless. In order that the manganese dioxide may be completely deposited it is well to allow the solution to stand for several hours at room temperature, during which time a crimson color develops at a rate varying with the substance oxidized.[12] The manganese dioxide is filtered off and thoroughly washed so as to redissolve any sodium salt of the new product which may have crystallized from the alkaline solution. The addition of dilute hydrochloric acid precipitates the new substance, which may separate as an emulsion but is soon obtained well crystallized, usually in small, bright yellow needles. The products usually crystallize well from either alcohol or petroleum ether.

Of the entire list of products, only two are described for the first time, namely, 2-*n*-hexyl- and 2-ethyl-3-hydroxy-1,4-naphthoquinone. Samples of all of the other compounds, with the exception of 2-phenyl-3-hydroxy-1,4-naphthoquinone, were available for comparison and mixed melting point determinations with the substances prepared by other methods showed no depressions. Microscopic examinations further established the identity of the oxidation products.

The Effect of Oxygen.—In special experiments the oxidation of 2-*n*-butyl-, 2-*n*-heptyl- and 2-*n*-hexyl-3-hydroxy-1,4-naphthoquinone was conducted in the absence of oxygen. The solutions of the quinone and of the permanganate were boiled to expel air and placed in vessels connected in a train whereby the system could be evacuated thoroughly and filled with nitrogen. The cooled solutions were mixed by forcing the permanganate solution into the quinone solution under nitrogen pressure. The oxidations proceeded exactly as when carried out with free access of air and no significant differences were noted.

Attempts to Arrest the Reaction.—Noting that the changes occur more slowly in a weakly alkaline medium, some attempts were made to isolate intermediate compounds under these conditions. 2-β-Phenylethyl-3-hydroxy-1,4-naphthoquinone was dissolved in 0.5% alkali and treated with a solution of potassium permanganate in water. The separation of manganese dioxide was complete only in one and one-quarter hours and when this was removed a pale red filtrate was obtained. On acidification there was obtained only a small amount of the normal oxidation product, 2-benzyl-3-hydroxy-1,4-naphthoquinone. On making the filtrate alkaline the solution gradually acquired a deeper crimson color, and more of the above compound separated on acidification. It was observed that the darkening of the solution occurred at the same rate whether the alkaline solution was allowed to remain undisturbed or was shaken vigorously with air.

2-Methyl-3-hydroxy-1,4-naphthoquinone seemed well adapted to a study of the intermediate stages of the reaction because the changes occur somewhat more slowly with

this compound than in other cases. Under the conditions outlined in Table I the solution could be filtered from the manganese dioxide without acquiring more than a light brownish-red color. The acidified solution was yellow and it was kept in the dark for several weeks without undergoing any apparent change. A small amount of hydroxynaphthoquinone separated, but no intermediate product could be obtained. From time to time portions of the solution were made alkaline, which caused the gradual appearance of a dark red-brown color. Hydroxynaphthoquinone was then obtained on acidification.

Test for Formic Acid.—In the attempt to establish the manner in which a single carbon atom is eliminated in the oxidation, the mother liquor remaining after acidifying the alkaline solution with sulfuric acid and collecting the reaction product was investigated for the presence of formic acid. The solution was distilled and the nearly colorless, faintly acidic distillate was heated with 5% mercuric chloride solution. There was no precipitate, although in control experiments it was found that an amount of formic acid equivalent to the quinone employed can be detected easily by this method.

Further Observation.—A number of attempts were made to obtain an oxidation product similar to those described above from 2-β-hydroxyisobutyl-3-hydroxy-1,4-naphthoquinone,[3] but the experiments were not successful. The alkalinity and the temperature were varied over a wide range, but a large part of the material was invariably converted into resinous products and 35–50% of the starting substance was recovered unchanged. There were some indications of the formation of 2-hydroxy-1,4-naphthoquinone, but the substance was not completely identified.

Color Test for Hydroxynaphthoquinones.—Volhard[13] has recorded that 2-phenyl-3-hydroxy-1,4-naphthoquinone gives with concentrated sulfuric acid and benzene containing thiophene a dark blue color. I have found that this reaction is a general one. Hydroxynaphthoquinone itself and those of its derivatives having saturated carbon chains in the quinone ring, with or without phenyl groups, respond to it.

The test can be made conveniently by dissolving a small quantity of the substance to be examined in two drops of concentrated sulfuric acid on a watch glass and adding to this 2 drops of benzene containing one drop of thiophene in 5 cc. As the sulfuric acid containing the hydroxynaphthoquinone or its derivative is thoroughly mixed with the benzene, a brown color usually first develops which passes slowly on standing through an olive green to a deep blue, the color being first observed at the edges of the solution as moisture is absorbed. Finally a blue precipitate is

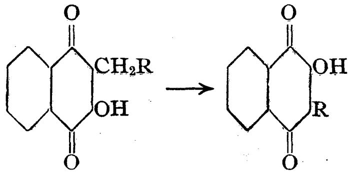
formed. All of the substances listed in Table I gave the test, and this was true also of hydrolapachol and of 2-isobutyl-3-hydroxy-1,4-naphthoquinone.[3]

Summary

It is shown how alkaline potassium permanganate oxidation of hydroxynaphthoquinone derivatives can result in a general reaction involving the following change:



Thus it is possible to eliminate CH_2 adjoining the quinone ring without otherwise disturbing the structure of the chain. In the course of the oxidation the quinone ring is split and then reformed. One carbon atom of the original ring is eliminated, another from the side chain taking its place, with the result that the chain is shortened by one carbon atom and the positions of the hydroxyl and the side chain are reversed in the new ring. The steps involved are fully discussed and many examples of the reaction are given. It is also shown how the oxidation can be of assistance in determining the structure of the side chain and, if unsaturated, the position of the double bond.

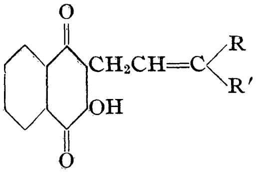
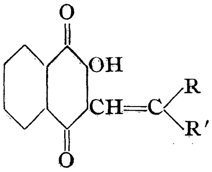
On the Oxidation of 2-Hydroxy-1,4-naphthoquinone Derivatives with Alkaline Potassium Permanganate. Part II. Compounds with Unsaturated Side Chains[1,2]

BY SAMUEL C. HOOKER AND AL STEYERMARK

It has been shown that the novel oxidation reaction described recently by one[3] of us is applicable to a large number of hydroxynaphthoquinones with saturated side chains in the quinone ring, but only one example of a substance containing a double bond in the side chain was included in the previous studies, namely, lapachol.[3a] Lapachol (I, R and R′ = CH_3) is converted by alkaline permanganate in the cold into the next lower homolog of the type II, in which CH_2 has been eliminated and the double bond shifted from the β,γ- to the α,β-position. In order to extend this observation the following additional compounds have been examined: the 2-allyl, 2-γ-methylallyl, and 2-cinnamyl derivatives of 3-hydroxy-1,4-naphthoquinone. The materials were in part kindly supplied by Dr. L. F. Fieser, who has described the preparation of all three of these quinones.[4]



I (Yellow)



II (Orange or red)

The three compounds of the type I are yellow, like lapachol, and on oxidation with permanganate they behave in an entirely similar manner yielding orange or red quinones of the type II. The product resulting from the oxidation of 2-γ-methylallyl-3-hydroxy-1,4-naphthoquinone (I, R = CH_3, R′ = H) proved to be identical with the substance prepared[5] by the condensation of propionaldehyde with hydroxynaphthoquinone, namely, 2-α-propenyl-3-hydroxy-1,4-naphthoquinone. The oxidation product of the cinnamyl compound similarly was identified by direct comparison with the compound II (R = C_6H_5, R′ = H) prepared[5] by the aldehyde synthesis.

The oxidation of the allyl compound presented some difficulties but conditions eventually were defined permitting the isolation of the sensitive reaction product, 2-vinyl-3-hydroxy-1,4-naphthoquinone (III). This compound, which is described for the first time, was fully identified by its conversion on catalytic hydrogenation into 2-ethyl-3-hydroxy-1,4-naphthoquinone (IV), a substance previously prepared[3b] in this Laboratory by the oxidation of the propyl compound (V).

These results fully confirm and extend the observations made in the case of lapachol. In all four of the examples investigated it has been found that the oxidation of a yellow alkyl hydroxynaphthoquinone having a double bond in the β,γ-position in the side chain leads to the re-

moval of CH_2 adjacent to the quinone ring with the formation of an orange or red quinone with the double bond in the α,β-position. It appears that the reaction is a very general one and that the relationship between lapachol and its product of oxidation extends to other cases and can be used with assurance in the determination of the position of a double bond in the side chain.

Experimental Part

Conversion of 2-Allyl-3-hydroxy-1,4-naphthoquinone into 2-Vinyl-3-hydroxy-1,4-naphthoquinone.—The required starting material was prepared by the method of Fieser.[4a] In carrying out the allylation of the silver salt of hydroxynaphthoquinone considerably more benzene was employed (2.6 times that specified) and the mixture was not heated but was allowed to stand in the dark in a stoppered flask with occasional shaking for two days. The yields of the *o*-quinone ether and allylhydroxynaphthoquinone were 54 and 18%, respectively. The fraction containing the *p*-quinone ether was discarded. The *o*-quinone ether was rearranged at a temperature lower than that specified by Fieser, the material being heated in an oil-bath at 125–127° for one and one-half hours (5-g. lots). The mass was soaked with cold 0.25% alkali for two days and the solution was filtered from an undissolved resin. The precipitated material was extracted with petroleum ether in the Soxhlet apparatus (yield 61–68%), and crystallized from glacial acetic acid, m. p. 116–117°.

2-Vinyl-3-hydroxy-1,4-naphthoquinone is difficult to obtain in a pure condition. As the result of many experiments it was found that it could be best prepared as follows. To 1 g. of 2-allyl-3-hydroxy-1,4-naphthoquinone dissolved in 100 cc. of 1% sodium hydroxide solution an aqueous solution of potassium permanganate containing 1.085 g. (10% in excess of the theoretical amount for two atoms of oxygen) in 100 cc. was added quickly, both solutions previously having been cooled in ice water. The oxidation occurred rapidly. The manganese dioxide separated in one to two minutes and was filtered off immediately, this operation taking about ten minutes. The filtrate was quickly diluted with 800 cc. of water and at once *poured into* 100 cc. of dilute hydrochloric acid (1:3). After standing for about eight minutes, during which microscopic orange needles formed from the emulsion produced by the addition to the acid, the oxidation product was collected as quickly as possible by suction filtration. Any delay in conducting these operations resulted unsatisfactorily, as the substance was found to change rapidly in the alkaline solution, and as an additional compound commenced to separate from the acid solution soon after the precipitation of the oxidation product. Although somewhat impure the substance as thus obtained is probably suitable for most purposes. The yield was about 40% of the weight of the allyl compound oxidized. Complete purification for analysis presented considerable difficulty as the substance underwent partial change in all the solvents used. Crystallization from methyl or ethyl alcohol, chloroform, acetic acid, benzene, ether, ethyl acetate or acetone decreased rather than increased the purity of the substance. Purification was finally accomplished by dissolving 0.94 g. in 50 cc. of ether at the laboratory temperature and gradually adding at intervals of some hours a total of 145 cc. of petroleum ether (b. p. 35–55°). When the cloud had cleared sufficiently the deposit was filtered off and discarded. The solution was then allowed to go to dryness in an Erlenmeyer flask tilted so as to promote more rapid evaporation. The residue consisted of small, red-brown crystalline masses scattered here and there over the surface of the flask surrounded by a finely divided yellow substance undoubtedly resulting from one or other of the changes above referred to. The brown-red crystalline masses were mechanically removed and after being washed with a few drops of ether melted at 121.5–123.5°. Analysis gave figures agreeing sufficiently well with those required by **2-vinyl-3-hydroxy-1,4-naphthoquinone.**

Anal. Calcd. for $C_{12}H_8O_3$: C, 71.96; H, 4.05. Found:[6] C, 71.79; H, 4.54.

The conclusion drawn from the analysis was confirmed by conversion of the substance into ethylhydroxynaphthoquinone by hydrogenation, the identity being established beyond question by direct comparison with the product previously obtained[3b] as described above and substantiated further by a mixed melting point determination.

Conversion of 2-Cinnamyl-3-hydroxy-1,4-naphthoquinone into 2-β-Phenylvinyl-3-hydroxy-1,4-naphthoquinone.—The permanganate oxidation of cinnamylhydroxynaphthoquinone occurs most satisfactorily in a very dilute alkaline solution and even then the yield of the desired substance does not much exceed 9% of the weight of the material oxidized. As the result of a number of trials the following method was adopted. The cinnamyl compound, 0.5 g., was dissolved in 100 cc. of 0.1% alkali, and potassium permanganate, 0.4 g., in 50 cc. of water. Both solutions were cooled to about 1° and quickly mixed as above. The manganese dioxide was filtered off promptly after separation, washing of the precipitate being avoided to prevent unnecessary dilution. About 140 cc. of a 25% alkali, a volume equal to that of the filtrate, was then added and the whole set aside for five days during which the sodium salt of the oxidation product crystallized in the form of dark violet needles. These were collected on glass wool and washed with 10% alkali. The alkaline mother liquor now brown in color was discarded. The violet needles were dissolved in 40 cc. of warm water and the deep violet solution after filtration acidified with dilute hydrochloric

---

(6) Microanalysis by Dr. D. Price of Columbia University.

acid. The resulting dark red precipitate consisting of microscopic needles was collected, washed with water and air dried, yielding approximately 0.045 g. The substance when crystallized from alcohol melted at 166–167°. It was compared directly with 2-β-phenylvinyl-3-hydroxy-1,4-naphthoquinone, prepared by the aldehyde condensation,[5] with which it is undoubtedly identical, the various points of similarity being further confirmed by a mixed melting point determination.

Conversion of 2-γ-Methylallyl-3-hydroxy-1,4-naphthoquinone into 2-α-Propenyl-3-hydroxy-1,4-naphthoquinone.—A solution of 0.1 g. of potassium permanganate in 10 cc. of water was cooled in an ice-bath and quickly added to a similarly cooled solution of 0.1 g. of the crotyl compound in 10 cc. of 1% alkali. Manganese dioxide separated in a few minutes leaving an almost colorless solution which rapidly became purple. After two hours the filtered solution was partially precipitated by cautiously adding dilute hydrochloric acid until the mother liquor, still alkaline, had become red. The orange, crystalline precipitate was collected, washed and air dried. The yield was 0.03 g. For purification it was dissolved in 6 cc. of a 0.5% solution of sodium hydroxide and then nearly but not completely reprecipitated with dilute acid. Washed and air dried it melted at 134–135° and gave a dark crystalline sodium salt which dissolved in water to an intensely violet solution. Comparison of its properties and a mixed melting point established its identity with the compound prepared from propionaldehyde by condensation with hydroxynaphthoquinone.[5] Oxidation in more strongly alkaline solution gave less satisfactory results.

Summary

Extending an observation regarding the oxidation of lapachol with potassium permanganate, three similarly constituted derivatives of 3-hydroxy-1,4-naphthoquinone having in the 2-position side chains of the type —CH_2CH=CHR have been converted into the corresponding compounds of the side chain —CH=CHR. The hitherto unknown vinyl derivative of hydroxynaphthoquinone has in this way been isolated.

Lomatiol. Part II. Its Occurrence, Constitution, Relation to and Conversion into Lapachol. Also a Synthesis of Lapachol.[1,2]

BY SAMUEL C. HOOKER

In a paper published in 1895 the late Dr. Edward H. Rennie[3] showed that the yellow coloring matter with which the seeds of *Lomatia ilicifolia* and *Lomatia longifolia* are more or less surrounded is closely related to lapachol; and he succeeded in converting the lomatia coloring matter into the hydroxy-β-lapachone which I had previously prepared indirectly from lapachol.[4] The results of Dr. Rennie's work together with the study of numerous compounds which I had obtained from lapachol led me to assign to the lomatia coloring matter the constitution of an hydroxyisolapachol, instead of that of hydroxylapachol proposed by Dr. Rennie, and as at least one other hydroxyisolapachol had been isolated, the name lomatiol was suggested for the lomatia coloring matter.[5]

At the time of this later publication Dr. Rennie had already courteously announced the determination of leaving the further study of the coloring matter to me, and it was my intention to pursue the work as soon as a sufficient supply of raw material had been secured in hope of eliminating all doubts regarding the structure of lomatiol. Conditions arose subsequently which made it impossible to carry out my intentions and it was not until after an interval of many years that I was able to resume the investigation.

Occurrence of Lomatiol.—In addition to the seeds of the two species above referred to, *L. ilicifolia* and *L. longifolia*, I have also examined the seeds of *L. silaifolia* from the Sydney district, New South Wales, and of *L. tinctoria* and *L. polymorpha* from Tasmania.[6] The seeds of all

---

(1) See Editor's note (1), THIS JOURNAL, **58**, 1163 (1936).

(2) The theoretical part of this paper is from an original manuscript written by Dr. Hooker and modified only to the extent of numbering the formulas and notes and making minor editorial changes. The experimental part has been constructed by consolidating, with some abridgment, descriptions of the experiments written by Dr. Hooker. The summary was supplied by the undersigned. In the experiments Dr. Hooker was assisted by Dr. G. H. Connitt.—L. F. FIESER.

(4) Hooker, *ibid.*, **61**, 611 (1892).

(5) Hooker, *ibid.*, **69**, 1381 (1896).

(6) The seeds of *L. silaifolia* were kindly sent to me by the late Mr. J. H. Maiden, Director of the Botanical Gardens, Sydney. For one sample of *L. tinctoria* I have to thank Dr. J. K. Small, of the New York Botanical Gardens, New York City; and for another, and also for the seeds of *L. polymorpha*, I am indebted to Mr. L. Rodway, then the Government Botanist, Hobart, Tasmania. Of the seeds forwarded by Mr. Rodway, those of *L. polymorpha* were collected near Macquarie Harbour, on the west coast of Tasmania; and those of *L. tinctoria*, principally near Eaglehawk Neck, about 50 miles from Hobart. For the several specimens from Chile I am indebted to Prof. Charles Sprague Sargent of the Arnold Arboretum of Harvard University; to Lt.-Col. Sir D. Prain, F. R. S., Director of the Royal Botanical Gardens, Kew; and to Dr. J. K. Small of the New York Botanical Gardens.

the varieties mentioned were surrounded with a yellow coloring matter which was positively identified as lomatiol in every case. The seeds of three varieties of *Lomatia* growing in Chile were also examined, namely, *L. dentata*, *L. ferruginea* and *L. obliqua*, but they failed to give any indication of the presence of lomatiol, two different specimens of *L. dentata* being tested, three of *L. ferruginea* and two of *L. obliqua*. Thus all the species from Australia were found to be associated with lomatiol; whereas the coloring matter was absent in the seeds of the several species examined growing in Chile.

The greater part of the substance accumulated for investigation was extracted from seeds of *L. longifolia*, obtained near Clarence in the upper parts of the Blue Mountains, about 85 miles from Sydney. For this material I am very much indebted to the late Mr. J. H. Maiden, who, through several seasons, and in the face of a number of difficulties, most courteously arranged for its collection.

The *Lomatia longifolia* fruits when quite ripe, the follicles being open and the seeds exposed, were found when air dried to yield rather more than 3.5% of lomatiol; and the seeds when detached from the follicles slightly over 12%. Fruits subsequently received which were not quite ripe and which had not opened yielded rather less than 1.5%, the amount actually present being slightly greater as the process of extraction in the case of the unripe material was not without waste.

Extraction of Lomatiol.—Lomatiol was extracted by Rennie by boiling the seeds with water slightly acidified with acetic acid, and subsequently purifying the material by recrystallization several times from hot water also acidified. The disadvantage of this method in handling considerable quantities of seeds lies in the large volume of boiling water which must be used inasmuch as each gram of lomatiol extracted requires nearly 300 cc. for its solution; and further in the decomposition which lomatiol slowly undergoes on prolonged heating with water.

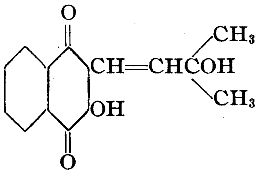
The following method of extraction will be found to give very satisfactory results: 250 g. of the seeds removed from the follicles are immersed in 3000 cc. of 0.75% sodium carbonate solution at the prevailing laboratory temperature. After digestion for about two hours, during which time the mixture is stirred frequently, the whole is transferred to a percolator and the alkaline solution drawn down to the level of the seeds and then completely displaced by cold water. Lomatiol, accompanied by a brown amorphous substance, is precipitated from the crimson alkaline extract by the gradual addition of dilute hydrochloric acid, it being desirable to add the acid at short intervals and to avoid at first a material excess, in order that a granular precipitate may be obtained which can be readily decanted, filtered off and washed with water. The mother liquor, rendered very slightly alkaline by the addition of sodium carbonate, may be concentrated in small portions at a time by evaporation on a water-bath avoiding in this way unnecessary exposure to heat. Upon the addition of hydrochloric acid to the concentrated solution a further quantity of lomatiol may be obtained in a less pure condition; the amount however is small and unless material is scarce perhaps hardly justifies the time and effort to obtain it.

Lomatiol dissolves freely in boiling benzene and being but slightly soluble in this solvent in the cold can be very satisfactorily purified by means of it, as the accompanying brown substance above referred to, which may be present in considerable quantity in the crude material, is practically insoluble in benzene and therefore readily separated. The dried crude lomatiol should be finely pulverized and refluxed for a few minutes with about 20 cc. of benzene per gram. The addition of a small quantity of blood charcoal previous to filtration gives a brilliancy to the lomatiol which cannot be readily obtained without it. If the above directions are followed the one crystallization suffices to yield a very pure material.

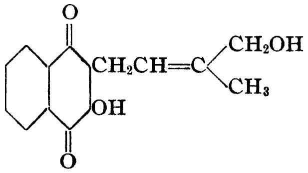
It was found necessary to modify the process of extraction in the case of unripe fruits as the opening of the follicles and the removal of the seeds proved to be a difficult matter. The air dried fruits after being ground in a pebble mill were immersed for a short time in a cold 1% solution of sodium carbonate. The solution when filtered was exposed to the air and allowed to ferment. After two weeks it was decanted off and filtered from the deposit which had formed; the deposit was discarded and the solution containing lomatiol oxidized by drawing through air, as the crimson color had been partly discharged below the surface. Lomatiol was then precipitated by the addition of hydrochloric acid at intervals, collected after several days and purified by crystallization from benzene. Whenever possible, lomatiol should be obtained from thoroughly ripe seeds, partly because of much better yields, and further because the extraction from the unripe material was found to be tedious and otherwise not fully satisfactory.

Chemical Investigations.—Since the appearance of my paper[5] in 1896 the chemistry of lomatiol and its derivatives has remained without further development. No additional facts whatever have been published regarding this coloring matter and no light has been thrown on its structure. The formula which I then suggested and indeed regarded as reasonably well fortified by experimental evidence was largely based upon the action of concentrated sulfuric acid in giving rise to hydroxy-β-lapachone. This change however, was thought to be far simpler than is actually the case for it involves a shift in the position of the double bond and also of the hydroxyl in the chain. Consequently deductions made in ignorance of this were erroneous.

I shall show in this communication that the formula I for lomatiol as accepted in the literature must be changed to II. In the light of our present knowledge the position of the double bond in I would alone condemn the structure of the chain in this formula, as lomatiol is yellow and I would undoubtedly be deep orange to red.[7] Moreover a compound of this formula has been obtained in my laboratory in alkaline solution.[8] On liberation by acids it forms an internal anhydride and its possible existence in a free condition is doubtful. These are in themselves sufficient reasons for abandoning the formula I.

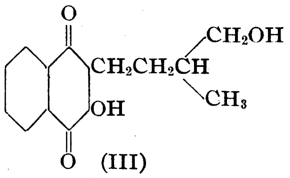


I

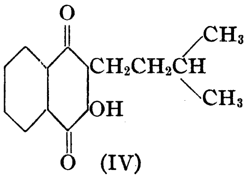


II

The hydrogenation of lomatiol gives rise to two substances (III and IV). Of these hydrolapachol (IV) is also obtained by the hydrogenation of lapachol. This demonstrates not only that lomatiol is a 3-hydroxy-1,4-naphthoquinone derivative but also that it has the same skeleton structure as that of lapachol, namely,  $-C-C-C\begin{matrix}C\\C\end{matrix}$. The ready absorption of hydrogen moreover proves the presence of a double bond in the lomatiol *chain* as the resulting hydrolapachol retains all the characteristics of a hydroxynaphthoquinone derivative.

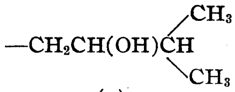


(III)
Hydrolomatiol

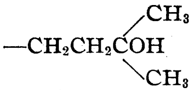


(IV)
Hydrolapachol

The formation of the second compound, hydrolomatiol (III), is of importance because it locates the position of the hydroxyl group in lomatiol. Of the three other possible isomeric substances in which hydroxyl is situated in the side chain two have been isolated in my laboratory and their structure determined with reasonable certainty. The location of hydroxyl in these compounds is as follows:

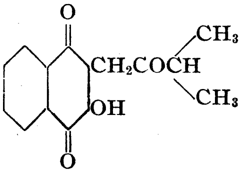


$-CH_2CH(OH)CH\begin{matrix}CH_3\\CH_3\end{matrix}$
(a)

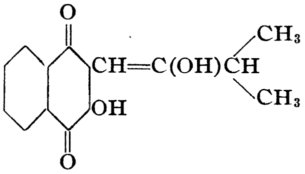


$-CH_2CH_2COH\begin{matrix}CH_3\\CH_3\end{matrix}$
(b)

The compound containing the chain (a) will be described in this paper. It is formed by the hydrogenation of hydroxyisolapachol, V, and also of isolomatiol VI, formerly regarded as a stereoisomer of lomatiol.

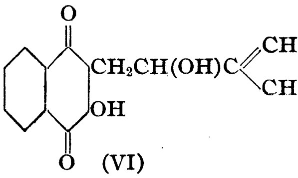


(Va)



(Vb)

Tautomeric forms of hydroxyisolapachol



(VI)
Isolomatiol

This conversion of isolomatiol and hydroxyisolapachol into the same hydrogenated compound determines the position of hydroxyl in isolomatiol, as the structure of hydroxyisolapachol is definitely known.[9] It is thus clear that the hydroxyl groups in lomatiol and isolomatiol are attached to different carbon atoms and that these substances cannot therefore be stereoisomers, as I previously suggested.

The chain (b) is contained in hydroxyhydrolapachol, a substance which results from the action

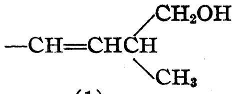
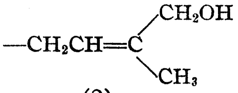
[9] Hooker, *J. Chem. Soc.*, **69**, 1355 (1896).

of alkalies on both α- and β-lapachone. The structure of this compound is also well established.[9] The third isomer in which hydroxyl occupies the α-position in the chain, though not isolated, is satisfactorily accounted for as it undoubtedly occurs as an intermediate product in the formation of isolapachol by the condensation of isovaleraldehyde and hydroxynaphthoquinone.[7,9] There is therefore only the δ-position available for the hydroxyl group in hydrolomatiol and consequently in lomatiol itself.

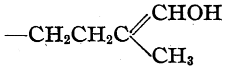
With the skeleton of the chain known, the hydroxyl located, and the existence of a double bond demonstrated, there remains only the position of the double bond to be determined in order that the constitution of lomatiol may be regarded as settled. There are four possible formulas which meet the requirements of an isoamyl skeleton and the hydroxyl in the δ-position. They are:



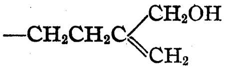
(1)



(2)

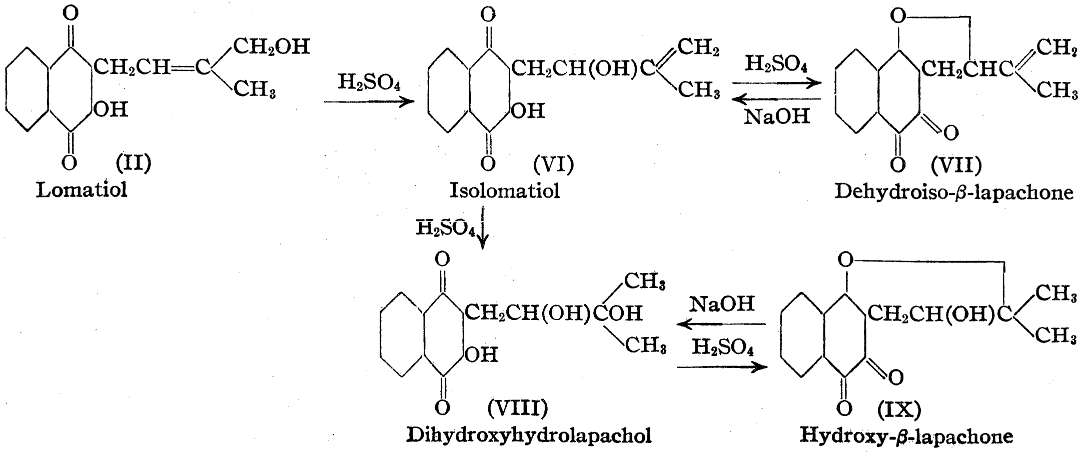


(3)



(4)

Of the above chains (1) is at once eliminated because lomatiol is yellow. Of the remainder (2) alone explains the behavior of lomatiol. The action of sulfuric acid is particularly illuminating, and is described by Rennie[3] in some detail. While recording the facts his theory fails to account satisfactorily for them. The discovery, however, that the hydroxyl group is attached to the β-carbon of the chain in isolomatiol and to the δ-carbon in lomatiol enables the reaction to be readily understood. Thus:



The intermediate compounds shown, while not isolated in the progress of the change, nevertheless can be obtained by the action of dilute alkalies on the closed ring substances and again reconverted into them by moderately concentrated sulfuric acid.

The action of concentrated sulfuric acid on lomatiol has thus brought about a change in the location of the hydroxyl group and, simultaneously, the double bond has necessarily shifted. Similar changes are already well known in compounds having like groupings (allylic rearrangement):[10] $>C{=}\underset{|}{C}CH_2OH \longrightarrow >C(OH)\underset{|}{C}{=}CH_2$. Thus these formulas for lomatiol and isolomatiol are in perfect harmony with all the experimental facts and enable satisfactory explanations to be advanced not only of the changes which these substances themselves undergo, but also of their relation to the very numerous compounds in this group which have been prepared in my laboratory.

The oxidation of lomatiol with alkaline permanganate following the general method given in recent papers[11] yields, with the elimination of CH_2, a *deep orange* compound[12] having the characteristic properties of a hydroxynaphthoquinone derivative. It can be safely inferred therefore from the color of this oxidation product that it has a double bond in the α,β-position in the chain and consequently the formula X, confirming the structure of chain (2) as that of the lomatiol chain. Chains (3) and (4) under similar circumstances, that is, with the elimination of CH_2, would have

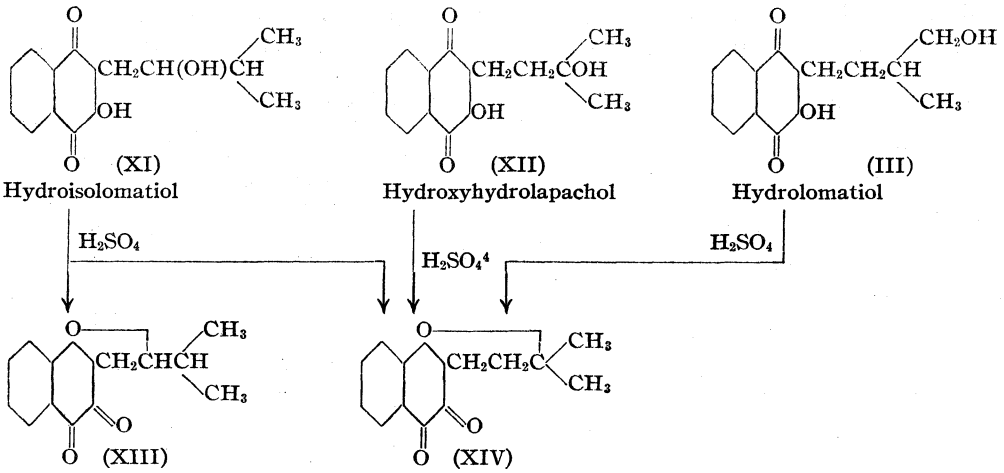
(X)

the *yellow* color of their respective compounds left unchanged owing to the double bonds in the oxidation products being otherwise situated than in the α,β-position.



(XI) Hydroisolomatiol

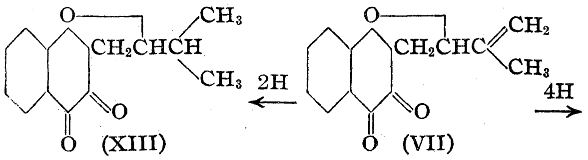
(XII) Hydroxyhydrolapachol

(III) Hydrolomatiol

(XIII) Iso-β-lapachone

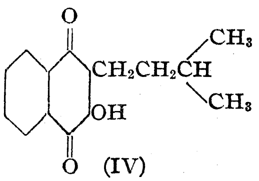
(XIV) β-Lapachone

The action of concentrated sulfuric acid on the three known hydroxy-amyl derivatives of hydroxy naphthoquinone is interesting because all give as the principal product or one of the principal products the same substance, β-lapachone, thus involving a migration of the hydroxyl group in two cases and indicating a general tendency toward the formation of a six-membered ring. Simultaneously, iso-β-lapachone is also formed from hydroisolomatiol and like β-lapachone is red and undoubtedly a β-quinone derivative. Iso-β-lapachone (XIII) is closely related to the red compound first obtained by Rennie[3] by the action of sulfuric acid on lomatiol. Rennie's compound is now recognized as dehydroiso-β-lapachone (VII), for on hydrogenation it yields iso-β-lapachone along with hydrolapachol, the latter substance arising from the cleavage of the oxide ring adjacent to the unsaturated carbon atom:



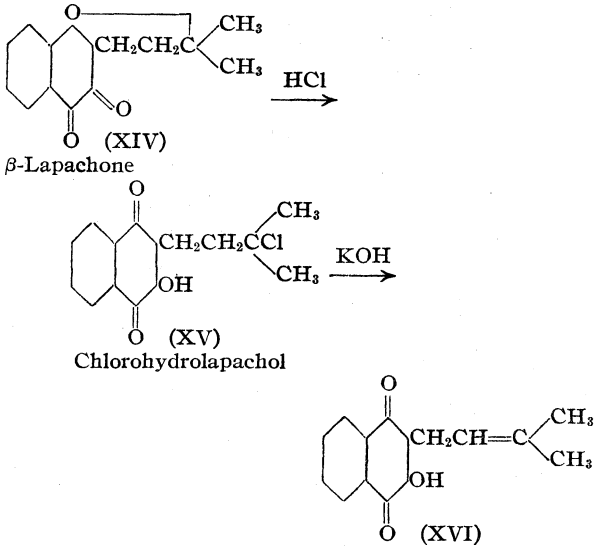
(XIII) Iso-β-lapachone

(VII) Dehydroiso-β-lapachone



(IV)
Hydrolapachol

Having converted lomatiol following hydrogenation into β-lapachone it is a simple matter to continue through to lapachol,[4] thus:



(XIV) β-Lapachone

(XV) Chlorohydrolapachol

(XVI) Lapachol

Also the conversion of hydroxyisolapachol, which has been obtained by synthesis as well as from lapachol,[9] into hydroisolomatiol by hydrogenation and then into β-lapachone completes the steps necessary for a synthesis of lapachol. A much more direct synthesis has been recorded already by Fieser.[13]

---

(13) Fieser, This Journal, **49**, 857 (1927).

The formation of isolomatiol from lomatiol and of β-lapachone from hydrolomatiol, as well as from the two isomeric compounds in which the hydroxyl occupies the β- and γ-positions in the chain, indicates the difficulties and dangers which exist in drawing conclusions as to the structure of the compounds of this group from a single reaction. Moreover, my experiments demonstrate that the shifting of the double bond in lapachol and lomatiol and their derivatives must be also recognized as an ever present possibility, and, therefore, that great caution must be exercised in attributing formulas to these substances.

Still another fact must be constantly borne in mind, namely, that changes from the para to the ortho quinone grouping occur frequently and insidiously in the conversion of open to closed ring compounds and *vice versa* in opening the ring. Also similar changes from ortho to para and from para to ortho quinones may take place in the case of the closed ring compounds themselves.

In the course of my investigations, however, I have been fortunate in being able to prepare a large number of substances in the formation of which many interesting and unexpected changes have been developed and studied, and as the formulas adopted are able to explain satisfactorily the relation of these numerous compounds to each other as well as to account for all observations so far made, they may be accepted, I believe, as representing with reasonable certainty the correct structure of the compounds to which they have been assigned. The very number of these compounds and the necessity of fitting each one into the complex whole, has prevented errors which might otherwise have occurred, as with fewer substances the number of available formulas would have been greater and the chances of wrong interpretation thus increased.

Experimental Part

Identification of Lomatiol.—Lomatiol may be positively and comparatively easily identified even in very small quantity owing to its striking characteristics admirably adapted for microscopic tests. Crude lomatiol is best purified by crystallization from benzene as above described, and if only a small quantity is available for identification the benzene can be allowed to evaporate almost to dryness on a watch glass and the resulting crystals may then be washed freely with the cold solvent. The substance is thus obtained matted in fine needles often accompanied by a few microscopic groups of heavier crystals of the same compound. It melts quite sharply at 127° and may be further identified by crystallization from water in which it is but sparingly soluble and in which it fuses at the boiling temperature. If the hot aqueous solution be allowed to cool gradually it becomes somewhat turbid and yellow needles separate which are visible to the naked eye. If the solution be quickly cooled, the emulsion which first results gives rise to minute spherical clusters of very fine needles together with irregular groups of crystals with thorn-like projections. These two forms appear to be invariably present and can be recognized with the help of the microscope. Thus examined the crystals are strikingly beautiful and characteristic.

Lomatiol may be further identified by the crimson color of its solution in alkalies and particularly by means of its barium salts[3] which are extremely typical, the one *orange* and the other dark *claret red*. The test may be made by moistening a very small quantity of lomatiol in contact with an excess of barium carbonate with a few drops of cold water, and filtering off the excess barium carbonate after an hour or so. If a very small quantity of the crimson filtrate be allowed to evaporate spontaneously on a glass slide, needles of the orange salt form readily, and a careful microscopic examination will reveal in addition minute masses of the dark claret colored salt, sometimes recognizable as consisting of thread-like forms suggesting cobwebs. If the solution be very dilute microscopic clusters of needles of lomatiol may also separate. The orange salt when vigorously rubbed on a hard surface yields a dark claret red, resin-like substance, the color change being quite striking.[14]

For further identification a trace of lomatiol may be moistened with an extremely small quantity of concentrated sulfuric acid. A bromine-colored solution is obtained, and if to this a drop or two of water be immediately added an orange-red emulsion forms from which microscopic ribbon-like orange-red crystals slowly separate, many grouped in characteristic root-like forms. After standing exposed to the air in contact with the acid solution the crystals completely disappear in the course of two to three days, an orange resin remaining in their place.[14]

Conversion of Lomatiol (II) into Hydrolomatiol (III) and Hydrolapachol (IV).—Several experiments in which from 1 to 5 g. of lomatiol dissolved in alcohol (50–100 cc.) was hydrogenated in the presence of reduced platinum oxide catalyst (Adams) at ordinary pressure or at a pressure of 38 lb. (2.53 atm.) at the laboratory temperature failed to give entirely concordant results. At times mostly hydrolapachol was obtained, at others mostly hydrolomatiol, a difference presumably due to variations in the condition of the catalyst. The hydrogenation was continued in each case until a drop of the solution, evaporated to dryness, gave with concentrated sulfuric acid a somewhat bromine-colored solution yielding a *yellow* emulsion on dilution. This indicates the absence of lomatiol, as the latter dissolves more to a brown and gives an *orange* emulsion when similarly treated.

In one experiment two 1-g. lots of lomatiol were hydrogenated with the same catalyst derived from 0.2 g. of platinum oxide and the combined, filtered solutions were allowed to stand overnight for oxidation. After evaporation to about 25 cc. the solution was diluted with about an equal volume of hot water. After standing for several

---

[14] Cf. Rennie, ref. 3.

hours the long needles which had formed were filtered off after chilling, washed with 30% alcohol, and dried, giving 1.14 g. of material melting at 92.5–93°. Recrystallized from dilute alcohol the substance melted at 93.5–94° and was identified as **hydrolapachol** by all the characteristics and properties previously described.[7] The melting point was not lowered by admixture with hydrolapachol from lapachol.

Anal. Calcd. for $C_{15}H_{16}O_3$: C, 73.77; H, 6.55. Found: C, 73.76; H, 6.64.

Hydrolomatiol was obtained in another experiment in which 5 g. of material was hydrogenated in the presence of the catalyst derived from slightly less than 0.3 g. of platinum oxide, about one-third having been used previously once and one-third twice. As attempts to obtain the substance well crystallized directly from the alcohol proved unsuccessful, the solution was allowed to go to dryness. After efforts to obtain from the residue satisfactory crystals from several solvents had failed, the larger part was dissolved in 500 cc. of 1% alkali and the substance was reprecipitated from the filtered solution by hydrochloric acid in three fractions (0.97, 1.92 and 1.08 g.), thus finally completely discharging the crimson color of the alkaline solution. In each case an emulsion was first formed and became crystalline on standing, an interval of an hour or more being allowed between the precipitations. The first fraction contained some hydrolapachol while the second and third were almost pure hydrolomatiol. The second fraction was dissolved in 14 cc. of hot benzene, filtered and allowed to stand overnight. The prismatic yellow needles of **hydrolomatiol** which separated weighed 1.75 g. and melted at 101–102°.

Anal. Calcd. for $C_{15}H_{16}O_4$: C, 69.23; H, 6.15. Found: C, 68.99, 69.23[15]; H, 6.07.

In other experiments fractional precipitation as above described proved generally a satisfactory method of separating the two compounds.

Hydrogenation of Hydroxyisolapachol (V).—The hydrogenation of hydroxyisolapachol has proved more uncertain than that of the other substances of this group. In two experiments the hydrogen was added readily, in others under apparently essentially similar conditions the starting material was recovered unchanged. Possibly a slight difference may have existed in the condition of the catalyst, platinum oxide-platinum black, and perhaps the fact that the stable form of hydroxyisolapachol is that having the chain —$CH_2COCH(CH_3)_2$ (since it is *yellow*) increases the difficulties of hydrogenation and renders the success of the operation dependent upon very exact conditions which have not been determined with sufficient precision. However this may be, the addition of hydrogen gives rise to hydroisolomatiol (XI), which was positively identified by direct comparison with the compound obtained from isolomatiol as described below.

In the successful experiments, using 0.1 g. of substance in 15 cc. of alcohol and 0.1 g. of catalyst, hydrogenation was complete in ten minutes. A drop of the solution, allowed to evaporate (and oxidize) on a watch glass, when tested with concentrated sulfuric acid no longer gave the dark brown almost immediately produced by hydroxyisolapachol, but an orange-red solution which held its color. The residue from another drop gave with 1% alkali a more crimson solution than hydroxyisolapachol, and on acidification the *deep* yellow cloud which formed gave way rapidly to characteristic needles, a behavior entirely different from hydroxyisolapachol, which under similar circumstances gives a *light* yellow jelly-like mass which soon becomes permeated with extremely minute bacillus-like, short crystals. These tests, which must of course be made with the help of a microscope, may be of assistance in following the progress of the hydrogenation.

After standing exposed for about forty-eight hours to ensure complete oxidation of the hydroquinone, the alcoholic solution was evaporated to about 5 cc. and an equal quantity of water was added. The yellow crystalline scales which had formed in the course of a few days weighed 0.055 g. Recrystallized first from alcohol and then from benzene the substance was obtained in fine, orange-yellow needles, m. p. 120–120.5°, identical in all properties with hydroisolomatiol described below. The melting point of the mixed substances from both sources remained the same as for the individual compounds.

Hydrogenation of Isolomatiol (VI): Hydroisolomatiol or β-Hydroxyhydrolapachol (XI).—No difficulty was found in readily obtaining hydroisolomatiol by this method. Several lots were prepared with slight variations, but the irregularities noticed in the hydrogenation of hydroxyisolapachol were not experienced. The catalyst differed slightly in amount in the several lots and possibly also in its condition, as varying amounts had been used previously. The results, however, were essentially the same. Isolomatiol (2 g.) was dissolved in alcohol (50 cc.), platinum oxide (0.4 g.) added and the whole agitated under pressure of 37–38 lb. (2.46–2.53 atm.) at laboratory temperatures. The progress of the hydrogenation can be followed by testing an evaporated drop of the solution, concentrated sulfuric acid giving, when the hydrogen absorption is complete, an orange-red solution which does not change to the brown characteristic of isolomatiol. The addition of water to the acid solution gives a yellow cloud which shortly crystallizes, whereas in the case of isolomatiol an orange-red precipitate is obtained. Ten minutes of contact with hydrogen under the above conditions was found to be sufficient.

Hydroisolomatiol was isolated from the solution essentially as described in the preceding section, 6.1 g. of material hydrogenated in four lots giving 5 g. of product. Recrystallized from alcohol the substance melted constantly at 120.5–121.5°.

Anal. Calcd. for $C_{15}H_{16}O_4$: C, 69.23; H, 6.15. Found: C, 69.26; H, 6.17.

Conversion of Lomatiol (II) into Dehydroiso-β-lapachone (VII).—It was found that the red compound obtained by Rennie[3] by the action of concentrated sulfuric acid on lomatiol can be prepared more satisfactorily by using acid of more moderate concentration, for further change is thus prevented. After various trials the following method was adopted.

A flask containing 10 g. of pulverized lomatiol is immersed in ice water and thoroughly cooled; 100 cc. of ice-cold acid prepared by mixing five volumes of concentrated sulfuric acid with three volumes of water is then added

---

(15) In this analysis the hydrogen was lost.

and well stirred for a few minutes until the lomatiol has dissolved completely, the flask being kept throughout in ice water. The bromine-colored solution is then immediately poured into water (750 cc.). The new substance separates as an orange-red emulsion which soon crystallizes, forming a voluminous precipitate. After standing until crystallization is complete (usually thirty minutes), the material is filtered off with the aid of suction, washed, broken up under water to facilitate the complete removal of acid, and again washed on the filter. The air-dried material (8.74 g.) is crystallized from 50 cc. of alcohol. As the solution cools dehydroiso-β-lapachone sometimes forms silky, radiating, red needles and sometimes heavier prismatic crystals. If the needles are allowed to stand in contact with the mother liquor they disappear in the course of a few days and the prismatic crystals take their place. Rennie analyzed the needles and reported the melting point 110–111°. The prisms were used for the analysis reported below and the melting point found was 116–116.5°. Dehydroiso-β-lapachone appears to be somewhat sensitive to light and unnecessary exposure should be avoided in its preparation. It dissolves in concentrated sulfuric acid to an orange-red solution.

Anal. Calcd. for $C_{15}H_{12}O_3$: C, 75.00; H, 5.00. Found: C, 74.96; H, 5.00.

The **azine** of dehydroiso-β-lapachone (VII) was easily formed by heating the red compound with *o*-phenylenediamine in glacial acetic acid solution for a minute or two. Crystallized from alcohol the substance formed yellow needles, m. p. 157.5–158°. It dissolves in concentrated sulfuric acid with a deep green color and gives a salmon-colored sulfate.

Anal. Calcd. for $C_{21}H_{16}ON_2$: C, 80.74; H, 5.17. Found: C, 80.45; H, 5.09.

Conversion of Dehydroiso-β-lapachone (VII) into Isolomatiol (VI).—Isolomatiol was first obtained by Rennie[3] by boiling dehydroiso-β-lapachone with strong potassium hydroxide solution, but the crude material precipitated on acidification had to be crystallized four or five times before it was obtained pure. Better results are possible by immersing 1 g. of the finely ground red compound in 75 cc. of 1% sodium hydroxide solution at the laboratory temperature. In the course of some hours solution is essentially complete, and after filtering to remove any possible trace of the unaltered substance dilute hydrochloric acid is added in slight excess to the intensely crimson solution. Isolomatiol is thus precipitated as a yellow oil which slowly crystallizes in groups of branch-like flattened needles with scales attached. Rosets of scales are also sometimes obtained. After washing with water and drying, the crude substance (1 g.) is dissolved in 10 cc. of alcohol, the solution filtered, warmed and gradually diluted with 10 cc. of water. Isolomatiol usually separates in clusters of scales melting at 109–110°. It appears to be sensitive to light.

Anal. Calcd. for $C_{15}H_{14}O_4$: C, 69.77; H, 5.42. Found: C, 69.71; H, 5.39.

Action of Sulfuric Acid on Isolomatiol (VI). (a) Dilute Acid.—Finely ground isolomatiol (0.25 g.) was quickly dissolved in 7.5 cc. of dilute sulfuric acid (5 vol. concentrated acid to 3 vol. water) by stirring for about two minutes and the solution was immediately poured into 75 cc. of cold water. The resulting red emulsion slowly became crystalline and the product (0.12 g.) after crystallization from alcohol was obtained as red needles, m. p. 116–116.5°, and fully identified as dehydroiso-β-lapachone.

(b) Concentrated Acid.—Isolomatiol (0.25 g.) was dissolved in concentrated sulfuric acid (5 cc.) and after four minutes the dark red-brown solution was poured into 65 cc. of cold water. The turbid solution after standing overnight was filtered from a small amount of resinous material and after standing four to five days the filtrate deposited orange-red prisms of hydroxy-β-lapachone (0.04 g.). After recrystallization from alcohol the product melted at 203–205°. The resinous material on further treatment with concentrated acid yielded a trace of yellow needles of what, most probably, was isopropylfurano-1,4-naphthoquinone,[9] but it was not fully identified.

Hydrogenation of Dehydroiso-β-lapachone (VII) and its Conversion into Iso-β-lapachone (XIII).—A solution of 1 g. of dehydroiso-β-lapachone in 100 cc. of alcohol containing 10 drops of acetic acid was agitated with 0.2 g. of platinum oxide catalyst at 38 lb. pressure of hydrogen for twenty minutes at 18°. Dehydroiso-β-lapachone dissolves in concentrated sulfuric acid to an orange-red solution which rapidly darkens on slight warming, and this property enables the end of the hydrogenation to be satisfactorily determined, as the new compound under similar circumstances gives an apricot color which is not darkened by slight heat. In preliminary experiments a drop or two of the solution was removed from time to time, evaporated and tested, and thus the time required was determined. When completely hydrogenated the colorless solution was filtered and exposed to the air until oxidation was complete, as indicated by no further increase in color. The solution was evaporated to 20 cc. and diluted with 10 cc. of water. Slight turbidity ensued and the following morning a red crystalline crust had formed on the bottom of the flask, and after another day the crystals of iso-β-lapachone were filtered off and washed with 50% alcohol; yield, 0.44 g. The mother liquor and washings were further diluted with 2.5 cc. of water and after standing overnight yellow crystals of hydrolapachol were found to have separated; yield 0.13 g. On further dilution a small additional amount of iso-β-lapachone was obtained in a somewhat resinous condition. This was digested with 1% alkali to remove resin and hydrolapachol and crystallized from alcohol.

Iso-β-lapachone crystallizes in dark orange-red plates or scales and melts at 124.5–125.5°. It has also been obtained in voluminous masses of tufts of needles materially lighter in color. The sample for analysis was recrystallized from dilute alcohol without unnecessary exposure to light.

Anal. Calcd. for $C_{15}H_{14}O_3$: C, 74.38; H, 5.78. Found: C, 74.32; H, 5.81.

I have not been successful in attempts to transform isopropylfurano-1,2-naphthoquinone[9] directly into iso-β-lapachone by hydrogenation. Using alcohol as the solvent the starting material was recovered unchanged; in ethyl acetate only a red oil was obtained.

Conversion of Iso-β-lapachone (XIII) into Hydroisolomatiol (XI).—This change was quantitatively effected by boiling powdered iso-β-lapachone (0.1 g.) for a minute or two with 1% sodium hydroxide solution (20 cc.). The deep crimson solution was filtered to remove possible traces of the unchanged substance, cooled and acidified with dilute hydrochloric acid, avoiding an undue excess. The oily, yellow suspension soon gave place to fine yellow needles which were filtered off on the following day. Crystallized from benzene the substance separated as needles and prisms melting at 121–122°.

Action of Concentrated Sulfuric Acid on Hydroisolomatiol (XI).—A solution of 0.5 g. of hydroisolomatiol in 10 cc. of concentrated sulfuric acid was allowed to stand for one hour in a corked vessel and poured into water (500 cc.). The emulsion first formed soon gave place to fine orange-red needles which were filtered off on the following morning and recrystallized a number of times from 50% alcohol (3 cc. at first and finally 2 cc.). Although the substance appeared to be pure under the microscope, the rise of the melting point with each crystallization from an initial 135–142° to eventually 153–154° clearly suggested the presence of more than one compound.

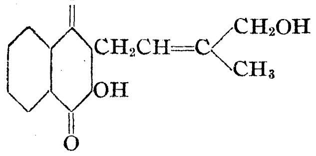
The crystals finally obtained pure were identified as β-lapachone by a mixed melting point and by conversion into γ-hydroxyhydrolapachol and its characteristic barium salt. The second substance, which proved to be iso-β-lapachone, was not itself isolated but its presence was proved by reconversion into hydroisolomatiol. In order to demonstrate the presence of iso-β-lapachone in the mixture another lot was prepared from 0.1 g. of hydroisolomatiol as before and collected one and one-half hours after pouring the acid solution into water. Microscopic examination of the material both while still wet and after being air dried definitely established the absence of yellow crystals of unchanged hydroisolomatiol. The material (0.07 g.) was immersed in cold 1% alkali which in the course of two hours had dissolved the greater part of the iso-β-lapachone, leaving 0.02 g. of β-lapachone unattacked. To the filtered crimson solution an excess (2.5 cc.) of dilute (1:3) hydrochloric acid was added. This gave a yellow suspension which soon crystallized in spherical groups of light needles characteristic of hydroisolomatiol. The crystals were allowed to stand in contact with the acid liquor so that any hydroxyhydrolapachol derived from the action of alkali on β-lapachone might be reconverted into β-lapachone. After a day or so microscopic examination revealed a very small quantity of orange-red crystals (assumed to be β-lapachone) which did not appear to increase on further standing (fifteen days). The mixture of crystals was then filtered off and immersed in a very dilute solution of sodium hydroxide to dissolve and thus separate the hydroisolomatiol from the orange crystals. Hydrochloric acid reprecipitated the yellow substance from the filtered solution and this was twice crystallized from benzene and identified by direct comparison with hydroisolomatiol by melting point (120–121°) and other characteristics.

Conversion of Hydrolomatiol (III) into β-Lapachone (XIV).—A small quantity of hydrolomatiol (0.1 g.) was dissolved in concentrated sulfuric acid (3 cc.) in a test-tube which was then corked to prevent the absorption of water and allowed to stand at the laboratory temperature. Action was slow. A drop of the solution was diluted from time to time and the color of the resulting emulsion taken as indicating the progress of the change. After one hour this was still yellow; subsequent tests tended more and more toward orange, and on the following morning the acid solution was poured into water (75 cc.). The resulting deep orange-red emulsion soon crystallized into root-like forms, which were thoroughly washed, dried (yield, 0.07 g.) and crystallized four times from alcohol, as, although the brilliant orange-red needles obtained appeared to be pure from the first, each crystallization resulted in a higher melting point. Identification was made as β-lapachone by direct comparison with this substance, by melting point (153–154°), mixed melting point and by conversion into hydroxyhydrolapachol and the characteristic barium salt of the latter. Owing to the repeated crystallizations necessary to obtain β-lapachone melting correctly, the presence of a second substance as the result of the action of concentrated sulfuric acid would seem to be indicated.

Summary

Various species of *Lomatia* from Australia have been found to be associated with lomatiol, whereas the coloring matter was absent in the seeds of several species examined growing in Chile. Methods of extracting lomatiol from both ripe and unripe fruits are described.

Lomatiol was found by Rennie to have the same skeletal structure as lapachol, from which it differs only in the character of the side chain. In the present investigation it is shown that the alcoholic hydroxyl group of hydrolomatiol is located in the δ-position in the chain ($-CH_2CH_2CH(CH_3)CH_2OH$) because substances having the other three possible structures have been obtained or characterized by synthesis or from lapachol. The double bond present in the lomatiol side chain is recognized as occupying the α,β-position with respect to the primary alcoholic group ($-CH_2CH{=}C(CH_3)CH_2OH$) by the observation that an allylic shift occurs in the conversion of lomatiol into isolomatiol, a substance having the chain $-CH_2CH(OH)C(CH_3){=}CH_2$. It is thus proved that lomatiol has the constitution of 2-[δ-hydroxy-β-isopentenyl]-3-hydroxy-1,4-naphthoquinone:



The formula is in perfect harmony with all the experimental facts and enables satisfactory explanations to be advanced of many changes which the compounds of the lomatiol series undergo and of their relationship to substances of the lapachol series. The transformations described in this paper include the conversion of lomatiol into lapachol through a series of intermediate substances, and since one of these can be prepared also from synthetic isolapachol, the work reported constitutes a synthesis of lapachol.

The Constitution of Lapachol and its Derivatives. Part V. The Structure of Paternò's "Isolapachone"[1,2]

BY SAMUEL C. HOOKER

"Isolapachone" was first referred to by Paternò[3] in 1882 in his "Ricerche sull'acido lapacico" (lapachol). It was obtained by the removal of two acetyl groups, followed by spontaneous oxidation, from a compound formed by the action of acetic anhydride and sodium acetate upon lapachol. Seven years later the compound was studied by Paternò and Minunni[4] and the conclusion reached that the substance is similar to and isomeric with lapachone (β), the compound resulting from the action of concentrated sulfuric acid on lapachol. This view was shown by me to be untenable,[5] for in investigations published in 1892 it was found that the so-called "isolapachone" and also the diacetyl compound from which it had been obtained had each two atoms of hydrogen less than required by the formulas assigned by Paternò and Minunni. At that time I suggested a structural formula for the diacetyl compound which twenty-three years later received additional support from the experiments of L. Monti.[6] The matter was discussed by Monti apparently in ignorance of the revised and now generally accepted formula[7] for lapachol which necessitated a corresponding modification in "isolapachone" and all the compounds derived from lapachol studied previous to 1896.

In the course of the study of the action of concentrated sulfuric acid upon lomatiol, the discovery by Rennie[8] of a compound isomeric with and in some respects similar to Paternò's "isolapachone" gave rise to uncertainties and errors of interpretation both as to its own structure and that of "isolapachone."[9] This was mainly due to misconceptions regarding the structure of lomatiol. In a recent paper[10] evidence has been presented which fully establishes the structure of lomatiol, and in the course of this work it was shown that Rennie's compound has the formula I and can be regarded as a dehydroiso-β-lapachone. An isomeric dehydro derivative of iso-β-lapachone was obtained in an earlier investigation[7] both from lapachol and by synthesis and it was assigned the structure II. The corresponding para quinone was also fully characterized. In this paper it will be shown that the preponderance of the facts now known favors formula III, or possibly IV, for "isolapachone." The equivalent of formula IV, based upon what was then believed to be the structure of lapachol, was previously suggested by me[5] but afterward aban-

(2) Dr. Hooker wrote a preliminary version of the introductory part of this paper in April, 1931, but he did not find time subsequently to incorporate in the manuscript certain modified views and new interpretations growing out of his more recent work on this and related problems. I was informed of his views throughout this period, however, through correspondence and conversations, and from the letters and from the notes of his assistant Dr. A. Steyermark, I have been able to revise the paper in accordance with Dr. Hooker's wishes and in large part in his own words. The experiments recorded were carried out with the collaboration of Mr. H. W. Shepard and Mr. J. G. Walsh, Jr., in 1891–1896, and of Dr. G. H. Connitt and Dr. A. Steyermark in the more recent period.—L. F. FIESER.

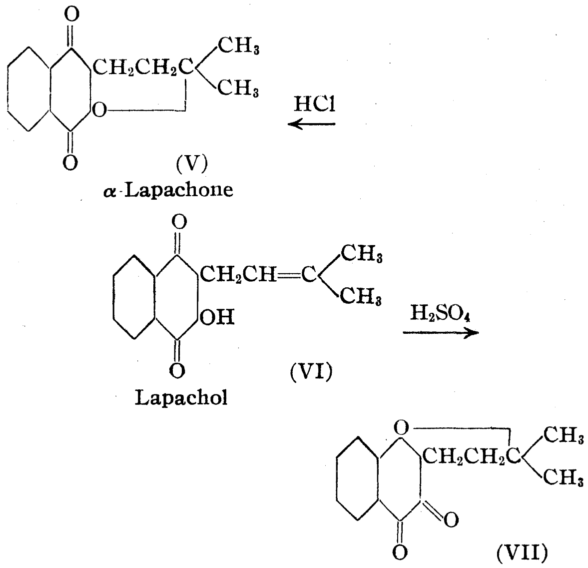
doned[9] for the reasons stated above, the compound thereafter being referred to as pseudodehydrolapachone. On the basis of the present work the name dehydrolapachone may be assigned to the compound.

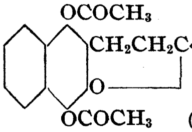
When lapachol is submitted to the action of mineral acids it can be converted quantitatively into either α-lapachone or β-lapachone according to the conditions under which the experiment is made.[5,7,11] By the action of acetic anhydride in the presence of zinc dust and sodium acetate the lapachones yield the diacetyl derivatives of their hydroquinones, VIII and IX.[4,6] I shall show that no fundamental change has occurred under the influence of acetic anhydride, as the removal of the acetyl groups followed by spontaneous oxidation enables the respective lapachones to be again obtained. Now Monti has found[6] that the diacetyl compound from which dehydrolapachone ("isolapachone") was obtained by Paternò can be converted by hydrogenation into VIII, thus substantiating the theory advanced by me.[5] Similarly I have since converted into IX the isomeric diacetyl compound which H. W. Shepard working in my laboratory observed was simultaneously formed when following Paternò's directions for the preparation of the diacetyl compound which he described. Shepard's experiments, mentioned briefly in an earlier communication,[5] are recorded in detail in the experimental part of the present paper. The second diacetyl compound was possibly overlooked by Paternò and by Monti on account of the melting points of both derivatives being almost identical. These compounds can, however, be readily distinguished by their color reactions with concentrated sulfuric acid.



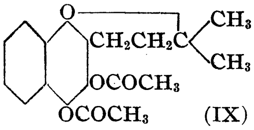
(V) α-Lapachone

(VI) Lapachol

(VII) β-Lapachone

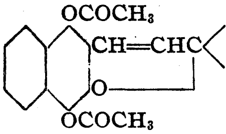


(VIII)

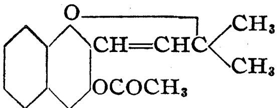


(IX)

It is evident from the results of the hydrogenations that the isomeric diacetyl compounds must bear the relations to α- and β-lapachone, respectively, which the formulas X and XI indicate.



(X)
Paternò's diacetyl compound



(XI)
Shepard's isomeric compound

The double bond must occupy the α,β-position in the chain, since no other location is available. It would be natural to expect that these diacetyl derivatives would yield in weak acid solution, followed by spontaneous oxidation, the α- and β-quinones III and IV, respectively, but this is not the case. Only one and the same substance, namely, dehydrolapachone (Paternò's "isolapachone"), has been obtained from each, notwithstanding that the conditions of the experiment have been varied materially. This change, however, is not entirely without precedent as α-lapachone can be converted by the action of sulfuric acid into β-lapachone, and the reverse action can be readily effected with hydrochloric acid.[5] The changes involve the conversion of the α-quinone into the β-quinone group as well as the opening and closing of the side ring. Similarly isopropylfurano-1,2-naphthoquinone (II) can be converted into the corresponding 1,4-naphthoquinone derivative by the action of hydrochloric or sulfuric acid,[7] and still other examples could be cited from my work. Since isomers of this type are not infrequently interconvertible by acids it is not possible to deduce from the above recorded experiments whether dehydrolapachone is a derivative of α- or β-naphthoquinone. Neither does hydrolysis of the diacetyl derivatives in alkaline solution lead to any definite

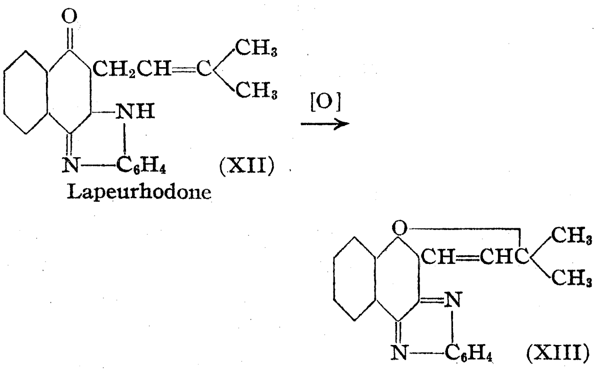
---

(11) Monti[6] states that when lapachol is treated with either concentrated sulfuric or hydrochloric acid in the cold β-lapachone is formed, while at higher temperatures α-lapachone is the product, it being entirely a matter of temperature and not of the acid used as was recorded by me.[5] Monti's statements are totally incorrect. On repeating the experiments with lapachol hydrochloric acid was found to give α-lapachone both at room temperature and at 55–60°, while with sulfuric acid β-lapachone was obtained at either 25 or 100°.

conclusion, as the side ring of compounds of the lapachone type is invariably more or less readily opened by alkalies, leading to the same hydroxynaphthoquinone derivative in both cases.[5]

Since Paternò has showed that dehydrolapachone can be reconverted into the diacetyl compound X from which it was obtained, it is clear that in the removal of the acetyl groups no fundamental change has occurred. This is further demonstrated by the ready conversion, described in the present paper, of dehydrolapachone into α-lapachone by hydrogenation. The following facts therefore would seem to furnish very strong arguments in favor of dehydrolapachone being an α-quinone derivative with the formula III: 1. The diacetyl derivative X can be again obtained from dehydrolapachone. 2. The derivative X can be readily converted by hydrogenation into the diacetyl compound VIII derived from α-lapachone. 3. Dehydrolapachone can be converted directly into α-lapachone (V).

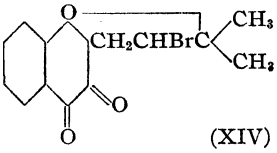
The evidence however is subject to some uncertainty because experiments can be advanced apparently proving almost equally satisfactorily that we are dealing with a derivative of β-napthoquinone. For instance dehydrolapachone gives with o-phenylenediamine in good yield an azine (XIII) which can be converted by hydrogenation into the azine of β-lapachone. Also, from lapachol and o-phenylenediamine a dark red compound with a metallic reflex can be obtained which has most probably the structure XII,[12] and this compound, which when treated with concentrated sulfuric acid yields the azine of β-lapachone, is converted into the azine of dehydrolapachone (XIII) by spontaneous oxidation when its ethereal solution is allowed to remain some days in contact with a moderately strong alkaline solution. The change is practically quantitative under proper conditions.



(XII) Lapeurhodone

(XIII) Dehydrolapazine

The formation of dehydrolapachone in small quantity in addition to dihydroxyhydrolapachol by the action of dilute sodium hydroxide solution on bromo-β-lapachone (XIV) has already been recorded.[5] At first sight this last method of formation also would seem to suggest the presence of the β-quinone group, but as the transformation occurred in alkaline solution it is probable that the side ring was opened and again closed on acidifying, but possibly in a different direction.



(XIV)
Bromo-β-lapachone

The several reactions by which dehydrolapachone itself or its derivatives have been obtained lead either to uncertain conclusions or to positively contradictory ones, and the question of whether the compound is an α- or a β-quinone must perhaps remain somewhat uncertain until the isomeric compound has been discovered. The very smooth conversion of dehydrolapachone directly into α-lapachone and also indirectly into the diacetyl derivative of α-lapachone, however, seem to outweigh its conversion into the azine of β-lapachone, as the yield of the intermediate azine of dehydrolapachone, notwithstanding that it is good, nevertheless falls materially below that obtained from other β-quinones in this group. This lower yield may perhaps be due to a preliminary and more or less imperfect change of the α- into the β-quinone before the azine formation occurs.

Perhaps slightly in favor of the α-group, but certainly not at all conclusively so, may also be mentioned the reduction potential determined by Fieser.[13] While this figure varies materially from that of more or less similar heterocyclic α-naphthoquinone substances examined, it falls on the whole better in line with the α-quinones than the β-quinones. The difference, however, is not convincing. The comparison was made by separately averaging the figures given by Fieser for α- and β-naphthoquinone derivatives containing an heterocyclic ring, omitting however the furan derivatives which vary considerably from the other.

It was formerly thought[5] that the orange-red color of dehydrolapachone distinctly favored its

---

[12] Hooker, *J. Chem. Soc.*, **63**, 1376 (1893).

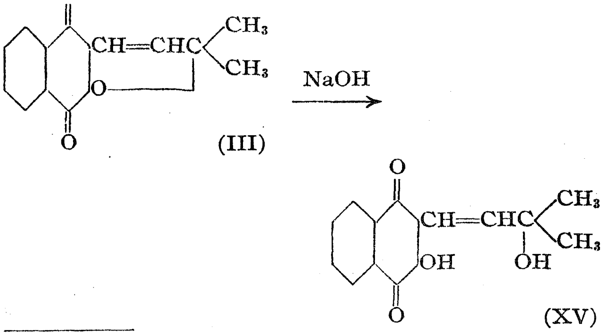
[13] Fieser, THIS JOURNAL, **50**, 450 (1928).

classification as a β-quinone, but in view of the recent recognition that hydroxy-α-naphthoquinone derivatives are usually red or orange-red when they contain a double bond in the α,β-position in the side chain,[14] as is the case with the compound in question, this argument is no longer valid. It would seem, therefore, that the most reliable evidence favors the α-quinone structure III for Paternò's compound and that all of the other observations are capable of being reconciled with this formula.[15]

In regard to the formation of the diacetyl derivatives from which dehydrolapachone is obtained, I am inclined to believe that the first step involved is the closing of the ring through oxidation, the quinone group itself acting as the oxidizing agent. There seems to be a pronounced tendency to form the six-membered ring[10] present in dehydrolapachone, and this can occur only by a shifting of the double bond. The actual mechanism involved must remain in doubt.

Lapachol itself on long standing appears to undergo a corresponding change by spontaneous oxidation and without help from the acetic anhydride. Crude lapachol which had been precipitated from an alkaline extract of Surinam greenheart in 1894 and kept in a wooden box was found after thirty years to be more or less covered with well-formed orange crystals of dehydrolapachone. The crude lapachol after drying had been broken up in moderate sized lumps, and it was in the cavities of these that the crystals had principally formed. In this case there is no positive proof that the dehydrolapachone was really produced directly from lapachol, as it may have had its origin in some other substance present in the crude material, or, as samples of pure lapachol have not been observed to undergo this change, it is also possible that the reaction may have been brought about through the agency of some impurity present. However, in view of the fact that oxidation also occurs in the compound obtained from lapachol and *o*-phenylenediamine (XII) when dissolved in ether and exposed to the air in contact with an alkaline solution, resulting in the azine of dehydrolapachone (XIII), it would seem likely that the orange crystals on the crude lapachol were really derived from lapachol itself.

In addition to this type of oxidation, it has been shown in another paper[16] that lapachol is converted by alkaline permanganate in the cold into 2 - β,β - dimethylvinyl - 3 - hydroxy - 1,4 - naphthoquinone (XVI, below), a compound having one less methylene group in the side chain. In the course of the present studies this same substance has been encountered as a product of the oxidation of dehydrolapachone by the air in alkaline solution. As mentioned above, it was found in the earlier work[5] that bromo-β-lapachone is converted by very dilute alkali in part into dehydrolapachone. In repeating the experiment it has now been found that with more concentrated alkali there is formed in place of dehydrolapachone a small amount of the orange-red compound resulting from the permanganate oxidation of lapachol. It seemed likely that dehydrolapachone is formed in all cases along with the main product, dihydroxyhydrolapachol, but that in the more strongly alkaline solution it undergoes further change and is converted by oxidation into the dimethylvinyl compound, and this was established by treating dehydrolapachone directly. When this substance is allowed to stand in contact with cold 10% sodium hydroxide it slowly dissolves to a dark red solution containing the salt of the acidic substance XV. The material which precipitates on acidification consists chiefly of the original substance III in an unchanged condition, but there is present a small percentage of the dimethylvinylhydroxynaphthoquinone XVI. When dehydrolapachone is treated with sodium hydroxide



(III)

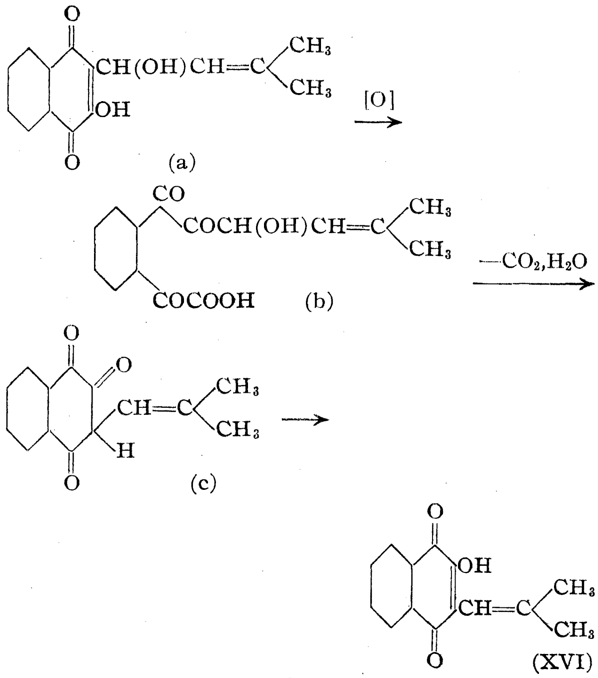
(XV)

---

[14] Hooker, THIS JOURNAL, 58, 1163 (1936).

[15] At Dr. Hooker's request in 1931 I tested dehydrolapachone for its ability to form an addition product with sodium bisulfite, a property characteristic of most, if not all, β-quinones. In recently repeated tests it was found that β-lapachone, bromo-β-lapachone and iso-β-lapachone dissolve easily in cold, saturated sodium bisulfite solution when the crystals are crushed to a powder. A colorless, crystalline addition product subsequently separates in each case, and when a dilute solution of the addition product is treated with sodium carbonate the original β-quinone is reprecipitated. Rennie's compound also dissolves in cold bisulfite solution but on adding soda a red solution is obtained, indicating hydrolysis of the side ring. Treated with bisulfite under similar conditions, dehydrolapachone remains undissolved after several hours. The observation supports Dr. Hooker's most recent conclusion (1934) that the substance "almost undoubtedly" is an α-quinone.—L. F. F.

[16] Hooker, THIS JOURNAL, 58, 1168 (1936).



in the presence of zinc dust, followed by air oxidation of the filtered solution, its conversion into XVI is completed within one hour and a yield of more than 80% can be obtained. The rapidity of the reaction may be due to the fact that the closed ring compound easily passes into solution in the form of the hydroquinone whereas it dissolves very slowly in the absence of the zinc dust.

In the course of this remarkable reaction the double bond migrates to a new position in the chain and a carbon atom is eliminated in the oxidation. In analogy with the recently described[10] conversion of lomatiol into isolomatiol, it appears possible that the migration of the double bond is due to an isomerization of the acidic substance XV to an intermediate of the structure (a). The remaining stages may be accomplished through the opening of the quinone ring (b) and its subsequent closing by oxidation (c), as in the formation of the final product (XVI) in the permanganate oxidation of lapachol.[16,17]

Experimental Part

Preparation of the Diacetyl Compounds X and XI from Lapachol.—A mixture of 40 g. of lapachol, 40 g. of anhydrous sodium acetate and 125 cc. of acetic anhydride was refluxed for fifteen minutes and the resulting green solution was poured into about 1 liter of water. A green oil separated and in the course of a few days it had solidified. After being thoroughly washed and dried, the crude material was fractionally crystallized from alcohol, using 5–6 cc. per gram and employing a liberal quantity of animal charcoal. Needles of Paternò's compound (X) separated first, followed by small crystalline balls of Shepard's compound (XI), the pure, colorless materials being obtained in the following amounts: 20 g. of X and 14 g. of XI. Paternò's compound melted at 131–132°, Shepard's at 128–129°. The first substance (X) dissolves in concentrated sulfuric acid to a light yellowish-green solution which immediately darkens to a deep green with a brownish tinge, while XI gives a garnet color on first contact with the acid and this changes to indigo, or to a very dark green, and finally becomes brown.

Anal. Calcd. for $C_{19}H_{18}O_5$: C, 69.93; H, 5.52. Found: (X) C, 69.55; H, 5.71; (XI) C, 69.74, 69.73; H, 5.53, 5.57.

Conversion of the Diacetyl Compounds X and XI into α- and β-Lapachone.—Monti[6] hydrogenated Paternò's diacetyl derivative (X) in the presence of palladium and found the product identical with the diacetyl compound VIII, which she prepared by the reductive acetylation of α-lapachone. In the present work Adams catalyst was used for the hydrogenation and the product, obtained in quantitative yield, melted at 169.8–170° and was fully identified by comparison with a sample of VIII prepared according to Monti. Shepard's compound (0.25 g.), XI, hydrogenated in alcoholic solution (35 cc.) using Adams catalyst (thirty minutes), gave colorless crystals (0.21 g.), m. p. at 162–162.6°, which did not depress the melting point of the diacetyl compound IX from β-lapachone prepared according to Monti.

The hydrolysis and oxidation of the saturated diacetyl derivatives VIII and IX was accomplished by dissolving 0.1 g. of the material in 8 cc. of glacial acetic acid, adding to the cooled solution 15 drops of a mixture of 1 cc. of sulfuric acid and 2 cc. of glacial acetic acid, and allowing the solution to stand in an open flask at room temperature for about ten days. On adding 25–60 cc. of water the product was precipitated as an emulsion which became crystalline on standing. The substance obtained from VIII, after recrystallization, melted at 117°, that from IX at 153.5–154°, and these compounds were found identical, by mixed melting point determinations, with α-lapachone and β-lapachone, respectively.

Conversion of the Diacetyl Compounds X and XI into Dehydrolapachone (III).—The hydrolysis and spontaneous oxidation of the unsaturated diacetyl compounds was studied under three sets of conditions, the first of which is the most satisfactory for preparative purposes.

(a) Sulfuric and Acetic Acids.—A solution of 2 g. of Shepard's compound (XI) in 25 cc. of warm glacial acetic acid was transferred to a flat dish so as to expose a large surface to the air and 5 cc. of a mixture of one volume of concentrated sulfuric acid with two volumes of water was added to the cooled solution. The solution was allowed to stand uncovered for five days, 40 cc. of glacial acetic acid being added to replace that which evaporated. A small amount of the starting material crystallized at first and later dissolved. Dehydrolapachone was slowly deposited and at the end of the period specified this was collected and purified by crystallization from 80% alcohol, giving 0.44 g. of orange prisms, m. p. 142.5–143°. An additional 0.13 g. of the product was obtained on diluting the acid liquor. The above crystallization of the

---

(17) Hooker, THIS JOURNAL, **58**, 1174 (1936).

crude material removed a dark brown, granular substance which is insoluble in alcohol and very sparingly soluble in glacial acetic acid. It appears to form a yellow azine with *o*-toluylenediamine.

Treated in the same way, 2 g. of Paternò's diacetyl derivative (X) gave 0.6 g. of dehydrolapachone and none of the brown by-product.

(b) **Aqueous Sodium Hydroxide.**—One gram of either X or XI was finely ground and boiled for about fifteen minutes with 200 cc. of 0.5% sodium hydroxide solution. The solution was filtered from an oily residue (0.23 g.) and on cooling it deposited a reddish oil which soon formed a resinous solid. This was dissolved in hot alcohol and on the addition of water dehydrolapachone was deposited as orange needles. The yields were poor.

(c) **Alcoholic Potassium Hydroxide.**—Ten grams of Shepard's compound (XI) was dissolved in 60 cc. of hot alcohol and the solution was cooled under the tap while 7 g. of solid potassium hydroxide was slowly added and dissolved. A current of air was drawn through the solution for fifteen minutes to ensure complete oxidation to the quinone and the alkali was neutralized with dilute hydrochloric acid (150 cc.). A red oil separated and after several hours it had partially crystallized. The material was removed and allowed to soak with 50 cc. of 1% alkali at room temperature for two days and the solution was poured off and replaced by a fresh portion. The crude residue (4.7 g.) was thoroughly washed with water and crystallized from alcohol, yielding 2.3 g. of pure dehydrolapachone. The combined alkaline extracts on acidification yielded a small amount of 2-β,β-dimethylvinyl-3-hydroxy-1,4-naphthoquinone, which formed orange needles, m. p. 119–120°, from alcohol.

The hydrolysis of Paternò's diacetyl compound (5 g.) by this method proceeded in much the same way, yielding 2.3 g. of crude dehydrolapachone. In the purification small amounts of a colorless and a yellow by-product were observed, but these were not investigated.

Reduction and Hydrogenation of Dehydrolapachone.—Paternò reported[3,4] the conversion of dehydrolapachone by reductive acetylation into the diacetyl derivative X from which he had obtained it, but since he was unaware of the existence of the isomeric compound of Shepard of essentially the same melting point it appeared advisable to repeat the experiment. On boiling for ten minutes a mixture of 0.25 g. of dehydrolapachone, 2.5 g. of zinc dust and 5 cc. of acetic anhydride and pouring the filtered, colorless solution into 30 cc. of water, there was obtained 0.33 g. of product which formed colorless needles, m. p. 130–130.5°, from alcohol. It was found by mixed melting point determination and by the color reaction with sulfuric acid to be identical with Paternò's diacetyl compound X, and there was no indication of the presence of Shepard's compound.

The hydrogenation of dehydrolapachone was conducted in alcoholic solution with Adams catalyst at room temperature for thirty minutes. The filtered solution after exposure to the air was concentrated and the product allowed to crystallize. The material, obtained in 73–80% yield, formed yellow needles, m. p. 117.5–118°, and it was identified as α-lapachone by direct comparison with a known sample. In one experiment the purified product melted at 124.5–125.5° but gave no depression when mixed with a known sample, m. p. 117°, the highest melting point recorded in the literature.

Reductive Acetylation of Isopropylfurano-1,2- and 1,4-naphthoquinone.—Since the isopropylfurano-naphthoquinones[7] such as II are isomeric with dehydrolapachone, they were converted into the diacetyl derivatives of their hydroquinones for comparison with the diacetyl compounds of Paternò and of Shepard. In each case 1 g. of the quinone was refluxed with 20 cc. of acetic anhydride and 10 g. of zinc dust for thirty minutes and the filtered solution was poured into 125 cc. of water. The product crystallized after a few hours and was obtained in each case in quantitative yield. Diacetyl isopropylfurano-1,4-naphthohydroquinone (a) formed colorless needles, m. p. 167–168° from alcohol. It also crystallizes well from glacial acetic acid or benzene. The solution in concentrated sulfuric acid is at first brown, then orange-red and finally a greenish precipitate forms as moisture is absorbed from the atmosphere. Diacetyl isopropylfurano-1,2-naphthohydroquinone (b) crystallizes from alcohol as colorless plates, m. p. 135.5–136.5°. In concentrated sulfuric acid it gives a greenish brown solution changing to dull red on exposure to the air.

Anal. Calcd. for $C_{19}H_{18}O_5$: C, 69.94; H, 5.52. Found. (a) C, 70.03; H, 5.49; (b) C, 69.34, 69.91; H, 5.37, 5.53:

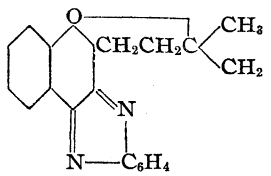
Dehydrolapazine (XIII).—A mixture of 2 g. of dehydrolapachone, 1.8 g. of *o*-phenylenediamine hydrochloride, 5.4 g. of crystalline sodium acetate and 40 cc. of glacial acetic acid was brought to the boiling point, the solution was filtered to remove salt, and allowed to cool. Dark, shield-shaped crystals of the reaction product separated and were collected after twenty-four hours and washed with alcohol and water and again with alcohol; yield 1.03 g. As examination of the mother liquor showed that it contained unchanged dehydrolapachone it was treated with more of the diamine, yielding an additional 0.4 g. of the azine. The product was purified by crystallization from alcohol and was obtained as brownish yellow scales, m. p. 156.5–157°. The substance imparts to concentrated sulfuric acid a green color which changes to cerise on slight dilution. Its ethereal solution has a strong green fluorescence.

Anal. Calcd. for $C_{21}H_{16}ON_2$: C, 80.76; H, 5.12; N, 8.97. Found (Hooker): C, 80.73; H, 5.43; N, 8.98.

Lapeurhodone (XII).—This was prepared from lapachol (20 g.) by essentially the method described above except that less solvent was employed (200 cc.) and the mixture was heated for two hours on the steam-bath. To this was then added 100 cc. of hot water and on cooling the solution deposited dark prisms of the reaction product. The collected material was washed successively with 50% acetic acid, with water, with 150 cc. of cold 1% alkali to remove unchanged lapachol and with water. The yield was 25.6 g. (97%). The substance crystallized from alcohol in the form of small, diamond-shaped scales with a metallic dark green reflex, m. p. 161.5–162.5°. From acetic acid it crystallizes both in the above form and as wooly, dark magenta colored needles. Cold 1% alkali dissolves the diamond-shaped crystals slowly and the needles more rapidly, giving a bright crimson colored solution. The solution in concentrated sulfuric acid is bright green, and water precipitates orange crystals of the sulfate.

Anal. Calcd. for $C_{21}H_{18}ON_2$: C, 80.25; H, 5.73; N, 8.91. Found (Hooker): C, 79.86; H, 5.80; N, 9.09.

Lapazine.—



The azine was prepared by each of the following methods and the samples were all compared and found to be identical.

(a) **From β-Lapachone.**—A mixture of 5 g. of the quinone, 13 g. of crystalline sodium acetate, 5 g. of *o*-phenylenediamine hydrochloride and 90 cc. of glacial acetic acid was heated on the steam-bath for two hours and the red-brown solution was diluted with water and allowed to stand overnight, the resulting oil slowly crystallizing during this time. The yellow globular masses of micro scales were washed with 50% acetic acid and with water; yield, quantitative. Crystallized from alcohol, lapazine was obtained either as yellow scales melting at 130.5–131.5°, or as yellow needles which melt at 121.5–122.5° to a clear liquid which then becomes opaque as the temperature rises and finally clears again at 130.5–131.5°. Either variety can be obtained by merely dissolving the crystals in hot alcohol and seeding with the type desired. No difference could be detected in the action of concentrated sulfuric acid on the two varieties, both dissolving to a deep green solution which became orange on slight dilution.

Anal. Calcd. for $C_{21}H_{18}ON_2$: N, 8.91. Found: N, 8.94.

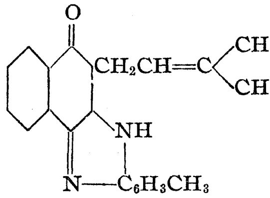
(b) **From Lapeurhodone (XII).**—A solution of 0.1 g. of lapeurhodone in 5 cc. of cold concentrated sulfuric acid was allowed to stand at room temperature for ten minutes and poured into 100 cc. of cold water. A brownish-red, flocculent precipitate formed and on being washed with water it became more crystalline and changed to a yellow color. The yield of lapazine was quantitative.

(c) **From Dehydrolapazine (XIII).**—Dehydrolapazine (0.05 g.) was hydrogenated in alcoholic solution (35 cc.) with Adams catalyst (forty-five minutes) and the filtered solution after exposure to the air was concentrated to a volume of 10 cc. The product, identified as lapazine, was deposited as extremely fine yellow needles mixed with yellow scales, the two forms having the properties recorded above.

Oxidation of Lapeurhodone (XII) to Dehydrolapazine (XIII).—A solution of 5 g. of lapeurhodone in 600 cc. of ether was transferred to a separatory funnel containing 250 cc. of 5% sodium hydroxide. The funnel was plugged with cotton and the mixture let stand at room temperature for eight days. The aqueous layer at the outset gradually turned red in color due to the presence of dissolved lapeurhodone. At the end of the period both layers had become lighter in color, the ether layer developing a strong green fluorescence and depositing some yellow crystals. The aqueous layer was discarded and the ethereal solution on evaporation yielded 3.4 g. of dehydrolapazine. The substance crystallized from alcohol in the form of brownish-yellow scales melting at 156.5–157°. It gave no depression when mixed with the azine from Paternò's dehydrolapachone and gave the same color reactions.

The above change also occurred when a solution of 0.1 g. of lapeurhodone in 20 cc. of 1% sodium hydroxide solution was refluxed for about twenty-four hours, the dehydrolapazine depositing from the alkaline solution as a yellow oil which solidified on cooling. The yield was good but the product was less satisfactory than that obtained by the other method.

Oxidation of Methyllapeurhodone.—Six grams of methyllapeurhodone (from lapachol and *o*-toluylenediamine)[12] was dissolved in 500 cc. of ether, 500 cc. of 5%



sodium hydroxide solution was added and the mixture was allowed to stand in a loosely stoppered flask for two days. Evaporation of the ether layer yielded 4.5 g. of a mixture of yellow needles and yellow scales. The two substances, which appear to be isomers differing in the location of the methyl group, were separated by fractional crystallization from alcohol, the needle-form separating first. The needles melted at 149–151.5°, the scales at 169.5–171.5°. Both substances give a green solution in concentrated sulfuric acid, the solution becoming carmine on dilution and depositing red needles of a salt.

Anal. Calcd. for $C_{22}H_{18}ON_2$: C, 80.98; H, 5.52; N, 8.59. Found: (needles) C, 80.74; H, 5.45; N, 8.55; (scales) C, 81.12; H, 5.60; N, 8.56.

By condensing dehydrolapachone with *o*-toluylenediamine in the usual way and fractionally crystallizing the product from alcohol, two methyldehydrolapazines were obtained having properties identical with those of the compounds described above and giving no depression in melting point when mixed with these substances.

Action of Sodium Hydroxide on Bromo-β-lapachone (XIV). (a) **1% Alkali.**—Finely ground bromo-β-lapachone was allowed to stand at room temperature with 1% sodium hydroxide solution for ten days and the crimson colored solution was filtered from unattacked material and acidified. Orange-yellow crystals of dihydroxyhydrolapachol,[5] m. p. 184–185°, were deposited, and the aqueous mother liquor slowly yielded an additional crop of crystals which were found to consist chiefly of dihydroxyhydrolapachol and an extremely small amount of material insoluble in cold dilute alkali and identified as dehydrolapachone.

(b) **5% Alkali.**—Treated as above, but with stronger alkali, the substance was attacked more rapidly. After one week the alkaline solution was filtered from unchanged material and acidified. The crystalline product consisted of a mixture of dihydroxyhydrolapachol (60–65% by weight) and the lapachol oxidation product XVI (5% by weight), m. p. 119–120°. A separation was accomplished by reprecipitation from an alkaline solution, the oxidation product separating rapidly while dihydroxyhydrolapachol is deposited slowly.

Conversion of Dehydrolapachone (III) into 2-β,β-Dimethylvinyl-3-hydroxy-1,4-naphthoquinone (XVI). — (a) Finely ground dehydrolapachone was allowed to stand in contact with 10% sodium hydroxide solution at room temperature and after one day the alkaline solution was filtered from unattacked material and acidified. The precipitate consisted largely of dehydrolapachone, but a small amount of an acidic substance was isolated by soaking the crude material with dilute alkali, which leaves the dehydrolapachone largely, if not entirely, undissolved, and reprecipitating with acid. The dimethylvinyl compound XVI was identified by melting point (119 – 120°), mixed melting point, and by its reaction with concentrated sulfuric acid.

(b) Ten grams of dehydrolapachone was ground to a paste with 200 cc. of water, this was treated with a solution of 50 g. of sodium hydroxide in 300 cc. of water, 50 g. of zinc dust was added and the container was stoppered and shaken at intervals. The substance dissolved within a few minutes owing to its rapid conversion to the hydroquinone, as indicated by the change in the color of the solution from crimson to yellow. After one hour the mixture was poured into 2.5 liters of water, the color changing at once to red and the dilute alkaline solution was filtered to remove the zinc. Air was drawn through the solution for a few minutes to ensure complete oxidation and the solution was then acidified by pouring it into dilute hydrochloric acid (a better product was obtained than when the acid was added to the alkaline solution). The crude material contained some unchanged dehydrolapachone, but this was largely left as a residue on extracting the product with 700 cc. of 0.5% alkali and filtering immediately. On acidification the reddish-purple filtrate yielded 6.7 g. of 2-β,β-dimethylvinyl-3-hydroxy-1,4-naphthoquinone in the form of red prismatic needles. Extraction of the mother liquor gave 1.3 g. more of the material. The purified product melted at 119–120° and was identical with that obtained by the permanganate oxidation of lapachol.

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.26. Found: C, 73.49; H, 5.54.

Action of Acetic Anhydride and Sodium Acetate on 2-Allyl-3-hydroxy-1,4-naphthoquinone.—It was observed by Fieser[18] that the allyl compound behaves in the acetylation reaction like lapachol, and he reported the isolation of a substance of m. p. 220–221°, dec., analogous to Paternò's diacetyl compound X. A further investigation of the reaction was undertaken with Dr. Steyermark in the hope of obtaining the parent quinone of which dehydrolapachone (III) is the dimethyl derivative, but the work was not completed. A second isomer, probably corresponding to Shepard's compound XI, was isolated from the reaction mixture by fractional crystallization from alcohol. From 1 g. of the allyl compound there was obtained 0.5 g. of Fieser's diacetyl compound, which after recrystallization melted at 223.5–224.5°, dec., and 0.4 g. of the new compound. The latter formed feather-shaped needles, m. p. 178.5–179.5°.

Anal. Calcd. for $C_{17}H_{14}O_5$: C, 68.43; H, 4.73. Found: C, 68.71; H, 4.70.

Fieser's compound on acid hydrolysis and exposure to the air gave a red quinone resembling dehydrolapachone, but the substance was not fully characterized.

Summary

It is shown in this paper that Paternò's "isolapachone" is in reality a dehydro derivative of α-lapachone in which the double bond occupies the α,β-position in the chain. Under certain conditions lapachol (a) or its derivatives can be transformed both directly and indirectly into Paternò's compound (b), or the corresponding derivatives of this substance. The actual mechanism of the change is still in doubt. Conditions also have been defined under which dehydro-α-lapachone (b) can be transformed by air oxidation in the presence of alkali into a substance (c) previously obtained by the oxidation of lapachol with alkaline potassium permanganate.

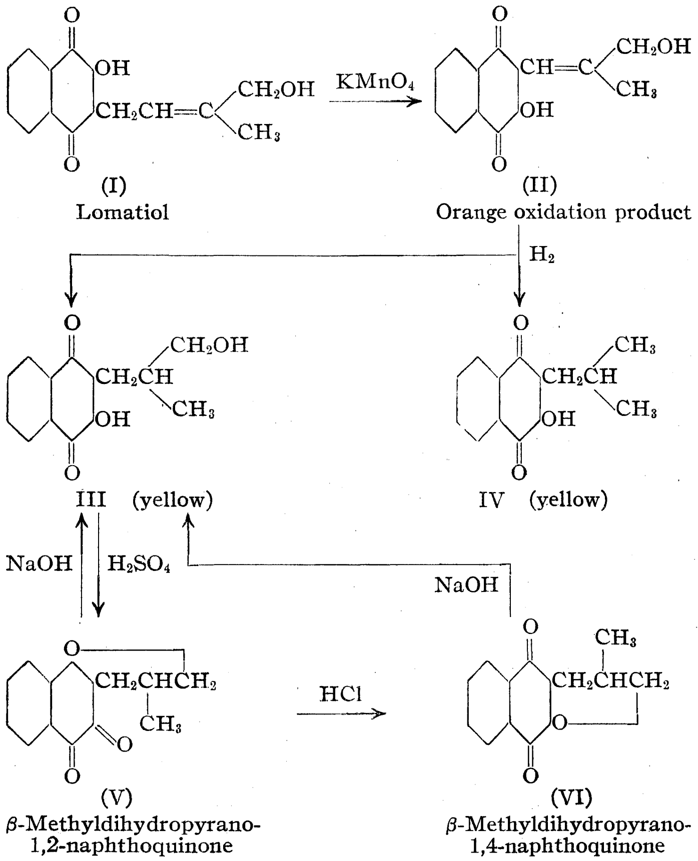
Lomatiol. Part III. Oxidation with Alkaline Potassium Permanganate[1,2]

BY SAMUEL C. HOOKER AND AL STEYERMARK

In a previous paper[3] evidence was presented indicating that lomatiol has the constitution represented by formula I, and it was reported that on oxidation with alkaline potassium permanganate the yellow substance yields an orange compound of the formula II, a change of the type observed[4] in the case of lapachol and related hydroxynaphthoquinone derivatives. The present paper includes a full account of the reaction and a description of a second substance which is formed in small amounts in the course of the oxidation.



The structure of the orange compound (II) is established by the following observations. On hydrogenation two substances are formed concurrently, one by the saturation of the double bond in the side chain (III), the other by the simultaneous replacement of hydroxyl by hydrogen and the addition of hydrogen to the double bond (IV). As such a reaction is characteristic of an allylic system, the original hydroxyl group must occupy a position adjacent to the double bond. The compound in which the hydroxyl has been removed from the side chain was found to be identical with a quinone previously described[4a] and known to have the structure of IV, and consequently the allylic system must be arranged either in the manner indicated in II or with the hydroxyl group in the α-position and the double bond at the end of the chain. A choice between the two possibilities is easily made, for it can be inferred from other observations[5] that if the latter structure were correct the alcoholic hydrogenation product (III) would readily lose water to form a substance with an unsaturated side chain. Instead it is converted by sulfuric acid into an orange closed-ring compound (V) very similar in properties to β-lapachone. That this is a β-quinone is shown by its ability to form an azine and by its conversion by means of hydrochloric acid into a yellow α-quinone, VI. Consequently the hydroxyl group must be at the end of the chain in the saturated alcohol III and in the oxidation product (II) itself.

The observations thus lend further support to the structure assigned to lomatiol and the oxidation is shown to proceed, as in the examples already studied, by the removal of CH_2 from the position adjacent to the quinone group. The change is all the more remarkable because both the primary alcoholic group and the double bond remain unattacked. Comparing the orange oxidation product II with the compounds which it yields on hydrogenation (III and IV) and with lomatiol, all of which are yellow, it is seen that

(2) The orange oxidation product from lomatiol and the interesting red closed ring compound obtained from it were isolated by Dr. Hooker as early as 1917, but as the nature of the oxidation was not at the time understood the matter was dropped for the time being. After the course of the reaction of lapachol with alkaline permanganate had been established, work on the present problem was later resumed in conjunction with Dr. Steyermark. Dr. Hooker wrote no manuscript describing the investigation and the paper has been constructed from his notes and from the notes and reports of his assistant.—L. F. FIESER.

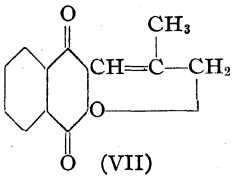
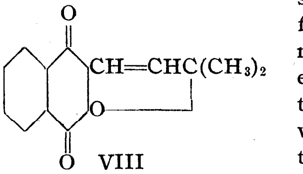
the presence of a double bond in II in the α,β-position of the chain could be safely inferred from the orange color.

The orange compound II easily loses a molecule of water under various conditions, for example when it is gently heated, or when the aqueous solution is boiled. The anhydride, which forms dark red needles, has been recognized as a para quinone of the structure VII by its conversion on hydrogenation into the yellow α-quinone VI.



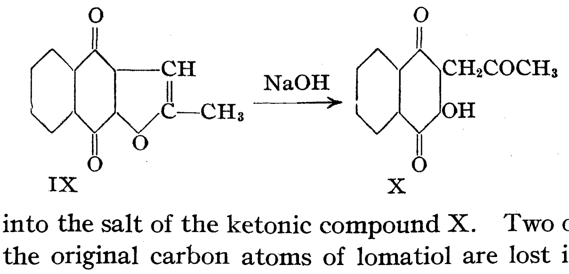
(VII)
β-Methylpyrano-1,4-naphthoquinone



VIII
Dehydrolapachone

The compound has the type of unsaturated, six-membered ring characteristic of Paternò's dehydrolapachone,[6] VIII, and it closely resembles this substance in its red color, which no doubt is due to the conjugation of the double bond with the quinone ring, in its behavior when treated with sulfuric acid, and its ready formation from the open chain compound. The substance has been found to undergo a number of additional changes, which will be described in a later paper.

As in the oxidation of other quinones having unsaturated side chains,[4a,c] the action of alkaline potassium permanganate is not limited to a single reaction and the quantity of the orange compound II produced amounts to no more than about one-third of the lomatiol used. As another product of oxidation there was isolated a small quantity of a yellow substance which was fully identified, by direct comparison with a sample prepared by a method which will be described in a later paper, as β-methylfurano-1,4-naphthoquinone, IX. On treatment with alkali the substance is converted



IX X

into the salt of the ketonic compound X. Two of the original carbon atoms of lomatiol are lost in the formation of this oxidation product, one probably being that next to the quinone ring and the other the carbon atom carrying the hydroxyl group at the end of the chain. The course of the reaction is not known.

Experimental Part[7]

Orange Oxidation Product, II (2-β-Methyl-γ-hydroxy-α-propenyl-3-hydroxy-1,4-naphthoquinone).—Four grams of lomatiol was dissolved in 400 cc. of 1% sodium hydroxide solution and this was cooled in ice water and treated quickly with a similarly cooled solution of 4 g. of potassium permanganate in 400 cc. of water. The solution turned green, then brown, and the manganese dioxide had largely separated within a minute or two. The solution was filtered at once from the precipitate and very carefully neutralized with dilute hydrochloric acid, avoiding an excess as this promotes the conversion of the material into the red anhydride (VII). The resulting orange solution was transferred to four flat dishes and evaporated at room temperature with the aid of electric fans to a volume of 45–140 cc. (four and one-half hours to five and one-half hours). By this time a considerable amount of crystalline, orange material had separated and this was collected and washed with a small volume of cold water. A small quantity of the red anhydride can be obtained by boiling the mother liquor.

The crude product (1.2–1.4 g.) was contaminated with a small amount of the red anhydride, but it was easily separated from this material by extraction with cold 1% sodium carbonate solution (33 cc. per g.), which does not attack the red compound on short contact. The orange material reprecipitated from the soda solution was crystalline and nearly pure (recovery, 86%). The substance separates from benzene or from benzene–ligroin as orange, crystalline masses, while from petroleum ether it forms woolly orange needles. It has no true melting point for it is rapidly converted into the red anhydride on being heated. Loss of water also occurs on boiling the aqueous solution for a few minutes or treating the compound with sulfuric or hydrochloric acid at room temperature. The change occurs on prolonged boiling of the solution in alcohol, in which the orange compound is very soluble, and even in the solid state the hydroxy compound undergoes slow, spontaneous cyclization.

Anal. Calcd. for $C_{14}H_{12}O_4$: C, 68.82; H, 4.96. Found: C, 68.79; H, 5.37.

The Red Anhydride, VII (β-Methylpyrano-1,4-naphthoquinone).—For the preparation of this substance in quantity it is convenient to effect the dehydration of the oxidation product II directly in the reaction mixture, rather than to first isolate it. In a typical experiment 10 g. of lomatiol was oxidized exactly as described above and the filtered alkaline solution was neutralized with dilute (1:3) hydrochloric acid and treated with an additional 50 cc. of the dilute acid. The orange solution was boiled gently for twenty minutes, avoiding any appreciable decrease in the volume, as the product is then contaminated with other substances. During this time the solution became red and crystals of the red anhydride were deposited from the hot solution. After cooling to room temperature, the product was collected and washed with water; yield 3 g. The crude material usually contains a small amount (2–3%)

---

(6) Hooker, THIS JOURNAL, **58**, 1190 (1936).

(7) Analyses by Dr. D. Price, Columbia University.

of the second oxidation product, β-methylfurano-1,4-naphthoquinone, IX, which was recognized in separate experiments by its greater resistance to alkaline hydrolysis. The substance is eliminated in the course of the crystallization.

The anhydride VII is sparingly soluble in alcohol and crystallizes from this solvent as fiery red, prismatic needles melting at 196.5–197.5°. It dissolves readily in benzene or glacial acetic acid and is very sparingly soluble in water, from which it is deposited as very fine, bright red needles.

Anal. Calcd. for $C_{14}H_{10}O_3$: C, 74.30; H, 4.45. Found: C, 73.93; H, 4.45.

Very characteristic of the red anhydride, as well as of Paternò's dehydrolapachone, is the following color reaction. The compound dissolves in concentrated sulfuric acid to give a clear, deep green solution and if this is exposed on a watch glass it gradually absorbs moisture from the atmosphere, acquires a plum pink color, and finally deposits the unchanged substance in the form of red needles, sometimes curved, leaving the solution colorless. The same changes are noted with Paternò's compound.

Heated for six hours with *o*-phenylenediamine in glacial acetic acid solution, the red anhydride was in part resinified and in part recovered unchanged. There was no evidence of azine formation.[8]

β-Methyldihydropyrano-1,4-naphthoquinone (VI).—A suspension of 4 g. of the red anhydride (VII) in 200 cc. of alcohol was agitated with hydrogen at 40 lb. (2.66 atm.) pressure in the presence of Adams catalyst. The red compound soon went into solution in the form of the hydroquinone and this gradually added hydrogen to the double bond. The course of the reaction was followed by removing a drop of the solution, allowing it to evaporate and oxidize on a watch glass, and adding a drop of concentrated sulfuric acid. The starting material gives a green color with the acid while the dihydro derivative gives a red color. The hydrogenation was found to be complete in forty-five minutes. After filtering and allowing time for oxidation, a part of the reaction product crystallized from the solution and further crops were obtained after concentration of the mother liquor; yield, 3.8 g. The product was purified by crystallization from alcohol, using animal charcoal, and it was obtained as bright yellow, elongated plates, m. p. 170.5–171°.

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.65; H, 5.30. Found: C, 73.74; H, 5.74.

The red solution of the quinone in concentrated sulfuric acid on exposure to the air deposits long yellow needles of the unchanged compound on absorption of moisture. The action of boiling alkali on the substance and its formation from the isomeric ortho quinone are described below.

2-γ-Hydroxyisobutyl-3-hydroxy-1,4-naphthoquinone (III).—This compound is most conveniently prepared by the saponification of the dihydropyrano-*p*-quinone VI, described immediately above. This material (2.9 g.) was finely ground and boiled with 1% sodium hydroxide solution (400 cc.) for about ten minutes, when it had completely dissolved. The resulting crimson colored solution was carefully treated with dilute hydrochloric acid and left faintly alkaline, as in the presence of excess acid the product is readily dehydrated to the dihydropyrano-*o*-quinone V. The crude product which precipitated (2.8 g.) contained in addition to the desired acidic compound a small amount of a neutral, yellow substance not identical with the starting material. The two were easily separated by extraction with cold 1% alkali, the hydroxy quinone III being recovered from the filtered solution by careful neutralization; yield, 2.6 g. The substance crystallizes from benzene or from benzene–ligroin in the form of yellow needles, m. p. 147.5–148.5°. It is very soluble in alcohol, but crystallizes well from dilute alcohol as needles.

Anal. Calcd. for $C_{14}H_{14}O_4$: C, 68.26; H, 5.73. Found: C, 68.25; H, 5.99.

The compound was obtained by the action of alkali on the isomeric *o*-quinone V in exactly the same manner.

β-Methyldihydropyrano-1,2-naphthoquinone (V).—A solution of 1.6 g. of the hydroxyquinone III in 20 cc. of concentrated sulfuric acid was prepared at room temperature and after standing for forty-five minutes the red solution was poured into 100 cc. of water. The reaction product separated in the form of orange needles and in a very pure condition; yield 1.5 g. The product, purified by crystallization from alcohol, was obtained either as orange prismatic needles or as elongated orange plates, m. p. 148–148.5°.

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.65; H, 5.30. Found: C, 73.32; H, 5.37.

The compound is also formed when the hydroxyquinone III is allowed to stand for one to two days in contact with dilute hydrochloric acid. It is insoluble in cold dilute alkali, but on boiling it soon dissolves with opening of the oxide ring. The conversion of the substance into the isomeric para quinone VI was accomplished by heating a solution of 0.1 g. of the material in 3 cc. of concentrated hydrochloric acid at 55–65° for one and a half hours. The red solution on cooling deposited yellow needles (0.09 g.) of the para quinone in a very pure condition.

The azine of the ortho quinone V was prepared by heating a solution of the substance and *o*-phenylenediamine in glacial acetic acid at the boiling point for a few minutes. The yellow product separated in part from the boiling solution. Recrystallized from alcohol (fluorescent solution), it formed yellow needles, m. p. 160–161°. The solution in concentrated sulfuric acid is deep green and deposits an orange sulfate on dilution.

Anal. Calcd. for $C_{20}H_{16}ON_2$: C, 79.97; H, 5.37. Found: C, 80.11; H, 5.25.

Hydrogenation of the Orange Oxidation Product II.—The two compounds III and IV, which are formed simultaneously in the hydrogenation of the unsaturated alcohol II, are not both easily separated as such from the reaction mixture, but on treatment with acids the saturated alcohol III is converted into its ortho quinone anhydride and IV can then be removed from it by extraction with alkali. The following procedure gave satisfactory results. A solution of 0.2 g. of the oxidation product II in 4 cc. of alcohol was submitted to hydrogenation (Adams catalyst) for forty-five minutes and on filtering and concentrating the solution to a small volume a small crop (0.06 g.) of 2-iso-

---

[8] Similarly, the quinone does not dissolve in cold sodium bisulfite solution.—L. F. F.

butyl-3-hydroxy-1,4-naphthoquinone (IV) was deposited. After allowing the mother liquor to evaporate to dryness the residue was dissolved in 0.25% alkali and the solution was filtered from a small amount of resin and acidified with dilute (1:3) hydrochloric acid, adding 5 cc. excess. The crystalline yellow precipitate, consisting of a mixture of the two products of hydrogenation, was allowed to stand in contact with the acid liquor for two days, during which time the alcohol III was converted into its ortho quinone anhydride. The collected material was then shaken with cold 0.25% alkali for one to two minutes and the solution was quickly filtered from unchanged orange needles of V (0.03 g.) and acidified, giving 0.04 g. of the yellow isobutyl compound IV. After recrystallization the orange substance melted at 148–148.5° and the yellow one at 132.5–133.5°. Identifications with known samples were made by mixed melting point determinations and by microscopic examination of the character of the precipitates resulting on the acidification of the solutions in alkali.

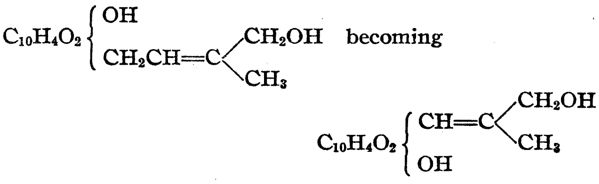
The Second Oxidation Product, IX (β-Methylfurano-1,4-naphthoquinone).—This compound is produced only in small quantities in the oxidation of lomatiol, but by the following procedure it is possible to free the substance from other products of the reaction and to obtain it in a very pure condition. The new compound was isolated from the acid mother liquor remaining from the oxidation of 10 g. of lomatiol, after removing the orange product in the form of its red anhydride as described above for the preparation of the latter substance. The acid filtrate was boiled down to a volume of about one liter and allowed to cool to room temperature, when about 0.6 g. of crude material was deposited. This contained, in addition to the new compound, some material easily soluble in alkali and some of the red anhydride, VII. It was first ground with 40 cc. of cold 0.25% alkali, and after standing for three hours the undissolved material was collected and boiled for about three minutes with 20 cc. of 1% alkali. This treatment left the new compound largely unattacked, but a small amount of the red anhydride also escaped the action of the alkali, and the orange residue (0.2 g.) was still impure. In order to remove the red anhydride, the crude product was submitted to hydrogenation in alcoholic solution, it having been established that the new compound is converted only into its hydroquinone under these conditions. This procedure removed the red color due to anhydride (VII), for the latter was converted into its yellow dihydro derivative VI, which is more soluble in alcohol and which can be removed by crystallization. After agitation with hydrogen the filtered alcoholic solution was exposed to the air and on standing it slowly deposited yellow needles of the purified product (IX). On further crystallization the substance was obtained as yellow needles or prisms, m. p. 246–247°.

Anal. Calcd. for $C_{13}H_8O_3$: C, 73.58; H, 3.57. Found: C, 73.75; H, 3.73.

The substance did not depress the melting point of a sample prepared by a method which will be described in a forthcoming paper. Both samples were converted into the same acidic substance X (m. p. 176.5–177.5°) by boiling sodium hydroxide solution.

Summary

The oxidation of lomatiol with alkaline potassium permanganate proceeds exactly as in the case of other examples studied in this Laboratory:



There is formed in addition a very small amount of a substance having one less carbon atom, but although the structure of the compound has been established the manner in which it is formed is still obscure. The principal product of the oxidation yields two substances simultaneously on hydrogenation, and it gives rise to an interesting red ring compound which has been recognized as an α-quinone of a type analogous to Paternò's dehydrolapachone.

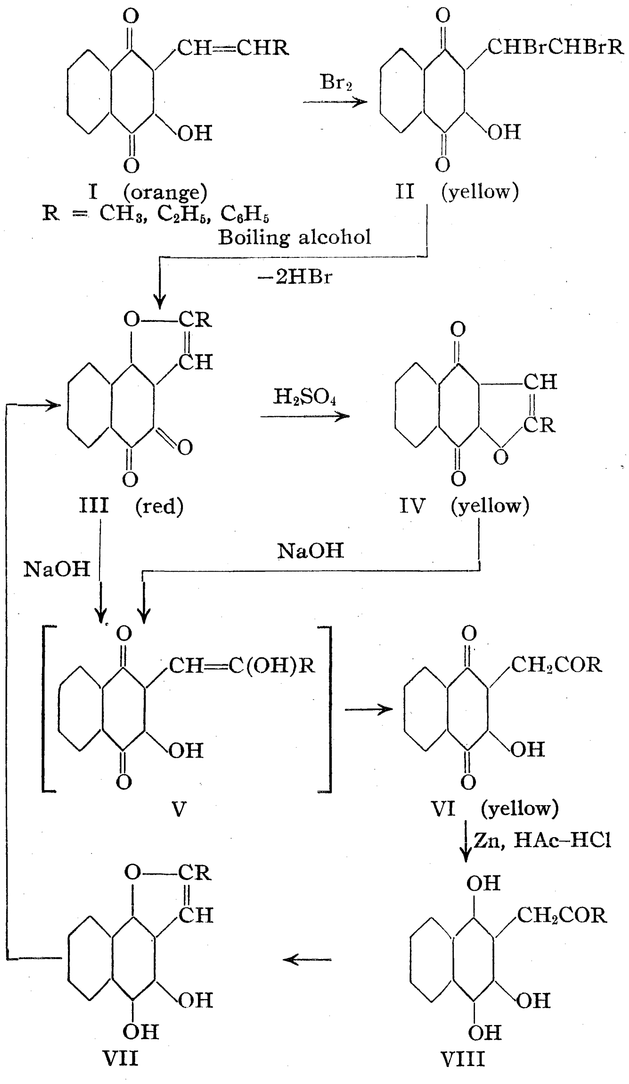
Conversion of Ortho into Para, and of Para into Ortho Quinone Derivatives. Part IV.[1] Synthesis of Furan Derivatives of α- and β-Naphthoquinones[2,3]

By Samuel C. Hooker and Al Steyermark

The ready conversion of isolapachol into isopropylfurano-1,4- and 1,2-naphthoquinone was described many years ago in connection with experiments on the structure of lapachol,[4] and the belief was then expressed that the reaction would prove to be a general one. This is abundantly substantiated by the experiments recorded in this paper. The accompanying table shows graphically the formation of the furan derivatives and some of the important reactions studied involving changes from para to ortho quinones and *vice versa*. In some instances the changes take place practically quantitatively, in others modifications occur with the formation of additional substances, but in general the table records the reactions common to the substances examined.



The parent compound of this group of furanonaphthoquinones, IX, was first obtained by Scholl and Zincke[5] from X by a series of changes following the formation of X by alkaline ferricyanide oxidation of alizarin. The furan compound was described as crystallizing in red needles, but in spite of this very characteristic property of ortho naphthoquinones of this type, to which attention has been called repeatedly in former papers,[1a,1b,6] Scholl and Zincke preferred to assign to their compound the formula XI which would be yellow. We shall show that they erred in this respect and that the substance is not a para quinone. In dealing with this subject of quinone change, it may again be emphasized that many compounds are now known of the general formulas XII, XIII and XIV, and that in the course of minor chemical changes of naphthoquinone derivatives *of this type* whenever a red compound passes into a yellow one or *vice versa* it may almost be taken for granted that a change corresponding to this change of color has occurred in the quinone groups.

Errors in the chemical literature have already been corrected[1a,b] where this change in color has been disregarded. There are, however, some known exceptions to the general rule, the causes of which have been fully discussed and explained in recent papers.[7] For instance, in compounds of the type I we have one of these exceptions. These substances, which served as the starting materials for the present syntheses,

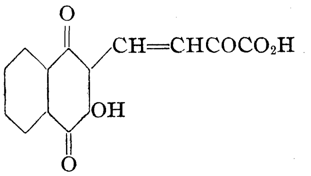
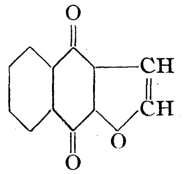
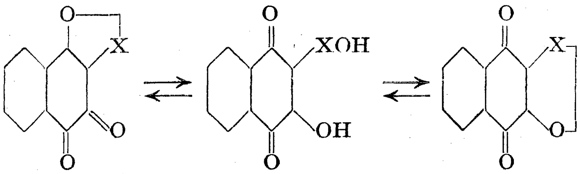
IX



X



XI



(XII) Red or deep orange (XIII) Yellow (XIV) Yellow

were prepared for the most part by the condensation of aldehydes with hydroxynaphthoquinone.[7a] The simplest member of the series, 2-vinyl-3-hydroxy-1,4-naphthoquinone, has not been obtained by this method, possibly because of its unusually sensitive nature, but it has been prepared by the oxidation of the allyl compound.[7d] The compounds in question (I) are not yellow as the para naphthoquinone grouping ordinarily requires, but are deeply colored, usually orange or brick red. This is due to the presence of a double bond in the α,β-position of the side chain. They add bromine readily in chloroform solution forming compounds of the general formula II which with the elimination of the double bond become *yellow*.

The bromine addition compounds (II) are comparatively unstable, being readily converted into furano-1,2-naphthoquinone derivatives, III, which are red. This change takes place gradually with loss of hydrogen bromide even in the dry, purified substances. The bromine compounds can be purified by crystallization from benzene or chloroform but even at ordinary temperatures there is usually slight decomposition. Solution in alcohol containing small amounts of water, sometimes even in the cold, brings about almost quantitative conversion into the corresponding deep red III, due to the passage of the para quinone group of the yellow dibromide into the ortho quinone group of the furan derivative.

In the case of the methyl, ethyl and phenyl derivatives, the red ortho quinones (III) can be isomerized to the yellow para quinones (IV) by the action of sulfuric acid. By boiling the quinones of either type with alkali the furan ring is opened and the same acidic substance is obtained from the two isomers III and IV. Since the resulting compound invariably is *yellow*, the structure must be that of VI, for the unsaturated compound of formula V would be orange or red. The ketonic compounds of the type VI on direct cyclization give mixtures of the ortho and para quinones, but after reduction to the hydroquinones (VIII) ring closure occurs selectively in a single direction and on oxidation the ortho quinones (III) can be obtained in a pure condition.

While the methyl and ethyl substituted compounds of the type IV are pure yellow in color and stand in marked contrast to the corresponding red quinones (III) of the ortho series, β-phenylfurano-1,4-naphthoquinone can be obtained both as golden yellow plates and as bright red needles. The red form is the less stable modification and changes into the yellow form when heated. Although it is unusual that a para quinone of this type should exist in any but a yellow condition, even as a metastable form, there is still a considerable contrast between the bright red color of this modification and the dark, purplish-red of the ortho isomer. The latter substance combines with *o*-phenylenediamine to form an azine, and the same characteristic property of an ortho quinone is shared by the methyl and ethyl derivatives, which from their red color alone would be regarded as ortho quinones.

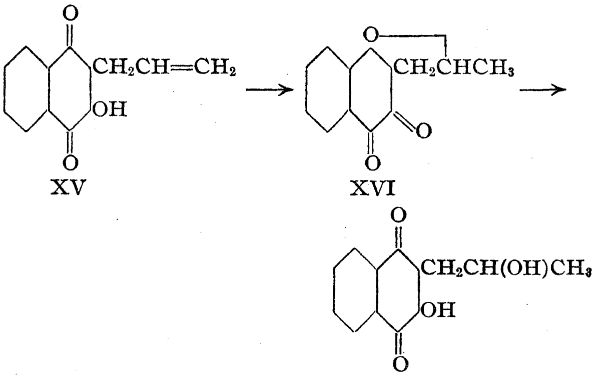
The preparation and characterization of the parent quinone of the furan group presented some difficulties, probably because the general instability of the vinyl derivative of hydroxynaphthoquinone is shared by the other open-chain compounds resulting from it. Only one of the two possible furanonaphthoquinones was isolated, namely, a deep red compound corresponding to the description of Scholl and Zincke. From its color and from the fact that it was obtained by the general method which in other cases leads to the formation of ortho quinones, it can be inferred that the substance is an ortho quinone of the formula IX, a conclusion which is convincingly established by the formation of a characteristic azine in good yield.[8] The quinone is unusually

---

[8] A further confirmation of the structure is that the substance dissolves in cold sodium bisulfite solution. The action is slower than in the case of the methyl and ethyl derivatives, as might be expected from the much higher melting point of the parent substance, but as with these compounds the quinone is precipitated unchanged on the addition of sodium carbonate.—L. F. F.

stable in concentrated sulfuric acid solution and, although some change occurs after the solution has stood for several weeks, no substance corresponding to a para quinone has been isolated. Attempts to open the furan ring by alkaline hydrolysis indicated that the aldehydic substance first formed undergoes further change in the course of the reaction.

The substituted furanonaphthoquinones of both the ortho and para series are converted by alkalies in good yield into the ketonic compounds of the formula VI. Although the properties of these substances have not been investigated extensively it has been found in one case that the carbonyl group of the side chain is easily reduced by hydrogen in the presence of platinum catalyst, and probably the reaction is a general one. The compound studied was 2-acetonyl-3-hydroxy-1,4-naphthoquinone (R = CH_3), and the alcoholic reduction product (XVII) proved to be identical with a substance obtained by Fieser[9] by cyclizing 2-allyl-3-hydroxy-1,4-naphthoquinone (XV) with sulfuric acid and opening the ring by treatment with alkali. The identity of the products verifies



the structures assumed by Fieser for XVI and XVII on the basis of the known rule of addition, and it is of interest that the rule holds for the allyl compound as well as for lapachol[4] although the former substance gives rise to the formation of a five-membered ring while with the latter a six-membered internal anhydride is produced.

Experimental Part[10]

Reaction of the Unsaturated Compounds (I) with Bromine

The bromine addition products were prepared by dissolving the unsaturated compound in chloroform (10–20 cc. per gram of material) at room temperature and either quickly treating this with, or adding it to, a solution of somewhat more than one equivalent of bromine in the same solvent (5 cc. per gram). The bromine was absorbed at once, following which the solvent was removed completely, except in the case of the less soluble phenyl compound, by distillation from a water-bath, avoiding unnecessary heating. The residual oil usually crystallized after standing for several hours, and this crude material was quite suitable for use in the next step in the synthesis. The substances were not all obtained in a completely pure condition.

In the case of 2-vinyl-3-hydroxy-1,4-naphthoquinone the chloroform solution of the crude material was filtered from some insoluble residue, cooled to 0°, and poured into the bromine solution. The crude reaction product was very unstable and it was converted at once into the furano-1,2-naphthoquinone. From 1 g. of the 2-α-propenyl compound and 0.65 g. of bromine there was obtained, after washing the crystalline reaction mass with 1 cc. of cold benzene to remove adhering resin, 1.5 g. of crude dibromo compound. It crystallized from benzene (5 cc. per gram) as yellow plates, m. p. 156–157°, dec., but the sample decomposed before an analysis could be made.

2 - α,β - Dibromo - *n* - butyl - 3 - hydroxy - 1,4 - naphthoquinone (II, R = C_2H_5) was prepared from 2 g. of the unsaturated compound and 1.3 g. of bromine. Recrystallized from 5 cc. of benzene, the substance formed yellow prisms, m. p. 133–134°; yield, 2.5 g.

Anal. Calcd. for $C_{14}H_{12}O_3Br_2$: C, 43.31; H, 3.11; Br, 41.19. Found: C, 43.60; H, 3.00; Br, 40.51.

2 - α,β - Dibromo - β - phenylethyl - 3 - hydroxy - 1,4 - naphthoquinone (II, R = C_6H_5).—A solution of 2 g. of 2-β-phenylvinyl-3-hydroxy-1,4-naphthoquinone in 25 cc. of chloroform was treated gradually at room temperature with 1.6 g. of bromine in 6 cc. of chloroform. After standing one to four days the solution deposited 1.1–1.4 g. of yellow prisms of the addition product, and after concentrating the mother liquor to one-half its volume an additional crop amounting to 0.3–0.4 g. was obtained. A second substance was obtained from the mother liquor as described below. The dibromide was crystallized from chloroform, taking care to avoid undue heating as this results in cyclization to the ortho quinone with the elimination of hydrogen bromide, and the compound was obtained as yellow prisms, m. p. 172.5–173.5°, dec.

Anal. Calcd. for $C_{18}H_{12}O_3Br_2$: C, 49.55; H, 2.78; Br, 36.66. Found: C, 49.84; H, 2.92; Br, 37.79, 35.99.

The substance is slowly attacked by concentrated sulfuric acid giving a bluish-green solution; hydrogen bromide is evolved and there is some sulfonation. Cold 1% alkali converts the compound into 2-benzoylmethyl-3-hydroxy-1,4-naphthoquinone, but this is contaminated with other products.

α - Bromo - β - phenyl - dihydrofurano - 1,2 - naphthoquinone was obtained from the mother liquor remaining after the removal of two crops of the dibromide as described above. The substance separated in admixture with some dibromide after further concentration of the chloroform solution. The dibromide was removed by immersion in cold 1% sodium hydroxide solution, and the undissolved material (0.3 g.) was crystallized from alcohol, in which

(10) Microanalyses by Dr. D. Price of Columbia University.

it is sparingly soluble. The compound first separates as voluminous red needles, which change, on standing in contact with the mother liquor, into dark red plates, m. p. 218–219°. It is readily soluble in benzene or chloroform, it forms an emerald-green solution in concentrated sulfuric acid, and on prolonged boiling with 1% sodium hydroxide it is converted into benzoylmethylhydroxynaphthoquinone, identified by melting point and mixed melting point determinations. During the latter process a part of the material is converted into a greenish-black, alkali-insoluble substance which is oxidized to the starting material by air when in a moist condition.

Anal. Calcd. for $C_{18}H_{11}O_3Br$: Br, 22.50. Found: Br, 22.48, 21.80.

Preparation and Properties of the Ortho Quinones (III)

Furano-1,2-naphthoquinone (IX).—The crude dibromide from 0.4 g. of 2-vinyl-3-hydroxy-1,4-naphthoquinone was dissolved in 25 cc. of cold alcohol and the solution was allowed to stand in the dark in a loosely stoppered flask for one to two months, during which time the solution had evaporated to a volume of about 8 cc. and dark red masses of the reaction product had been deposited. After being washed well with alcohol and dried, the crude material (0.17 g.) was crystallized from alcohol, giving 0.08 g. of product melting at 207°. After two more recrystallizations it was obtained as deep red needles, m. p. 209.5–210°. There was no depression in the melting point when the substance was mixed with a sample prepared by the method of Scholl and Zincke,[5] and both samples gave the identical azine and showed the same behavior in the following test: the solution in concentrated sulfuric acid is blackish-green; on the absorption of moisture from the atmosphere it becomes blue, then purple and finally red needles of the unchanged material are deposited. The substance is more stable in sulfuric acid solution than its homologs, and although some change occurs after the solution has stood for several weeks, a pure transformation product has not been isolated. No change occurred when a solution of the compound in glacial acetic acid was treated with a few drops of concentrated sulfuric acid and boiled for several hours.

The above method of preparation gave better yields than more rapid processes. Thus on boiling the same amount of dibromide with 50 cc. of water for five minutes, filtering the hot solution from resinous material and allowing it to cool, there was deposited 0.015 g. of the quinone, m. p. 206°. The yield was about the same when the dibromide was allowed to stand in contact with water for ten days at room temperature.

β-Methylfurano-1,2-naphthoquinone (III, R = CH_3) was prepared by refluxing for one-half hour a solution of 1.4 g. of the dibromopropyl derivative in 25 cc. of alcohol. The solution became deep red and on cooling deposited 0.5 g. of red needles of the reaction product. Recrystallized from alcohol the substance formed small red needles melting at 164–164.5°.

Anal. Calcd. for $C_{13}H_8O_3$: C, 73.58; H, 3.57. Found: C, 73.44; H, 3.71.

On concentrating the mother liquor remaining after collecting the ortho quinone there was obtained 0.1 g. of the isomeric para quinone. This probably arises from the action of the hydrogen bromide liberated in the reaction on the ortho compound, for the latter substance can be converted in part into the yellow isomer by the action of boiling alcoholic hydrochloric acid.

β-Ethylfurano-1,2-naphthoquinone (III, R = C_2H_5) was obtained by allowing a solution of 2 g. of the dibromide in 10 cc. of alcohol to stand at room temperature for two days; 0.6 g. of the product crystallized from the solution and 0.8 g. more was obtained on concentration of the mother liquor. The compound forms red needles, m. p. 143.5–144°, from alcohol.

Anal. Calcd. for $C_{14}H_{10}O_3$: C, 74.31; H, 4.46. Found: C, 73.97; H, 4.75.

The mother liquor was found to contain a mixture of substances from which cold 1% alkali extracted an acidic compound probably having before hydrolysis the side chain $—CH{=}CBrCH_2CH_3$, for on acidifying the solution the ketonic compound of the type VI was obtained.

β-Phenylfurano-1,2-naphthoquinone (III, R = C_6H_5).—A solution of 2 g. of the dibromide in 100 cc. of alcohol was refluxed for one and one-half hours, during which time dark red plates of the ortho quinone separated from the boiling solution. After cooling, this material was collected (1.1 g.) and recrystallized from alcohol, in which it is sparingly soluble; dark red plates or needles, m. p. 219.5–220.5°.

Anal. Calcd. for $C_{18}H_{10}O_3$: C, 78.81; H, 3.68. Found: C, 78.87; H, 3.74.

The mother liquor yielded a mixture (0.1 g.) of the quinones III and IV with a small amount (0.02 g.) of a substance which could be extracted with cold alkali. The material recovered on acidifying the deep blue filtrate crystallized from alcohol in the form of purple-bronze needles melting with decomposition at about 275°. The substance forms a crystalline, blue sodium salt and gives a purple solution in concentrated sulfuric acid. From the analysis it appears to be a **hydroxyphenylfurano-1,2-naphthoquinone.**

Anal. Calcd. for $C_{18}H_{10}O_4$: C, 74.49; H, 3.45. Found: C, 74.04; H, 3.80.

Azines of the Ortho Quinones.—These derivatives were obtained in nearly quantitative yield by heating a mixture of the quinone, *o*-phenylenediamine hydrochloride, crystalline sodium acetate and glacial acetic acid at the boiling point for a few minutes. Most of the material separated in a crystalline condition on cooling and the remainder was obtained on dilution. The melting points and analyses of the compounds are recorded in Table I. These azines are all yellow and they crystallize well from alcohol or glacial acetic acid, usually as needles.

TABLE I

AZINES OF FURANO-1,2-NAPHTHOQUINONES

Substituents	M. p., °C.	%C Calcd.	%C Found	%H Calcd.	%H Found
None	195–196	79.97	79.14	3.73	4.01
β-Methyl	209.5–210.5	80.25	80.26	4.26	4.19
β-Ethyl	159–160	80.51	80.65	4.73	4.64

The Para Quinones (IV)

The methyl and ethyl derivatives were obtained in quantitative yield by dissolving one part of the ortho quinone in 50 parts by volume of cold concentrated sulfuric acid and allowing the solution to stand at room temperature for twenty-four hours, during which time the initially blue-green solution after passing through intermediate stages became crimson. On pouring the solution into water the yellow product separated in a microcrystalline condition. The compounds crystallize well from alcohol, acetic acid, or benzene. The properties are given in Table II.

TABLE II

FURANO-1,4-NAPHTHOQUINONES

Substituents	M. p., °C.	Description	% C Calcd.	% C Found	% H Calcd.	% H Found
β-Methyl	246–247	Yellow needles	73.58	73.64	3.57	3.79
β-Ethyl	145–145.5	Yellow needles	74.31	74.46	4.46	5.03

	......	Bright red needles	78.81	79.02	3.68	3.97

Since the phenyl derivative of the ortho series is rather easily sulfonated the procedure was in this case modified as follows: 1 g. of the quinone was dissolved in 200 cc. of a mixture of 5 volumes of concentrated sulfuric acid with 1 volume of water, and the solution was heated in a boiling water-bath for one hour. The initially deep blue-green solution gradually became deep violet in color and on pouring the solution into water the product was obtained as a flocculent orange precipitate in about 80% yield. Crystallized from benzene, alcohol, glacial acetic acid or chloroform, the compound separated either as slender, bright red needles or as golden-yellow plates. On standing in contact with the mother liquor for a few days the red variety usually changes into the yellow form. Both forms show the same melting point, for when the red needles are heated at about 195° they soon become yellow while retaining the original form of crystal, and the melting point is that of the yellow modification.

The isomerization of the phenylated ortho quinone can be accomplished also by boiling an acetic acid solution of the substance containing a very small amount of sulfuric acid. The phenylated para quinone dissolves in concentrated sulfuric acid with an intense blue color which slowly changes; the methyl and ethyl compounds give crimson solutions which are more stable. The para quinones sublime readily without charring, while the ortho isomers undergo some decomposition.

The para quinones were obtained in small amounts by allowing solutions of the unsaturated compounds of the type I in concentrated sulfuric acid to stand at room temperature for twenty-four hours, but the yields were poor. No pure product was obtained from the vinyl compound by this method.

The Ketonic Compounds (VI)

The cleavage of the furan ring of the quinones of both the ortho and para series usually was effected by boiling under the reflux a suspension of one part of the finely powdered material in 100 parts of 1% sodium hydroxide solution until the material had completely dissolved. The phenylfurano-1,2-naphthoquinone is very resistant to attack and in this case the heating was interrupted at two-hour intervals, the solution was filtered, and the residual material, which had become blue as the result of a reduction process, was exposed to the air for re-oxidation and then boiled with a fresh portion of alkali. The isomeric phenylfurano-1,4-naphthoquinone was attacked with still greater difficulty and successive fresh portions of alkali were used; in this case, however, no insoluble blue substance was noticed. The alkaline solutions were orange-brown, and on acidification the reaction product separated as a buff-colored, crystalline precipitate. The pure substances were obtained by crystallization from alcohol or benzene, using animal charcoal. They are all yellow and usually crystallize in the form of needles. The yields, properties and analyses are given in Table III.

TABLE III

KETONIC DERIVATIVES OF 3-HYDROXY-1,4-NAPHTHOQUINONE

		Time and yield from *p*-Quinone		Time and yield from *o*-Quinone		% C		% H	
Substituent	M. p., °C.	Hrs.	%	Hrs.	%	Calcd.	Found	Calcd.	Found
2-Acetonyl	176.5–177.5	5	71	0.5	75	67.87	67.89	4.35	4.47
2-γ-Methylacetonyl	165–165.5	3	70	0.25	80	68.83	68.94	4.96	5.19
2-Benzoylmethyl	182.5–183.5	10–12	15	6	70	73.94	73.73	4.14	4.32

Concentrated sulfuric acid converts these substances first into the ortho furano-1,2-naphthoquinones which then undergo rather rapid transformation into the para isomers. Consequently mixtures of the two compounds are usually obtained on pouring the solutions into water. The orthoquinone can be obtained as the sole product by the method previously[4] used in the lapachol series and indicated in the chart. Thus one part of either of the three compounds listed in Table III was dissolved in 70–100 parts of warm, dilute (55–80%) acetic acid, depending on the solubility, one part of zinc dust was added followed by 16–20 parts of dilute (1:3) hydrochloric acid, and the solution was refluxed for five minutes. Reduction occurred rapidly and the solution of the hydroquinone was filtered to remove the zinc dust, reheated if necessary to bring all of the material into solution, and treated with a solution of 0.25 part of chromic anhydride in 10 parts of water. Red needles of the ortho quinone began to deposit almost immediately, and the material which did not separate on cooling was obtained by diluting the mother liquor. The substances were obtained in practically quantitative yield and in a very pure condition.

2 - β - Hydroxypropyl - 3 - hydroxy - 1,4 - naphthoquinone (XVII).—2-Acetonyl-3-hydroxy-1,4-naphthoquinone (0.05 g.) was hydrogenated in alcoholic solution using Adams catalyst, and the solvent was removed from the filtered solution by distillation and evaporation in warm air. The oily residue was taken up in 1% alkali and on acidifying the crimson solution the product separated as a yellow oil which slowly solidified (0.04 g.). Crystallized from benzene or benzene–ligroin the substance melted at 115.5–116.5° and gave no depression when mixed with a sample prepared according to the method of Fieser,[9] although Fieser gave the melting point as 108–110°. In a number of determinations with highly purified samples from both sources the melting point 108–110° was sometimes observed, and after allowing the melt to resolidify it then melted sharply at 115.5–116.5°. At other times the higher melting point was reached without previous melting. Microscopic examination of the samples prepared by the two methods also indicated their identity. The oil which first separates on acidifying the alkaline solution rapidly crystallizes in the form of very characteristic clusters of yellow needles.

Summary

The methods developed in 1896 for the synthesis of furan derivatives of β-naphthoquinone, and for the conversion of these substances into the corresponding α-naphthoquinones and open-chain compounds, have been studied in additional cases and found capable of rather general application. The parent compound of this group of furanonaphthoquinones has the ortho quinone structure and is not a para compound as assumed in the literature. The usual relationship between the color and the structure of the quinone group is maintained among the compounds investigated.

Lomatiol. Part IV. A Violet Quinone from the Oxidation Product[1,2]

BY SAMUEL C. HOOKER AND AL STEYERMARK

It has been shown[3] that the quinone I resulting from the oxidation of lomatiol easily loses water with the formation of a red ring compound of the formula II. When this is boiled with alkali the pyran ring opens and there is produced a deep crimson solution resembling that formed by the oxidation product I. While I can be recovered without great difficulty by the careful neutralization of its alkaline solutions, the solution prepared from II contains a very unstable hydroxy compound (III) which when in the free condition undergoes cyclization so readily that it has not been possible to isolate the substance. Evidently some change occurs in the side chain of I when the pyran ring is closed and subsequently opened, but it is not known whether the difference is in the spatial arrangement of the groups attached to the double bond, in the respective positions of the hydroxyl group and the double bond in the allylic system, or in other modifications of the original structure. The unstable substance III on liberation from its salts changes into a beautiful, deep violet quinone isomeric with the red anhydride II. The violet compound forms a characteristic azine, indicating the presence of an ortho quinone group, and on catalytic hydrogenation two atoms of hydrogen are added to the unsaturated ring with the formation of the known[3] β-methyldihydropyrano derivative V, and on the basis of these observations the violet substance is assigned the structure of β-methylpyrano-1,2-naphthoquinone, IV.[4]

The new compound differs from the red anhydride II only in the nature of the quinone group, and it is interesting that with this pair of isomers the ortho compound has the deeper color, as in other cases, although on account of the presence of an active double bond in the side ring both quinones are deeper in color than the corresponding naphthoquinones more commonly encountered. The violet ortho quinone (IV) is a highly reactive substance and in aqueous or alcoholic solution it is unstable, particularly in the presence of hydrochloric acid, and undergoes isomerization to the red quinone II. Perhaps it is because of a

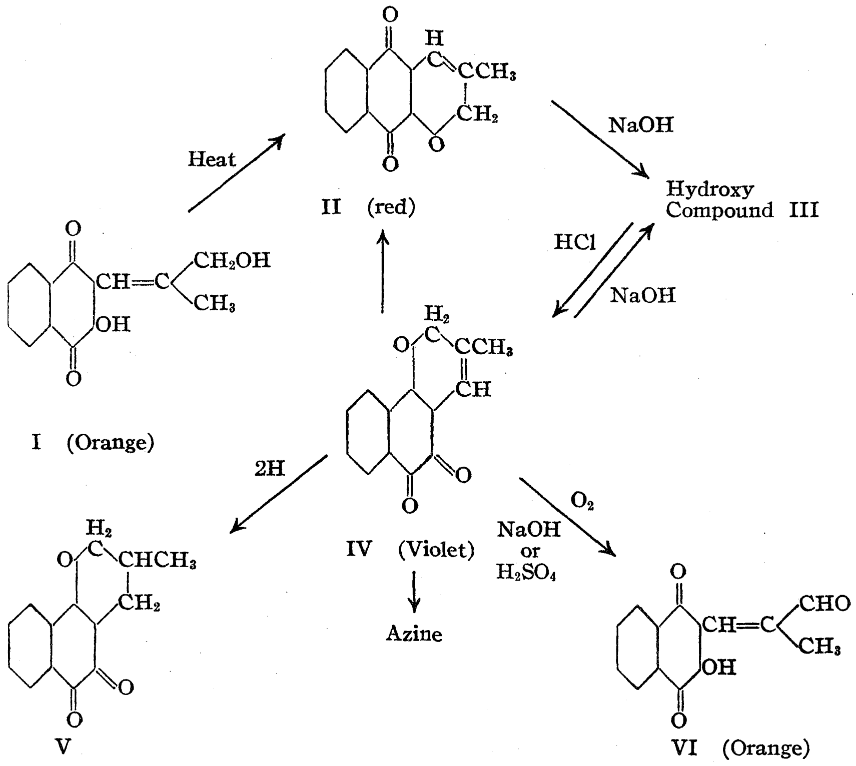
---

(1) See Editor's note (1), THIS JOURNAL, **58**, 1163 (1936).

(2) Although the violet compound was discovered by Dr. Hooker in 1917, most of the experiments described in this paper are of recent date (1934–1935) and no manuscript was left for the paper. At the time of his death Dr. Hooker was undecided as to the exact nature of the key compound and he was uncertain regarding the interpretation to be placed on its various transformations. He thought that a potentiometric analysis might settle the major point of uncertainty, and in a recently completed experiment I have found this to be the case (see footnote 4), although the result is the opposite of that which Dr. Hooker was inclined to anticipate. Seen from this fresh point of view the observations become less puzzling than before, and since I am sure that Dr. Hooker would have modified his early and incomplete views in the light of the later evidence, I have decided to present the theoretical interpretation which appears to be indicated by the facts now available and for which I assume full responsibility. —L. F. FIESER.

(3) Hooker and Steyermark, THIS JOURNAL, **58**, 1198 (1936).

(4) Because of the unusual color of the substance and the peculiar changes occurring in its solutions in acids and bases, and in consideration of early analyses with material later found to be impure, Dr. Hooker at the time of his death was inclined to regard the violet compound as a quinhydrone. He recognized, however, that further evidence was required to settle the matter, and I believe that the following experiment, carried out in my laboratory after his death, provides a sound basis for decision. In an electrode vessel connected to a hydrogen half-cell containing 50% alcoholic 0.1 *N* hydrochloric acid a sample of the substance was introduced to a portion of the same buffer which had been swept free from oxygen by a stream of nitrogen, and the potential was followed from the start. A fairly steady value (0.480 v.) was soon reached and after the material had dissolved a titration with titanous chloride gave a curve of the usual form for a quinone in the completely oxidized condition. The normal potential, E_0 = 0.435 v., is consistent with the ortho quinone structure, for it is 70 mv. higher than that of Paternò's dehydrolapachone, a similarly constituted pyrano compound of the para quinone series.—L. F. F.



similar instability that the ortho isomer of Paternò's dehydrolapachone[5] has eluded isolation.

The violet quinone dissolves easily in concentrated sulfuric acid and if the solution is promptly diluted with water the compound is precipitated in an unchanged condition. Likewise, after the quinone has been brought into solution by the action of boiling alkali, the original compound can be recovered if the solution of the hydroxy quinone III is at once acidified. If, however, either solution is allowed to stand for several hours a series of rather remarkable changes occurs which can be summarized briefly as follows. When exposed to the air in an open dish the alkaline solution in a few days deposits red needles of the para quinone II, and the sulfuric acid solution slowly deposits the same substance as it absorbs moisture from the atmosphere. When the freshly prepared solutions are placed in an evacuated system and allowed to stand for some time in the absence of air no red needles are deposited. Changes nevertheless occur under these conditions, for on subsequently exposing the alkaline solution to the air the red compound soon begins to separate and after this material has been removed the alkaline filtrate is found to contain 2-hydroxy-1,4-naphthoquinone, an oxidation product. Under more drastic conditions, as when the alkaline solution is refluxed for several hours, or when air is passed through the solution for a prolonged period, there is produced as a second product of oxidation an orange substance which appears to be an aldehyde of the formula VI. When the sulfuric acid solution of the violet quinone is allowed to stand *in vacuo* for several days and then poured into water, the precipitated material seems to consist largely of the hydroquinone of the orange aldehyde, for when it is dissolved in alkali or in ether in the presence of air there is a rapid color change and the solution is found to contain the aldehydic quinone VI.

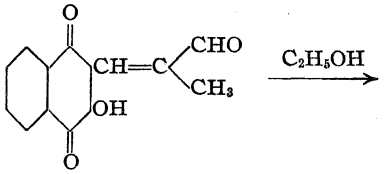
The following interpretation of the changes seems to accord with all of the observations. It may be assumed that the pyran ring is opened by sulfuric acid as it is by alkali, and that in any case it is the unknown hydroxy compound III, in the form of the sodium salt or the sulfuric acid ester, which undergoes reaction. The essential change appears to consist in a disproportionation involving the reduction of the quinone group and the oxidation of the side chain. In the early stages of the process the solution contains a considerable amount of the hydroquinone of the hydroxy compound III and this undergoes partial, reversible cyclization to the hydroquinone of the red anhydride II, ring closure occurring more readily with the phenolic reduction product than with the more strongly acidic hydroxy quinone. In the presence of air the hydroquinone is oxidized and the red anhydride is deposited, even from the alkaline solution. In the absence of air the reaction proceeds in the same way at the outset, but when hydroxynaphthoquinone and the aldehyde VI tend to accumulate as oxidation products they are largely reduced by the hydroquinone of the starting material and the latter substance (III) eventually is completely consumed.

The orange aldehyde VI can be obtained in 40–

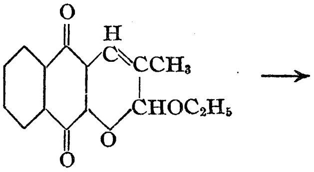
---

(5) Hooker, THIS JOURNAL, 58, 1190 (1936).

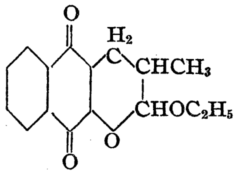
45% yield by boiling a solution of the violet compound in alkali for several hours, and in this case it is considered that the hydrogen atoms removed from the side chain reduce the quinone group and that the hydroquinone produced throughout the reaction is reoxidized by the air. The structure of the aldehydic substance has not been established rigidly, but the formula suggested accords with the analysis, with the acidic nature of the compound, with evidence indicating the presence of a double bond in the side chain, and with the observation that the substance easily forms derivatives resembling hemiacetals on reaction with various alcohols. In attempting to crystallize the orange compound from methyl, ethyl or butyl alcohol it was found that on mere boiling of the solution a reaction with the alcohol occurs and a yellow, non-acidic product separates on cooling. The reaction products can be reconverted into the starting material by dissolving them in concentrated sulfuric acid or by the action of boiling alkali. The hemiacetal structure VII would account well for the formation of such a compound from VI, for its neutral character, and for its conversion into a dihydro derivative (VIII) on hydrogenation. There is some further support for the hemiacetal structure in the qualitative observation that while the orange compound yields a crystalline, yellow derivative on reaction with aqueous ammonia the alkylated compounds remain unchanged on similar treatment. The yellow color is not easily explained on the basis of this formula, however, for in analogy with the red anhydride II, for which the structure of a pyrano-1,4-naphthoquinone is well established, a compound of the formula VII would be expected to be orange or red, unless the ethoxyl group has an effect opposite to that of the double bond in the side ring. On the other hand, it seems very unlikely that a compound of the formula VI could yield a normal hydroxy quinone ether under the conditions of the experiments or even in the presence of an esterification catalyst. Thus alkyl substituents in the quinone ring of 2-hydroxy-1,4-naphthoquinone effectively hinder a reaction with alcohol and hydrogen chloride, hydrolapachol, for example, being unaffected by such treatment. The hemiacetal formula appears to be the more probable, but further evidence will be required before a final decision can be reached.



VI (Orange)



VII (Yellow)



VIII (Yellow)

For the orange compound the open-chain structure VI is indicated by the fact that the substance dissolves easily in cold alkalies, and the formula is consistent with its color. In organic solvents such as benzene or petroleum ether there may be an equilibrium with a cyclic form. In boiling glacial acetic acid the compound is partially converted into a non-acidic substance having the composition of a bimolecular anhydride. Since such a reaction has not been encountered with other 2-alkyl-3-hydroxy-1,4-naphthoquinones, it seems likely that the elimination of water occurs between two molecules of the cyclic form of the orange compound.

Experimental Part[6]

The Violet Compound: β-Methylpyrano-1,2-naphthoquinone (IV).—It was found convenient to use for the preparation of this compound the crude β-methylpyrano-1,4-naphthoquinone (II) resulting from the oxidation of lomatiol.[3] Five grams of this material was finely ground and boiled with 500 cc. of 1% sodium hydroxide solution for two to four minutes, which sufficed to dissolve the red compound, and the bluish-crimson solution was quickly cooled to room temperature and filtered from about 0.1 g. of the yellow by-product[3] (β-methylfurano-1,4-naphthoquinone). On carefully acidifying the alkaline filtrate there was obtained a yellow emulsion which immediately darkened to violet and began to deposit brownish-violet needles of IV in a fairly pure condition; yield 4–4.5 g. On evaporating the mother liquor to one-tenth its volume, extracting the material which then separated with cold 1% alkali, and crystallizing the extracted substance from alcohol there was obtained about 0.015 g. of a by-product which forms red needles, m. p. 239–240°, dec. (Found: C, 70.52; H, 4.56.)

The violet compound is best purified by crystallization from alcohol, avoiding undue heating of the solution, and it separates either as needles or as diamond-shaped plates of an intense violet color with a somewhat brownish metallic luster, m. p. 156–158°, dec. The substance is also soluble in benzene and in glacial acetic acid, but changes appear to occur when the solutions are boiled.

Anal. Calcd. for $C_{14}H_{10}O_3$: C, 74.31; H, 4.46; mol.

[6] Microanalyses and molecular weight determinations by Dr. D. Price of Columbia University.

wt., 226.1. Found: C, 74.62; H, 4.62; mol. wt., 238.0, 236.5.

The **azine**, prepared in good yield by heating a solution of the components in glacial acetic acid for a short time, forms gold-yellow needles melting at 163–163.5°. It forms a yellow-green solution in concentrated sulfuric acid and bronze-purple needles of the sulfate separate on dilution.

Anal. Calcd. for $C_{20}H_{14}ON_2$: C, 80.51; H, 4.73. Found: C, 80.34; H, 4.87.

On applying the method[7] found useful for the preparation of other ortho quinones, which in this case consisted in heating the lomatiol oxidation product I with a mixture of zinc dust, hydrochloric and acetic acids, followed by oxidation with chromic acid, there was obtained a mixture of the isomeric violet and red compounds IV and II.

The violet quinone can be converted quantitatively into the red isomer by boiling a solution of the substance in 95% alcohol for four hours, by boiling the material with water for about one hour, or by boiling it with very dilute hydrochloric acid for ten to fifteen minutes. (The violet quinone dissolves easily in cold sodium bisulfite solution, but no precipitate appears when the reagent is neutralized with soda solution.—L. F. F.)

For hydrogenation 0.1 g. of the violet quinone was dissolved in 20 cc. of warm (not boiling) ethyl alcohol and agitated with hydrogen and Adams catalyst for forty-five minutes. The end of the reaction was determined by evaporating a drop of the solution and adding a drop of concentrated sulfuric acid: initial color, blue; final color, red. There was obtained in all 0.07 g. of product which, when recrystallized, was identified by melting point and mixed melting point determinations as β-methyl-dihydropyrano-1,2-naphthoquinone, V.[3]

Action of Alkali on the Violet Compound.—By the action of boiling alkali the violet quinone is soon dissolved, giving a deep red solution. When the solution was at once cooled and neutralized with either hydrochloric acid or carbon dioxide the violet compound was reprecipitated. Allowed to stand exposed at room temperature, the alkaline solution began to deposit red needles of II within two to three days and the amount continued to increase for ten to fourteen days, the total conversion being about 55% of the starting material. During this period a test portion of the alkaline filtrate remaining after the removal of the red needles was shaken with ether, but no color was imparted to the ether layer and consequently the red anhydride was not simply present in solution. The alkaline mother liquor remaining after the final collection of the separated product gave a precipitate of impure 2-hydroxy-1,4-naphthoquinone on acidification. In another experiment the freshly prepared alkaline solution was allowed to stand in a vacuum desiccator, and no red needles appeared after seven days. On then exposing the solution to the air the red anhydride soon separated in 20% yield and the mother liquor yielded a quantity of hydroxynaphthoquinone amounting to about 20% of the weight of the starting material. When air was bubbled through a freshly prepared alkaline solution for fifteen hours and the solution was then allowed to stand in a loosely stoppered flask for three months, none of the red compound was observed but on fractionally precipitating the material in the alkaline solution with dilute acid there was obtained about 15% by weight of the orange compound VI, followed by 65% by weight of hydroxynaphthoquinone, the substances being fully identified by comparison with known samples.

The Orange Compound (VI).—This substance is best prepared by the action of alkali and air on the red anhydride II, the crude material being conveniently employed. A suspension of 1 g. of the powdered substance in 200 cc. of 0.25% sodium hydroxide solution was boiled under the reflux for fifteen minutes and the resulting deep red solution was cooled and filtered to remove the yellow by-product. The refluxing was then continued for a total of seven hours. The brownish-red solution was cooled, filtered from some mineral matter, and acidified. The crude product separated as a buff-colored precipitate which soon became crystalline and from which the sometimes cloudy mother liquor was best removed by decantation. After thorough washing, the crude product was shaken with 100 cc. of cold 0.25% alkali and the resulting solution was quickly filtered and acidified, the material separating as a brownish-orange microcrystalline mass; yield 0.4–0.45 g.

For analysis the substance was crystallized from benzene, in which it is sparingly soluble, and it was obtained in the form of bright orange needles, m. p 229–230°, dec.

Anal. Calcd. for $C_{14}H_{10}O_4$: C, 69.42; H, 4.13. Found: C, 69.44, 69.24; H, 4.42, 4.06.

The compound gives an orange solution in concentrated sulfuric acid. It dissolves readily in cold dilute alkali giving a crimson solution. When this evaporates on a watch glass the dark red sodium salt is deposited in branch-like forms or as interlacing hair-like needles which begin at the edges of the solution and grow inward. Attempts to obtain an acetate by the action of acetic anhydride or acetyl chloride on the orange compound were unsuccessful. A reaction with ammonia was observed as follows: the orange compound was obtained in a fine suspension by re-precipitation from dilute alkali and in this condition it dissolved at once on adding concentrated ammonium hydroxide solution, giving a deep red solution which soon became yellow and deposited bright yellow needles of a substance melting at 136–137°. Having used filtered solutions, the material was analyzed without further purification with the following results: C, 76.11; H, 4.42; N, 13.02. The compound can be crystallized from benzene or alcohol; it is not soluble in cold alkali but on boiling it yields a light brown-red solution which on cooling deposits nearly colorless needles. The study of the compound was not completed.

Hemiacetals (or Ethers?) of the Orange Compound.—The **ethyl** derivative of the probable formula VII was prepared by refluxing for one and one-half hours a solution of 1 g. of the orange compound in 50 cc. of ethyl alcohol. On cooling about 0.7 g. of the ethyl hemiacetal was deposited in the form of yellow prisms and a further 0.3 g. was obtained on concentrating the solution. The substance is somewhat sparingly soluble in ethyl alcohol and melts at 184.5–185.5°.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.11; H, 5.18; mol. wt., 270.1. Found: C, 70.72, 70.70; H, 5.09, 5.19; mol. wt., 268.3.

---

[7] Hooker, *J. Chem. Soc.*, **69**, 1376 (1896).

The compound appears to be partially converted into the methyl derivative on crystallization from methyl alcohol. It is insoluble in dilute alkali in the cold but dissolves slowly on boiling and the orange compound is precipitated when the red alkaline solution is acidified. The hydrolysis is more easily accomplished with the use of alcoholic alkali, followed by dilution with water and acidification. The substance dissolves easily in cold concentrated sulfuric acid and the orange compound precipitates when the solution is poured into water.

The dihydro derivative (VIII) of the ethyl hemiacetal was obtained by hydrogenation of the substance (0.5 g.) in ethyl alcoholic solution (125 cc.) in the usual way; yield, 0.4 g. The reaction product crystallizes slowly but very well from ethyl alcohol, forming yellow crystals melting at 185–186°.

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.59; H, 5.88; mol. wt., 272.1. Found: C, 70.57; H, 5.35; mol. wt., 279.2.

Although the melting point is nearly the same as that of the unhydrogenated substance, a mixture of the two compounds melted about 20° lower. The dihydro derivative gives a red solution in concentrated sulfuric acid, but in contrast to the starting material water precipitates a mixture of alkali-soluble and alkali-insoluble material.

The *n*-butyl hemiacetal was prepared by refluxing for thirty minutes a solution of 0.2 g. of orange compound in 20 cc. of *n*-butyl alcohol; yield 0.18 g. The substance forms yellow rectangular plates, m. p. 121.5–122°.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.48; H, 6.04; mol. wt., 298.1. Found: C, 72.21; H, 6.31; mol. wt., 292.8.

The **methyl hemiacetal** is similar in properties and melts at 160–161°.

Anhydride of the Orange Compound.—This was obtained by dissolving 1 g. of the material in 70 cc. of glacial acetic acid and refluxing the solution for one-half hour. The reaction proceeds only to the point of an equilibrium, and on cooling the solution deposited 0.7 g. of a mixture of orange needles of the starting material and yellow plates of the anhydride. (A mixture was also obtained on adding water to the mother liquor.) A separation of the two compounds was easily effected by treatment with 70 cc. of cold 0.25% alkali, which rapidly dissolved the orange needles. The solution was quickly filtered and the undissolved yellow plates were washed well with water. By using filtered solutions the anhydride was in this way obtained in a form suitable for analysis, the yield being about 0.1 g. The substance melts with decomposition at 243–244°.

Anal. Calcd. for $C_{28}H_{18}O_7$: C, 72.10; H, 3.86. Found: C, 72.21, 71.79; H, 4.05, 4.11.

The anhydride can be obtained equally well by using propionic or *n*-butyric acid. That an equilibrium is established is shown by the fact that on redissolving the anhydride in any of the solvent acids it is converted into a mixture of the two compounds. The orange compound can be obtained by boiling the anhydride with dilute alkali or by dissolving it in concentrated sulfuric acid and pouring the solution into water.

Action of Sulfuric Acid on the Violet Compound.—The violet quinone gives a deep, rich blue solution in concentrated sulfuric acid, but the color changes to red in one to two hours. When the solution was exposed to the air in an open dish it began to deposit red needles of II within two to three days. The changes occurring in the absence of air are illustrated by the following experiment.

A solution of 1 g. of the violet compound in 100 cc. of concentrated sulfuric acid was allowed to stand in a stoppered flask for two days at room temperature and the solution, which had become red after the first two hours but which deposited no red needles, was poured into 1500 cc. of cold water. The resulting blue-red solution deposited a brown flocculent precipitate which was collected after twenty-four hours and set aside (0.46 g.). On extracting the wine-red filtrate with ether it was noted that on contact with the solvent the aqueous layer generally changed in color from red to yellow and at times orange-yellow microcrystals separated and then dissolved in the ether. It appeared that an oxidation was involved. Evaporation of the ether extract left a residue of yellow crystals mixed with brown resin. On digesting this with 100 cc. of cold 0.25% alkali most of the material quickly dissolved and usually the solution was initially yellow and then rapidly darkened to a crimson color, evidently as the result of the oxidation of a hydroquinone. On filtering the alkaline solution there was a slight residue consisting of yellow plates (0.02 g.) identified as the ethyl hemiacetal of the orange compound, which probably had arisen from reaction with ethyl alcohol present in small amounts in the ether used. After allowing time for oxidation to proceed to completion, the alkaline filtrate on acidification gave a precipitate which was no longer resinous but which consisted of crystalline groups of the orange compound in a nearly pure condition; yield, 0.26 g. Somewhat better yields were obtained in further experiments using less material.

Summary

β-Methylpyrano-1,2-naphthoquinone, a violet colored quinone of a hitherto unknown structural type, has been obtained from the substance resulting from the oxidation of lomatiol. The most interesting and unusual properties of the compound, aside from the striking color, are its ready isomerization to the corresponding para quinone and its conversion, probably through a disproportionation mechanism, into a quinone having an aldehydic side chain. The latter substance also displays novel properties, combining readily with alcohols without the assistance of catalysts, and yielding a bimolecular anhydride.

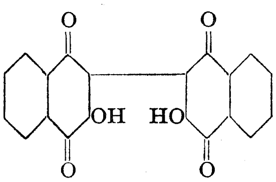
The Action of Light on β-Hydroxy-α-naphthoquinone[1,2]

BY SAMUEL C. HOOKER

In this paper an account will be given of an interesting substance (I) which was first obtained in the author's laboratory by Mr. J. T. Walsh, Jr., in 1893–1894 from mother liquors in the preparation of 2-hydroxy-1,4-naphthoquinone. It was subsequently established that neutral and acid aqueous solutions in which small quantities of pure hydroxynaphthoquinone are dissolved deposit on standing minute globular masses (dots) of a compound readily distinguished from hydroxynaphthoquinone by the much more crimson color of its solution in alkalies. The substance may be observed floating on the surface of the solution in the course of a few days, or it may not separate for two or three weeks. After standing a number of months, however, unchanged hydroxynaphthoquinone is still present in the solution. The substance is also formed when a small quantity of hydroxynaphthoquinone is dissolved in concentrated sulfuric acid and the acid solution allowed to stand exposed. As water is absorbed crystals of hydroxynaphthoquinone first separate and then eventually give way in part to microscopic globular masses of the condensation product. After observing the phenomenon many times under various conditions it was concluded that the ("dot") compound is formed by the action of light, and as a result of a number of experiments a satisfactory method of preparation was found in exposing an aqueous solution of hydroxynaphthoquinone to ultraviolet light at 70°. The reaction product was obtained in a very good condition in yields of over 40%. When pure it consists of orange-yellow microcrystals melting at 270–275°, dec. It displays various characteristic color reactions and gives a very distinctive pattern when fused on a cover glass and examined under the microscope. Considering the source and acidic character of the material, the composition found for the compound and the observation that it is sparingly soluble in most organic solvents strongly suggested the formula of di-β-hydroxy-α-naphthoquinone, I. A substance regarded as having this structure was prepared many years ago by Chattaway[3] and described as a dark red powder melting at about 215°. Some of the original sample was kindly supplied to the author by Dr. Chattaway in 1922 for purposes of comparison, and it was examined carefully and tested by a number of methods. The material did not appear to be homogeneous, however, and although in some respects it behaved as though it contained the compound described in the present work, attempts to purify the small sample to an extent sufficient to permit a positive identification were not successful.



I

Independent evidence that the oxidation product of hydroxynaphthoquinone has the structure I was found in its behavior under the influence of dehydrating agents. Theoretically a substance of this formula should be capable of yielding in addition to the normal internal anhydride (II) two isomeric anhydrides, III and IV, correspond-

(1) See Editor's note (1), THIS JOURNAL, **58**, 1263 (1936).

(2) Following the initial observation of 1893–1894 (see text), Dr. Hooker devoted considerable time in the period 1918–1926 to a study of the formation and properties of the "dot" compound, assisted in part by Dr. G. H. Connitt and by Mr. A. F. Sullivan. Apparently the work was interrupted before it was quite complete, and the observations had been summarized only partially. In repeating some of the experiments in order to comprehend fully the original notes, I was fortunate enough to find a method of preparing in a pure condition the third (red) anhydride, which Dr. Hooker had observed only as an unpurified by-product. The substance was identified by comparison with Dr. Hooker's original, well-preserved slides, and it was thus possible to supply the completing details of the investigation.—L. F. FIESER.

(3) Chattaway, *J. Chem. Soc.*, **67**, 662 (1895).

ing to the conversion of one or both para quinone groups into ortho quinone groups in the course of the dehydration. Analogous changes have been abundantly illustrated in previous work in this Laboratory. Actually it was possible to obtain three such anhydrides, using sulfuric acid as the active dehydrating agent in each case but operating under different conditions. The pure, crystalline compounds are, respectively, orange-yellow, orange and red in color, and although the distinction between the first two is but slight the relationship, in analogy with known cases, is such as to suggest that they have the α,α'-, the α,β'- and the β,β'-structures, in the order named. This was fully confirmed by the behavior of the compounds when boiled with *o*-phenylenediamine in glacial acetic acid solution or suspension. The orange-yellow anhydride, although its solubility in the medium is more than adequate to permit a reaction, was recovered unchanged, as would be expected for the α,α'-quinone II. A mono-azine was obtained from the orange anhydride (III), and the red isomer, in spite of its extremely slight solubility, yielded a diazine (m. p. 409–410°), corresponding to the two β-quinone groups of IV. These observations establish with certainty the structure of the substance formed from 2-hydroxy-1,4-naphthoquinone by the action of light, and it appears that the process involves the oxidative coupling of two molecules at the 3-position.

The occurrence of a second reaction was revealed on investigating the aqueous liquor remaining after removing the main product from the hot solution. This usually deposited in the course of twenty-four hours a brick red crystalline substance amounting to about 15% of the starting material. The material dissolved in 1% alkali to a browner solution than pure hydroxynaphthoquinone, but on exposure on a watch glass the solution soon became lighter in color and eventually corresponded in shade to that of the sodium salt of hydroxynaphthoquinone and on evaporation yielded crystals of this salt. The red color of the substance suggested a β-quinone structure, and its behavior the possibility that the hitherto unknown α-hydroxy-β-naphthoquinone had been discovered. For this reason considerable study was devoted to the matter. By varying the conditions under which the brick red substance was obtained, however, it was found that the color of its alkaline solution was not constant and in some lots this even approached a dark olive green. As the individual crystals of each lot when dusted on the surface of the alkaline solution gave a perfectly uniform color, it seemed probable that the red substance consisted mainly of ordinary hydroxynaphthoquinone modified in its properties by another substance which crystallized with it in varying proportions. This was found to be the case. Starting with 5 g. of the red substance repeated crystallizations from benzene eventually yielded as the less soluble fraction crystals which gave a dark blue solution in alkali. Further purification of these crystals from acetone resulted in their resolution into two substances. The one present in by far the larger quantity dissolved in alkali to a bright blue solution and the other, obtained in exceedingly small amount, gave a dull cherry red solution. The former substance melted at 280°, its blue solution in sodium hydroxide became colorless on exposure, with dilute sodium carbonate a violet solution was obtained, and with concentrated ammonia the substance gave a sparingly soluble, dark violet salt. These properties correspond with those of isonaphthazarin,[4] and a direct comparison with a known sample of this quinone fully established the identity.

Under the influence of light and air in aqueous solution, hydroxynaphthoquinone is partly dehydrogenated and partly hydroxylated, the attack in each case occurring at the free position in the quinone ring.

Experimental Part

Preparation of 2-Hydroxy-1,4-naphthoquinone.—In preparing large quantities of 1,2,4-triacetoxynaphthalene from samples of β-naphthoquinone of various degrees of purity by the method of Thiele and Winter,[5] the crude material precipitated by water was invariably found to contain a by-product which was separated by the following method. The crude material, which varied from orange to brown in color, was boiled with alcohol (10 cc. per gram) until the bulk of the solid had dissolved and the solution was filtered from a small amount of the less soluble by-product. The solution on cooling at first remained clear and deposited heavy crystals of the triacetate. After an hour or so, simultaneously with the commencement of the separation of the by-product, the solution became cloudy and at or before this point the mother liquor was quickly poured off from the heavy crystals. After allowing time for a mixture of the two substances to crystallize from the decanted solution, this was heated to boiling. The triacetate largely dissolved while the second substance passed into solution so slowly that a considerable amount of the material could be collected on filtration. By continuing this process a

---

(5) Thiele and Winter, *ibid.*, **311**, 345 (1900).

fairly complete separation was possible and the pure triacetate was obtained in about 46% yield from a mixed lot of β-naphthoquinone.

The by-product, which amounted to about one-tenth part of the quinone used, was identified as the tetraacetyl derivative of dinaphthyldihydroquinone by analysis and by direct comparison with a known sample of this substance.[6]

Anal. Calcd. for $C_{28}H_{22}O_8$: C, 69.14; H, 4.56. Found: C, 69.07, 68.92; H, 4.62, 4.80.

On being heated in the capillary tube both samples, as well as the mixture, exhibited the peculiar behavior essentially as described by Straus, Bernoully and Mautner.[7]

For the hydrolysis of the triacetate and oxidation to hydroxynaphthoquinone the following method was found more satisfactory than any described in the literature. A 10-g. portion of the triacetate was immersed in 200 cc. of 5% sodium hydroxide solution in a flat dish and allowed to stand at the laboratory temperature. The solution darkened considerably as the triacetate gradually dissolved and in three to four hours the red sodium salt of hydroxynaphthoquinone commenced to separate. In four to five days the solution became much lighter and cleaner and ultimately approximated in shade that of the sodium salt of pure hydroxynaphthoquinone, indicating that the oxidation was complete. The salt was collected, washed with 5 cc. of water, dissolved in 600 cc. of water at the laboratory temperature, and the filtered solution was acidified, giving a pale yellow crystalline precipitate of hydroxynaphthoquinone in a very pure form and in over 90% of the theoretical yield.

Identification of 2-Hydroxy-1,4-naphthoquinone.—This can be very satisfactorily accomplished with an exceedingly small quantity of the substance even when it is comparatively impure, by first subliming it in a test-tube or on a cover slip. Irregular microscopic yellow crystals are formed, sometimes also needles easily visible to the naked eye. A drop or two of 1% sodium hydroxide is used for dissolving the sublimed crystals and a small portion of the solution allowed to evaporate spontaneously readily yields characteristic red crystals of the sodium salt. To the remainder of the alkaline solution one or more drops of 0.25% hydrochloric acid is added, when with aid of the microscope characteristic needles changing in the course of a few hours to irregular crystals can be observed. The pyridine compound is also characteristic for on evaporation of a drop of the solution in pyridine clusters of bright red needles of the salt are deposited and then the pyridine is spontaneously lost and the crystals lose their red color and their luster but retain their form.

Di-β-hydroxy-α-naphthoquinone (I).—Pulverized hydroxynaphthoquinone (4 g.) was dissolved in 3 liters of boiling tap water and the hot solution was transferred to a 28-cm. crystallizing dish set on a slab of copper heated by a jet burner adjusted to maintain a temperature of about 70°. A Uviarc lamp was so placed that the center of radiation was about 29.2 cm. above the surface of the solution and the exposure was continued for two hours in all. At intervals of thirty minutes three successive 0.5-g. portions of hydroxynaphthoquinone, each dissolved in 400 cc. of boiling water, were added to the main solution, the last addition thus being made thirty minutes before the conclusion of the exposure. Shortly after the commencement of the experiment the compound began to separate on the surface of the solution as a yellow-brown, microcrystalline powder, and at the close of the exposure the substance was immediately filtered off and washed with water. By carefully following the above directions 2.4 g. of di-β-hydroxy-α-naphthoquinone will be obtained in a condition of satisfactory purity. By allowing the temperature to drop materially not only is the action retarded but the compound may be mixed with crystals of hydroxynaphthoquinone. Should this be the case the hydroxynaphthoquinone may be removed by extracting the substance with boiling water (500 cc. per gram).

Di-β-hydroxy-α-naphthoquinone does not dissolve to any appreciable extent in boiling benzene and it is only sparingly soluble in alcohol. The substance dissolves slowly in glacial acetic acid (100 cc. per g.) at the boiling point and the solution on cooling deposits an orange-yellow sandy powder consisting of small crystalline tablets which appear under the microscope to be almost rectangular. The presence of a persistent impurity often gives a brown appearance to the crystals, but this can be removed with the use of blood charcoal. The compound is fairly soluble in nitrobenzene and crystallizes well from this solvent. It is readily soluble in cold pyridine, and it also dissolves in cold dilute alkali and imparts a characteristic, bright crimson color to the solution.

Anal. Calcd. for $C_{20}H_{10}O_6$: C, 69.35; H, 2.91. Found: C, 69.16; H, 3.00.

When heated in a melting point capillary the compound begins to sublime at about 250° and melts with decomposition at about 270–275°. When heated on a cover glass it fuses, simultaneously giving a faint sublimate. When withdrawn from the source of heat the fused material crystallizes to a highly characteristic striated mass of yellow needles frequently suggestive of a map of city streets. The fused material appears to be an anhydride, as it is insoluble in dilute alkali but dissolves slowly on boiling.

α,α′-Anhydride (II).—This compound is the chief product resulting from the action of a mixture of acetic acid and dilute sulfuric acid on di-β-hydroxy-α-naphthoquinone, but it is invariably accompanied by a small amount of the α,β′-anhydride. In preparing the compound the heating should not be prolonged beyond the time necessary to effect the dehydration, as this results in a darker, less pure product. The following method was found most satisfactory. One-half gram of finely powdered di-β-hydroxy-α-naphthoquinone was suspended in 40 cc. of glacial acetic acid and 5 cc. of a solution of equal parts by volume of concentrated sulfuric acid and water, and the mixture was rapidly brought to the boiling point. Within five minutes the starting material had completely passed into solution and in another five minutes the anhydride began to separate. After continuing the boiling for a total of fifteen minutes the mixture was cooled and the crystalline product collected and washed; yield 0.39 g. The material so obtained varies in color from deep golden yellow to dark brown, and it sometimes contains traces of unchanged starting material which can be removed by

---

(6) The identification was made by Mr. J. T. Dunn in my laboratory. Microanalyses by Mrs. G. M. Wellwood.—L. F. F.

(7) Straus, Bernoully and Mautner, *Ann.*, **444**, 188 (1925).

digestion with cold 1% alkali. The product was purified by crystallization from glacial acetic acid, using about 230 cc. to the gram and clarifying the solution with animal charcoal. The originally yellow or brown material then acquires a definitely orange cast, the substance separating as well-formed, detached needles of a clear orange-yellow color. The recovery amounted to about 60%, and the mother liquor on spontaneous evaporation deposited first yellowish needles of the same substance, followed by orange tufts of the α,β′-anhydride. After further recrystallization the α,α′-anhydride melted at 349–350°[8] with some decomposition.

Anal. Calcd. for $C_{20}H_8O_5$: C, 73.16; H, 2.46. Found: C, 73.06; H, 2.50.

The substance gives an orange-red solution in concentrated sulfuric acid and the reprecipitated material is pure yellow. The compound was recovered unchanged after being heated for one hour with *o*-phenylenediamine and glacial acetic acid. The anhydride gives a very characteristic fusion test (microscope) strongly resembling that obtained from di-β-hydroxy-α-naphthoquinone. On hydrolysis with boiling alkali the compound is converted into di-β-hydroxy-α-napthoquinone.

α,β′-Anhydride (III).—Five grams of di-β-hydroxy-α-naphthoquinone was dissolved in 250 cc. of cold concentrated sulfuric acid and after standing at room temperature for thirty minutes the deep red solution was poured into 3 liters of water. The flocculent orange-red precipitate was washed and dried; yield 4.35 g. This material proved to consist largely of the α,β′-anhydride mixed with a small amount of the red β,β′-isomer. The latter is much the less soluble in organic solvents and its complete removal is not easily accomplished. The α,β′-anhydride can be obtained in a pure condition by repeated crystallization from glacial acetic acid, using each time a quantity of solvent insufficient to dissolve all of the material (250 cc. per gram), but the process is tedious for the β,β′-anhydride dissolves to a very slight but definite extent in acetic acid. A better method was found in the use of dilute (2:1) nitric acid. It was found that the α,β′-anhydride crystallizes very well from the acid while the β,β′-isomer does not appear to dissolve at all in acid of this concentration. When boiled with stronger acid it slowly passes into solution but it apparently is oxidized, for the colorless solution on spontaneous evaporation leaves a residue of colorless crystals. As a result of these tests the following method was adopted. One-tenth gram of the anhydride mixture was added to a mixture of 50 cc. of concentrated nitric acid and 25 cc. of water, heated just below the boiling point. There was a lively evolution of gas and a large part of the material rapidly dissolved. The solution was cooled slightly, filtered through a suitable paper supported by a platinum cone from some undissolved, crimson red material (largely β,β′-anhydride), reheated, and allowed to cool. The α,β′-anhydride crystallized in fine hair-like needles forming a bright orange silky felt. This material was very pure, and the mother liquor yielded a further quantity of equally pure α,β′-anhydride and there was no indication of the presence of the isomer. About half of the weight of the mixture was recovered as pure α,β′-anhydride. Material which had been crystallized twice from glacial acetic acid dissolved nearly completely in the nitric acid solution.

The pure α,β′-anhydride closely resembles the α,α′-isomer in appearance except that it has a brilliant, pure orange color with no suggestion of yellow. It is fairly readily soluble in boiling nitrobenzene and crystallizes as short orange needles. It is more soluble in glacial acetic acid than the α,α′-isomer. The solution in concentrated sulfuric acid is deep red and the reprecipitated material is orange-yellow. The anhydride is slowly attacked by boiling alkali to give a red solution from which di-β-hydroxy-α-naphthoquinone is precipitated on acidification. The α,β′-anhydride melts at 317–318°[8] with some decomposition. It gives a good fusion test.

Anal. Calcd. for $C_{20}H_8O_5$: C, 73.17; H, 2.44. Found: C, 73.28; H, 2.64.

Azine of the α,β′-Anhydride.—One-half gram of the anhydride was dissolved in 200 cc. of glacial acetic acid by boiling and to this was added a filtered solution prepared from 0.6 g. of *o*-phenylenediamine hydrochloride, 2.5 g. of crystalline sodium acetate, and 50 cc. of glacial acetic acid. Heated on the water-bath for forty-five minutes the hot solution deposited yellow crystals of the azine in a good condition, the yield of the washed and dried material being 0.44 g. Crystallized from glacial acetic acid (500 cc.) the substance formed golden yellow plates melting at 329–330°.[8]

Anal.[9] Calcd. for $C_{26}H_{12}O_3N_2$: N, 7.00. Found: N, 6.86.

β,β′-Anhydride (IV).[10]—This bright red, sparingly soluble quinone appears to be the sole anhydride formed when di-β-hydroxy-α-naphthoquinone is treated with acetic anhydride in combination with either sulfuric acid or sodium acetate. The substance was satisfactorily prepared by dissolving 0.5 g. of the dihydroxy quinone in 50 cc. of nitrobenzene, cooling the solution to 50°, and adding a solution prepared by dissolving 5 cc. of concentrated sulfuric acid in 20 cc. of acetic anhydride with cooling. The solution became cherry red and almost immediately began to deposit glistening, bright red plates of the β,β′-anhydride. After cooling the material was collected and washed thoroughly with alcohol and benzene; yield 0.43 g. The substance thus obtained was entirely homogeneous and appeared to be directly pure. Recrystallized from nitrobenzene (about 200 cc.) it formed fiery red plates of great beauty.

Anal.[9] Calcd. for $C_{20}H_8O_5$: C, 73.16; H, 2.46. Found: C, 72.68; H, 2.46.

The exceedingly slight solubility of the compound in glacial acetic acid and the action of nitric acid on the substance have been mentioned above. In a capillary tube the anhydride decomposes at about 335–345° without showing signs of melting. When heated on a cover glass and examined microscopically the compound does not seem to melt but strikingly beautiful, deep red scales having a high luster collect on top of the substance heated. When boiled with dilute alkali it becomes green at first, due to a reduction, and then it dissolves to a red solution of the salt of di-β-hydroxy-α-naphthoquinone.

[8] Determined with a Berl–Kullmann copper block (uncorr.) by L. F. F.

[9] Analysis by Mrs. G. M. Wellwood.

[10] Preparative experiments by L. F. F.

Di-azine of the β,β'-Anhydride.[10]—The anhydride (0.2 g.) was suspended in glacial acetic acid (200 cc.) and refluxed with a solution of *o*-phenylenediamine prepared as above. The red plates were rapidly replaced by hair-like yellow needles of the reaction product, and after refluxing the mixture for two hours the conversion was nearly complete. As microscopic examination revealed the presence of a few unchanged plates of the anhydride, the material was digested for a short time with alkaline hydrosulfite solution containing some alcohol. The unattacked material was crystallized twice from nitrobenzene, in which it is only moderately soluble, clarifying the solution with animal charcoal. The compound was obtained as small, somewhat dull yellow needles, m. p. 409–410°.[8]

Summary

Exposed to the light in aqueous solution, hydroxynaphthoquinone is largely converted into a diquinone by a process of dehydrogenation, and to a lesser extent it is hydroxylated in the quinone ring. A method is described for the preparation of the main reaction product in quantity, and by the isolation of three isomeric internal anhydrides it is established that the substance has the structure of di-β-hydroxy-α-naphthoquinone.

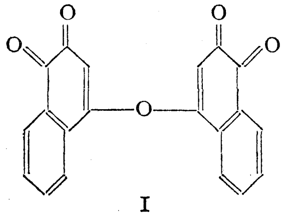
Concerning Wichelhaus' "Di-β-naphthoquinone Oxide"[1,2]

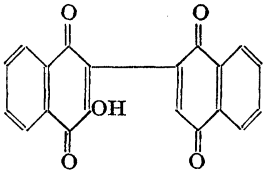
BY SAMUEL C. HOOKER AND LOUIS F. FIESER

In 1897 Wichelhaus[3] discovered that β-naphthoquinone is converted by warm aqueous ferric chloride solution into a substance which evidently is formed from two molecules of the starting material and which Wichelhaus regarded as having the structure of an oxide, I. Although this formula seems inconsistent with Wichelhaus' own observation that the substance dissolves in cold alkali or even soda solution and may be recovered unchanged from the red solutions, the matter does not appear to have received any further attention. On repeating the preparation it was found in the present work that the reaction is very smooth and that the oxidation product can be obtained in a good condition in nearly quantitative yield. The precipitated material first obtained is pure yellow, but it forms orange-red needles when crystallized from acetic acid. That it contains a free hydroxyl group, as suggested by the marked acidic properties, was established by the formation of a monoacetyl derivative. Clearly the oxide structure is inadmissible, and the substance is more properly regarded as a hydroxy dinaphthyldiquinone.



I

The yellow color of the precipitated compound at first suggested the structure of an α-naphthoquinone, and it seemed that the substance could possibly be accounted for by assuming the formation of hydroxynaphthoquinone by oxidation and the condensation of two molecules of this oxidation product with the elimination of water, giving II. This might have been confirmed by the formation of the compound from hydroxynaphthoquinone, but under the above experimental conditions the hydroxyquinone was largely unchanged and yielded none of the condensation product. It was thought also that if the Wichelhaus compound has the structure II it might be expected to yield di-β-hydroxy-α-naphthoqui-



II

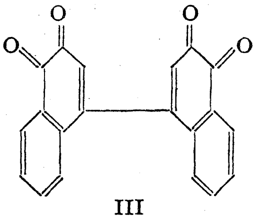
(2) In a letter written to me a few weeks before his death Dr. Hooker commented as follows on a prospective extension of experiments which he had started in 1926–1927 and continued with Dr. G. H. Connitt in 1927–1928 on the structure of the so-called di-β-naphthoquinone oxide: "A number of interesting compounds and reactions resulted from my work with this substance which I shall be glad to see satisfactorily explained." His hope to resume work on the problem was not realized, and the notes which subsequently came to my hand included a formula for the "oxide" which was regarded as purely provisional. The acetyl derivative was described and methods were given for the preparation of the "oxide" and of compounds A, B (first method), C (first method), and D, for the oxidation of A, and for the conversion of D into B, but no formulation was suggested for the new compounds. Following a course which I believe to be in accordance with Dr. Hooker's wishes, I have attempted to carry the work to completion.—L. F. FIESER.

(3) Wichelhaus, *Ber.*, **30**, 2199 (1897).

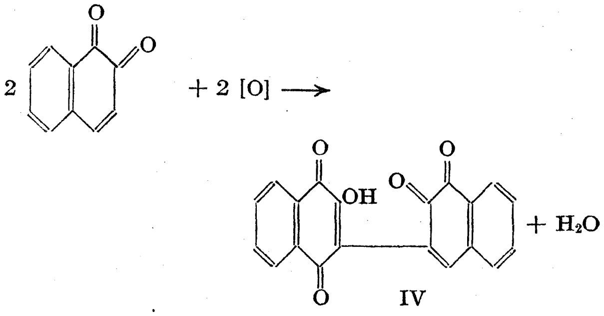
none[4] on oxidation in alkaline solution. This does not seem to be the case, for although oxidation occurs on exposing the alkaline solution to the air the product has quite different properties, as will be described below.

Another hypothesis regarding the formation of the "oxide" was suggested by the observation that on crystallization of the crude product there was isolated a small quantity of the dinaphthyldiquinone III. Although this may arise merely by the oxidation of a trace of dinaphthyldiquinhydrone present in the starting material, it seemed possible that III is an intermediate in the reaction. Experiment showed, however, that the diquinone is practically unchanged even when boiled with aqueous ferric chloride solution. The possibility of the formation of hydroxynaphthoquinone and its immediate condensation with unchanged β-naphthoquinone was similarly eliminated in test experiments, and the problem was then attacked by degradation.



III

On submitting the Wichelhaus compound to zinc dust distillation there was obtained a hydrocarbon which was fully identified as β,β-dinaphthyl by comparison with samples prepared by the zinc dust distillation of di-α-naphthoquinone[5] and by synthesis. Since there is considerable uncertainty in the literature as to the identity of a substance described by Watson Smith[6] as α,β-dinaphthyl, this hydrocarbon was prepared for comparison by synthesis from α-tetralone and β-naphthylmagnesium bromide. The properties of the compound are precisely those reported by Smith and the hydrocarbon is quite different from the above degradation product. The isolation of the β,β-compound provides a significant clue to the structure of the hydroxy dinaphthyldiquinone. Since there is no reason to believe that four of the oxygen atoms do not occupy their original positions in the naphthalene rings, as for example in formula II, and since the pronounced acidity of the compound indicates that the hydroxyl group is situated in a quinone ring, the substance very probably has the structure IV. The presence of a β-quinone group accounts for the orange-red color of the crystalline material, while the color of the alkaline solution is that expected for a β-hydroxy-α-naphthoquinone derivative. The mechanism of the remarkable oxidation reaction is still obscure.



IV

As mentioned above the hydroxy dinaphthyldiquinone is easily oxidized by air in alkaline solution, and an investigation of the reaction product has furnished additional support for the formula IV. The oxidation was accomplished by allowing an alkaline solution of Wichelhaus' compound to go to dryness in an open dish at room temperature, and there was obtained from the residue in over 50% yield a yellow compound ($C_{20}H_{12}O_7$) which gives an orange solution in alkali. This substance, which will be designated A, is quite susceptible to other changes in the presence of acids and bases and even in neutral solvents. In the course of purifying the yellow substance it was discovered that in boiling acetic acid a rather rapid isomerization takes place giving a more stable, yellow compound B which dissolves in alkali with a crimson color. When A is boiled for some time with alcohol it also yields some of the isomer B, but there is formed in addition another yellow compound, C, which differs in composition from the starting material by the elements of carbon dioxide. Compound C can be obtained in good yield by heating A in pyridine with a small amount of copper powder. This decarboxylation clearly shows that the oxidation of the hydroxydinaphthyldiquinone in alkaline solution involves the opening of one of the rings. A similar oxidation can be accomplished with the use of hydrogen peroxide in glacial acetic acid solution, but in this case isomerization also occurs and the product is B.

There are definite indications that the hydroxynaphthoquinone grouping of IV remains intact in the course of the oxidation, one being that on ex-

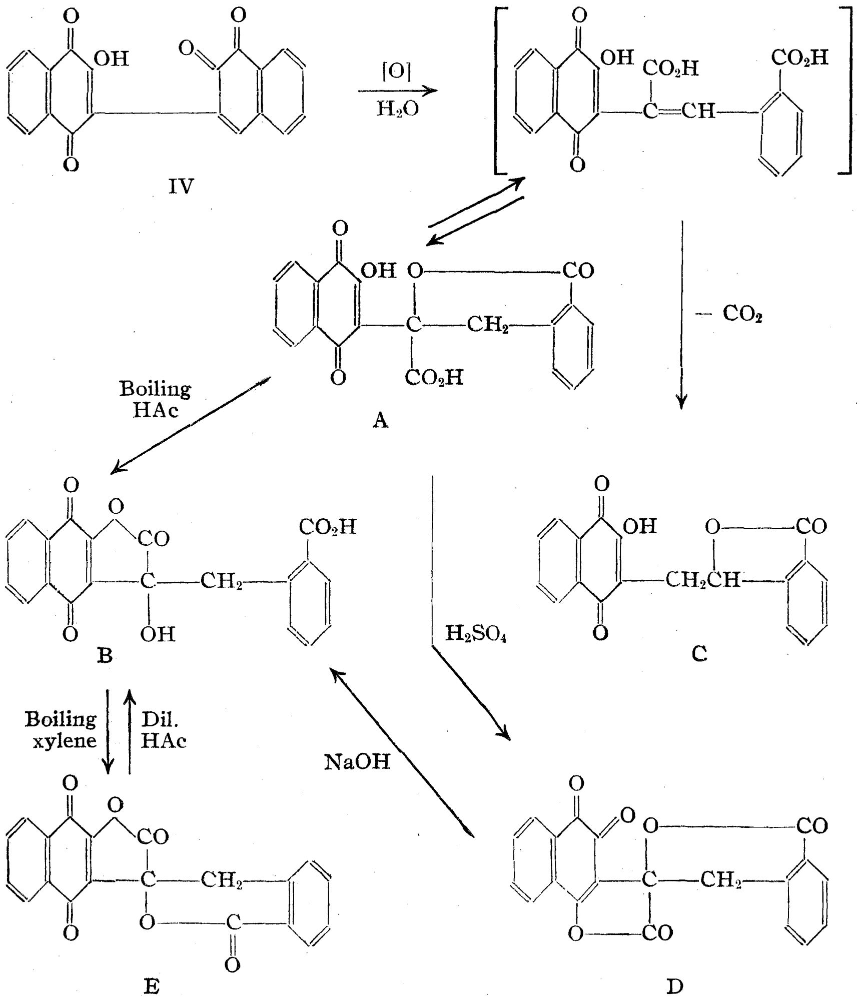
posing an alkaline solution of A to the air the substance is converted in part into hydroxynaphthoquinone. The yellow color of compounds A, B and C also suggests the α-quinone structure. By the action of cold, concentrated sulfuric acid A, however, is converted into a red anhydro compound D which appears to be a quinone of the β-series, for it forms a bisulfite addition compound. Dilute alkali converts the substance into B. This interconversion of ortho and para quinone derivatives is likewise indicative of the structure of a hydroxynaphthoquinone.



The facts at present available concerning these and other transformation products suggest a provisional interpretation which is believed to be fundamentally sound if still uncertain in some details. The composition of the oxidation product A is such as to indicate that the reaction involves the rupture of the molecule between two singly linked carbon atoms with the acquisition of two hydroxyl groups. A normal α-diketone oxidation would yield a substance of the formula shown in brackets, but there is evidence that this cannot represent the structure of A. Such a substance probably would be orange or red, because of the unsaturated character of the side chain, and it would surely react with three moles of diazomethane; but A is yellow and yields a dimethyl derivative on treatment with this reagent. The presence in A of but one acidic group in addition to the original hydroxyl group of the quinone ring suggests that the dicarboxylic acid initially formed undergoes lactonization, and for reasons which will be given below compound A is regarded as a δ-lactone of the formula shown. That A is not the primary product is indeed clearly indicated by the color changes observed in carrying out the oxidation. On exposing the alkaline solution of IV to the air it acquires an intensely crimson color as the oxidation proceeds to completion, but the substance (A) which slowly separates after the solution has been acidified dissolves in alkali to an orange, and not a crimson, solution. A satisfactory explanation seems to be that the dibasic acid responsible for the crimson color isomerizes in the acidic solution to the less soluble lactone A. The change seems to be reversible, for on warming the orange alkaline solution of A it acquires a crimson color which persists on cooling.

It seems necessary to assume that A contains a δ- rather than a γ-lactone ring in order to account for the properties of the still more stable isomer B. Only one acidic group is present in B for the substance yields a monomethyl ester on reaction with diazomethane. The ester gives some methane on treatment with methylmagnesium iodide, but apparently other changes obscure the full reaction expected for an alcoholic hydroxyl group. This group seems to be in tertiary combination, for the ester is not acetylated in the presence of either acidic or basic catalysts. This is the chief reason for believing that in the formation of A the lactone ring does not close in the γ-position, for then B would contain a secondary alcoholic group amenable to acetylation. The properties of B, moreover, are suggestive of a δ- rather than a γ-hydroxy acid, for it is not very prone to form a dilactone. On boiling a xylene solution of the substance water is easily eliminated giving a yellow anhydro compound (E) which is regarded as a dilactone, but on simply crystallizing the compound from dilute acetic acid it reverts to B with the opening of the second lactone ring. The red compound D is regarded as a dilactone differing from E only in the character of the quinone group, and its ready formation directly from A is understandable in terms of the formulas suggested. According to the above interpretation the isomerization of A to B in acetic acid solution involves the opening of a δ-lactone ring and the closing of a more stable γ-lactone ring incorporating the acidic hydroxyl group of the quinone.

The ready formation of C in the decarboxylation reaction suggests that the carboxyl group is eliminated not directly from the lactone A but from the unsaturated acid with which A appears to be in equilibrium, particularly in pyridine solution. If an unsaturated hydroxyquinone acid is the immediate product of the decarboxylation it apparently lactonizes at once, for C is yellow, rather than orange-red, and has but one acidic group. The formula suggested for the compound is preferred to that of a dihydrofurano-α-naphthoquinone with a free carboxyl group because like other 2-hydroxy-3-alkyl-1,4-naphthoquinones, the compound can be methylated with diazomethane but not with methyl alcohol and a mineral acid. It seems likely that the substance is a γ-rather than a δ-lactone because it is quite stable and shows no tendency to revert to a hydroxy acid similar to B in aqueous solvents. In cold concentrated sulfuric acid solution C is slowly converted in part into a red anhydro compound F. This was obtained in only very small amounts and it has not been fully characterized, but it does not appear to be an ortho quinone. It is conceivable that the substance is the lactone (ϵ) of an unsaturated hydroxy-α-quinone acid, but there is as yet no evidence on this point.

With the possible exception of F the various compounds seem to be satisfactorily accounted for by the formulas suggested and on the basis of the structure IV for the substance resulting from the oxidation of β-naphthoquinone with ferric chloride. A rigid proof of the individual structures, however, is not available, and the above formulation may require some revision with respect to the exact character of the lactone rings.

Experimental Part

2 - Hydroxy - 3,3′ - dinaphthyl - 1,4,1′,2′ - diquinone (IV).—For the best results in the oxidation the conditions should be controlled more carefully than indicated by Wichelhaus.[3] β-Naphthoquinone of good quality (10 g.) was finely ground, made into a paste with a part of 400 cc. of water, rinsed into a flask, and treated with 40 g. of ferric chloride crystals dissolved in the rest of the water. The mixture is heated in a water-bath kept at 65–70° and the flask is constantly agitated. The quinone darkens and partly dissolves, and in about one hour the product suddenly becomes uniform brownish-yellow and settles, leaving a clear supernatant solution; the oxidation is then complete. Ordinarily the material is obtained in very satisfactory condition; yield 10.2 g. When the very pure, crystalline β-naphthoquinone described by Fieser and Fieser[7] is used the grinding of the sample is unnecessary and it is convenient simply to introduce the reagents and provide mechanical stirring. The yield is the same but the product is pure yellow.

For purification the amorphous brown or yellow material was crystallized from glacial acetic acid, using 45 cc. per gram. The first crop (7.7 g.) separated as deep orange-red needles of the best quality. The mother liquor from the crystallization of the brownish-yellow crude material was allowed to stand overnight and a compact orange-red deposit separated. This proved to be almost certainly the dinaphthyldiquinone (III) studied with Walsh,[8] identification being made by means of the color reactions with 1% sodium hydroxide solution.

The pure hydroxydiquinone when introduced to a bath at 230° darkens at about 240° and melts at 253–254° with decomposition. It imparts a bromine color to concentrated sulfuric acid and on absorption of moisture the solution deposits clusters of microcrystals. Water precipitates the unchanged compound as amorphous flocks changing to microcrystalline dots of very characteristic appearance. The compound dissolves easily in dilute alkali in the cold, as well as in sodium carbonate or bicarbonate solution. The solutions are orange-red and became darker when heated. On spontaneous evaporation of a drop of the alkaline solution there appears around it a very characteristic, almost black ring of microcrystals of the sodium salt.

In investigating the formation of the oxidation product the dinaphthyldiquinone III was boiled with strong ferric chloride solution, but it remained unchanged. At 65–70° hydroxynaphthoquinone was attacked to only a minor ex-

[8] Hooker and Walsh, *J. Chem. Soc.*, **65**, 321 (1894).

tent by aqueous ferric chloride. A mixture of equimolecular amounts of β-naphthoquinone and hydroxynaphthoquinone gave, after recrystallization, no more of the hydroxydiquinone than could be obtained from the β-naphthoquinone used.

The **acetyl derivative of IV** was prepared by slowly stirring 1 g. of the hydroxy compound into a solution of 0.2 cc. of concentrated sulfuric acid in 7 cc. of acetic anhydride at 30–40° for about one hour, a part of the acetate crystallizing during this period. The mixture was poured into water and after several hours the crystalline product (1.1 g.) was collected. The compound is readily soluble in benzene or glacial acetic acid, moderately soluble in alcohol. It crystallizes from methyl alcohol as orange-red prisms or tablets, m. p. 205–205.5°. It is slowly hydrolyzed by 1% sodium hydroxide to the starting material.

Anal. Calcd. for $C_{22}H_{12}O_6$: C, 70.96; H, 3.25. Found: C, 70.99, 70.97; H, 2.96, 3.39.

It may be noted that the analysis reported by Wichelhaus[3] for a compound, m. p. 164–165°, which he obtained by reductive acetylation and regarded as a tetraacetyl derivative agrees equally well with the percentages calculated for a pentaacetyl compound.

Conversion to β,β-Dinaphthyl.—A finely ground mixture of 2 g. of the hydroxy dinaphthyldiquinone (IV) and 80 g. of zinc dust was placed in a flask, covered with 60 g. of zinc dust, and heated to redness. The distillate, which amounted to about three drops, promptly solidified. The material from three runs was clarified and dried in ether solution, and after taking off most of the ether there was obtained a good yellow solid which was collected and washed with a little ether. After two crystallizations from alcohol it was obtained as thin, iridescent, faintly yellow-green plates, m. p. 180–181°; picrate, m. p. 182–183°.

The zinc dust distillation of di-α-naphthoquinone in the same way gave in similar yield a substance of identical appearance and properties and showing no depression in the melting point. A sample of β,β-dinaphthyl was also prepared by Dr. E. B. Hershberg from β-naphthylmagnesium bromide and β-bromonaphthalene and crystallized from benzene–ligroin. This material was almost colorless (but fluorescent) and melted 1.5–2° higher than the above samples but mixtures of the hydrocarbons and the picrates showed no depression. The synthetic hydrocarbon melted at 185–186°, corr.; picrate, orange-yellow needles from benzene, m. p. 186–187°, corr.

Synthesis of α,β-Dinaphthyl.[9]—A solution of 8.8 g. of α-tetralone in absolute ether was slowly added to a solution of the Grignard reagent prepared from 15 g. of β-bromonaphthalene and after refluxing the resulting clear solution for one hour the mixture was worked up in the usual way and the product distilled in vacuum. Vigorous elimination of water occurred at 170–200°, 1–2 g. of naphthalene came over in the fore-run, and the main fraction of unsaturated hydrocarbon distilled at 217–219° (3 mm.) as a yellowish oil; yield 11.3 g. (74%). This material (10.5 g.) was dehydrogenated by heating it with sulfur (1.35 g.) at 230–250° for forty-five minutes and the product was distilled at 2 mm. pressure. The resulting viscous oil slowly solidified and on crystallization there was obtained 9.1 g. of material, m. p. 72–73°. After two recrystallizations the hydrocarbon melted constantly at 74.5–75°, and a sample recovered from the purified picrate melted at the same temperature.

Anal.[10] Calcd. for $C_{20}H_{14}$: C, 94.44; H, 5.55. Found: C, 94.52; H, 5.72.

The hydrocarbon crystallizes from petroleum ether in small, ball-like clusters of microcrystals, and the molten material is very slow to solidify. In all of its properties the substance corresponds closely with the compound regarded by Watson Smith[6] as α,β-dinaphthyl (m. p. 76°), and the present results indicate that, contrary to the conclusions of Meyer and Hofmann,[11] Smith was completely successful in isolating the pure hydrocarbon from a mixture consisting chiefly of the two isomers.

The **dipicrate** was best prepared by using two equivalents of picric acid: 4.5 g. of the acid was dissolved in a hot solution of 2.54 g. of α,β-dinaphthyl in 40 cc. of absolute alcohol. The dipicrate which separated on cooling was dissolved with 2 g. of picric acid in 40 cc. of absolute alcohol, and on cooling there was obtained 5.4 g. of heavy, bright orange needles, m. p. 127–127.5°, corr. The melting point was not changed by further crystallization.

Anal.[10] Calcd. for $C_{20}H_{14}\cdot 2C_6H_3O_7N_3$: N, 11.80. Found: N, 11.57.

A monopicrate does not appear to be stable, for a solution of equivalent quantities of the components deposited almost exactly the theoretical quantity of the dipicrate and the pure hydrocarbon was recovered from the mother liquor. These observations clearly support the conclusion of Gump[12] that the compound which Wegscheider[13] had in hand was not α,β-dinaphthyl.

Compound A.—A solution of 18 g. of 2-hydroxy-3,3′-dinaphthyl-1,4,1′,2′-diquinone in 3600 cc. of 6% sodium hydroxide was distributed amongst six shallow trays of about 645 sq. cm. surface and allowed to evaporate spontaneously in a light room. The at first orange-red solution slowly changed to a permanent crimson. After two weeks the solutions had gone to dryness, and the residues were combined and dissolved in 13.2 liters of water. The intensely crimson alkaline solution was acidified with 480 cc. of concentrated hydrochloric acid made up to a volume of 1200 cc. with water, and the flocculent precipitate which separated immediately was filtered off without delay and discarded (as attempts to purify the material were not successful). The yellow acid filtrate, which should be refiltered quickly in case it is not perfectly clear, was allowed to stand at room temperature for five days, during which time the oxidation product (A) slowly separated as a dull brown-yellow microcrystalline deposit; yield 10.7 g. (54%).

In purifying the crude product care must be taken to avoid prolonged heating of the material in contact with solvents in which it is appreciably soluble (acetic acid or alcohol). One gram of the substance will dissolve in 74 cc. of glacial acetic acid if refluxing is continued for fifteen minutes, but by this time the compound is in part isomerized to B and only 0.22 g. of A separates on cooling. Very

(11) Meyer and Hofmann, *Monatsh.*, **37**, 710 (1916).

(12) Gump, THIS JOURNAL, **53**, 380 (1931).

(13) Wegscheider, *Monatsh.*, **5**, 238 (1884); *Ber.*, **23**, 3199 (1890).

satisfactory material was obtained by refluxing for two minutes a suspension of 10 g. of the crude oxidation product with 100 cc. of glacial acetic acid, filtering the solution, and washing the undissolved substance with cold glacial acetic acid. The washed material was pure, bright yellow in color and weighed 8.6 g. The wash liquor deposited a crust of brown crystals which can be used for the preparation of B. In recrystallizing A it is not advisable to allow time for complete saturation of the solution. Thus 1 g. of the washed product was added to 75 cc. of boiling glacial acetic acid and after refluxing for three minutes the solution was filtered, leaving a residue of 0.56 g. of undissolved substance. The filtrate was reheated until clear (one minute) and on cooling it deposited 0.20 g. of bright yellow, diamond-shaped plates. Heated in a capillary tube the substance softens at about 201°, runs up the tube with gassing at 203–205°, and then gives a clear yellow liquid. It dissolves in dilute alkali or soda solution in the cold, giving orange solutions which become crimson on warming.

Anal. Calcd. for $C_{20}H_{12}O_7$: C, 65.93; H, 3.29. Found: C, 65.50, 65.71; H, 3.53, 3.50.

The **dimethyl derivative of A** was obtained by allowing the substance to stand in contact with an ethereal solution of diazomethane, taken in large excess, for several hours. The acid is sparingly soluble in the medium and it is converted only slowly into the ester, which appears as a less highly colored yellow solid. When nitrogen was no longer evolved the solvent was removed and the residue taken up in glacial acetic acid, in which it is moderately soluble. The solution was diluted at the boiling point with an equal volume of water and after standing at room temperature for several hours it deposited heavy, yellow, prismatic needles. The substance softens at about 220° and melts at 225–226°. It is insoluble in dilute alkali in the cold and hydrolysis occurs slowly at the boiling point, giving a red solution. In the Zerewitinoff test the compound liberated no gas from a Grignard reagent in diphenyl ether–xylene on being heated at 100° for ten minutes.

Anal.[10] Calcd. for $C_{20}H_{10}O_5(OCH_3)_2$: OCH_3, 15.82. Found: OCH_3, 15.74.

Oxidation of A.—While compound A can be recovered unchanged from its orange solution in cold 1% alkali if precipitated at once, the solution becomes much darker on standing, and on investigating the material recovered from such a solution after it had been exposed for two days it appeared to contain small amounts of A and B and a positive identification of hydroxynaphthoquinone was made by microscopic tests of the sodium and pyridine salts, the material precipitated from alkaline solution, and the color in sulfuric acid solution.

Compound B.—One gram of the substance A was refluxed with 100 cc. of glacial acetic for one and three-quarters hours and the resulting yellow solution was diluted with 100 cc. of hot water. On cooling the pure product slowly separated in the form of rather heavy, flat, yellow needles; yield 0.85 g. The behavior of the substance when heated in a capillary tube is quite characteristic. When introduced to a bath at 200° the material froths vigorously with the liberation of water and then subsides to a dry solid, but when heated gradually in a bath initially at room temperature no change can be detected in the appearance of the crystals as the material is more gently dehydrated. At about 247° minute droplets are formed at the surface of the glass, giving the appearance of orange lines across the tube, and at 264° the substance completely melts to a clear liquid showing some signs of decomposition.

Anal. Calcd. for $C_{20}H_{12}O_7$: C, 65.93; H, 3.29. Found: C, 65.85, 66.02; H, 3.48, 3.50.

The compound is stable to the prolonged action of hot glacial acetic acid with or without added hydrochloric acid. It dissolves in cold concentrated sulfuric acid to a light orange-yellow solution from which water precipitates the unchanged compound in an amorphous form rapidly crystallizing to branching curved needles. A drop of the solution exposed on a slide deposits characteristic frond-like clusters and circular groups of crystals. The sulfuric acid solution reddens on warming and then becomes dull brown-red. Compound B dissolves readily in cold 1% sodium hydroxide yielding a crimson solution. On attempting to acetylate B in pyridine solution the material was recovered, after crystallization, in an unchanged condition.

Compound B was also obtained by warming a suspension of 1 g. of the finely powdered hydroxy dinaphthyl-diquinone IV in 30 cc. of glacial acetic acid with 1.5 cc. of 30% hydrogen peroxide. After about thirty minutes the material had dissolved to an orange-yellow solution, and this became pure yellow at the end of one hour. The solution was treated with 20 cc. of hot water and on cooling it slowly deposited 0.4 g. of orange-yellow needles. This material was boiled with 15 cc. of glacial acetic acid for one hour, and after adding 7 cc. of water and cooling there was obtained 0.3 g. of yellow needles of B. The substance was identified by the usual tests and by conversion to the ester and the anhydride.

The **methyl ester of B**, prepared as above with diazomethane, crystallized very slowly from a solution in glacial acetic acid which had been diluted at the boiling point with an equal volume of water. It forms flat, pale yellow needles melting at 249–250°, with some previous softening.

Anal.[10] Calcd. for $C_{21}H_{14}O_7$: OCH_3, 8.20. Found: OCH_3, 8.38.

The ester is moderately soluble in glacial acetic acid, sparingly soluble in alcohol or benzene. It is not affected by boiling xylene and crystallizes from this solvent in one or two large, compact clusters of needles. The substance is insoluble in cold alkali but it is hydrolyzed rather readily at the boiling point. It was recovered unchanged after being heated at 100° with acetic anhydride in pyridine solution or in the presence of sulfuric acid. In the Zerewitinoff test 0.1 mole of methane was liberated in the cold and a total of 0.3 mole was evolved after heating at 100° for five minutes.

Compound E (α-Anhydride of B).—One-tenth gram of B was brought into solution in 15 cc. of xylene by gentle heating and shaking and the clear yellow solution was boiled for a minute or two on the hot-plate. A ring of moisture appeared and was allowed to escape, and soon the anhydride began to crystallize from the boiling solution as clusters of fine yellow needles. The material collected after cooling amounted to 0.08 g. and it was analyzed without further purification.

Anal.[10] Calcd. for $C_{20}H_{10}O_6$: C, 69.36; H, 2.91. Found: C, 69.62; H, 2.95.

Introduced in a capillary tube to a bath at 220° the substance shows no signs of frothing or other change, orange lines appear across the sample at about 249° and melting is complete at 264°. Except for any indication of loss of water, the behavior is identical with that of B, and it is inferred that the latter yields E on being heated without solvent. The anhydro compound is readily soluble in dioxane or tetrachloroethane but does not crystallize well even on the addition of benzene, in which it is sparingly soluble. It dissolves easily in glacial acetic acid and after dilution with hot water the solution deposits needles of B, easily distinguished from the anhydride by the frothing at 200° in a melting point capillary. Compound E dissolves easily in cold alkali or soda solution with a crimson color. On acidifying the cold alkaline solution this turns yellow and cloudy and a small amount of yellow material slowly separates. On boiling this at first dissolves to a clear solution which then deposits a yellow, granular product having the properties of E rather than B (no frothing at 200°). Compounds B and E behave exactly the same in this test and in the tests with sulfuric acid.

Compound D (β-Anhydride of B).—One gram of A was dissolved in 50 cc. of concentrated sulfuric acid at room temperature and after standing for one hour the red solution was poured into 1 liter of water. The flocculent orange-red precipitate was washed and dried (0.98 g.) and crystallized from 25 cc. of glacial acetic acid. The substance forms clusters of red, prismatic blades, m. p. 248–249.5°.

Anal. Calcd. for $C_{20}H_{10}O_6$: C, 69.36; H, 2.91. Found: C, 69.10; H, 3.09.

It dissolves slowly in cold sodium bisulfite solution and a colorless addition product separates. Addition of hydrochloric acid to a solution of the colorless material precipitates D. The compound dissolves rapidly in cold 1% sodium hydroxide solution and the yellow material which precipitates on acidification was identified, after crystallization, as B. Reaction occurred on treatment of D with diazomethane and the substance rapidly dissolved in the ether. A glass-like resin was left on evaporating the solvent and it could not be crystallized.

Compounds C.—One gram of A was refluxed with 50 cc. of alcohol for five and one-half hours and the resulting solution was allowed to cool and seeded with a crystal of B. After standing overnight 0.16 g. of needles of B deposited. The mother liquor was then evaporated to a volume of 25 cc. and on standing overnight a small additional quantity of B separated. After about ten days a mixture of B and C had crystallized and on warming the solvent in contact with this material the crystals of C dissolved and those of B were filtered off. On standing the mother liquor deposited 0.26 g. of plates of C in a nearly pure condition, m. p. 174–175°.

The substance was obtained in better yield as follows. A solution of 1 g. of A in 15 cc. of pyridine was heated with 0.05 g. of copper powder just at the boiling point for fifteen minutes, when carbon dioxide was no longer evolved, and the red solution was diluted with 100 cc. of water, filtered through a pad of Norite and treated with an excess of hydrochloric acid. The precipitate often carries down some of the pyridine salt, which gives it an orange color, but this can be decomposed by vigorous shaking, giving pure yellow material; yield 0.9 g. Recrystallized from alcohol or alcohol–water the substance formed lustrous yellow plates (0.7 g.) melting at 177.5–178° and giving no depression when mixed with the above sample. It is readily soluble in benzene, alcohol or ether.

Anal. Calcd. for $C_{19}H_{12}O_5$: C, 71.24; H, 3.77. Found: C, 71.12; H, 3.93.

The compound dissolves easily in cold dilute alkali (or soda) to a light cherry red solution which does not darken on warming, and the unchanged material is precipitated on acidification. It is not altered by prolonged heating at 100° with a mixture of equal parts of glacial acetic acid and concentrated hydrochloric acid, or by boiling the solution in xylene, or by refluxing for three hours a solution in methyl alcohol containing sulfuric acid.

Ester of C.—The reaction with diazomethane proceeds very rapidly and the material all passes into solution. The ester crystallizes very slowly from alcohol, in which it is readily soluble, forming bright yellow, elongated prisms, m. p. 165–166°. It is hydrolyzed slowly by hot 1% sodium hydroxide.

Anal.[10] Calcd. for $C_{20}H_{14}O_5$: C, 71.84; H, 4.22; OCH_3, 9.28. Found: C, 72.11; H, 4.41; OCH_3, 8.85.

Compound F (Anhydride of C).—The substance C (0.2 g.) gives a light orange-yellow solution in cold concentrated sulfuric acid (5 cc.) and if the fresh solution is poured into water the unchanged starting material is precipitated. The acid solution darkens on standing and after fifteen hours only a small amount of brown material is precipitated. At intermediate periods C is converted in part into F, as can be seen clearly by observing under the microscope the crystals deposited when a drop of the solution is exposed on a slide, the anhydride forming small rosets of orange-red needles. After three and one-half hours there seemed to be no further increase in the amount of this material and the orange product obtained on precipitation at this point consisted chiefly of unchanged C mixed with about 0.02 g. of the new substance. Being much less soluble in dilute alcohol than C, compound F was easily separated by dissolving the mixture in alcohol and adding water at the boiling point. The substance separated as bundles of hair-like, red needles. It decomposes at about 220–225° and does not dissolve appreciably in cold sodium bisulfite solution.

Anal.[10] Calcd. for $C_{19}H_{10}O_4$: C, 75.49; H, 3.34. Found: C, 75.45; H, 3.81.

Summary

It is shown that the substance obtained by Wichelhaus by the action of ferric chloride on β-naphthoquinone has the structure of 2-hydroxy-3,3′-dinaphthyl-1,4,1′,2′-diquinone. On exposure of the alkaline solution of the compound to the air for several days a smooth oxidation takes place with the cleavage of the *o*-quinone ring and the formation of an unsaturated hydroxynaphthoquinone dicarboxylic acid derivative which subsequently lactonizes. The resulting substance

has given rise to a number of interesting lactones and dilactones of both the α- and the β-naphthoquinone series and reminiscent of some of the compounds of the lapachol and lomatiol group. These compounds have been investigated and the changes have been for the most part satisfactorily explained.

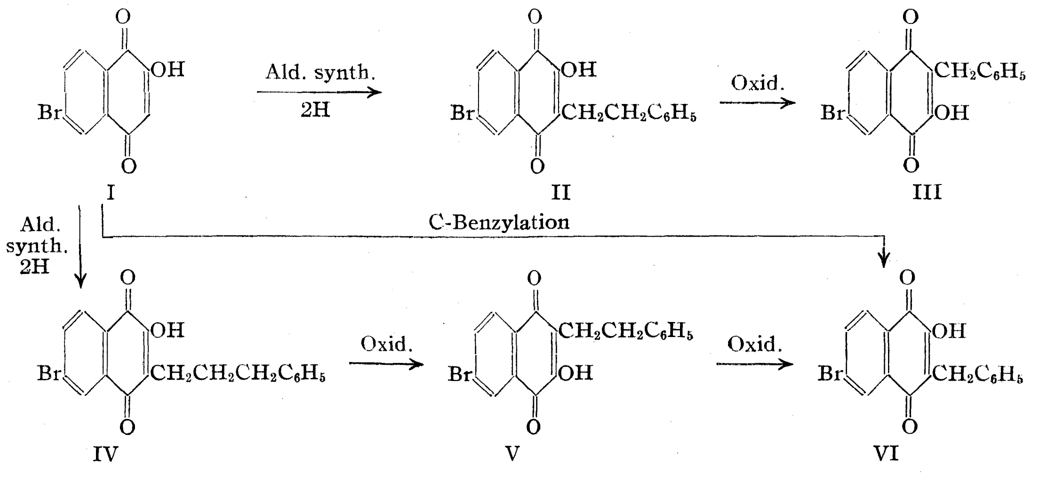
Concerning the Mechanism of the Hooker Oxidation

BY L. F. FIESER, J. L. HARTWELL[1] AND A. M. SELIGMAN[1]

In the course of his investigations of the oxidation of alkyl and alkenyl derivatives of hydroxynaphthoquinone,[2] the late Dr. Samuel C. Hooker came to the conclusion that the essential step in the remarkable reaction discovered by him consists in the opening of the quinone ring and its subsequent closing in a different manner, and consequently that the alkyl and hydroxyl groups exchange places as a result of the oxidation. In understanding with Dr. Hooker, and as already mentioned in one of his papers,[2b] we undertook to provide a rigid test of this part of the mechanism by studying the oxidation of naphthoquinones marked with a distinguishing substituent in the aromatic ring.



2-Hydroxy-6-bromo-1,4-naphthoquinone,[3] I, served as a convenient starting material for the preparation of compounds of the type desired, and it was converted into the derivatives II and IV by condensation with the appropriate aldehydes and hydrogenation of the unsaturated side chain of the condensation products, following the general synthetic method of Hooker.[4] Submitted to the Hooker oxidation with alkaline permanganate, the hydrocinnamyl derivative IV yielded a lower homolog isomeric with the synthetic β-phenylethyl compound II but not identical with this substance. The oxidation product therefore has the alternate structure V and the hydroxyl and alkyl groups have assumed new positions with respect to the bromine atom, in accordance with the theory of Hooker. A second oxidation should result in a reversion to the original positions, with the hydroxyl and bromine located at 2 and 6, respectively. That the second oxidation product indeed has the structure VI was established by the independent synthesis of this compound from the silver salt of I by the method of Fieser.[5] According to the theory an isomer of this benzyl derivative should result from the oxidation of the synthetic β-phenylethyl compound II, and this prediction also was verified.

---

(1) The work on the bromonaphthoquinones and the experiments in the lapachol series were completed by J. L. Hartwell in 1933; the experiments with the alkylnaphthoquinones were carried out by A. M. Seligman in 1934.

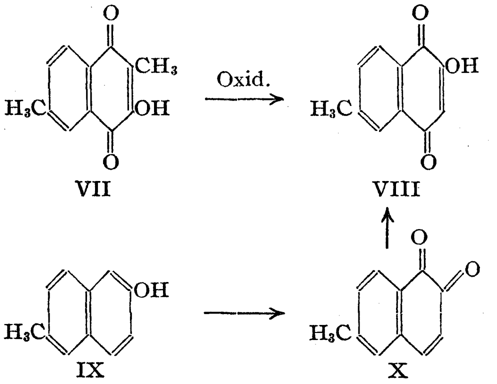
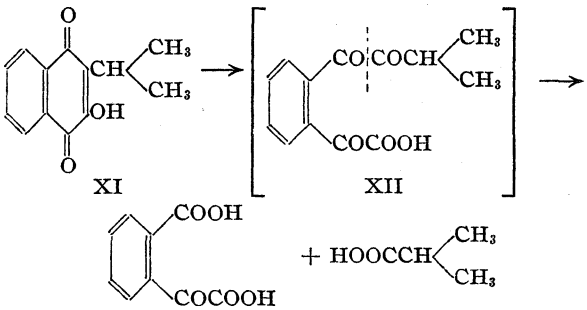
(5) Fieser, *ibid.*, **48**, 3201 (1926).

While these experiments adequately establish the point at issue it seemed desirable to include in the study a case in which the structure of the product of a single oxidation, rather than of two successive oxidations, could be proved by direct synthesis. 2,6-Dimethyl-3-hydroxy-1,4-naphthoquinone[6] (VII) was investigated for the purpose and when oxidized by the Hooker method it was found to give in good yield a hydroxynaphthoquinone having one less methyl group. That it is the methyl group of the quinone ring which has been eliminated is shown very clearly by the observation that the oxidation product easily yields an ether on reaction with methyl alcohol in the presence of a trace of mineral acid, whereas under similar conditions the starting material (VII) is unchanged.[6] As in other cases[7] a substituent in the hydroxyquinone ring effectively blocks the addition reaction. That the hydroxyl group assumes a new position with respect to the remaining methyl group as a result of the oxidation was established by the synthesis of a compound of the structure VIII from 6-methyl-2-naphthol,[8] IX, as indicated. The compound proved to be identical with the oxidation product from VII. Regarding the structure of the starting material IX, obtained from β-methylnaphthalene by sulfonation and fusion, it was found that the substance forms a characteristic 1,8-phthaloyl derivative which can be rearranged with concentrated sulfuric acid to a methylhydroxybenzanthraquinone, showing that the 7(β)-position of the methylnaphthol is unoccupied. This provides an independent proof in confirmation of other, less direct, evidence[8,9] that the substituents are located in the 2- and 6-positions as in formula IX.



It may be concluded from these results that the hydroxyl group and the modified alkyl substituent exchange places as a result of the oxidation, exactly as predicted on the theory that the quinone ring opens in the course of the reaction. In the hope of securing still more direct evidence on this point we undertook to investigate the oxidation of a compound of such a structure that the quinone ring, once opened, could not subsequently be reestablished. A compound suitable for the purpose was obtained by submitting hydrolapachol[4] to two successive oxidations with alkaline permanganate, 2-isopropyl-3-hydroxy-1,4-naphthoquinone (XI) being easily obtained in this way in good yield. When this was treated with alkaline permanganate in the regular manner oxidation proceeded to the colorless stage as usual, but no pink or red color subsequently developed, even on long standing. According to the theory the oxidation should lead to the formation of the triketo acid XII which, lacking a methylene group in the proper position of the side chain, cannot undergo cyclization to a hydroxynaphthoquinone. On working up the acidified, colorless solution there was isolated in place of this substance phthalonic acid and isobutyric acid, which very probably arise from the oxidative cleavage of XII between the two adjacent carbonyl groups.



These observations lend considerable support to the view that the quinone ring opens in the first step of the Hooker oxidation, but our work casts no further light on the exact mechanism of the subsequent ring closure. There is perhaps a rough analogy in the conversion of 2-aceto-1-naphthylglyoxylic acid into 1,2-naphthindanedione,[10] but the reaction occurs in an acidic rather than an alkaline medium and the process definitely is one of oxidation, a point not yet clearly established in the case at hand.

In conclusion the senior author wishes to acknowledge his indebtedness to the late Dr. Hooker

Experimental Part

Condensation of Aldehydes with 2-Hydroxy-6-bromo-1,4-naphthoquinone, Hydrogenation

The starting material, previously mentioned only incidentally in the literature,[3] was prepared conveniently from 6-bromo-1,2-naphthoquinone[3,11] as follows. On reaction with acetic anhydride–sulfuric acid by the usual procedure[12] this gave **1,2,4-triacetoxy-6-bromonaphthalene** in 62% yield, the purified material forming colorless needles, m. p. 162°, from alcohol.

Anal. Calcd. for $C_{16}H_{13}O_6Br$: C, 50.4; H, 3.44. Found: C, 50.6; H, 3.69.

On adding 145 g. of the powdered triacetate to a cold solution of 160 g. of potassium hydroxide in 730 cc. of 95% alcohol the temperature soon rose nearly to the boiling point and the solid dissolved to give a solution which rapidly turned dark brown. Oxidation to the quinone was completed by bubbling in air for one-half hour, after which the potassium salt of the product soon separated completely as small red crystals. Washed with alcohol, then with ether, the material was obtained in a very pure condition and in quantitative yield. As the potassium salt is sparingly soluble in water it was merely suspended in hot water and treated with dilute acid. The hydroxyquinone was obtained as a lemon-yellow, crystalline precipitate. It formed beautiful yellow needles, m. p. 204–205°, from alcohol containing a trace of acetic acid.

2 - Hydroxy - 3 - β - phenylvinyl - 6 - bromo - 1,4 - naphthoquinone was prepared by Hooker's method[4] but using more solvent. A solution of 10 g. of the hydroxybromoquinone in 225 cc. of glacial acetic acid was treated at 93° with 30 cc. of previously warmed concentrated hydrochloric acid, followed immediately by 22 cc. of phenylacetaldehyde. After digestion at 80° for one hour a large crop of red, crystalline material had separated and this was collected while the solution was still hot, as on cooling a brown substance separated. The collected material, after being washed with acetic acid, was obtained in a good condition; yield 56%. Crystallized from benzene it formed glistening, deep red needles, m. p. 243–244°, violet solution in alkali.

Anal. Calcd. for $C_{18}H_{11}O_3Br$: C, 60.9; H, 3.12. Found: C, 60.8; H, 3.32.

Reductive acetylation with zinc dust, acetic anhydride, and sodium acetate gave the **hydroquinone triacetate** in 86% yield, the compound forming colorless needles, m. p. 197–198°, from benzene–absolute alcohol.

Anal. Calcd. for $C_{24}H_{19}O_6Br$: C, 59.6; H, 3.96. Found: C, 59.8; H, 4.12.

Hydrogenation of the hydroxyquinone proceeded smoothly in alcoholic solution using Adams catalyst, giving **2-hydroxy-3-β-phenylethyl-6-bromo-1,4-naphthoquinone (II)**, which crystallizes from alcohol containing a little acetic acid as flat, golden-yellow needles, m. p. 180–181°; red color in alkali.

Anal. Calcd. for $C_{18}H_{13}O_3Br$: C, 60.5; H, 3.67. Found: C, 60.3; H, 3.81.

The hydroquinone triacetate of II formed fine, colorless needles from alcohol–benzene, m. p. 188–189°.

Anal. Calcd. for $C_{24}H_{21}O_6Br$: C, 59.4; H, 4.36. Found: C, 59.3; H, 4.49.

2 - Hydroxy - 3 - γ - phenyl - α - propenyl - 6 - bromo - 1,4-naphthoquinone was prepared as above, using hydrocinnamaldehyde, but the product did not separate from the hot reaction mixture. On pouring this into water there was obtained a brown precipitate mixed with black tar. After decanting the aqueous liquor the material was warmed with two portions of alcohol, for although this extracted some of the product it effectively removed the tar and left a fairly clean, crystalline yellowish residue (40% yield). For further purification the product was dissolved in 2% alcoholic potassium hydroxide and the violet solution was filtered from some dark residue and acidified. The precipitated material then crystallized well from benzene–petroleum ether to which a small amount of acetic acid was added, finally forming bright orange needles, m. p. 177–178°.

Anal. Calcd. for $C_{19}H_{13}O_3Br$: C, 61.8; H, 3.55. Found: C, 61.8; H, 3.85.

The hydroquinone triacetate formed colorless needles, m. p. 170–171°, from alcohol, benzene, or glacial acetic acid.

Anal. Calcd. for $C_{25}H_{21}O_6Br$: C, 60.4; H, 4.26. Found: C, 60.4; H, 4.31.

This triacetate slowly absorbed hydrogen in the presence of Adams catalyst giving the corresponding saturated compound, **1,2,4-triacetoxy-3-hydrocinnamyl-6-bromonaphthalene,** which formed needles, m. p. 170–172° (depresses the m. p. of the starting material).

Anal. Calcd. for $C_{25}H_{23}O_6Br$: C, 60.1; H, 4.64. Found: C, 60.1; H, 4.80.

The saturated triacetate was dissolved in hot acetone and hydrolyzed with alcoholic alkali, the solution being exposed to the air until quite red, diluted, and acidified. The yellow precipitate of **2-hydroxy-3-hydrocinnamyl-6-bromo-1,4-naphthoquinone,** IV, (92% yield) crystallized from alcohol–benzene containing a trace of acetic acid as golden-yellow scales melting at 170–171°.

Anal. Calcd. for $C_{19}H_{15}O_3Br$: C, 61.5; H, 4.08. Found: C, 61.4; H, 4.35.

Benzylation of 2-Hydroxy-6-bromo-1,4-naphthoquinone

A suspension of 6.2 g. of the silver salt of the hydroxyquinone with 3 g. of benzyl bromide in 70 cc. of absolute ether was allowed to stand in a stoppered flask overnight, when the red salt had been replaced by silver bromide. Three products were obtained, namely, **4-benzyloxy-6-bromo-1,2-naphthoquinone** (a), **2-hydroxy-3-benzyl-6-bromo-1,4-naphthoquinone** (b), and **2-benzyloxy-6-bromo-1,4-naphthoquinone** (c), and they were separated in this order as follows. The ethereal solution was filtered and set aside, while the residue was extracted with 100 cc. of hot benzene. On cooling the benzene solution the *o*-quinone ether (a) separated in a nearly pure condition; yield 0.6 g. (10%); crystallized from benzene it formed orange-yellow needles, m. p. 227–228°. The benzene mother

---

(12) Thiele and Winter, *Ann.*, **311**, 345 (1900).

liquor and the ethereal solution were combined and extracted with 2% alkali and the red alkaline solution on acidification gave 1.4 g. (24%) of the acidic isomer (b), which crystallized from absolute alcohol–benzene, with a trace of acetic acid, as golden-yellow plates, m. p. 192°. On drying and concentrating the benzene–ether mother liquor 0.6 g. (10%) of the *p*-quinone ether was obtained. It formed pale yellow needles from benzene, m. p. 201–202°.

Anal. Calcd. for $C_{17}H_{11}O_3Br$: C, 59.5; H, 3.23. Found: (a) C, 59.5; H, 3.59; (b) C, 59.5; H, 3.63; (c) C, 59.5; H, 3.49.

The structures of the non-acidic isomers (a) and (c) are inferred from the colors of the compounds, in analogy with known cases. It was noted that on the addition of a drop or two of sodium or potassium hydroxide to a solution of the *p*-quinone ether in acetone the solution became deep purplish-blue, the color changing after a few minutes to dull green with loss of strength. Both the alkali and the solvent acetone appear to be necessary for the production of the blue color, as other bases and other solvents were ineffective. The *o*-quinone ether gave only a faint pink coloration, and the test was negative with α-naphthoquinone and several of its simple derivatives. 2-Methoxy-1,4-naphthoquinone gave an exactly similar coloration.

Reductive acetylation of the acidic isomer gave **1,2,4-triacetoxy-3-benzyl-6-bromonaphthalene;** fine needles, m. p. 202–203°.

Anal. Calcd. for $C_{23}H_{19}O_6Br$: C, 58.6; H, 4.06. Found: C, 58.6; H, 4.29.

Oxidation of the Bromo Compounds

The Hydrocinnamyl Compound IV.—On account of the sparing solubility of the brominated quinones, the procedure was slightly modified as follows. A solution of 3 g. of IV in the required amount of hot benzene was stirred into 600 cc. of hot 1% sodium hydroxide solution and the red solution was cooled to 0° and treated with 189 cc. of 1% potassium permanganate solution, also at 0°. The color changes were as described by Hooker, the solution becoming practically colorless (spot test) and then reaching a maximum intensity of red in one to two hours. The yield of precipitated, nearly pure, material was 36%.[13] Crystallized from alcohol containing acetic acid the **3-hydroxy-2-β-phenylethyl-6-bromo-1,4-naphthoquinone** (V) formed golden-yellow needles, m. p. 173–175°. A mixture with the isomer II melted at 148–153°.

Anal. Calcd. for $C_{18}H_{13}O_3Br$: C, 60.5; H, 3.67. Found: C, 60.5; H, 3.93.

Further Oxidation of V.—From 0.9 g. of the above compound (V), oxidized in the same way, there was obtained in 54% yield a substance crystallizing as golden-yellow plates, m. p. 188–189°, and giving no depression with synthetic 2-hydroxy-3-benzyl-6-bromo-1,4-naphthoquinone, VI.

Oxidation of the Synthetic β-Phenylethyl Compound, II.—The oxidation product, obtained in 43% yield, crystallized from alcohol with a trace of acetic acid as golden-yellow needles, m. p. 158–159°. The melting point of the **3-hydroxy-2-benzyl-6-bromo-1,4-naphthoquinone** (III) was depressed about 10° by admixture with the isomeric 3-benzyl compound.

Anal. Calcd. for $C_{17}H_{11}O_3Br$: C, 59.5; H, 3.23. Found: C, 59.2; H, 3.43.

The **hydroquinone triacetate,** which formed colorless needles, m. p. 196–197°, also gave a depression with the isomeric 3-benzyl compound.

Anal. Calcd. for $C_{23}H_{19}O_6Br$: C, 58.6; H, 4.06. Found: C, 58.5; H, 4.34.

2-Isopropyl-3-hydroxy-1,4-naphthoquinone

Preparation.—Lapachol kindly supplied for the purpose by Dr. Hooker was converted into the hydro derivative[4] and this was oxidized[2a] to 2-isobutyl-3-hydroxy-1,4-naphthoquinone. The acetate of this substance formed pale yellow needles, m. p. 53.5–54° (Calcd.: C, 70.6; H, 5.93. Found: C, 70.6; H, 5.40). Oxidation of the hydroxy compound in 1% sodium hydroxide solution with 1% aqueous potassium permanganate gave **2-isopropyl-3-hydroxy-1,4-naphthoquinone** (XI) in 52% yield. The compound gave bright yellow needles, m. p. 92–93° from alcohol–acetic acid.

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.2; H, 5.60. Found: C, 72.4; H, 5.76.

Oxidation.—When a solution of 1 g. of the quinone in 1% alkali was treated with an aqueous solution of 1.08 g. of potassium permanganate according to Hooker's procedure the oxidation was somewhat slower than usual and the supernatant liquor became colorless only after about two hours. Air was bubbled through the solution for two hours, but no reddening occurred. After removing the manganese dioxide and acidifying the colorless solution a strong odor of isobutyric acid was noted and the substance was expelled by distilling the solution to a small volume, adding water and repeating the process. The acid distillate neutralized 42 cc. of 0.1038 *N* alkali, corresponding to a yield of 61% of isobutyric acid. In another experiment 5 g. of the starting material gave an acid distillate containing isobutyric acid equivalent to a 65% yield, on the basis of titration. The neutral solution of the salt on evaporation left a residue (1.25 g.) which was treated with hydrogen chloride in the presence of ether. After filtering, and removing the solvent, the free acid (0.91 g.) was refluxed with *p*-toluidine (3.2 g.), and after extracting the unused reagent with dilute hydrochloric acid the residue was dried and crystallized from ligroin. Colorless plates, m. p. 104–105°, were obtained and a mixed melting point with a known sample of the *p*-toluide of isobutyric acid, m. p. 106–106.5°, established the identity of the substance.

The residue from the steam distillation in the first experiment (1 g. of starting material) was made faintly alkaline and treated with 0.4 g. of phenylhydrazine hydrochloride and a few drops of acetic acid. After heating the mixture for four hours on the steam-bath and cooling, a pale yellow solid separated mixed with resinous matter. The yellow substance was extracted with soda solution, leaving the resin undissolved, and on acidifying the filtrate a pale yellow crystalline precipitate separated (0.25 g.). The substance melted at 215° with gas evolution and it was identified as 3-phenyl-4-phthalazone-1-carboxylic acid by a mixed melting point determination with a sample of the

---

[13] At the time of the experiment it was not recognized in Dr. Hooker's laboratory or in our own that the yield is generally improved by employing a higher concentration of alkali.

substance, m. p. 216–217°, dec., prepared from phthalonic acid and phenylhydrazine.[14]

Oxidation of 2,6-Dimethyl-3-hydroxy-1,4-naphthoquinone

Conversion to 2-Hydroxy-6-methyl-1,4-naphthoquinone.—In trial experiments it was found, in conformity with Hooker's observations,[2b] that the reaction proceeds best in a strongly alkaline medium, and the following method was adopted as the most satisfactory. A solution of 1.13 g. of the dimethylhydroxynaphthoquinone (VII) in 100 cc. of 6% sodium hydroxide was chilled in ice and treated all at once with a solution of 1.26 g. of potassium permanganate and 6 g. of sodium hydroxide in 126 cc. of water, also at 0°. After standing for two hours at room temperature, the manganese dioxide was removed and the filtered solution, which had become quite red, was acidified. Small yellow plates of the oxidation product separated in a good condition (0.78 g.) and a further amount (0.05 g.) was obtained by extracting the filtrate with ether; yield, 75%. The substance crystallized from benzene–ligroin as golden-yellow plates and from acetic acid as stout yellow needles; m. p. 199°, dec. It is sparingly soluble in water, moderately soluble in benzene, readily soluble in alcohol. The solutions in both alkali and sulfuric acid are red.

Anal. Calcd. for $C_{11}H_8O_3$: C, 70.19; H, 4.29. Found: C, 70.20; H, 4.30.

The methyl ether was obtained in good yield by refluxing for one and one-half hours a solution of 0.5 g. of the hydroxyquinone and 0.5 cc. of concentrated sulfuric acid in 25 cc. of methyl alcohol. The ether separated on cooling as fine, pale yellow needles, and after recrystallization it melted at 167–167.5°.

Anal. Calcd. for $C_{12}H_{10}O_3$: C, 71.25; H, 4.99. Found: C, 71.31; H, 5.01.

The hydroquinone triacetate formed small, colorless needles from benzene–ligroin, m. p. 157–158°.

Anal. Calcd. for $C_{17}H_{16}O_6$: C, 64.53; H, 5.10. Found: C, 64.34; H, 5.04.

Synthetic Preparation of 2-Hydroxy-6-methyl-1,4-naphthoquinone.—β-Methylnaphthalene (100 g.) was sulfonated according to Dziewoński, Schoenówna and Waldmann[8] but the filtered solution of the reaction product in water (1 liter) was neutralized with concentrated alkali. The sodium salt which separated was obtained in a pure condition after one recrystallization; yield, 80%; *p*-toluidine salt, flat needles from dilute alcohol, m. p. 250–251°. For conversion to 6-methyl-2-naphthol[8] 140 g. of the sodium salt was fused with a melt from 460 g. of potassium hydroxide and 7 cc. of water and the crude, precipitated material was coagulated by boiling, dried, and vacuum distilled, giving 50 g. (55%) of slightly pink material melting at 123° and suitable for further use. The methylnaphthol was coupled with diazotized sulfanilic acid and the dye was reduced with hydrosulfite essentially as described for the case of β-naphthol,[15] with allowance for a lower solubility in the present series, the yield of very nearly colorless 1-amino-6-methyl-2-naphthol hydrochloride being 50%. The oxidation to 6-methyl-1,2-naphthoquinone presented some difficulties and ferric chloride gave only what appeared to be a dimolecular product. The following details can be supplemented to the brief statement in the literature.[8] A suspension of 7 g. of the amine hydrochloride in 200 cc. of water was neutralized with 14 g. of sodium acetate crystals, 10 cc. of concentrated sulfuric acid was added and the mixture was poured into 3 liters of water. After adding an additional 30 cc. of the acid the solution on filtration was water-clear, and it was stirred well and treated all at once with a cold solution of 7 g. of potassium dichromate and 30 cc. of concentrated sulfuric acid in 150 cc. of water. The quinone separated as orange micro-crystals, m. p. 126°, in 60% yield.

Potassium 6-Methyl-1,2-naphthoquinone-4-sulfonate.—Attempts to introduce an hydroxyl group by the Thiele reaction were unsuccessful; a colorless product, m. p. 156–158°, slowly separated from the mixture but it did not have the properties of a hydroquinone triacetate. The addition of bisulfite, on the other hand, proceeded normally. The quinone (3.5 g.) was added very slowly with stirring to a solution at 25° of 3.6 g. of sodium bisulfite in 40 cc. of water and after one-half hour the resulting solution was filtered, treated with 0.4 cc. of concentrated sulfuric acid, boiled, cooled to 25°, and treated with 2.4 g. of potassium dichromate and 1.8 cc. of concentrated sulfuric acid in 7 cc. of water, followed by 40 cc. of saturated potassium chloride solution, added in portions as crystallization of the quinone sulfonate proceeded. On dissolving the compound in water containing a trace of bromine at 60°, clarifying the solution and adding potassium chloride,[16] the quinone sulfonate separated as fine orange needles of a monohydrate; yield 50%.

Anal. Calcd. for $C_{11}H_7O_5SK \cdot H_2O$: S, 10.40. Found: S, 10.48.

2-Methoxy-6-methyl-1,4-naphthoquinone was obtained by mixing 0.8 g. of the above sulfonate with a solution of 0.5 cc. of concentrated sulfuric acid in 5 cc. of methyl alcohol at 0°, gradually warming the mixture on the steam-bath, adding 5 cc. more methyl alcohol, and refluxing until the salt had disappeared. On cooling the methoxy compound separated as very fine, pale yellow needles (70% yield). On recrystallization the substance melted at 167–167.5° and gave no depression when mixed with the ether of the quinone obtained above as an oxidation product. The hydroxy compound was obtained on hydrolysis of the synthetic ether and both this substance and its hydroquinone triacetate were compared with the above samples and the identity fully established.

1,8-Phthaloyl-6-methyl-2-naphthol (1-Hydroxy-5-methylpleiadenedione).—On condensing 6-methyl-2-naphthol (10 g.) with phthalic anhydride in the presence of aluminum chloride at 200° by the previously described procedure,[17] the reaction product was obtained in a pure condition after one crystallization from glacial acetic acid; yield, 14.7 g. (81%). It forms bright yellow needles, m. p. 194–194.5°.

poorly and much material was lost through sulfonation. Three grams of the pleiadenedione was quickly stirred into a solution of 160 cc. of concentrated sulfuric acid and 80 cc. of water preheated to 170°. The initially yellow-red solution soon turned brown and after three minutes it was poured into boiling water, and after boiling the mixture to coagulate the red precipitated material this was collected and washed; yield 0.9 g. The material was purified through the acetate which crystallizes from glacial acetic in cottony clusters of canary-yellow needles, m. p. 218–219°. This was hydrolyzed with alcoholic alkali giving, after dilution, an intensely blue solution of the sparingly soluble sodium salt from which the hydroxyquinone separated on acidification as a fiery red precipitate of hair-like micro-needles. From alcohol the substance crystallized as orange-red plates, m. p. 256–258°, dec. Treated with sodium hydrosulfite, the blue alkaline solution gives a transient red color and then an orange-yellow vat.

Summary

By using 2-alkyl-3-hydroxy-1,4-naphthoquinones having reference groups in the aromatic ring it has been possible to prove that the substituents in the 2- and 3-positions exchange places in the course of the Hooker oxidation in exactly the manner predicted by the discoverer of the reaction. Hooker's view that the quinone ring is opened in the first step of the process has been substantiated by the isolation of products evidently arising from the type of intermediate postulated.

The Electron Affinity of Free Radicals. X. A Potentiometric Method for Determining ΔF for the Addition of Sodium to an Organic Compound[1]

By H. E. Bent and N. B. Keevil

Most compounds containing sodium are very stable. A reaction leading to the formation of a compound involving the pure metal goes so nearly to completion that it is not possible to obtain an equilibrium constant from the concentration of unreacting material. Such reactions can be studied, however, with the aid of mercury.[2] Sodium forms compounds with mercury which are so stable that it is possible to remove sodium from other compounds by shaking them with mercury or a dilute amalgam. By choosing an amalgam of the proper concentration an equilibrium can be established favorable for analysis and the computation of an equilibrium constant. At equilibrium the reaction may be considered as a distribution experiment, the sodium in the mercury being in equilibrium with the sodium in the solution of the compound being studied. Since the thermodynamic properties of amalgams have been rather thoroughly studied, it is possible to calculate the free energy change which would have accompanied the reaction if solid sodium had been used.

The method is capable of quite general application but has certain disadvantages. In the first place the range of concentration of sodium amalgams which are liquid at room temperature is small. The increase in temperature necessary to extend the range of concentration appreciably would be so great as to decompose many organic compounds. The consequence of this rather narrow range of liquid amalgam is that only compounds which have a correspondingly narrow range of stability can be studied by this method. A second difficulty was encountered when studying reactions characterized by a large activation energy. Sometimes many months were required for the establishment of substantially equilibrium concentrations. The potentiometric method to be described seems likely to be free from these objections.

Both difficulties are inherently absent in a potentiometric method since a reaction does not need to proceed to the equilibrium point. The potential is a measure of the distance the system is from equilibrium and hence one might expect to be able to study with the aid of liquid amalgams reactions which would require solid amalgams by the analytical method. Furthermore, a reaction which proceeds very slowly might be expected to supply sufficient energy for a delicate electrical measurement while requiring years for substantial completion. Preliminary calculations indicated this to be the case.

[1] Presented before the Division of Physical and Inorganic Chemistry at the 91st meeting of the American Chemical Society, Kansas City, Mo., April 13–17, 1936.

[2] Bent, This Journal, **52**, 1498 (1930).

The very delicacy of a potentiometric method, however, introduces new difficulties. The amounts of materials necessary to give a detectable e. m. f. are so small that traces of impurities are capable of producing side reactions which may be confused with the reaction being studied. Furthermore, the course of the reaction cannot be determined by an analysis of the products of the reaction. These difficulties may be overcome to a great extent by varying the concentrations of the substances involved in the reaction and noting the corresponding variation in the e. m. f. of the cell. As a further check on the reliability of the potentiometric method we have studied certain reactions by both methods. The compounds which have been studied in the greatest detail by the analytical method are organic free radicals. We have chosen three free radicals to study by the potentiometric method.

A cell is constructed in which the over-all reaction is the addition of sodium to an ethane to give two molecules of the sodium derivative of a free radical. These cells are constructed with one electrode of liquid sodium amalgam and the other of bright platinum. The electrolyte is an ether solution of the product of the reaction, that is, the sodium addition compound, NaR, R representing a free radical. The ethane is enclosed in a small glass capsule directly over the bright platinum electrode. When the cell has been brought to constant temperature in a thermostat and is ready for measurement the capsule is broken, thus saturating the electrolyte in the neighborhood of the platinum electrode with the ethane. A sintered Pyrex disk prevents the amalgam and solution in contact with the amalgam from coming in contact with the platinum. After some time the ethane diffuses through the ether to the amalgam but this is a process which is sufficiently slow to give no trouble. The over-all cell reaction may be considered as involving two primary reactions. At the amalgam electrode the reaction is $Na \longrightarrow Na^+ + \ominus$ while at the platinum electrode the reaction is $R_2 + 2\ominus \longrightarrow 2R^-$. These reactions are followed by the combination of the ions to form ion pairs.

An unexpected difficulty arose from certain fluctuating potentials which were observed before the capsule containing the free radical was broken. These potentials and the methods of eliminating them are discussed in the experimental section of the paper.

Materials

Details of the preparation of materials have been given in previous papers. The appropriate carbinol is first converted by hydrochloric acid into the chloride and this then converted either into the free radical or the sodium derivative of the free radical. All preparations were carried out in closed glass systems in the final stages. A slight improvement in technique has been developed. The sodium derivatives are prepared by shaking chloride with dilute sodium amalgam and then decanting the solution into a second tube and from there into small capsules, which are finally sealed off. In order to calculate the concentration of the resulting solution from the original amount of chloride introduced and the volume of ether it is necessary to avoid distillation during the final step of sealing off the capsules. In order to prevent decomposition of ether in contact with the hot glass it is also necessary to cool the capsules in liquid air or dry ice. This cooling may be accomplished quite readily without distillation by closing each tube leading to the capsule with a steel ball bearing which fits a seat previously ground in the glass by the same size ball bearing. These ball bearings may conveniently be moved around in the apparatus by means of a horseshoe magnet.

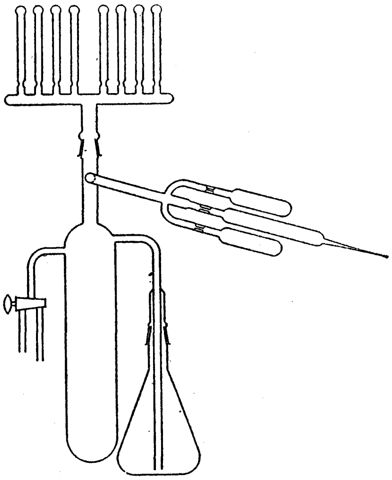

Fig. 1.

The apparatus shown in Fig. 1 was used in the preparation of the free radical. The operation of the apparatus is almost self-evident. The bulb containing the ring seal is used for the initial preparation of the free radical from the chloride and lead amalgam. By controlling the pressure, using nitrogen where necessary, the solution may be decanted over into the second tube without tipping or disturbing the precipitate of metallic chloride. This first tube may then be cleaned and refilled with suitable solvents for recrystallizing and washing, always flushing the tube with nitrogen. The capsules above the second tube are for three purposes. In two capsules solution saturated with free radical is removed for the purpose of determining the solubility and in another a sample is removed for determining the purity by oxygen absorption. After these samples have been removed the solvent is removed and the dry material loosened if necessary from the sides of the container by removing the ground joint and scraping with a steel wire, again using a counter stream of nitrogen. Finally the top of the apparatus is again attached and the solid free radical distributed between the small round-bottomed capsules. The ends of these capsules are sufficiently thin to allow crushing with a magnetic hammer in the final cell.

The apparatus for determining the purity of the free radical by oxygen absorption has been previously described.[3]

Experimental Procedure

The design of the cell was changed frequently in the course of the research. The last type to be used is illustrated in Fig. 2. A sintered glass disk[4] prevents rapid diffusion of the free radical from the platinum electrode to the amalgam where it would react. The disk also permits construction of a cell with relatively small resistance as the amalgam can flow against the disk without danger of passing through. It is important to have a notch filed in the top of the disk two or three millimeters in diameter in order to have a vapor connection between the two sides of the cell. If this is not done slight changes in temperature will cause surging of the liquid and consequent stirring.

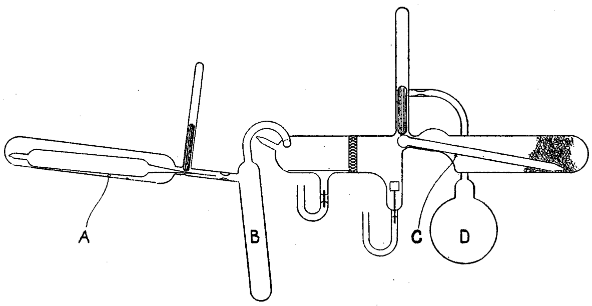

Fig. 2.

The sodium addition compound dissolved in ether, and free radical, are contained in capsules so arranged as to be broken by magnetic hammers. The cell is first baked and sparked as much as is possible without warming the organic materials. The amalgam is then introduced and then the electrolyte. The cell is placed in a thermostat and kept dark in order to avoid any possible effect of light on the free radical. Next tests are made for any potential which may be present before the capsule of the free radical is broken, and finally the free radical is introduced. A Wolf potentiometer reading directly to 10^{-5} v. was used with a L and N type HS galvanometer sensitive to 10^{-11} amp. The resistance of the cells was of the order of 10^6 ohms although in some of the earlier cells it was as high as 10^{12} ohms, thus making measurement difficult.

An unexpected difficulty was encountered in determining the potentials of the cells. The cells were found to possess a potential of the order of magnitude of 0.1 v. before the free radical had been introduced. This potential could not be eliminated and was difficult to explain. A great many experiments were performed to discover the cause of the potential but no theory was formulated which could account for all of the experiments. Assuming that the solution was not at equilibrium with the amalgam, cells were constructed which would allow further shaking of the solution and amalgam in the cell. This procedure altered the magnitude of the potential but did not eliminate it. A cell was constructed with gold, platinum and amalgam electrodes all in the same cell. No potential was obtained between two amalgam electrodes, and none between two platinum or between a gold and a platinum electrode. However, a very persistent potential was present between the gold or platinum and the amalgam electrode. This experiment seems to eliminate surface effects in the platinum as the sole cause of the potential as it would be improbable that the gold would behave in exactly the same manner. It seems very likely that the potential is due at least in part to the electrolyte as in some cells which had stood so long as to give very low potentials an addition of more electrolyte would give a larger voltage. This is rather hard to understand in the light of the fact that the reaction of amalgam with triphenylchloromethane is so rapid as to appear to be complete in ten or fifteen minutes. The cells had often been shaken for several days. The potential would persist for weeks in spite of all attempts to destroy it by short-circuiting the cell or even applying an external potential to the cell. After several weeks the value was usually reduced to a few millivolts. Under the circumstances the difficulty could be handled in two ways. In the first place it would be possible to wait until this initial e. m. f. had disappeared or become too small to be of importance. This would have involved a great delay in making measurements and introduced an additional uncertainty due to possible decomposition of the free radical. Furthermore it would seem entirely possible that the addition of the free radical might be a disturbing factor which would again give rise to the mysterious e. m. f. A better method seemed to be to assume that the mechanism giving rise to the initial e. m. f. involves such small amounts of material as to have but a very small capacity factor and that the addition of the large amount of free radical would mask completely any potential due to a side reaction. To test this assumption cells were constructed and measurements taken without delay when the initial e. m. f. was near its highest value. These cells seem to justify the assumption that the e. m. f. may be neglected.

Discussion of Results

The e. m. f. of a cell in which the over-all cell reaction is the addition of sodium to an ethane ($2Na + R_2 \longrightarrow 2NaR$) may be most conveniently considered in terms of the addition of sodium to the free radical ($Na + R \longrightarrow NaR$). The e. m. f. of the cell is then given by the equation

$$E = E_0 - \frac{RT}{nF} \ln \frac{(NaR)}{(Na)(R)} \qquad (1)$$

in which E_0 equals (RT/nF) ln K and "K" is the equilibrium constant for the reaction. The reason for treating the cell reaction in this fashion is that in earlier papers we have determined the free energy change accompanying the addition of sodium to various free radicals and from these

	2.57	.106	5.04	.602		.639	.524

data can calculate the value of E_0. The values of E_0 so calculated have been found to be remarkably constant. We may summarize the results by saying that in twenty cases in which a group attached to the central carbon has been changed the average of the effects on the free energy change for the reaction is about one kilogram calorie and the maximum effect is three. These substitutions involve groups which are aliphatic, aromatic, polynuclear and heterocyclic. The small differences observed in passing from one free radical to another may be predicted roughly from the series to which the compound belongs and the number of benzene rings in the compound. The average value for E_0 is 1.08 v.

We have determined the value of E_0 of equation (1) for triphenylmethyl, diphenyl-α-naphthylmethyl and phenyl-diphenyl-α-naphthylmethyl by the potentiometric method. The purpose of these experiments was to test the method and in particular to discover whether or not we are justified in ignoring the initial potential which was observed before the introduction of the free radical. The results of these experiments are reported in Table I.

The concentration of NaR is determined at both the beginning and the end of the experiment. The activity of the sodium referred to pure metal as the standard state is calculated from the concentration of the amalgam with the aid of the equation of Bent and Hildebrand.[5] The first two runs reported on hexaphenylethane are not considered as good as the latter runs due to the unusually high resistance of the cell. Some of the cells could be measured to hundredths of a millivolt but it is doubtful if the results are significant to more than a few millivolts. The average of the last four cells on hexaphenylethane is in very good agreement with the average of the analytical measurements previously reported and recorded in the third from the last column of the table.

The results for the next two compounds are much less satisfactory. These compounds have not been studied as thoroughly by either the analytical or potentiometric method so that agreement as good as in the case of hexaphenylethane is hardly to be expected. We have no explanation, however, for such a large discrepancy as is shown by the next to the last value recorded in the table.

Table I leads to the conclusion that the potentiometric method measures the free energy of addition of sodium to the compound being studied. The evidence is particularly good in the case of hexaphenylethane. The variation in concentration of sodium in the amalgam and also of the product of the reaction in solution result in the expected effect on the potential of the cell. The results of the potentiometric method agree with

---

(5) Bent and Hildebrand, THIS JOURNAL, **49**, 3011 (1927).

the analytical results at least as well as the results by the first method agree with each other.

We hoped to study by the method just described compounds which react too slowly to be measured by a direct analytical method. In particular we wished to study ethanes which dissociate into free radicals to such a slight extent that the reaction cannot be detected by ordinary means. If one knows E_0 in equation (1), the activity of the sodium in the amalgam used as an electrode and the concentration of the product of the reaction, then one has a method of calculating the concentration of free radical from the observed e. m. f. This concentration would then allow one to calculate the equilibrium constant for the dissociation of the ethane into the free radical and hence the strength of the C–C bond, providing certain assumptions are made regarding ΔS for the reaction.

The compound chosen was dibiphenylene-diphenylethane. This compound was prepared and studied in exactly the same kind of cell discussed above. The extent to which the ethane is dissociated is not definitely known but it has been estimated that ΔF for the process is greater than 7 kcal. This would mean that the observed e. m. f. should be small on account of the small concentration of free radical present. To our surprise we obtained a much larger value. This can only mean that our original assumption that E_0 is the same for all free radicals breaks down in the case of the first compound to which we attempt to apply it. If we reverse our procedure and attempt to calculate E_0 by assuming ΔF for the dissociation of the free radical to be at least 7 kcal. we obtain a value of at least 1.5 v. This result makes it seem very unlikely that the extension of the potentiometric method to the calculating of the strength of C–C bonds in this manner can be justified. It also indicates that one must be very cautious in drawing conclusions from experiments using sodium amalgam or sodium potassium alloy to cleave organic compounds. Since the stability of the sodium compound can vary by as much as 0.4 v. (9 kcal.) the reaction cannot be considered solely in the light of the breaking of a C–C bond.

It is interesting to discover that the large difference between the value of E_0 for triphenylmethyl and dibiphenylene-diphenylethane is quite in harmony with the relative strength of the corresponding hydrogen compounds as acids.[6] The following equations indicate the close connection between these two reactions.

$$\begin{aligned}
\mathrm{NaR} + \mathrm{HR'} &= \mathrm{NaR'} + \mathrm{HR} && (1)\\
\mathrm{Na^+} + \mathrm{R^-} &= \mathrm{NaR} && (2)\\
\mathrm{NaR'} &= \mathrm{Na^+} + \mathrm{R'^-} && (3)\\
\mathrm{H} + \mathrm{R'^*} &= \mathrm{HR'} && (4)\\
\mathrm{HR} &= \mathrm{H} + \mathrm{R^*} && (5)\\
\hline
\mathrm{R^-} + \mathrm{R'^*} &= \mathrm{R'^-} + \mathrm{R^*} && (6)\\
2\mathrm{Na} + \mathrm{R_2} &= 2\mathrm{NaR} && (7)
\end{aligned}$$

In these equations R and R′ are taken to represent triphenylmethyl and biphenylenephenylmethyl. Reaction (1) represents the action of a weak acid on the salt of a still weaker acid. The fact that the reaction takes place indicates that HR′ is a stronger acid than HR. In order to discover the fundamental property of the molecule which determines its acid strength we have written equations (2) to (5). According to Kraus and Fuoss the dissociation constant of a salt in a given solvent of low dielectric constant is determined primarily by the size of the ion. Since the two anions under consideration each contain just three benzene rings it seems very probable that the value of ΔF for reactions (2) and (3) will cancel as they are written. We next make the very plausible assumption that the strength of the hydrogen–carbon bond is the same in these two molecules. This is implied when we write reactions (4) and (5) and assume that ΔF for these two reactions will cancel. The asterisk on the free radical implies that only the hydrogen bond has been broken and that the free radical so formed is not stabilized by resonance energy. The free radical under discussion is therefore purely hypothetical and is introduced for convenience in discussing the significance of the resonance energy. The sum of reactions (1) to (5) is given in equation (6). This equation shows that two factors are involved in determining the strength of an acid. The first of these is the destruction of the charge on one ion and the creation of a charge on the other, that is, the transfer of an electron. The second is the destruction of the resonance energy present in one ion and the creation of resonance energy in the other anion. These two factors are also involved in the addition of sodium to an ethane as illustrated by equation (7). If we consider NaR to be an ion pair[7] then the addition of sodium to an ethane involves the creation of a negative ion with its accompanying resonance energy. We therefore come to the conclusion that the ease with which

---

(6) Conant and Wheland, THIS JOURNAL, **54**, 1212 (1932).

(7) Fuoss and Kraus, THIS JOURNAL, **55**, 1019 (1933).

sodium will add to an ethane is determined not only by the strength of the carbon–carbon bond but also by those factors which determine the strength of the corresponding methane as an acid. According to McEwen[8] the difference in acid strength for these two methanes is about 16 kcal. The difference in the free energy of addition of sodium to the free radicals is found to be greater than 12 kcal. These results give a consistent explanation of the behavior of phenylfluorene as an acid and the stability of the sodium salt.

The results of the measurements on dibiphenylene-diphenylethane may be expressed in terms of the reaction $2Na + R_2 \longrightarrow 2NaR$ without any assumptions regarding the dissociation of the ethane into a free radical. ΔF so calculated is -61.9 kcal.

Summary

1. A potentiometric method is described for determining the free energy of addition of sodium to an organic compound.

2. An e. m. f. is reported which is not accounted for by accepted ideas of the nature of the compounds studied.

3. Dibiphenylene-diphenylethane is reported to have an abnormally large electron affinity which is directly related to the strength of phenylfluorene as an acid.

Mesityl Phenyl Diketone

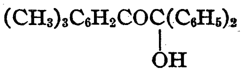
BY H. H. WEINSTOCK, JR., AND REYNOLD C. FUSON

Mesityl phenyl diketone (I) was selected for study because it appeared to afford an opportunity of determining the behavior of one of the carbonyl groups of an alpha diketone without interference from the other. It was supposed that the carbonyl group adjacent to the mesityl radical would be unaffected by most reagents, and that the diketone would, in fact, behave as a monoketone, in which, however, the carbonyl group would be unusually reactive. In general, this expectation has been supported by the experimental evidence; however, in certain reactions, both carbonyl groups seem to be directly involved.

The diketone behaves as a monoketone toward phenylmagnesium bromide, which converts it into the carbinol (II). Likewise the diketone gave a monoxime, a monosemicarbazone and a mono-2,4-dinitrophenylhydrazone. Also, it could not be induced to react with *o*-phenylenediamine. On the other hand, toward hydrogen peroxide the diketone behaves normally. Reduction with zinc and acetic acid gave a mixture of the two isomeric benzoins (III and IV).[1]

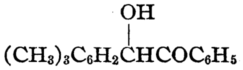
$(CH_3)_3C_6H_2COCOC_6H_5$

I



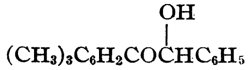
$(CH_3)_3C_6H_2CO\underset{\underset{\textstyle OH}{|}}{C}(C_6H_5)_2$

II



$(CH_3)_3C_6H_2\overset{\overset{\textstyle OH}{|}}{C}HCOC_6H_5$

III



$(CH_3)_3C_6H_2CO\overset{\overset{\textstyle OH}{|}}{C}HC_6H_5$

IV

Vigorous reduction of the diketone yields the desoxybenzoin, V.

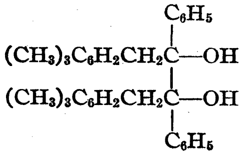
$(CH_3)_3C_6H_2CH_2COC_6H_5$

V

$(CH_3)_3C_6H_2COCH_2C_6H_5$

VI

This compound formed a phenylhydrazone and a dinitrophenylhydrazone, and with isopropylmagnesium bromide or ethylmagnesium bromide it was reduced to the pinacol (VII).



$$\begin{array}{r}C_6H_5\\ |\\ (CH_3)_3C_6H_2CH_2C{-}OH\\ |\\ (CH_3)_3C_6H_2CH_2C{-}OH\\ |\\ C_6H_5\end{array}$$

VII

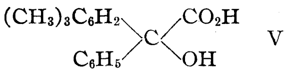
The structure of V was proved by synthesizing it from mesitylacetyl chloride and benzene. The isomeric desoxy compound (VI) is known. Both of these desoxybenzoins yield the benzil (I) when oxidized with selenium dioxide. Here it would appear that reduction had taken place preferentially at the hindered carbonyl group. However, the explanation is evidently not so simple as this, because when either of the benzoins (III and IV) is reduced the product is invariably V, no trace of VI being produced. This is especially

---

[1] Fuson, Weinstock and Ullyot, THIS JOURNAL, 57, 1803 (1935).

notable in the case of IV; here the yield of V is 78% of the theoretical amount.

The action of alkali brought about the benzilic acid rearrangement, yielding mesitylphenylglycolic acid (VIII).



$$\begin{array}{r}\mathrm{(CH_3)_3C_6H_2}\\ \mathrm{C_6H_5}\end{array}\!>\!\mathrm{C}\!<\!\begin{array}{l}\mathrm{CO_2H}\\ \mathrm{OH}\end{array}$$

VIII

The structure of this acid was proved by reducing it to mesitylphenylacetic acid.

Experimental

Mesityl Phenyl Diketone (I).—This compound was first obtained by the action of phenylmagnesium bromide on mesitylglyoxal,[2] but is more conveniently made by oxidation of benzyl mesityl ketone. The following procedure gave the diketone in yields of 83%.[3] A mixture of 80 g. of benzyl mesityl ketone,[4] 42 g. of selenium dioxide, 1200 cc. of dioxane, and 5 cc. of water was heated under reflux, with stirring, for three hours. The solution was decanted from the precipitated selenium and concentrated to a volume of 200 cc. When this solution was allowed to cool, the diketone separated in the form of yellow crystals, melting at 136–137°. A mixture with a specimen prepared by the method of Gray and Fuson showed no lowering of the melting point.

The monoxime of mesityl phenyl diketone was colorless, and melted at 155°.

Anal. Calcd. for $C_{17}H_{17}NO_2$: N, 5.24. Found: N, 5.43.

The monoxime was recovered unchanged when heated for forty-eight hours with an excess of hydroxylamine.

The mono 2,4-dinitrophenylhydrazone of mesityl phenyl diketone was orange in color, and melted at 232–232.5°.

Anal. Calcd. for $C_{23}H_{20}N_4O_5$: N, 12.96. Found: N, 12.72.

This compound was also obtained when 0.5 g. of IV was boiled for two minutes with 0.4 g. of 2,4-dinitrophenylhydrazine and 2 cc. of concentrated hydrochloric acid in a solution of 50 cc. of ethyl alcohol. The melting point was 230–231°. A mixed melting point with a sample of the mono-2,4-dinitrophenylhydrazone of mesityl phenyl diketone showed no depression.

Attempted Reaction with *o*-Phenylenediamine.—The starting material was quantitatively recovered in a high state of purity after treatment of I with the calculated amount of *o*-phenylenediamine in boiling solutions of absolute alcohol or glacial acetic acid.

Reaction with Hydrogen Peroxide.—Two grams of I, 25 cc. of 30% hydrogen peroxide, and 50 cc. of dioxane were boiled under reflux for two hours. There was obtained 1.85 g. of alkali-soluble material. Treatment with boiling water gave 0.95 g. of an insoluble substance; m. p. 152°. A mixed melting point with an authentic sample of 2,4,6-trimethylbenzoic acid was 152°. On cooling of the water solution, there was obtained a white product which melted at 121° after several recrystallizations from water. A mixed melting point determination proved the substance to be benzoic acid.[5]

Reaction with Phenylmagnesium Bromide.—To a solution of phenylmagnesium bromide prepared from 0.5 g. of magnesium, 4 g. of bromobenzene and 100 cc. of dry ether was added 1 g. of mesityl phenyl diketone. The mixture was stirred for three hours, and then decomposed with dilute hydrochloric acid. The *carbinol* (II) crystallized from alcohol in the form of colorless needles melting at 169.5–170°.

Anal. Calcd. for $C_{23}H_{22}O_2$: C, 83.63; H, 6.69. Found: C, 83.67; H, 6.85.

Reduction to the Benzoins.—A solution of 2 g. of mesityl phenyl diketone in 75 cc. of glacial acetic acid was heated to boiling and 10 g. of powdered zinc was added cautiously. The mixture was heated under reflux for five minutes, partially cooled and filtered. The filtrate was diluted with water until turbidity ensued. There resulted a precipitate of 0.65 g. of crystals melting at 94–98°. Recrystallization from alcohol gave the pure *2,4,6-trimethylbenzoin* (IV). The product alone or when mixed with an authentic specimen of the compound melted at 101–102°.

To 0.2 g. of the benzoin in 30 cc. of dry, high-boiling petroleum ether was added 1 cc. of phenyl isocyanate. The solution was heated under reflux for four hours and allowed to cool. The urethan formed colorless crystals melting at 160–161°. A mixed melting point with a sample of the *urethan of 2,4,6-trimethylbenzoin* was 160–161°.

When the filtrate from which the 2,4,6-trimethylbenzoin was obtained was further diluted, there was obtained the *2′,4′,6′-trimethylbenzoin* (III); after recrystallization from alcohol, it melted at 93.5–94°.

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.31; H, 7.14. Found: C, 80.15; H, 7.04.

The *urethan* melted at 141–142°.

Anal. Calcd. for $C_{24}H_{23}O_3N$: N, 3.76. Found: N, 3.89.

The *2,4-dinitrophenylhydrazone* melted at 211.5–212°.

Anal. Calcd. for $C_{23}H_{22}O_5N_4$: N, 12.90. Found: N, 12.72.

Oxidation converted 2′,4′,6′-trimethylbenzoin into mesityl phenyl diketone. The structure of this benzoin has been established by synthesizing it from mesitylene and phenylglyoxal.[6]

Phenyl 2,4,6-Trimethylbenzyl Ketone (V)

(a) From I by Reduction with Zinc and Acetic Acid.—A mixture of 7 g. of the diketone, 100 cc. of glacial acetic acid and 15 g. of zinc dust was boiled under reflux for ten hours, filtered, diluted with water and allowed to cool. The desoxybenzoin melted (from alcohol) at 163.5–164°; yield, 45%.

Anal. Calcd. for $C_{17}H_{18}O$: C, 85.7; H, 7.56; mol. wt., 238. Found: C, 85.4; H, 7.63; mol. wt., 228.

[2] Gray and Fuson, THIS JOURNAL, **56**, 739 (1934).

[3] Hatt, Pilgrim and Hurran [*J. Chem. Soc.*, 93 (1936)] have recently prepared the diketone by a similar method.

[4] This compound was made by the method of Klages and Lickroth [*Ber.*, **32**, 1564 (1899)] who described it as a solid melting below 30°. It has been found to melt (from alcohol) at 32–32.5°.

[5] A similar result has been reported by Hatt, Pilgrim and Hurran, ref. 3.

[6] Arnold and Fuson, THIS JOURNAL, **58**, 1295 (1936).

(b) From I by Reduction with Zinc and Alkali.—A mixture of 10 g. of I, 35 g. of zinc dust, 35 g. of potassium hydroxide (in 25 cc. of water) and 250 cc. of alcohol was boiled under reflux for four hours and allowed to stand overnight. The yield of V was 33% of the theoretical amount.

(c) From I by Reduction with Tin and Hydrochloric Acid.—A mixture of 3.0 g. of I, 5 g. of granulated tin, 20 cc. of concentrated hydrochloric acid and 100 cc. of ethyl alcohol was boiled under reflux for twelve hours. The yield of V was 76%.

(d) From the Benzoins.—The ketone (V) results when either III or IV is heated with zinc and acetic acid. A typical procedure is the following: a mixture of 1 g. of 2,4,6-trimethylbenzoin, 50 cc. of glacial acetic acid and 6 g. of zinc dust was boiled under reflux for twelve hours. A yield of 0.3 g. of V was obtained; m. p. 162–163°.

(e) From IV by Reduction with Tin and Hydrochloric Acid.—A mixture of 2.0 g. of IV, 5 g. of granulated tin, 20 cc. of concentrated hydrochloric acid and 100 cc. of ethyl alcohol was boiled under reflux for twenty hours. The yield of V was 78% of the theoretical amount. The melting point of the crude material was 161–164°.

(f) From Mesitylacetic Acid.—To 7.2 g. of mesitylacetic acid was added 25 cc. of thionyl chloride; the solution was allowed to stand for two hours, then it was heated for thirty minutes at 60°. The mixture was distilled under diminished pressure, the mesitylacetyl chloride being collected at 126–130° (10 mm.). The acid chloride was dissolved in 50 cc. of dry benzene and this solution was added dropwise to a mixture of 10 g. of aluminum chloride and 50 cc. of benzene. The mixture was allowed to stand at room temperature for five hours. There was obtained 2.5 g. of product melting at 145–152°. Recrystallization from alcohol gave the pure ketone (V), melting at 163.5–164°. Mixtures with samples prepared under (a) and (b) showed no depression of the melting point.

The *phenylhydrazone* of phenyl 2,4,6-trimethylbenzyl ketone had an orange color, and melted (from alcohol) at 104–105°.

Anal. Calcd. for $C_{23}H_{24}N_2$: N, 8.54. Found: N, 8.63.

The *2,4-dinitrophenylhydrazone* of phenyl 2,4,6-trimethylbenzyl ketone was orange in color and melted at 163°.

Anal. Calcd. for $C_{23}H_{22}O_4N_4$: N, 13.39. Found: N, 13.41.

A second compound was isolated from the mixture resulting from the action of 2,4-dinitrophenylhydrazine and the ketone. It had an orange color, melted at 190° and appeared to be a second 2,4-dinitrophenylhydrazone.

Anal. Calcd. for $C_{23}H_{22}O_4N_4$: N, 13.39. Found: N, 13.21.

The pinacol (*VII*) was produced when phenyl 2,4,6-trimethylbenzyl ketone was treated with an excess of ethylmagnesium bromide or isopropylmagnesium bromide. The pinacol is very insoluble in alcohol, but can be recrystallized from glacial acetic acid. It melts at 241–242°.

Anal. Calcd. for $C_{34}H_{38}O_2$: C, 85.35; H, 7.95; mol. wt., 478. Found: C, 85.40; H, 7.96; mol. wt. (Rast), 437.

Oxidation of 1 g. of V with 0.5 g. of selenium dioxide in 25 cc. of dioxane and 0.5 cc. of water gave 0.6 g. of the diketone (I). The reaction was carried out by heating the mixture for ten hours at 80°.

The *p*-Chlorobenzal Derivative of Benzyl Mesityl Ketone.—A mixture of 1 g. of *p*-chlorobenzaldehyde, 10 cc. of 10% sodium hydroxide solution, 0.66 g. of benzyl mesityl ketone and 50 cc. of alcohol was allowed to stand overnight. A precipitate formed. The solution was diluted with an equal volume of water, and the product removed on a filter. There resulted 0.89 g. of product melting at 135–137°. Recrystallization from alcohol raised the melting point to 141°.

Anal. Calcd. for $C_{24}H_{21}OCl$: C, 79.85; H, 5.83. Found: C, 79.96; H, 6.08.

It was found that the foregoing procedure could be used for the detection of small amounts of benzyl mesityl ketone.

Mesitylacetic acid was prepared by reduction of mesitylglycolic acid with iodine and phosphorus, as reported by Claus.[7] A mixture of 3.0 g. of red phosphorus, 1.0 g. of iodine and 100 cc. of glacial acetic acid was allowed to stand at room temperature for fifteen minutes. There was added 5 cc. of water and 8.8 g. of mesitylglycolic acid. The mixture was boiled under reflux for four hours, and filtered while hot into 100 cc. of a saturated solution of sodium bisulfite. The yield of the acid (m. p. 166°) was 90%.

Mesitylphenylglycolic acid was not obtained as the free acid. It crystallized with one molecule of alcohol of solvation.

A mixture of 5.0 g. of mesityl phenyl diketone, 10 g. of potassium hydroxide in 20 cc. of water, and 250 cc. of methyl alcohol was boiled under reflux for ten hours. The solvent was removed at 60°, water was added and the alkali-insoluble material removed by filtration. The aqueous solution was poured into a mixture of ice and concentrated hydrochloric acid. The gum which separated was recrystallized from methyl alcohol. The yield of the colorless compound, melting at 87–89°, was 62%.

Anal. Calcd. for $C_{18}H_{22}O_4$: C, 71.52; H, 7.28; neut. equiv., 302. Found: C, 71.55; H, 7.24; neut. equiv., 300.

The *methyl ester* was obtained in good yields when the acid was treated with methyl sulfate in alkaline solution. It separated from alcohol solutions as colorless crystals, melting at 111–111.5°.

Anal. Calcd. for $C_{18}H_{20}O_3$: C, 76.06; H, 7.05. Found: C, 76.38; H, 7.04.

A second acid was obtained when the above acid was recrystallized several times from ethyl alcohol. It appeared to have one molecule of ethyl alcohol of solvation; it melted at 84–85°.

Anal. Calcd. for $C_{19}H_{24}O_4$: C, 72.15; H, 7.59; neut. equiv., 316. Found: C, 72.03, 72.36; H, 7.74, 7.80; neut. equiv., 313.

This compound was also isolated from the acidified mother liquor when I was treated with zinc and potassium hydroxide in ethyl alcohol solution in the preparation of V.

Mesitylphenylacetic acid was prepared from mesitylphenylglycolic acid by reduction with iodine and phosphorus by the procedure analogous to that utilized for the preparation of diphenylacetic acid.[8] The melting point

---

[7] Claus, *J. prakt. Chem.*, **41**, 508 (1890).

[8] "Organic Syntheses," John Wiley and Sons, Inc., New York N. Y., Coll. Vol. I, p. 82.

of the colorless compound was 173–173.5°, which agrees with that given by Maxwell and Adams.[9]

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.31; H, 7.09; neut. equiv., 254. Found: C, 80.29; H, 7.39; neut. equiv., 256.

Mesitylphenylacetic acid was also synthesized by boiling a mixture of 1 g. of mesitylphenylglycolic acid, 30 cc. of glacial acetic acid and 6 g. of zinc under reflux for eighteen hours. There was obtained 0.5 g. of product which, on recrystallization, melted at 173°. A mixed melting point with the product obtained in the iodine and phosphorus reduction of mesitylphenylglycolic acid showed no depression.

Summary

Mesityl phenyl diketone reacts as a monoketone toward the Grignard reagent, semicarbazide, 2,4-dinitrophenylhydrazine and hydroxylamine. Toward hydrogen peroxide, as well as in the benzilic acid rearrangement, the diketone behaves normally.

Reducing agents convert the diketone to a mixture of the two isomeric benzoins. Drastic reduction *affects only the hindered carbonyl group* and gives phenyl 2,4,6-trimethylbenzyl ketone.

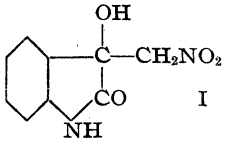
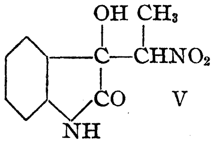
Oxindole Amines from Isatin[1]

By William R. Conn[2] and H. G. Lindwall

It has been reported previously[3] that nitromethane will condense with beta-naphthisatin to yield 3-hydroxy-3-(nitromethyl)-β-naphthoxindole. It has now been found that a similar reaction with nitromethane occurs in the case of isatin, and of certain substituted isatins in the presence of diethylamine, with the formation of the corresponding aldol-like condensation products. Isatin and nitromethane yield 3-hydroxy-3-(nitromethyl)-oxindole (I); substituted derivatives of I (II, III and IV) result from the condensations employing, respectively, N-ethylisatin, 5-bromo-N-ethylisatin and N-methylisatin. Nitroethane and isatin yield an analogous product (V).



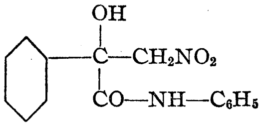
I



V

At room temperature or for short periods of heating, these five nitro compounds exhibit unexpected resistance toward dehydrating agents such as acetic anhydride, acetyl chloride or hydrochloric acid. When heated with neutral solvents gradual decomposition takes place with the formation of the original isatin and the nitroalkane. The extent of this decomposition can be greatly decreased by the presence of a small amount of glacial acetic acid in the solvent. Heated alone, these nitro compounds again decompose through reversal of the aldol condensation; examination of the melts shows the presence of the isatin and the nitro-alkane. Heating in water containing even small amounts of organic or inorganic base causes speedy reversal of the condensation.

For purposes of generalization, a straight-chain alpha-keto-amide, benzoylformanilide, was condensed with nitromethane. The product, VI, has properties similar to those described above for compounds I–V.



VI

Reduction of 3-hydroxy-3-(nitromethyl)-oxindole (I) catalytically with Adams platinic oxide catalyst[4] or by treatment with concentrated hydrochloric acid and mossy tin, gave the hydrochloride of 3-hydroxy-3-(aminomethyl)-oxindole (VII). Similar treatment of II and III with tin and hydrochloric acid yielded in the same manner the hydrochlorides of the aminomethyloxindoles, respectively, IX and X.

In one of several runs of the reduction of I to form VII by the tin–hydrochloric acid method, VII was obtained contaminated with a compound which was found to be the intermediate reduction

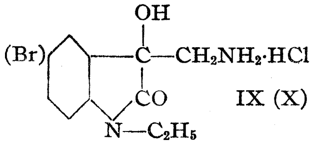
VII

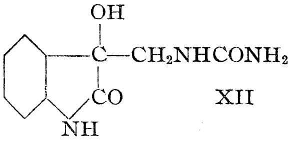


IX (X)

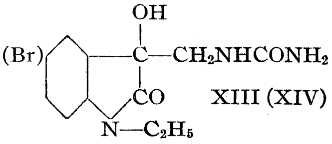
product (VIII) 3-hydroxy-3-(hydroxylaminomethyl)-oxindole hydrochloride. Compound VIII was not encountered in the other runs of this reaction.

Reduction of VI (the product of condensation of nitromethane with benzoylformanilide) with tin and hydrochloric acid did not follow the normal course; the reduction product was not investigated.

Compounds VII, IX and X were found to exhibit several of the properties common to primary amines. With potassium cyanate the corresponding substituted ureas, the uramidomethyloxindoles, XII, XIII and XIV, respectively, are formed.

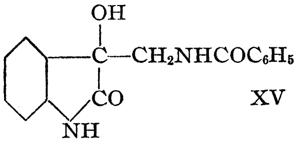


XII

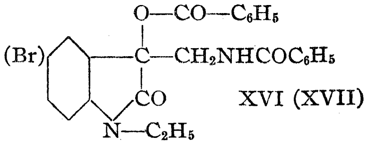


XIII (XIV)

Treatment of VII with benzoyl chloride brings about benzoylation of the amino group and yields 3 - hydroxy - 3 - (benzoylaminomethyl) - oxindole (XV). For compounds IX and X the hydroxy group, as well as the primary amino group, is benzoylated, yielding XVI and XVII, respectively.

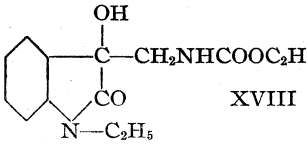


XV

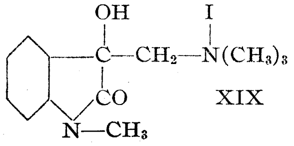


XVI (XVII)

Furthermore, treatment of IX with ethyl chloroformate causes the formation of the urethan (XVIII). Methylation of VII with methyl iodide gives the quaternary ammonium salt (XIX).



XVIII



XIX

It is planned to continue this work on the synthesis of oxindole-amine derivatives. Certain of these products will be studied physiologically.

Experimental Part

3-Hydroxy-3-(nitromethyl)-oxindole (I).—Isatin (44.1 g.) was suspended in a solution of nitromethane (36.6 g.) and 40 cc. of absolute ethyl alcohol. After cooling in ice, 3 cc. of diethylamine was added. In one day at ice-box temperature 71% of crude product separated. Crystallization from glacial acetic acid yielded hexagonal colorless crystals, m. p. 135–140°, dec., soluble in alcohol, acetone, benzene. Compounds II, III and IV were prepared by the same general method, and have solubilities similar to those of I.

Anal. Calcd. for $C_9H_8O_4N_2$: C, 51.90; H, 3.88; N, 13.46. Found: C, 52.24; H, 3.82; N, 13.24.

3 - Hydroxy - 3 - (nitromethyl) - 1 - ethyloxindole (II) from N-ethylisatin and nitromethane; yield, crude, 60% after two days; colorless prisms from carbon tetrachloride; m. p. 84–85°, dec.

Anal. Calcd. for $C_{11}H_{12}O_4N_2$: N, 11.86. Found: N, 11.91.

3 - Hydroxy - 3 - (nitromethyl) - 5 - bromo - 1 - ethyloxindole (III) from 5-bromo-N-ethylisatin and nitromethane; yield, crude, 93% after overnight; small colorless plates from ethyl alcohol containing a trace of glacial acetic acid; m. p. 123–125°, dec.

Anal. Calcd. for $C_{11}H_{11}O_4N_2Br$: N, 8.89. Found: N, 8.65.

3 - Hydroxy - 3 - (nitromethyl) - 1 - methyloxindole (IV) from N-methylisatin and nitromethane; yield, crude, 70% after two days; large needles from hot benzene containing a trace of glacial acetic acid; m. p. 98–99°, dec.

Anal. Calcd. for $C_{10}H_{10}O_4N_2$: C, 54.03; H, 4.54; N, 12.61. Found: C, 54.42; H, 4.70; N, 12.55, 12.42.

3-Hydroxy-3-(α-nitroethyl)oxindole (V) from isatin and nitroethane; yield, crude, 80% after two days; hexagonal crystals from glacial acetic acid; m. p. 145–150° with reddening at 140°.

Anal. Calcd. for $C_{10}H_{10}O_4N_2$: N, 12.61. Found: N, 12.20, 12.40.

Properties of I, II, III, IV, V. (A) Dehydrating Agents.—Compound I, boiled in acetic anhydride for one minute, was unchanged; prolonged refluxing caused decomposition with evolution of red fumes. Short boiling of I with acetyl chloride, or long standing at room temperature with that reagent, had no effect. Four hours in acetic anhydride at 100° caused no change in IV. Three minutes of boiling in concentrated hydrochloric acid had no effect upon II and IV. Compound IV was unchanged after standing for one week at room temperature in absolute alcohol saturated with dry hydrogen chloride.

(B) **Alkali.**—All five of these nitro compounds were decomposed, through reversal of the condensation reaction, to form the original reactants when heated in water or organic solvents containing traces of organic or inorganic bases. Isatin, or the respective isatin derivative, was identified in each case. Compound IV, dissolved in potassium hydroxide solution, imparted a yellow color to the solution; acidification with hydrochloric, acetic or carbonic acids yielded a red gum which became colorless and crystalline upon standing for a few minutes; the product was the original IV.

(C) **Heat.**—All five nitro compounds decomposed into the original reactants when melted; this was shown by examination of the melts. Slow decomposition, quantitative in a few hours, takes place when these compounds are heated in neutral organic solvents or in water; this decomposition is effectively avoided when a small amount of acetic acid is present in the solvent.

2 - Phenyl - 2 - hydroxy - 3 - nitropropaneanilide (VI).—Diethylamine (10 drops) was added to the cooled mixture of benzoylformanilide (13.5 g.), nitromethane (4.1 g.), and 10 cc. of absolute alcohol. Crystals began to form after five minutes; after overnight a 96% yield of crude product resulted; colorless needles after crystallization from glacial acetic acid; m. p. 143–144°, dec.; soluble in alcohol, acetone. Boiling in concentrated hydrochloric acid, or in acetic anhydride, for two hours produced no change; two minutes of boiling in water containing a small amount of diethylamine caused decomposition as shown by the identification of benzoylformanilide.

Anal. Calcd. for $C_{15}H_{14}O_4N_2$: N, 9.79. Found: N, 9.67.

3 - Hydroxy - 3 - (aminomethyl) - oxindole Hydrochloride (VII). (A) Catalytic Reduction of I.—Compound I (20.8 g.) was dissolved in 240 cc. of absolute alcohol containing 11 cc. of glacial acetic acid. To the clear solution was added 0.2 g. of Adams platinic oxide catalyst[4] and the mixture was subjected to the action of hydrogen under 3 atm. pressure at room temperature with mechanical agitation. In two hours the pressure dropped the calculated amount for absorption of three moles of hydrogen; the time varied somewhat with different runs. The catalyst was removed, 12 cc. of concentrated hydrochloric acid was added, and the solution was evaporated to half its original volume at room temperature under diminished pressure. Crystals separated as needles, the yield being augmented to 62% upon further concentration. Acetic acid was necessary in the reduction; without it a non-crystalline substance, not identified, separated before the calculated amount of hydrogen had been used. Compound VII is soluble in alcohol, glacial acetic acid; crystallized from the latter, it is obtained as colorless leaflets, m. p. 195–197°, dec.

Anal. Calcd. for $C_9H_{11}O_2N_2Cl$: N, 13.05; Cl, 16.52; active hydrogen atoms, 5. Found: N, 12.92, 12.86; Cl, 16.41, 16.34; active hydrogen atoms,[5] 5.

Picrate of VII.—Soluble in alcohol, acetic acid, acetone, benzene; long needles from 50% alcohol, which become powdered upon desiccation; m. p. 165–166°, dec.

Anal. Calcd. for $C_{15}H_{13}O_9N_5$: N, 17.20. Found: N, 16.40.

(B) Reduction of I by Tin and Hydrochloric Acid. (VII).—A sample of I was warmed at 45° with twice the theoretical amount of mossy tin and concentrated hydrochloric acid until most of the tin had been used. The mixture was then diluted and tin removed as the sulfide. Concentration of the solution at room temperature yielded VII. (In one run of several, VIII, described below, was obtained.) The yield of VII after repeated crystallizations from glacial acetic acid was 10%.

3 - Hydroxy - 3 - (hydroxylaminomethyl) - oxindole (VIII) was obtained in one run of Method B (VII, above); insoluble in the more common organic solvents; crystallized from dilute hydrochloric acid as colorless needles, m. p. 194°.

Anal. Calcd. for $C_9H_{11}O_3N_2Cl$: Cl, 15.39. Found: Cl, 15.40.

Picrate of VIII.—Fine needles from acetic acid; m. p. 174°.

3 - Hydroxy - 3 - (aminomethyl) - 1 - ethyloxindole Hydrochloride (IX) from II.—Compound II (23.6 g.) was suspended in 87 cc. of concentrated hydrochloric acid and heated on a steam-bath while 47.6 g. of mossy tin was added gradually. The mixture was then held at its boiling point for three hours with the gradual addition of more tin (23.8 g.) and more hydrochloric acid (45 cc.). The tin was finally removed as the sulfide, and the solution was evaporated to dryness at room temperature; leaflets from isoamyl alcohol; m. p. 180–182°, dec.; yield, 50%; soluble in alcohol, glacial acetic acid.

Anal. Calcd. for $C_{11}H_{15}O_2N_2Cl$: C, 54.41; H, 6.23; N, 11.54; Cl, 14.63; active hydrogen atoms, 4. Found: C, 54.17; H, 6.55; N, 11.54; Cl, 14.46, 14.57; active hydrogen atoms, 4.

Picrate of IX. Yellow flakes from ethyl alcohol; m. p. 168–169°.

Anal. Calcd. for $C_{17}H_{17}O_9N_5$: N, 16.10. Found: N, 16.42.

3 - Hydroxy - 3 - (aminomethyl) - 5 - bromo - 1 - ethyloxindole Hydrochloride (X) from III.—This was prepared by the same method as that used above for the preparation of IX; small needles from isoamyl alcohol; m. p. 192–194°, dec.; yield 27%.

Anal. Calcd. for $C_{11}H_{14}O_2N_2ClBr$: Cl, 11.03. Found: Cl, 11.02, 11.16.

Picrate of X.—Small yellow leaflets from ethyl alcohol; m. p. 182–183°.

Anal. Calcd. for $C_{17}H_{16}O_9N_5Br$: N, 13.62. Found: N, 13.39.

Compound XI by the Reduction of VI.—Reduction of VI, by means of tin and concentrated hydrochloric acid, yielded XI which crystallizes as colorless prisms from glacial acetic

---

[5] Zerewitinoff, *Ber.*, **40**, 2028 (1907); **41**, 2239 (1908).

acid; yield 8 g. from 14 g. of VI; m. p. 208–210°. Analyses for C, H, N did not agree with the formula for the simple primary amine; the compound has not been investigated further.

3 - Hydroxy - 3 - (uramidomethyl) - oxindole (XII) from VII; 3-Hydroxy-3-(uramidomethyl) - 1 - ethyloxindole (XIII) from IX; 3-Hydroxy-3-(uramidomethyl)-5-bromo-1-ethyloxindole (XIV) from X.—Compounds XII, XIII and XIV were prepared by treatment of the respective amine hydrochlorides in water solution with potassium cyanate. In each case the product was recrystallized from hot water; yields, 90% approx.

Compound XII.—M. p. 208–209°, dec.

Anal. Calcd. for $C_{10}H_{11}O_3N_3$: N, 19.00. Found: N, 18.65.

Compound XIII.—M. p. 216–217°, dec.

Anal. Calcd. for $C_{12}H_{15}O_3N_3$: C, 57.81; H, 6.07; N, 16.86. Found: C, 57.81; H, 6.35, 6.13; N, 16.21.

Compound XIV.—M. p. 218–220°, dec.

Anal. Calcd. for $C_{12}H_{14}O_3N_3Br$: N, 12.82. Found: N, 12.84.

3-Hydroxy-3-(benzoylaminomethyl)-oxindole (XV) from VII.—One gram of VII was dissolved in 10 cc. of water containing 3 g. of sodium carbonate; benzoyl chloride (slightly more than two moles) was added with shaking. The product separated over a period of several hours. It was washed with sodium carbonate solution; flat colorless rods from acetone; m. p. 177°; soluble in alcohol, acetic acid; yield 75%.

Anal. Calcd. for $C_{16}H_{14}O_3N_2$: C, 68.07; H, 5.01; N, 10.08. Found: C, 68.45; H, 5.65; N, 10.07.

3 - (Benzoylhydroxy - 3 - (benzoylaminomethyl) - 1 - ethyloxindole (XVI) from IX; 3 - (Benzoylhydroxy) - 3 - (benzoylaminomethyl) - 5 - bromo - 1 - ethyloxindole (XVII) from X.—Compound IX, or X, was dissolved in 10% sodium hydroxide solution, or in sodium carbonate solution, and an excess of benzoyl chloride was added with shaking. Compounds XVI and XVII, respectively, resulted; each was recrystallized from ethyl alcohol. Yields, 90% approx.

Compound XVI.—Hexagonal crystals; m. p. 191°, with dec.

Anal. Calcd. for $C_{25}H_{22}O_4N_2$: C, 72.43; H, 5.35; N, 6.76. Found: C, 72.02; H, 5.31; N, 6.80.

Compound XVII.—Prisms; m. p. 204°.

Anal. Calcd. for $C_{25}H_{21}O_4N_2Br$: C, 60.85; H, 4.30; N, 5.68. Found: C, 60.68; H, 4.70; N, 5.71.

3 - Hydroxy - 3 - (ethylcarbamidomethyl) - 1 - ethyloxindole (XVIII) from IX.—Compound IX (1.2 g.) was dissolved in 6 cc. of water containing 2.1 g. of potassium carbonate. The solution was cooled, and an excess of ethyl chloroformate was added. A quantitative yield of product separated; colorless prisms from ethyl alcohol; m. p. 166°.

Anal. Calcd. for $C_{14}H_{18}O_4N_2$: C, 60.41; H, 6.52; N, 10.07. Found: C, 60.12; H, 6.59; N, 10.32.

(3 - Hydroxy - 1 - methyloxindolyl - 3) - methyltrimethylammonium Iodide (XIX) from VII.—Compound VII (1.1 g.) dissolved in 28 cc. of absolute alcohol was treated with 2.5 g. of barium hydroxide hydrate and 2.6 g. of methyl iodide. After standing at room temperature for two days, the mixture was heated at 40° for two days, and finally was heated on the steam-bath for three hours, with addition of 0.5 g. more of methyl iodide. After cooling, 1 cc. of concentrated hydrochloric acid was added, and the solution was dried. To isolate the product, ether was added dropwise; yield 43%; feather-like clusters from ethyl alcohol; m. p. 227°, dec.

Anal. Calcd. for $C_{13}H_{19}O_2N_2I$: C, 43.08; H, 5.29; N, 7.73. Found: C, 42.64; H, 5.41; N, 7.50.

Summary

Isatin, N-ethylisatin, 5-bromo-N-ethylisatin and N-methylisatin react with nitromethane to yield aldol-like nitro condensation products. Isatin and nitroethane react similarly, as does benzoylformanilide with nitromethane.

The products derived thus from isatin, N-ethylisatin, and 5-bromo-N-ethylisatin were reduced to the corresponding primary amine hydrochlorides. These amines yield urea derivatives and benzoylated products. Certain urethan and quaternary ammonium salt formations are described.

Preparation of Dibenzyl Ketone and Phenylacetone

BY CHARLES D. HURD AND CHARLES L. THOMAS

Recently there was described[1] the preparation of dibenzyl ketone by heating a mixture of acetic anhydride and phenylacetic acid. Additional experience with this synthesis has shown that the method as originally published is not given in sufficient detail to ensure infallible results. These details are supplied in the present paper. It has been found also that potassium acetate is a helpful ingredient in the reaction mixture. With it, the product seems to be more easily purified than otherwise.

In addition to dibenzyl ketone it has been found that phenylacetone is also a product of the reaction. These steps account for the changes which occur

$$C_6H_5CH_2COOH + (CH_3CO)_2O \longrightarrow C_6H_5CH_2COOCOCH_3 + CH_3COOH \quad (1)$$

$$C_6H_5CH_2COOCOCH_3 \longrightarrow C_6H_5CH_2COCH_3 + CO_2 \quad (2)$$

$$C_6H_5CH_2COOCOCH_3 \longrightarrow (C_6H_5CH_2CO)_2O + (CH_3CO)_2O \quad (3)$$

$$(C_6H_5CH_2CO)_2O \longrightarrow C_6H_5CH_2COCH_2C_6H_5 + CO_2 \quad (4)$$

Phenylacetone and dibenzyl ketone evidently are pyrolytic products of phenylacetic acetic anhydride and phenylacetic anhydride, respectively. That dibenzyl ketone is formed in greater yields than phenylacetone is evidence that reaction 3 has a greater reaction rate than reaction 2. Or, if reaction 3 is an equilibrium reaction the evidence would indicate that phenylacetic acetic anhydride disappears more rapidly through reactions 3 and 4 than through reaction 2. Indirectly this may indicate that reaction 4 is faster, under the conditions obtaining in the experiment, than reaction 2.

Experimental Part

Fifty grams of phenylacetic acid was weighed into a 250-cc. three-necked flask. Then 50 g. of redistilled acetic anhydride and 2.5 g. of fused, anhydrous potassium acetate were added. A thermometer was placed in the liquid and the mixture refluxed for two hours, during which time the thermometer in the liquid registered 149–150°. A good fractionating column was inserted in place of the reflux condenser and the mixture distilled. The distillation was carried out very slowly so that the distillate was mainly acetic acid. The following table gives a typical distillation.

Time, min.	Temp., °C. Vapor	Temp., °C. Liquid
0	119	150
45	121	154
57	122	160
70	122.5	165
74	120	171
78	118	182
80	115	193
81	114	199
83	113	204

After forty-five minutes carbon dioxide was evolved slowly. The rate increased to a maximum at about seventy-five minutes, but carbon dioxide was still being evolved slowly when the distillation was stopped. A total of 4 liters of gas was collected which was pure carbon dioxide (over 99.3% CO_2). Heating the liquid above 200–205° produced resinification with a decreased yield of ketones.

The residue was placed in a 50-cc. Claisen flask. Acetic anhydride (5 cc.) was used as a rinse. The mixture was distilled at 3 mm.: 30–75°, chiefly acetic anhydride; 75–160°, a 26-g. fraction; residue, 16 g. Redistillation (755 mm.) of the 26-g. fraction gave 8 g. (16% yield) of phenylacetone, b. p. 215–220°, and 16 g. (41% yield) of dibenzyl ketone, b. p. 317–320° (m. p. 30°). The phenylacetone was identified as the phenylhydrazone,[2] m. p. 84.5–85°.

Dibenzyl ketone may be prepared in almost the theoretical yields from phenylacetic acid by passing it over a special thoria catalyst[3] at 345°. The present method, however, possesses the advantage of simplicity and convenience which might in many instances more than make up for the lower yield.

Summary

A detailed technique is given for producing dibenzyl ketone from phenylacetic acid and acetic anhydride. Phenylacetone is formed concurrently.

The Dielectric Constant of Dioxane–Water Mixtures between 0 and 80°

BY GÖSTA ÅKERLÖF AND OLIVER A. SHORT

Dioxane is in many respects a remarkable substance. In accordance with its symmetrical structure dioxane has a very small dipole moment, which possibly even may be equal to zero. Yet dioxane is completely miscible in all proportions with such a highly polar compound as water and quite large quantities of strong electrolytes are needed to salt it out. However, this particular property, combined with a very low dielectric constant, makes dioxane–water mixtures highly suitable as solvents for the study of the behavior of electrolytes in media of continuously and rapidly varying dielectric constant. This has been pointed out and made use of already by Kraus and Fuoss,[1] who studied the conductance of certain strong electrolytes in dioxane–water mixtures. The values they used for the dielectric constants of these mixtures were obtained by G. S. Hooper and our results to be presented below are in good agreement with his, but since the measurements were carried out only at a single temperature and principally confined to mixtures containing small quantities of water, a more complete study was deemed desirable.

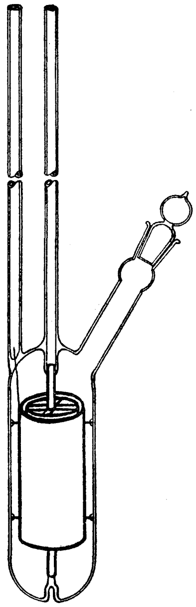

Fig. 1.—Cell.

Apparatus and Materials.—The experimental method employed was practically identical with the procedure previously given[2] and therefore a repetition is unnecessary. The wave length used was, also as before, 150 meters. Due to the relatively great length of the leads to the test cell in the present case they were twisted together and the readings of the resonance circuit were calibrated at a large number of points against a continuously variable precision condenser calibrated by the Naval Research Laboratory and kindly loaned to us by Professor Norman I. Adams of the Sloane Physics Laboratory. The design of the test cells is given by Fig. 1. The electrodes were made of platinum and firmly held in place, the outer grounded one by a number of short wires, one end of which was welded to the electrode and the other end fused into the wall of the glass vessel. The inner electrode was held by an upper and a lower cross welded to a center tube, also of platinum. Two cells were employed, one with a capacity of about 13.70 and the other of 55.0 $\mu\mu$F. For the calibration of the smaller cell water was used employing the value obtained by Wyman[3] for its dielectric constant at 20°. The large cell was calibrated by readings at several temperatures with a 70 wt. % dioxane–water mixture, the dielectric constant of which previously had been measured at the same temperatures with the small cell. The use of platinum electrodes was resorted to after a futile attempt

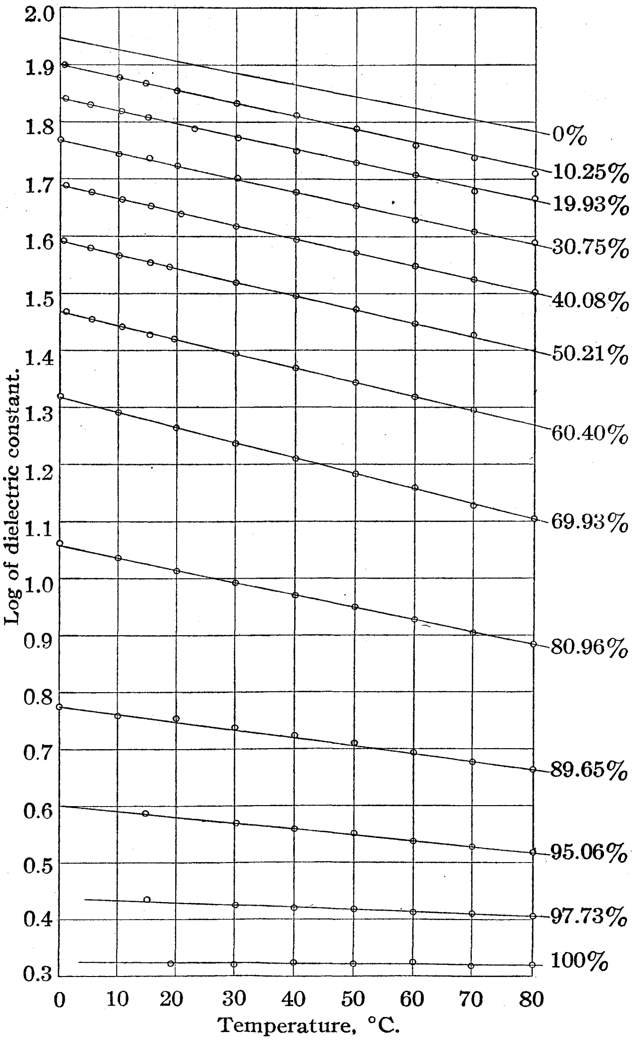

Fig. 2.—Curves for the logarithm of the dielectric constant of dioxane–water mixtures of constant composition and varying temperature.

50	69.85	61.57	53.43	45.38	37.41	29.72	22.40	15.37	9.41	5.10	3.49	2.60	2.096
60	66.62	68.60	50.75	43.01	35.39	28.08	21.15	14.52	8.93	4.91	3.41	2.57	2.094
70	63.50	55.77	48.20	40.76	33.48	26.52	19.97	13.73	8.48	4.73	3.33	2.55	2.092
80	60.58	53.07	45.77	38.63	31.67	25.05	18.86	12.97	8.05	4.56	3.25	2.52	2.090

to use cells with silver films for the same purpose.[4] The results obtained with the silver films were erroneous but the closest approach to the true values for the dielectric constant was found in the case of mixtures containing a high percentage of dioxane.

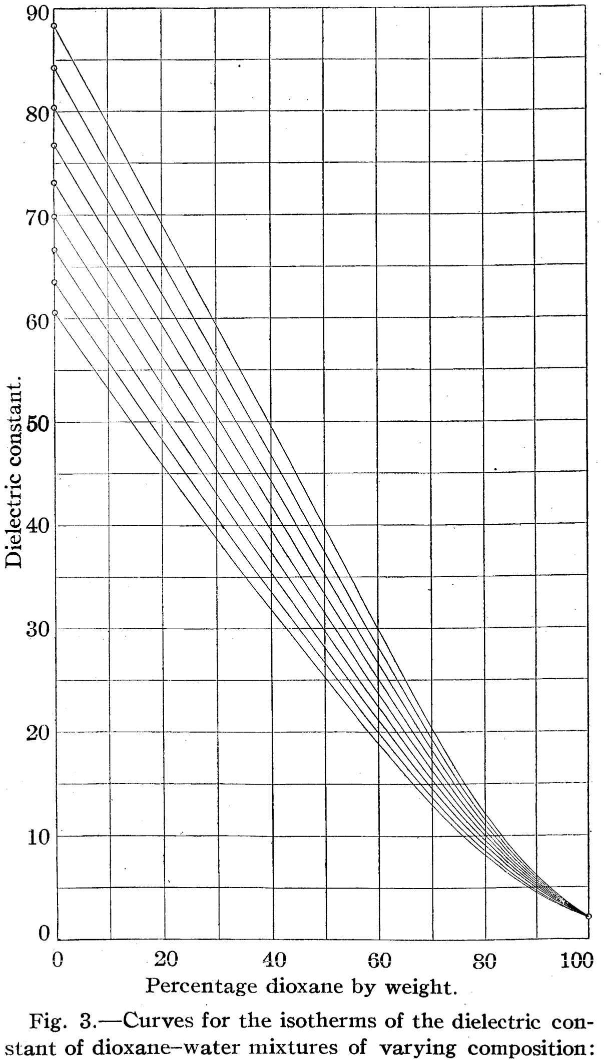

Fig. 3.—Curves for the isotherms of the dielectric constant of dioxane–water mixtures of varying composition: top curve 0° isotherm, then follow in order those for 10, 20, 30, 40, 50, 60, 70 and 80°.

The raw material for the dioxane employed was a commercial varnish remover from the Carbide and Carbon Chemicals Corporation and it consisted apparently of practically pure dioxane. The raw dioxane was first refluxed in an all-glass apparatus with sodium metal for several hours. The distilled product was then subjected to a fractional crystallization in an apparatus with a mercury-sealed stirrer. After four recrystallizations the freezing point had gone up to 11.78°, which value did not show any further visible changes upon repeating the freezing process. Water was obtained from a Barnstead still for conductivity water.

Experimental Results.—The dielectric constant data obtained have been plotted in Fig. 2 using the equation employed by Åkerlöf

$$\log D = \log a - bt \qquad (1)$$

where D is the observed dielectric constant of the solvent mixture, a and b are empirical constants and t is the temperature. As previously had been found in numerous other cases this equation was also in the case of dioxane–water mixtures able to express the experimental data well within their estimated accuracy. Using equation (1) the original measurements have been interpolated to round temperatures and weight per cent. of dioxane and a summary of the result is given in Table I. For interpolation to odd temperatures the following table may be used:

Dioxane, wt. %	Log a	b
0	1.9461	0.00205
10	1.8969	.00215
20	1.8398	.00224
30	1.7734	.00233
40	1.6935	.00241
50	1.5965	.00247
60	1.4747	.00249
70	1.3090	.00245
80	1.0860	.00225
90	0.7896	.00164
95	.5923	.00100
100	.3234	.00004

---

[4] The design of the cells was practically identical with that of the cells used by Sugden, *J. Chem. Soc.*, 768 (1933); *cf.* Sayce and Briscoe, *ibid.*, 315 (1925); Ball, *ibid.*, 570 (1930).

A graphical representation of the isotherms for the variation of the dielectric constant of the dioxane–water mixtures with changing composition is shown in Fig. 3.

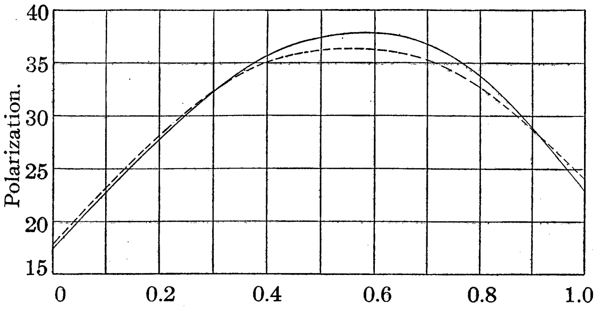

Fig. 4.—Curves for the dielectric polarization of dioxane–water mixtures at 20 and 70°; dotted curve 70° isotherm.

The curve for the molar dielectric polarization of dioxane–water mixtures is considerably different from that of a number of other organic solvent–water mixtures. In the case of methyl and ethyl alcohol–, ethylene glycol– and glycerol–water mixtures, a practically linear variation of the polarization over the entire mixture range is obtained when it is plotted against the mole fraction of one of the components. The polarization of a mixture P_{12} is given by the equation

$$P_{12} = f_1P_1 + f_2P_2 = \frac{D-1}{D+2}\,\frac{f_1M_1 + f_2M_2}{d} \qquad (2)$$

where f_1 and f_2 denote mole fractions, M_1 and M_2 molecular weights and d is the density of the mixture. In Table II is given the calculated values for 20 and 70° and the corresponding curves are shown in Fig. 4. Data used for the density of dioxane–water mixtures were those of Herz and Lorenz.[5]

TABLE II

THE DIELECTRIC POLARIZATION OF DIOXANE–WATER MIXTURES AT 20 AND 70°

Dioxane, wt. %	Dioxane mole fr.	P_{12} at 20°	P_{12} at 70°
0	0	17.39	17.59
10	0.0222	18.66	18.82
20	.0487	20.10	20.31
30	.0806	21.83	22.11
40	.1200	23.94	24.26
50	.1699	26.54	26.84
60	.2349	29.69	29.83
70	.3232	33.21	33.00
80	.4501	36.65	35.78
90	.6481	37.47	35.78
95	.7954	34.06	32.92
98	.9093	28.35	28.40
100	1.0000	22.90	24.06

According to present theory, if a substance is non-polar its polarization is constant and independent of the concentration. Thus since dioxane as already mentioned probably is non-polar we might calculate the variations of the polarization of water in dioxane–water mixtures. The calculated values vary approximately linearly when plotted against the dioxane mole fraction as shown in Fig. 5 for the 20° isotherm, but the theoretical significance of this result is difficult to understand. The polarization of water in pure dioxane at 20° extrapolates to 88.0, while the corresponding value in pure water is only 17.4.

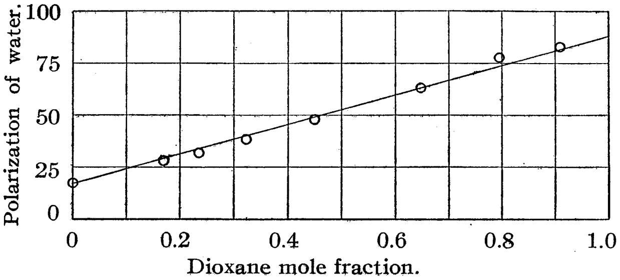

Fig. 5.—Curve for the dielectric polarization of water in dioxane–water mixtures at 20°.

The authors wish to express their appreciation of the help given them by Professor Norman I. Adams.

Summary

The dielectric constant of a series of dioxane–water mixtures has been measured over the temperature range 0 to 80° for a wave length of 150 meters and using a resonance method.

The Catalytic Decomposition of Hydrogen Peroxide in a Bromine–Bromide Solution. Effect of Light on the Steady-state Rate

BY ROBERT LIVINGSTON AND E. A. SCHOELD

That exposure to diffuse daylight produces a pronounced decrease in the steady-state concentration of bromine in a hydrogen peroxide–bromine–bromide mixture was remarked in 1923 by Bray and Livingston.[1] On the basis of the mechanism which they adopted for the catalytic decomposition of hydrogen peroxide occurring in these solutions, they predicted that the irradiation of the reaction mixtures with light of constant intensity would not affect the steady-state rate of the decomposition. However, this prediction was not tested experimentally.

More recently[2] it has been suggested that the decomposition of hydrogen peroxide may be a chain reaction in acid as well as in basic solutions. In so far as the halogen–halide catalyzed reactions are concerned, this suggestion appears to be based entirely upon analogy, and is in contradiction to several experimental observations of these reactions.[3]

The measurements presented here substantially check the predictions of Bray and Livingston,[1] and afford definite evidence that the bromine sensitized photochemical decomposition of hydrogen peroxide is not a chain reaction.

Experimental Methods.—The analytical methods for the determination of hydrogen peroxide and bromine in the reacting mixtures were similar to those of Bray and Livingston.[1] The "dark reaction" mixture was kept in a black-coated flask, which was immersed in a large water thermostat, maintained at 35°.[4] The "light-reaction" vessel was a short Pyrex cylinder, with sealed on plane ends. It was provided with a water-sealed glass stirrer, to prevent the development of concentration gradients due to the photochemical action. The oxygen, evolved during the reaction, escaped through the water seal of the stirrer. This reaction vessel and a similar vessel, which was kept filled with distilled water, were sealed into a flat metal box, which was provided with openings into which the ends of the cylinders fitted. Water from the large thermostat was circulated through this box. Although the ends of the reaction vessel were not jacketed, tests showed that the temperature of the reaction mixture was not more than 0.1° below that of the large thermostat.

In beginning an experiment, a volume of reaction mixture was prepared from stock solutions of hydrogen peroxide and hydrogen bromide, sufficient to fill both the "dark" and "light-reaction" vessels. Both vessels were filled, and the cylindrical cell was irradiated with light of constant intensity. After sufficient time (about three hours) was allowed for steady-state conditions to be attained, samples were removed from each of the reaction mixtures and were analyzed for hydrogen peroxide. After a measured lapse of time, of from one to four hours, samples were again removed from each of the vessels and were analyzed both for peroxide and for bromine.

These measurements made possible the computation of the first order rate constant k of equation 1

$$-d(H_2O_2)/dt = k(H_2O_2) \tag{1}$$

and the termolecular catalytic rate constant, K of equation 2

$$-d(H_2O_2)/dt = K(H_2O_2)(H^+)(Br^-) \tag{2}$$

In the computation of K, correction was made for tribromide formation[1] (p. 1262). However, no correction was made for the kinetic salt effect,[5] since in these experiments we were interested primarily in the comparison of the "light" and "dark" rates of initially identical solutions.

The light source used in these experiments was a 500-watt "stereopticon" tungsten-filament lamp provided with a system of condensing lenses and a Corning heat-absorbing neutral-green filter. The light intensity was measured with a galvanometer–surface thermopile system, which was

[1] Bray and Livingston, THIS JOURNAL, **45**, 1264 (1923).

[2] See for example, Moelwyn-Hughes, "Kinetics of Reactions in Solution," Oxford Univ. Press, New York, 1933, p. 211.

[3] If these processes were chain reactions it should be expected that they would be sensitive to the presence of inhibitors, including those substances which are commonly used as hydrogen peroxide preservatives. That this is not the case for the iodine–iodide catalysis was shown by Bohnson, *J. Phys. Chem.*, **25**, 19 (1925); for the bromine–bromide catalysis by Bray and Livingston, reference 1, p. 1260; and for the chlorine–chloride catalysis by Livingston and Bray, THIS JOURNAL, **47**, 2069 (1925).

[4] A lower temperature would have been preferable, but would have required somewhat more elaborate equipment, since these experiments were performed during the summer months, when the average temperature of both air and cooling water was above 25° and the relative humidity was high.

[5] See Livingston, THIS JOURNAL, **48**, 53 (1926).

calibrated against a U. S. Bureau of Standards standard lamp, in the usual manner. The water jacket, which surrounded both the "light reaction" cell and the similar vessel filled with water, was so arranged that it could be slid along a track to place either cell in the path of the beam of light. The intensity of the light absorbed by the reaction mixture was obtained by comparing the energy transmitted through the two cells, taking into account the difference in transmission of the cells when they were both filled with water, and the effect of the second window of the reaction cell.

Measurements and Computations.—The results of the experiments are summarized in Table I. All concentrations are expressed as moles per liter. In computing the rate constants, k and K, natural logarithms were used and time was expressed in minutes. The symbol $\Sigma(Br_2)$ represents the molar concentration of the total titratable bromine, expressed as Br_2. R is the steady-state function[1], and is defined by the equation $R = (Br_2)/(H^+)^2(Br^-)^2$. $I_{abs.}$ is the intensity of the light absorbed expressed in deflection of the galvanometer in centimeters.

The last three columns compare the results of corresponding measurements in the dark and in the light. Experiment 1 was a "blank," in that the light reaction cell was not illuminated.

In thirteen of the fifteen experiments performed the first order reaction constant, k, was greater for the "light reaction" than for the "dark;" in no case was it less. However, it is noteworthy that this increase in k is about six-fold less than the corresponding change (which is in the opposite direction) in the steady-state concentration of the bromine. The values of the third order rate constant, K, do not exhibit any consistent effect of light. The average value of K_l/K_d is 1.005 ± 0.008, where the error is the average error of the averaged value.[6] These results may be taken as evidence that the only effect of visible light on this system is to increase the specific reaction rate of the reduction of bromine by hydrogen peroxide. To a first approximation equation 2 represents the rate of the light reaction as well as the dark reaction, the increase in the absolute rate being completely accounted for by the increase in the steady-state concentration of the hydrobromic acid.

The quantum yield, M/Q, was computed with the aid of the following assumptions. The average wave length of the absorbed light was assumed to be 5300 Å. This value was chosen upon the basis of a qualitative consideration of the energy distribution of the light from a tungsten filament and of the absorption curve for bromine. Although the average wave length of the absorbed light is undoubtedly a function of the concentration of bromine, it is quite probable that the present assumption does not introduce an error of more than 20%. The rate of the purely photochemical reaction was assumed to be equal to $(k_l - k_d)(H_2O_2)$. The quantum yield was computed by means of the expression

$$(k_l - k_d)(H_2O_2)VNh\nu/S \cdot I_{abs.}$$

Where (H_2O_2) is the average concentration of hy-

---

[6] The corresponding average of k_l/k_d is 1.037 ± 0.006. This value is given only for purposes of comparison, since the ratio k_l/k_d is undoubtedly a function of the intensity of the absorbed light.

drogen peroxide during an experiment, V is the volume of the "light reaction" vessel, N is Avogadro's number, $I_{\text{abs.}}$ is the average intensity of the absorbed light expressed as galvanometer deflection in centimeters, $h\nu$ is the energy of a photon of λ 5300 Å., and S is the sensitivity of the galvanometer thermopile system in ergs per minute per cm. deflection. This expression will give the true value of the quantum yield only if it is directly proportional to the concentration of the hydrogen peroxide.[7] However, if the quantum yield were independent of the concentration of hydrogen peroxide, the error introduced by the use of this approximate relation would be less than the average error of the experimental determination of the quantum yield. The average value of the quantum yield (so computed) is 0.4.[8] It is noteworthy that this value is less than unity, and is therefore not in agreement with any chain mechanism of the reaction. More exact measurements of the effect of light on the steady-state rate and function (preferably at a lower temperature and at lower concentrations of peroxide) must be available before a detailed discussion of the mechanism of the photochemical process will be justifiable.

Summary

1. The steady-rate of the decomposition of hydrogen peroxide in bromine–bromide solutions has been measured in the dark and in the light, under otherwise comparable conditions. Although light increases the absolute rate of the reaction, within the limits of experimental error the rate for either the dark or light reaction may be represented by the equation $V = K(H_2O_2)(H^+)(Br^-)$. The increase in the absolute rate is satisfactorily accounted for by the increase in the steady-state concentration of hydrobromic acid.

2. The quantum yield for the bromo sensitized decomposition of hydrogen peroxide has been computed (with the aid of certain simplifying assumptions), and has been shown to have an average value less than unity.

MINNEAPOLIS, MINN. RECEIVED MAY 6, 1936

---

[7] Even for this case the method is an approximate one, since $k_d(H_2O_2)$ does not properly represent the rate of the thermal reaction which is taking place in the illuminated solution. Although this quantity may be readily corrected for the differences in the steady-state concentrations of H^+, Br^- and Br_2 in the "light" and "dark" reacting mixtures, the corrected values of the quantum yield do not differ greatly from the approximate values given in Table I. Therefore, for the sake of simplicity and brevity only the approximate method is presented here.

[8] The value of M/Q for experiment 14 appears to be out of the range of the random distribution of errors and has been excluded from the average.

The Action of Magnesium on Homonuclear Dibromodiphenyls

BY FRANCIS H. CASE

The study of the action of magnesium on homonuclear dibromo aromatic hydrocarbons has thus far been confined to the compounds *m*- and *p*-dibromobenzene,[1] 3,4-dibromotoluene, *sym*-tribromotoluene, 1,3-dimethyl-4,6-dibromobenzene,[2] and 1,2 and 1,4-dibromonaphthalenes.[3] In the case of *p*-dibromobenzene, which has been rather extensively investigated, it was first believed that in the presence of two atoms of magnesium[4] only one atom of bromine is capable of reacting. Later investigations, however, showed that in an inert atmosphere a part of the second atom[5] of magnesium will react to form a di-Grignard, but this reaction never reaches completion. Thus it has been found that with both *p*- and *m*-dibromobenzene, 87% of the original two atoms of magnesium enters the reaction; 3,4-dibromotoluene, 83%; 1,3-dimethyl-4,6-dibromobenzene, 49.6% of the total bromine; *sym*-tribromotoluene, no reaction; 1,4-dibromonaphthalene, 72% magnesium; 1,2-dibromonaphthalene, 75.5% magnesium. It is worthy of note that in the few cases where unsymmetrical dibromides have been investigated, in only one instance (1,2-dibromonaphthalene) have results been obtained that would indicate which of the bromine atoms is more readily attacked by the magnesium.

The object of the present investigation has been to determine the extent to which certain homonuclear dibromodiphenyls react with two atoms of magnesium, and in the case of unsymmetrical de-

rivatives, which bromine atom is preferentially attacked. The compounds chosen for this study were 2,5, 3,5, 2,4 and 3,4-dibromodiphenyls. The preparation of the first three of these dibromides was according to the directions of Scarborough.[6] It should be noted however that 2,4-dibromodiphenyl, which was not obtained in a state of purity by this author, has now been isolated. The preparation of the 3,4-isomer is described in another paper from this Laboratory.[7]

In the experiments to be described, the amount of di-Grignard formation in each case was estimated by weighing the amount of diphenyl solidifying in the receiver after fractional distillation of the hydrolytic products. This method cannot be regarded as strictly accurate as the diphenyl obtained in this way is not entirely pure, yet it gives a better idea of the amount of di-Grignard formation than if the diphenyl obtained were recrystallized, since losses involved in crystallization are large. The nature of the mono-Grignard reagent simultaneously formed was established by oxidizing the monobromodiphenyl resulting from hydrolysis and identifying the corresponding bromobenzoic acid. The unused magnesium was determined by measuring the hydrogen evolved on treatment of the mixture after completion of the reaction with dilute sulfuric acid. The bromine going into water solution was determined gravimetrically.

The results of the experiments in which each of the four isomeric dibromodiphenyls mentioned above was treated with two atoms of magnesium show that the isomers, arranged in the order of decreasing extent of reaction with magnesium, are 2,4, 2,5, 3,5, 3,4. In fact the last-mentioned compound could not be made to react when treated with the activated copper–magnesium alloy of Gilman.[8] From the hydrolytic products of the reactions involving the 2,4- and 2,5-isomers, liquids were obtained which both yielded on oxidation with chromic anhydride, *o*-bromobenzoic acid, thus indicating that in each case the bromine in 2-position was the one less readily attacked. A similar process yielded in the case of 3,5-dibromodiphenyl, *m*-bromobenzoic acid. The close check between the amount of magnesium consumed and the amount of bromine in water solution (indicating a ratio of one atom of each) and the small amount of high boiling residue obtained indicate the absence of any considerable amount of coupling.

The activated copper–magnesium alloy was also used with each of the isomeric dibromodiphenyls, increasing the yield of di-Grignard in the cases of those which reacted with ordinary magnesium.

By treating the 2,5 and 3,5-isomers, respectively, with one atom of magnesium, followed by carbon dioxide, the acids 2-bromodiphenyl-5-carboxylic acid, prepared by Cook and Cook[9] by the oxidation of 2-bromo-5-methyldiphenyl, and 3-bromodiphenyl-5-carboxylic acid, heretofore unknown, were obtained.

In only one case (the 2,5-isomer) was the dicarboxylic acid resulting from the action of carbon dioxide on the di-Grignard formed by the action of 2 atoms of copper–magnesium alloy on the corresponding dibromide, isolated in a state of purity. The 3,5-isomer yielded an acid which could not be freed entirely from bromine even by repeated crystallization. This recalls the difficulties experienced by Gilman[5b] in attempts to obtain pure terephthalic acid from *p*-dibromobenzene. In the case of the 2,4-dibromide, no dicarboxylic acid was found. In the cases of the 2,5, 3,5, and 2,4-isomers, relatively large amounts of monobromocarboxylic acid were isolated. One must therefore conclude that although, as shown by previous experiments, the di-Grignard is formed to a large extent, yet on treatment with carbon dioxide it is partly unaffected as shown by the presence of a certain amount of diphenyl after hydrolysis, and is subject to side reactions leading to the formation of acidic resins obtained as by-products.

Experimental

Preparation of Dibromodiphenyls.—These compounds were tested for absence of nitrogen, and gave a correct bromine analysis.

Preparation of 2,4-Dibromodiphenyl.—By the hydrolysis of 78.5 g. of 4,6-dibromo-3-acetaminodiphenyl with alcoholic hydrobromic acid was obtained 69.2 g. of crude base. The base, dissolved in alcohol, and treated with excess of 1–1 sulfuric acid, was deaminized by means of sodium nitrite. In order to remove from the final product all traces of nitrogenous matter, it was dissolved in absolute ether and filtered from a white precipitate which formed, then washed successively with aqueous hydrobromic acid, and sodium bicarbonate solution. On redistillation, 28 g. was obtained, b. p. 174–176° (7 mm.).

Anal. Calcd. for $C_{12}H_8Br_2$: Br, 51.25. Found: Br, 51.11.

Action of Dibromodiphenyls on Two Atoms of Magnesium.—Fifteen and six-tenths grams (0.05 mol) of dibromodiphenyl dissolved in absolute ether was refluxed not less than fifteen hours with 2.4 g. of magnesium in the presence of a trace of iodine. With the 3,5 and 2,5 isomers and plain magnesium, an atmosphere of nitrogen was maintained, but in all other experiments hydrogen was the inert gas used. On completion of the reactions, hydrolysis was effected by dilute sulfuric acid, the evolved hydrogen being collected over water. Ether vapors were removed by absorption in concentrated sulfuric acid. The ether layer was carefully separated from the water layer, the latter being analyzed for bromine, after removal of the iodine by means of sodium nitrite. The ether layer was evaporated, and the residue fractionated in a vacuum, the amount of solid collecting in the receiver being weighed as diphenyl. The higher boiling liquid was oxidized by means of chromic anhydride in glacial acetic acid, and the resulting bromobenzoic acid identified by a mixed melting point with an authentic specimen. The results are shown in Table I.

TABLE I

ACTION OF DIBROMODIPHENYLS ON TWO ATOMS OF MAGNESIUM

Isomer (0.05 mole)		3,5	2,5	2,4
Mg unused, g.		0.83	0.83	0.73
Bromine in solution	g.	4.86	5.29	5.59
	%	61	66	70
Diphenyl	g.	2.0	3.0	4.3
	%	26	39	56
Mono-Br-diphenyl, g.		7	4.5	3.9
Benzoic acid from oxidation of mono-Br-diphenyl		*m*-Br-	*o*-Br-	*o*-Br-

Action of the Dibromodiphenyls on Two Atoms of Copper-Magnesium Alloy.—Fifteen and six-tenths grams of dibromodiphenyl, dissolved in absolute ether, was refluxed for not less than fifteen hours with approximately 3 g. of activated copper–magnesium alloy prepared according to the directions of Gilman, Peterson and Schulze.[8] The results are shown in Table II.

TABLE II

ACTION OF DIBROMODIPHENYLS ON TWO ATOMS OF Cu-Mg ALLOY

Isomer (0.05 mole)		3,5	2,5	2,4	3,4
Bromine reacting	g.	5.57	6.44	6.56	No reaction
	%	69.6	80.5	82.0	
Yield of diphenyl, g.		2.7	5.3	6.0	....
Diphenyl, %		35.1	68.8	77.9	....

The 3,4-dibromodiphenyl would not react even though a small amount of the activated magnesium of Gilman and Kirby was added to the reaction mixture.[10]

Action of 3,5-Dibromodiphenyl on 1 Atom of Mg + CO_2.—One-twentieth mole of 3,5-dibromodiphenyl was treated with 1.2 g. of magnesium as before. After complete solution of the magnesium, carbon dioxide was passed into the mixture, cooled by ice and salt, for two hours. Decomposition was then effected by dilute hydrochloric acid. The ether solution was washed with alkali, the acid reprecipitated with concd. hydrochloric acid and extracted with ether. After removal of the ether the acid was crystallized from benzene and petroleum ether; yield 3.5 g.; m. p. 177–178°.

Anal. Calcd. for $C_{13}H_9O_2Br$: Br, 28.85. Found: Br, 29.21.

Action of 2,5-Dibromodiphenyl on 1 Atom of Mg + CO_2.—The procedure was the same as with the 3,5-isomer. Two grams of a monobromodiphenyl carboxylic acid was obtained, m. p. 247–248°. The 2-bromodiphenyl-5-carboxylic acid of Cook and Cook melted at 242–243°. The identity of the acid obtained above was further confirmed by the fact that the mono-Grignard reagent on hydrolysis yields only *o*-bromodiphenyl.

Anal. Calcd. for $C_{13}H_9O_2Br$: Br, 28.85. Found: Br, 28.72.

Action of the Dibromodiphenyls on 2 Atoms of Cu–Mg alloy + CO_2.—The quantities used were the same as when the Grignard was directly hydrolyzed. The results are shown in Table III.

TABLE III

ACTION OF CARBON DIOXIDE ON DIPHENYL DI-GRIGNARD REAGENTS

Dibromodiphenyl (15.6 g. used)		3,5	2,5	2,4
Yield of bromocarboxylic acid	g.	5.7	1.9	2.0
	%	41	14	15
Yield of dicarboxylic acid	g.	1.3	2.2	0
	%	11	18	0
Diphenyl isolated, g.		0.2	1.0	0.6

Action of 3,5-Dibromodiphenyl.—After the decomposition of the carbon dioxide–Grignard complex with hydrochloric acid, the precipitated acids were extracted with ether, and removed from the ether by extraction with potassium hydroxide. After reprecipitation with concd. hydrochloric acid, 10 g. of crude acid was obtained. This was separated by means of hot benzene into a soluble fraction which on recrystallization from a methyl alcohol–water mixture yielded 5.7 g. of crude 3-bromodiphenyl-5-carboxylic acid, m. p. 168–170°. The benzene-insoluble portion, weighing 1.9 g. was recrystallized four times from glacial acetic acid, yielding 0.6 g. of an acid melting at 330–334° but still containing 1.19% bromine. Equivalent weight: calcd. for $C_{14}H_{10}O_4$: 121. Found: 126.

Action of 2,5-Dibromodiphenyl.—The mixed acids (12.5 g.) obtained by adding hydrochloric acid to the alkaline extract of the original ether solution, and again extracting with ether, were extracted with hot benzene, yielding 4.5 g. of benzene insoluble material, which after repeated crystallization from a benzene–ether mixture yielded 0.5 g. of pure diphenyl-2,5-dicarboxylic acid, m. p. 274–275°.

Anal. Calcd. for $C_{14}H_{10}O_4$: C, 69.40; H, 4.16. Found: C, 69.62; H, 4.35.

The benzene soluble portion of the above extraction, after several crystallizations from a benzene–petroleum ether mixture, yielded 1.9 g. of 2-bromodiphenyl-5-carboxylic acid, m. p. 247–248°, previously described. The original ether solution, after extraction with sodium hydroxide solution, yielded after evaporation 1 g. of diphenyl.

Action of 2,4-Dibromodiphenyl.—The original ether solution, after extraction with sodium hydroxide solution, acidification of the alkaline solution with hydrochloric

acid, and extraction with ether yielded 10 g. of crude acid, which dissolved in hot benzene. After several crystallizations from methyl alcohol, 2 g. of an acid was obtained, melting at 213–214°, yielding finally an acid of m. p. 218–219°, which melted unchanged with 2-bromodiphenyl-4-carboxylic acid, prepared from 4-methyl-2-bromoaniline by the method of Gomberg and Pernert.[11]

The original ether solution, after extraction with sodium hydroxide, yielded 0.6 g. of diphenyl.

The author acknowledges the assistance of Mr. Henry Sloviter in connection with a portion of the analytical work in this paper.

Summary

1. A study has been made of the extent of the reaction of 3,5, 2,5, 2,4 and 3,4-dibromodiphenyls, respectively, with (a) one and two atoms of magnesium; (b) two atomic proportions of activated copper–magnesium alloy.

2. The nature of the resulting products has been determined when the Grignard reagent is (a) directly hydrolyzed; (b) first treated with carbon dioxide and then hydrolyzed.

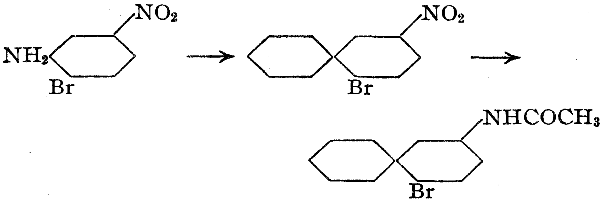
The Preparation of 3,4-Dibromodiphenyl

BY FRANCIS H. CASE

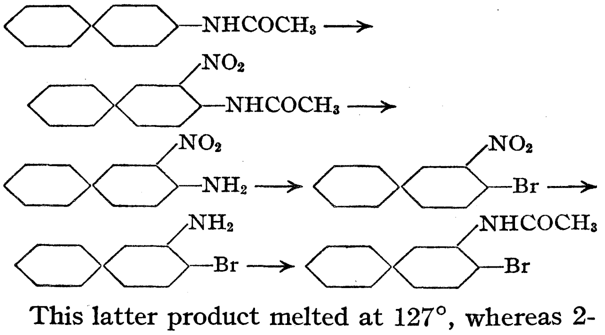
The preparation of 3,4-dibromodiphenyl has previously been reported by Scarborough,[1] who stated that it could be obtained by the replacement by bromine of the amino group in the bromo amine resulting from the hydrolysis of what he believed to be 4-bromo-3-acetaminodiphenyl. Scarborough's evidence for the structure of the dibromodiphenyl is based on its oxidation by chromic anhydride to 3,4-dibromobenzoic acid. Reasoning back he therefore concluded that on monobromination 3-acetaminodiphenyl is substituted in the 4-position rather than in the more to be expected 6-position.

In a study of the action of magnesium on various homonuclear dibromodiphenyls,[2] the so-called 3,4-dibromodiphenyl of Scarborough was subjected to the action of two atoms of magnesium–copper alloy, followed by carbon dioxide. The two acids resulting were identified as 2-bromodiphenyl-5-carboxylic acid, and diphenyl-2,5-dicarboxylic acid. This suggested the possibility that Scarborough's dibromodiphenyl was derived from 2-bromo-5-acetaminodiphenyl, the normal bromination product. On repeating the oxidation of the dibromodiphenyl, however, a small amount of 3,4-dibromobenzoic acid was obtained, in addition to the expected 2,5-dibromobenzoic acid (also in small quantity). The amounts of the two dibromo acids isolated after oxidation do not, however, give a satisfactory idea of the amounts of dibromides present in the original mixture, as experiments with the pure dibromides indicate that the 2,5-isomer is much more easily destroyed by oxidation than the 3,4.

2-Bromo-5-acetaminodiphenyl was next synthesized by the reaction of Gomberg and Pernert,[3] as follows:



4-Bromo-3-acetaminodiphenyl was prepared by the following series of reactions



This latter product melted at 127°, whereas 2-bromo-5-acetaminodiphenyl prepared by Gomberg's method melts at 162–163°, and Scarborough's bromo-3-acetaminodiphenyl at 163–164°. The latter two products when mixed showed no change in melting point. Since the dibromodiphenyl obtained from Scarborough's

product by hydrolysis and use of the Gattermann reaction yields on oxidation both 3,4- and 2,5-dibromobenzoic acid, and gives with magnesium the mono and dicarboxylic acids related to 2,5-dibromodiphenyl, it seems evident that Scarborough's bromoacetaminodiphenyl is a mixture of two isomers, having a constant melting point. This type of mixture is not unfamiliar in the diphenyl series, as a similar one is obtained by brominating *p*-acetaminodiphenyl.[4]

3,4-Dibromodiphenyl was prepared in this Laboratory by hydrolyzing 4-bromo-3-acetaminodiphenyl to the free base and applying the Gattermann reaction. This product, on oxidation, yielded exclusively 3,4-dibromobenzoic acid.

In the process of identification of the acids resulting from the action of magnesium on Scarborough's dibromodiphenyl, two hitherto undescribed bromo acids were prepared: namely, 3-bromodiphenyl-4-carboxylic acid and 4-bromodiphenyl-3-carboxylic acid.

Experimental Part

3-Nitro-4-bromodiphenyl.—This was prepared in quantity by combining the reaction mixtures from unit batches of 50 g. of 3-nitro-4-aminodiphenyl and working them up together. For a unit batch 50 g. of finely powdered nitro amine was warmed on the steam-bath with 300 cc. of 40% hydrobromic acid. When the mixture had turned to a light brown color, it was cooled to 10°, and diazotized by slowly adding 23 g. of powdered sodium nitrite and shaking the stoppered flask. After standing for a half-hour the mixture was treated with 7 g. of copper powder and heated with a low flame for about half an hour after all apparent reaction had ceased. At this point all the batches were combined, the 3-nitro-4-bromodiphenyl extracted with ether, and twice distilled; yield from 294 g. of 3-nitro-4-aminodiphenyl, 249 g. of 3-nitro-4-bromodiphenyl, b. p. 210–220° (5 mm.). The pure product boils at 210–215° (6 mm.).

Anal. Calcd. for $C_{12}H_8NO_2Br$: Br, 28.75. Found: 28.86.

3-Amino-4-bromodiphenyl.—To 307 g. of $SnCl_2{\cdot}2H_2O$ dissolved in 900 cc. of absolute alcohol was added 126 g. of 3-nitro-4-bromodiphenyl, the reaction mixture being cooled at first with ice, and then refluxed overnight. After removal of the alcohol the residue was treated with concentrated sodium hydroxide to dissolve the tin salts, and the base was then extracted with ether. On removal of the ether, the 3-amino-4-bromodiphenyl was crystallized from a mixture of benzene and petroleum ether. It was found that the bromine atom was removed either by catalytic reduction or by reduction with tin and hydrochloric acid; yield 74 g.; m. p. 97–98°.

Anal. Calcd. for $C_{12}H_{10}NBr$: Br, 32.22. Found: Br, 32.44.

3-Acetamino-4-bromodiphenyl.—This was prepared by the action of acetic anhydride on the base. It crystallizes from methyl alcohol, m. p. 127°.

Anal. Calcd. for $C_{14}H_{12}NOBr$: Br, 27.56. Found: Br, 27.50.

3,4-Dibromodiphenyl.—A mixture of 37.2 g. of 3-amino-4-bromodiphenyl and 192 cc. of 40% hydrobromic acid cooled to 10° was diazotized by the slow addition of 13 g. of sodium nitrite, the flask being repeatedly stoppered and shaken. After standing a half-hour, the mixture was heated with copper powder, the heating being continued for a half hour after the reaction subsided. The dibromodiphenyl was extracted with ether and distilled *in vacuo.* The crude liquid was washed with aqueous hydrobromic acid to remove unchanged base, then dried, dissolved in absolute ether and saturated with dry hydrogen bromide. The precipitated hydrobromide was filtered off, the ether solution washed with sodium bicarbonate, dried and the process repeated. The yield of nitrogen-free base was 33 g., b. p. 192–195° (5 mm.).

Anal. Calcd. for $C_{12}H_8Br_2$: Br, 51.25. Found: Br, 51.23.

2-Bromo-5-nitroaniline.—This was prepared by the bromination of *m*-nitroaniline according to the directions of Wheeler.[5] That it was this isomer was proven by the isolation of *p*-nitrobromobenzene from the deaminized product.

2-Bromo-5-nitrodiphenyl.—The cooled paste made by heating 90 g. of 2-bromo-5-nitroaniline with 100 cc. of concd. hydrochloric acid and 40 cc. of water was diazotized with a saturated solution of 36 g. of sodium nitrite. To the diazonium salt solution was added 300 cc. of benzene and then 128 cc. of 5 *N* sodium hydroxide, keeping the temperature below 5°. After standing overnight, the benzene was removed, yielding 36 g. of a product boiling at 190–215° (10 mm.), and solid at room temperature. On recrystallization from benzene–petroleum ether it melted at 80–81°.

Anal. Calcd. for $C_{12}H_8NO_2Br$: Br, 28.75. Found: 28.36.

2-Bromo-5-acetaminodiphenyl.—The 2-bromo-5-nitrodiphenyl was reduced by the theoretical quantity of stannous chloride in absolute alcohol to the amine, and this was acetylated by means of acetic anhydride. The 2-bromo-5-acetaminodiphenyl thus obtained was recrystallized from methyl alcohol, melting at 162–163°, and unchanged when mixed with the product resulting from the bromination of 3-acetaminodiphenyl.

Anal. Calcd. for $C_{14}H_{12}NOBr$: Br, 27.56. Found: Br, 27.51.

The 2-bromo-5-acetaminodiphenyl was converted to the corresponding dibromodiphenyl which yielded on oxidation 2,5-dibromobenzoic acid, m. p. 153–154°.

Action of Magnesium on Scarborough's Dibromodiphenyl.—The complex prepared by passing carbon dioxide into the Grignard reagent from 15.6 g. of the above dibromodiphenyl was decomposed with hydrochloric acid,[2] the acid solution extracted with ether and the organic acids removed by extraction of the ether solution with sodium hydroxide solution. After reprecipitation with hydro-

chloric acid, reëxtraction with ether, and removal of the ether, a gummy solid was obtained weighing 9 g. This was extracted with benzene. The benzene insoluble part, after several crystallizations from a benzene–methyl alcohol mixture, melted at 276–277°, and unchanged when mixed with a sample of diphenyl-2,5-dicarboxylic acid.[2] The benzene-soluble part after several crystallizations from benzene–petroleum ether, melted at 248–249°, and unchanged when mixed with a sample of 2-bromodiphenyl-5-carboxylic acid.[2] From the ether solution extracted by alkali, 1.1 g. of diphenyl was isolated.

4-Bromodiphenyl-3-carboxylic Acid.—Seventy-one grams of 4-bromo-3-methylaniline, obtained by brominating 3-acettoluide, was treated with 110 cc. of water and 76 cc. of concd. hydrochloric acid. The suspension was then diazotized with 27.5 g. of sodium nitrite in saturated solution, treated with 300 cc. of benzene and gradually with 110 cc. of 5 *N* sodium hydroxide keeping the temperature below 5°. After standing overnight the benzene was removed, yielding 18 g. of a liquid boiling at 165–170° (3 mm.). On oxidation with aqueous permanganate and crystallization from benzene, 4-bromodiphenyl-3-carboxylic acid was obtained, m. p. 194–195°.

Anal. Calcd. for $C_{13}H_9O_2Br$: Br, 28.85. Found: Br, 28.70.

3-Bromodiphenyl-4-carboxylic Acid.—4-Nitro-2-aminotoluene was prepared by the nitration[6] of *o*-toluidine. It was converted to 4-nitro-2-bromotoluene by the Gattermann reaction. From this, by reduction with stannous chloride in hydrochloric acid, was prepared 2-bromo-4-aminotoluene (acetyl derivative, m. p. 111–112°. Beilstein gives 113°). Sixty-five grams of 2-bromo-4-aminotoluene was treated with 70 cc. of concd. hydrochloric acid and 60 cc. of water, and diazotized with 26 g. of sodium nitrite in 50 cc. of water. The resulting solution was treated with 300 cc. of benzene and gradually with 100 cc. of 5 *N* sodium hydroxide solution. After standing overnight, the benzene solution was separated and the benzene removed by distillation, yielding 19.5 g. of an oil boiling at 165–170° (7 mm.). On oxidation with aqueous potassium permanganate solution and crystallization from methyl alcohol–petroleum ether, 3-bromodiphenyl-4-carboxylic acid, m. p. 179–180° was obtained.

Anal. Calcd. for $C_{13}H_9O_2Br$: Br, 28.85. Found: Br, 29.05.

The author acknowledges the assistance of Mr. Max Gabis in the preparation of certain intermediates involved in this work.

Summary

1. The "3,4-dibromodiphenyl" of Scarborough has been shown to be a mixture containing largely the 2,5-isomer, and some of the 3,4.

2. 3,4-Dibromodiphenyl has been synthesized.

3. The bromination product of 3-acetaminodiphenyl is believed to be a constant melting mixture of 4-bromo-3-acetamino- and 2-bromo-5-acetaminodiphenyls.

4. Both of these pure products have been synthesized.

5. The syntheses of 4-bromodiphenyl-3-carboxylic acid and of 3-bromo-diphenyl-4-carboxylic acid are described.

Saponins and Sapogenins. IV. The Isolation of Amolonin and Determination of the Products of Hydrolysis

By P. C. Jurs and C. R. Noller

The hydrolysis of crude methyl alcoholic extracts of the bulbs of *Chlorogalum pomeridianum*, Kunth, commonly known as California soap plant or amole, has been shown to yield two crystalline sapogenins.[1] One of these was assigned the formula $C_{26}H_{40}O_2(OH)_2$ and the name *chlorogenin*, it being isomeric with but different than gitogenin, while the other was found to be identical with tigogenin, then believed to have the formula $C_{26}H_{41}O_2(OH)$. Recent work[2] indicates that gitogenin and tigogenin have the formulas $C_{27}H_{42}O_2(OH)_2$ and $C_{27}H_{43}O_2(OH)$, respectively, and chlorogenin is now known to have the formula $C_{27}H_{42}O_2(OH)_2$.[3]

The isolation of two sapogenins indicated that at least two saponins were present and early attempts by Liang to isolate the saponins proved this to be the case.[4] On cooling hot aqueous solutions of the mixed saponins or hot methyl alcoholic extracts of the roots, a product deposited that on hydrolysis yielded pure tigogenin, while hydrolysis of the more soluble fractions in the filtrates yielded largely chlorogenin. It appeared

that it should be possible to isolate the less soluble saponin in a pure state and the present paper deals with the isolation of a pure crystalline saponin and with the quantitative determination of the products formed on hydrolysis.

At first an attempt was made to purify the less soluble saponin fraction by a triangular fractional crystallization from methyl and ethyl alcohol. This was partially successful and resulted in the isolation of two saponins, one of which was crystalline and the other amorphous, and which differed in specific rotation and solubility in methyl and ethyl alcohols. Both of these saponins yielded tigogenin on hydrolysis, a fact that increases the minimum number of saponins present in the plant.

Fractional crystallization was tedious but it was found that these two saponins possessed a marked difference in solubility in *t*-butyl alcohol and this gave a rapid method for obtaining the less soluble fraction in a pure form and in quantity. The mixed saponins were repeatedly extracted with hot *t*-butyl alcohol to remove most of the amorphous saponin, and the insoluble portion repeatedly crystallized from ethyl and methyl alcohol until the product was crystalline (Fig. 1) and had a constant rotation. These crystals apparently contain alcohol of crystallization since on drying they fall to an amorphous powder. Although this saponin is only slightly soluble in cold water, its aqueous solutions show all the typical properties of a saponin such as the formation of a stable foam on shaking, toxicity to fish and hemolysis of red blood corpuscles.

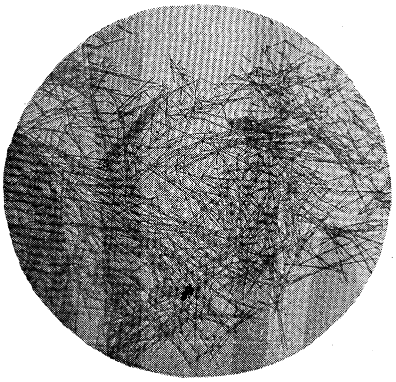

Fig. 1.—Photomicrograph of crystalline amolonin.

The pure crystalline saponin, which has been named "*amolonin*," was hydrolyzed and the sugars identified by the usual procedures. Positive tests were obtained for *d*-glucose, *d*-galactose, *l*-rhamnose and ketoses. Tests for pentoses, mannose and uronic acids were negative. Quantitative estimations showed that the hydrolysis could be represented by the equation

$$\underset{\text{amolonin}}{C_{63}H_{87}O_{14}(OH)_{17}} + 6H_2O \longrightarrow$$
$$\underset{\text{tigogenin}}{C_{27}H_{43}O_2(OH)} + \underset{d\text{-glucose}}{3C_6H_{12}O_6} + \underset{d\text{-galactose}}{C_6H_{12}O_6} + \underset{l\text{-rhamnose}}{2C_6H_{12}O_5}$$

The ketoses are present only in small amounts in the hydrolytic products and probably arise from the aldohexoses by a Lobry de Bruyn–van Ekenstein[5] interconversion.

The formula $C_{63}H_{87}O_{14}(OH)_{17}$ was confirmed by the preparation of a septadeca-acetyl derivative.

Experimental

Isolation of Saponins by Fractional Crystallization.—The bulbs were collected in March, the hairy covering and leaves discarded and the remainder ground in a food chopper. The liquid portion of the ground pulp was removed by a cider press and the press cake washed twice with cold water and twice with methyl alcohol, pressing each time to remove the liquid. The damp press cake was repeatedly extracted with boiling methyl alcohol until the extract no longer gave a precipitate on cooling. The gelatinous brown precipitates were filtered and evaporated to dryness under a vacuum. Further crops were obtained by concentrating the alcoholic filtrates.

When the crude saponin obtained in this way was subjected to a fractional crystallization with sufficient treatments with Norite to remove the color completely, two main fractions were obtained. The less soluble fraction consisted of definitely crystalline needles, $[\alpha]_{546}$ −74.2°, in pyridine. One gram on hydrolysis in 50% aqueous methyl alcohol containing 5% hydrogen chloride gave 0.304 g. of tigogenin, m. p. 197–201° (corr.); after crystallization from isopropyl alcohol and then from benzene it melted at 200–207°. This saponin fraction had a solubility in methyl alcohol of 0.36 g. and in ethyl alcohol of 0.24 g. per 100 g. of solvent at 25° and was practically insoluble in hot *t*-butyl alcohol. The more soluble fraction was usually amorphous although sometimes hair-like crystals were observed under the microscope. The specific rotation in pyridine varied from −68.7 to −63.8° and apparently became less as purification proceeded. One gram on hydrolysis gave 0.411 g. of sapogenin, m. p. 189–204° (corr.) which after crystallization from isopropyl alcohol and from benzene melted at 197–202°. A mixed melting point determination with the sapogenin from the needles showed no depression. The amorphous saponin had a solubility in methyl alcohol of 1.62 g. and in ethyl alcohol of 2.45 g. per 100 g. of solvent at 25° and was quite soluble in hot *t*-butyl alcohol. Both saponins had a low solubility in benzene, acetone, carbon tetrachloride and ether and a high solubility in pyridine, dioxane and glacial acetic acid.

Isolation of Amolonin by Extraction.—The crude dried saponin obtained as above was ground to a powder and

[5] Lobry de Bruyn and van Ekenstein, *Rec. trav. chim.*, **14**, 156, 204 (1895); Spoehr and Wilbur, *J. Biol. Chem.*, **69**, 421 (1926).

extracted with ten times its weight of boiling *t*-butyl alcohol. The drying, grinding and extraction of the insoluble portion was repeated three or four times until the loss in weight on an extraction was less than 2%. The light brown dried powder was recrystallized from ethyl alcohol and then repeatedly from methyl alcohol until the product was colorless, completely crystalline under the microscope and had a constant rotation. The recrystallizations from methyl alcohol were best performed by dissolving in a minimum of boiling solvent and then concentrating to from one-half to one-fifth of the original volume and cooling rapidly. The product was deposited as amorphous spheres which on standing for some time changed into microscopic needles (Fig. 1). During the first crystallization the crystals appeared to be mixed with small, spherical, gelatinous globules when examined under the microscope but these disappeared as the purification proceeded.

The crystals obtained in this way fell to an amorphous powder on drying. This product gave no perceptible ash on ignition; $[\alpha]^{23}_{546}$ −75.5° in pyridine, −67.5° in dioxane.

Qualitative Detection of Hydrolytic Products.—Pure amolonin was hydrolyzed completely by heating with twenty times its weight of 50% aqueous methyl alcohol containing 5% sulfuric acid. The mixture was heated in a pressure bottle at 100–110° with shaking for two days. The tigogenin was filtered and the filtrate analyzed qualitatively by a procedure essentially as recommended by van der Haar[6] unless otherwise noted.

The usual naphthoresorcinol color reaction for uronic acids, when applied to both the original saponin and to the barium uronate fraction[7] of the sugars, gave doubtful positive tests. Spectrographic examination of benzene extracts compared with controls, especially after the extracts had stood for several hours, showed definitely the absence of uronic acids.

Both types of reactions recommended by van der Haar[6] for the detection of ketoses gave positive tests. Later quantitative work, however, showed that the ketoses were present in such small amount that their presence may be explained by a Lobry de Bruyn–van Ekenstein interconversion[5] during the preparation of the sugar solution. It is possible that fructose does not occur in other saponins where it has been reported as a hydrolytic product.[8]

Nitric acid oxidation of the mixed sugars gave mucic acid, identified by its melting point (209–210°) and mixed melting point, crystal form and the crystal form of its insoluble thallous salt, and saccharic acid identified by the crystal form of its acid potassium salt and by the preparation and analysis of the silver salt. This indicates the presence of galactose and of glucose in the saponin molecule. That these sugars are the *d*-forms is shown by the fact that they are fermented by the yeasts, *Torula lactosa* and *Torula alactosa*, which do not ferment the *l*-forms. The non-formation of a phenyl-hydrazone was taken to indicate the absence of mannose.

For the detection of pentoses and methyl pentoses the tests depending on their conversion to furfural and methylfurfural and on the color reactions for these compounds were used. Both visual and spectroscopic examination of the color reactions showed the absence of pentoses and the presence of methyl pentoses. To identify the methylpentose, the glucose was removed by fermentation with baker's yeast and the solution of galactose and methyl pentose treated with α-methylphenylhydrazine. The formation and identification of the methylphenylhydrazone of galactose, m. p. 187.8° (corr.) further proved the presence of this sugar. After the removal of galactose as the hydrazone, the methylpentose was regenerated and the solution freed of methylphenylhydrazine by treatment with formaldehyde as recommended by van der Haar.[6] On subsequent reaction with *p*-bromophenylhydrazine an osazone formed which appeared to be identical with *p*-bromophenylrhamnosazone as determined by melting point (213–214° corr.) and mixed melting point with an authentic specimen. This identification was not considered entirely satisfactory because the product could not be recrystallized, and the melting points were really decomposition points. Examination under the polarizing microscope did not yield further information since *p*-bromophenylrhamnosazone needles show parallel extinction. The β-naphthylhydrazone was a much more satisfactory derivative and proved to be identical (m. p. 190–191°, $[\alpha]_{546}$ −12.6° in pyridine) with the β-naphthylhydrazone of *l*-rhamnose. The extinction angle of the crystals is 42.3°.

No other products of hydrolysis were detected and the following quantitative work shows that no other components can be present in the saponin molecule.

Estimation of Tigogenin.—Samples of pure amolonin weighing from 0.3 to 3.0 g. were hydrolyzed under different conditions and the amount of tigogenin formed was determined by filtering, washing and drying to constant weight at 100°. Hydrolyses in 50% aqueous methyl alcohol containing 5% hydrogen chloride at the boiling point for seventy hours gave 30.4 and 29.4% tigogenin. Using 5% sulfuric acid and shaking in a sealed tube at 90° for sixty-five hours gave 28.4 and 28.0% tigogenin. Using water containing 4% sulfuric acid and shaking in a sealed tube at 90° for five days gave 30.4%. The average of these five determinations is 29.3%.

Preparation of Sugar Solutions for Analysis.—The filtrates after removal of tigogenin were treated with freshly prepared pure barium carbonate, made from barium hydroxide and carbon dioxide, care being taken to avoid an excess of barium carbonate and to maintain the *p*H at 6.0 ± 0.5. In this way appreciable conversion of the aldohexoses to ketoses is avoided. The solutions were evaporated in a vacuum desiccator at 40–50° until a thick sirup was obtained. Any precipitate that formed during the evaporation was filtered and the *p*H of the filtrate adjusted before further evaporation. Solutions of this sirup failed to ferment and it was thought at first that this might be due to the traces of barium salts that always remained. Solutions neutralized with sodium bicarbonate, however, behaved in the same way. It was found that non-fermentation was due to the presence of barium or of sodium methyl sulfate, an appreciable amount of methyl hydrogen sulfate having been formed during the hydrolysis in 50%

methyl alcohol. These salts were removed either by repeated extraction of the sugars with absolute alcohol and evaporation to dryness, or by boiling the sirup with dilute sulfuric acid for several hours and precipitating the sulfuric acid with barium carbonate. The sugar sirups prepared in this way were diluted to a known volume and aliquot portions analyzed according to procedures recommended by van der Haar.[6]

Rhamnose.—In order to avoid undue decomposition of the rhamnose the determinations were made on sugar solutions from which barium methyl sulfate had not been removed completely. The sugars from 1.8835 g. of amolonin were diluted to 10 cc. and 3.67 cc. of this solution yielded 0.1204 g. of methylfurfural phloroglucide. From Ellet's tables as given by van der Haar this corresponds to 0.1826 g. (0.00100 mole) of rhamnose hydrate. The corresponding amount of amolonin would have yielded 0.00048 mole of tigogenin so that the molecular ratio is 2 to 1.

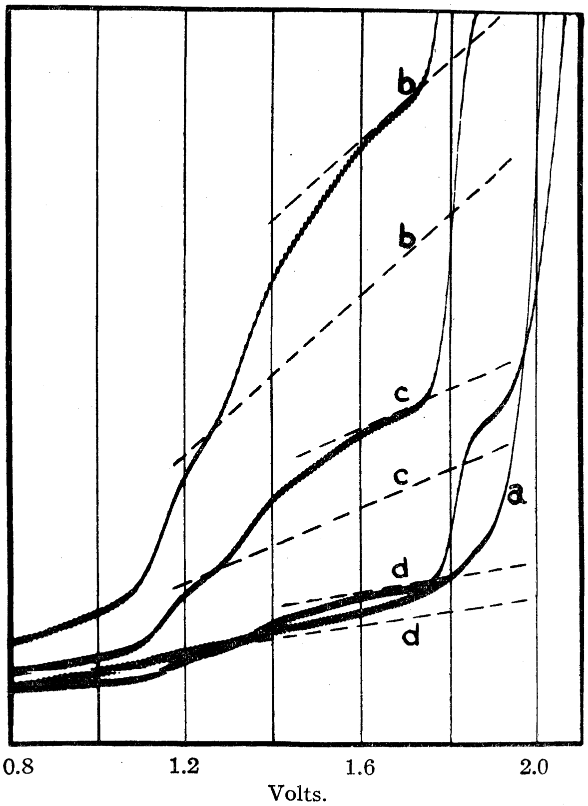

Fig. 2.—Polarigram of sugar solution from the hydrolysis of amolonin.

Ketoses.—The simplest procedure for the estimation of ketoses in the presence of aldoses is by means of the polarigraph since ketoses are reduced at the dropping mercury cathode whereas aldoses are not.[9] If a polarigram is made of a solution of a ketose, the potential at which the wave develops depends on the sugar, the temperature and somewhat on the concentration, while the height of the wave, that is, the vertical distance between two lines tangential to the curve at the points of inflection, is directly proportional to the concentration. The test solution was made by diluting the sugars from 2.9081 g. of amolonin to 25 cc. Figure 2 shows four curves: (a) 5 cc. of 0.2 *M* calcium chloride in the cell, hydrogen bubbled through for twenty minutes and the curve taken at $s = 0.1$ (s = sensitivity of the galvanometer); (b) 0.1 cc. of test solution added to the cell, hydrogen passed through for ten minutes and the curve taken at $s = 0.1$; (c) repeat of (b) at $s = 0.05$; (d) repeat of (b) at $s = 0.02$. Figure 3 gives curves for a solution of fructose of known concentration which gave curves similar to the unknown when run under the same conditions. The correct concentration to accomplish this was arrived at by trial and was 0.0111 mg. of fructose per cc. in approximately 0.2 *M* calcium chloride solution. The letters have the same significance as in Fig. 2. It is seen that the fructose wave occurs at approximately the same voltage as the unknown. Height bb in Fig. 3 is 3.16 cm. while height cc at half the sensitivity is 1.51 cm., which checks the reproducibility of separate runs. Taking the height of 1.51 cm. as corresponding to a concentration of 0.0111 mg. of fructose per cc., the height cc in Fig. 2 of 1.01 cm. corresponds to 0.00743 mg. per cc. of calcium chloride solution or 0.379 mg. (0.0000021 mole) per cc. of original sugar solution. The corresponding amount of amolonin would have yielded 0.000081 mole of tigogenin, or one mole of fructose for 38 moles of tigogenin, an impossible ratio.

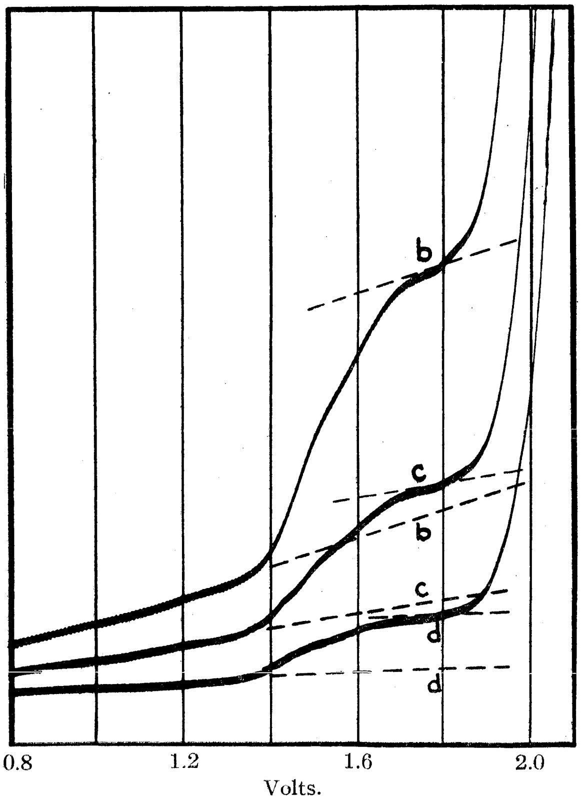

Fig. 3.—Polarigram of standard fructose solution.

It should be noted that two minor waves occur in Fig. 2 beginning at approximately 1.1 and 1.8 volts that do not

occur in Fig. 3. The wave at 1.8 v. is due to traces of barium ion but the impurity causing that at 1.1 v. is unknown.

Glucose and Galactose.—These sugars were determined by fermentation in van Iterson–Kluyver tubes according to the general procedure given by van der Haar. Special yeasts, different from those recommended by van der Haar, were obtained in pure culture through the courtesy of Professor T. Skogsberg of the Hopkins Marine Station. These yeasts were *Torula lactosa* and *Torula alactosa*, both of which ferment *d*-glucose and *d*-galactose, and *Torula datilla* and *Torula monosa*, which ferment glucose but not galactose. None of these yeasts ferments *l*-rhamnose.[10] Controls were run on 1, 2 and 4% solutions of glucose and galactose with each yeast in order to determine the carbon dioxide evolved and the amount of carbon dioxide remaining in solution. The latter volume depended on the type of yeast and the sugar, and for the mixture of sugars a weighted average was used and added to the volume read. Table I gives the average values for the data obtained on the controls. The gas volumes are for 0° and 760 mm.

TABLE I

CONTROL FERMENTATIONS OF GLUCOSE AND GALACTOSE

	Vol. of CO_2 dissolved per cc. of solution		Mg. of hexose per cc. of CO_2 formed	
Sugar	Glucose	Galactose	Glucose	Galactose
T. datilla	0.51	...	4.65	..
T. monosa	.42	...	4.75	..
T. alactosa	.51	0.48	4.70	4.61
T. lactosa	.65	.14	4.37	5.10

In a typical run the purified sugars from 2.9081 g. of amolonin were diluted to 25 cc. and 3 cc. of this solution mixed with 6 cc. of nutrient broth. The solution was passed through a Chamberland filter and 1 cc. placed in each of four fermentation tubes and inoculated under sterile conditions with the four yeasts. The volumes of carbon dioxide evolved after three days at 32° were corrected to 0° and 760 mm. and the estimated amount of dissolved carbon dioxide added. This gave for *T. datilla*, 3.28 cc., *T. monosa*, 3.24 cc.; *T. alactosa*, 4.22 cc., *T. lactosa*, 4.12 cc. The first two volumes can be converted to glucose directly and correspond to 15.3 and 15.4 mg. per cc. The volumes of carbon dioxide from galactose can be obtained by subtracting each of the volumes from *T. datilla* and *T. monosa* from each of the volumes from *T. alactosa* and *T. lactosa*, giving, respectively, 0.94, 0.98, 0.84, and 0.88 cc. When the first two volumes are multiplied by 4.61 and the last two by 5.1, one obtains 4.3, 4.5, 4.3 and 4.5 mg. of galactose per cc. Multiplying by the aliquot factor, 75, one obtains 1.1512 g. (0.00639 mole) of glucose and 0.330 g. (0.00183 mole) of galactose from 2.9081 g. of amolonin which yields 0.00203 mole of tigogenin. The ratio of tigogenin to glucose to galactose is therefore 1 to 3 to 1.

The results of the determinations of rhamnose, glucose and galactose were checked by comparison with total aldoses by iodine oxidation.[11] Thus a solution of the mixed sugars gave rhamnose 12.6 mg. per cc. and total hexoses by fermentation 29.5 mg. per cc. or a total of 42.0 mg. per cc. The average aldose content found by iodine oxidation on the assumption of 2 moles of methylpentose to 4 moles of hexose was 40.1 mg. per cc.

Septadeca-acetylamolonin.—Amolonin was fully acetylated by dissolving 0.970 g. in 5.4 cc. of pyridine and 4.9 cc. of acetic anhydride. After standing for one day at room temperature, the solution was poured into water and filtered. The precipitate was crystallized from dilute methyl alcohol and dried in vacuum at 100°; $[\alpha]^{20}_{546}$ −33.65° in pyridine; recrystallized and dried, $[\alpha]^{20}_{546}$ −33.53°. Analysis for acetyl:[12] Calcd. for $C_{63}H_{87}O_{14}(OCOCH_3)_{17}$: % acetyl, 35.32. Found: 35.67, 35.14.

Combustion Analyses.—Amolonin Calcd. for $C_{63}H_{104}O_{31}$: C, 55.71; H, 7.74. Found: C, 55.39, 55.38, 55.56, 55.32; H, 7.99, 7.98, 8.02, 7.94. Amolonin Septadeca-acetate. Calcd. for $C_{97}H_{138}H_{48}$: C, 56.23; H, 6.71. Found: C, 55.85 55.78; H, 6.90, 6.82.

Summary

Amolonin, a crystalline saponin obtained from *Chlorogalum pomeridianum* has the formula $C_{63}H_{87}O_{14}(OH)_{17}$. On hydrolysis it yields for each mole of tigogenin, one mole of *d*-galactose, two moles of *l*-rhamnose and three moles of *d*-glucose. The septadeca-acetyl derivative of amolonin has been prepared.

Mechanism of Symbiotic Nitrogen Fixation. I. The Influence of pN_2[1]

BY P. W. WILSON

Research on fixation of elemental nitrogen through association of leguminous plant and bacteria (*Rhizobia sp.*) has been conducted for almost a century, but the chemical mechanism of the process has remained practically unattacked. The scanty nature of our knowledge of this aspect of the problem arises mainly from lack of suitable techniques to carry on the research; the isolation of intermediates, which has been so successful in elucidating the mechanism of a fermentation reaction, is not readily applied because of difficulties in separating from the plant cells products which may be definitely ascribed to the fixation process.

Application of physical chemistry techniques to the problem hitherto has not been attempted.[2] Even without definite knowledge of the exact nature of the key-reactions, many of their properties may be ascertained by determining the effect of controlled changes in the physical and chemical environment, *e. g.*, temperature, *p*H, oxidation–reduction potentials, and pressure of gases (nitrogen, oxygen, carbon dioxide). In this paper are discussed the effects of changes in the pN_2 of the atmosphere supplied inoculated clover plants on the fixation reaction.

Experimental and Results

Technique.—Red clover (*Trifolium pratense*) was used as the host plant and inoculated with an efficient strain of the proper organism, *Rhizobium trifolii*. Twenty plants were grown in a 10-liter Pyrex pressure bottle on a nitrogen-poor sand substrate to which was added the required plant nutrients. An atmosphere of any desired composition was maintained in these bottles by evacuation followed by addition of the required gases. Cylinder gases, passed through a purifying chain of sodium hydroxide, sulfuric acid, alkaline potassium permanganate, distilled water, and finally a sterile cotton filter were used in all the experiments. The atmospheres were renewed twice a week; the pCO_2 was maintained inside the bottles at 0.1 to 0.5% by the method described by Smyth.[3] In a few experiments 64-oz. (2-liter) flint glass bottles were used as the plant container, but these were not so satisfactory because of difficulty in maintaining uniform pCO_2 and of the restriction on the growth of the plant. The experiments were conducted in a greenhouse equipped with artificial lighting and other means for controlling light and temperature.[4] At the start of each experiment the plants were supplied with air containing 0.1% carbon dioxide until fixation was well under way and the period of nitrogen hunger was passed. They were then transferred to the various atmospheres and allowed to grow for fifteen to fifty-five days before harvest. No combined forms of nitrogen were furnished the inoculated plants, but a sufficient quantity of all other plant nutrients was available; hence the limiting factor for growth was primarily rate of fixation of free nitrogen. Plants given combined nitrogen were supplied with 3 to 5 mg. of NH_4NO_3–N per bottle at the start which enabled them to be at the same stage of development as the inoculated plants at the time atmospheres were first changed. Five to 10 mg. of NH_4NO_3–N was then added weekly to all cultures of the combined nitrogen series depending on the rate of growth maintained by the plants; this addition of NH_4NO_3–N was uniform to all plants in the combined nitrogen series in a given experiment, *i. e.*, each culture received the same quantity at each time of addition.

In the first experiments it was found that replicates of the same treatment might vary 10 to 20% in total nitrogen per 10 plants at time of harvest. In an effort to reduce the variation, plant cultures *in a given experiment* were selected for uniformity at time they were placed under the different atmospheres and various technical devices employed, *e. g.*, rotation of cultures on the benches in the green house, in an effort to eliminate the non-uniformity of environmental factors. In spite of these precautions variations of 5 to 10% frequently were observed in duplicates. Since plant growth tends to be logarithmic in the early stages of development, initial small differences may be increased considerably unless the experiments are extremely short-time in nature. The best solution of this technical difficulty appears to be to draw conclusions only after numerous replications of the experiments have been made under conditions which will vary the *rate* and *extent of growth* together with a statistical analysis of the data. In this report data are considered from a total of 20 experiments covering a time period of two years. The experiments were made during all seasons with consequent differences in (1) rate of growth (average daily gain per 10 inoculated plants has varied from 0.2 to 1.0 mg.); (2) extent of growth (from 5 to 35 mg. total nitrogen per 10 plants); (3) length of experiment (from 15 to 57 days); and (4) initial size of plant (initial nitrogen content from 1.05 to 3.50 mg.).

Preliminary experiments were made as follows: one series of clover plants was grown under a vacuum of 0.5 atm., a second at atmospheric pres-

sure and a third at a pressure of 1.8 atm. maintained by added nitrogen gas. In this manner plants developed under pN_2 of 0.39, 0.78 and 1.56 atmospheres; under these conditions it was found that the fixation of nitrogen is independent of the pN_2 used as is indicated by the data in Table I, experiments I and II.

IX	11/9/34–1/2/35	27	2.50
X	12/9/35–2/4/36	29	2.05

These observations were confirmed and extended by experiments in which the pN_2 was varied from 0.06 to 0.80 atm., the pO_2 being kept constant in a given experiment, and no inert gas being added, *i. e.*, the plants were grown under different total pressures. The results of experiments III and IV show (Table I) that the nitrogen fixation by red clover is independent of the pN_2 above 0.11 atm. but if the pN_2 is decreased to 0.06 atm. a definite inhibition of fixation occurs. This decrease of fixation with pN_2 at pressures below 0.11 atm. was further confirmed in experiments V and VI in which only the lower pressures were included. As shown by the data at the bottom of the table the response is independent of the length of time of experiment (time varied three-fold) or the development of plant at time placed under different pN_2 (initial nitrogen content varied two-fold).

In order to demonstrate that the response to pN_2 is concerned with the nitrogen fixation process in the plant and not with the general development, it is necessary to demonstrate that growth of uninoculated plants receiving combined nitrogen is completely independent of the pN_2. This was done in a series of experiments whose results are summarized in Table II.

Duplicate determinations are given for experiments VII and VIII in order to illustrate the variation found. Because of the limited number of bottles available not all the cultures were made in duplicate in these first experiments, but in later work this was always done, and by improvements in the technique already described, the variation was somewhat reduced. The values given in tables for experiments III to VI and IX to XV are averages of duplicates whose total nitrogen content differed by 10% or less. The data presented in Table II indicate that fixation of nitrogen by clover is essentially independent of the pN_2 of the atmosphere until the latter is decreased to a pressure below 0.10 atm. The effect of the pN_2 in this lower range is clearly on the fixation process and not on the general development of the plant since the nitrogen content of plants supplied combined nitrogen is independent of the pN_2 over the entire range studied.

That the characteristics of the pN_2 function do not arise because of growing the plants under reduced pressures was demonstrated in further experiments in which the nitrogen removed was replaced by the inert gases, helium and argon. Since the argon used contained 16% nitrogen, it was not feasible to use partial pressures of nitrogen below 0.16 atm. when this gas was added. Experiments XI, XII and XV were made in 64-oz. bottles, the others in 10-liter bottles. The data in Table III indicate that fixation of elemental nitrogen by inoculated clover plants grown in the presence of helium, argon, or no added inert gas is independent of the pN_2 as this is varied from about 0.10 to 0.80 atm. Below a pN_2 of 0.10 atm. fixation decreases rapidly with the nitrogen content of the atmosphere. As observed in the other experiments this effect of the pN_2 is on the fixation process since plants supplied combined forms of nitrogen assimilate these independent of the pN_2 in the atmosphere.

From the data of Table III certain generalizations concerning the symbiotic nitrogen-fixing enzyme system in red clover may be formulated, but before this is done, it is necessary that the essential characteristics of the pN_2 function be established definitely. In addition to the experiments reported in the tables, 5 other experiments have been made with essentially the same results. The data from these 20 experiments, 11 of which included combined nitrogen series, were placed on a comparable basis by calculating the *relative* total nitrogen and % N in the plants using the air controls ($pN_2 = 0.80$ atm.) as the base, 100. The plot of the data in Fig. 1 shows that in a given experiment inoculated plants grown under a pN_2 greater than 0.10 atm. may contain more or less nitrogen than the air controls, the relative values varying from 80 to 120; the mean value for all the experiments was 90 to 100 for these pressures. On the other hand for pN_2 less than 0.10 atm. the relative values range from 35 to 65 with a mean value of 45. Final total nitrogen content of the plants supplied with combined nitrogen exhibited the same type of variation about the 100% value but the mean values were 98 to 104% and apparently independent of the pN_2 throughout the range under investigation.

It was noted in the course of these and other experiments that one of the best indicators of inhibition of the fixation process was a decline in the % N in the plant. In some respects this datum is more sensitive to factors which affect the nitrogen fixation system than is total nitrogen. For example, two plant cultures which differ by a comparatively small amount at the start of an experiment are given different treatments. At the end of the test the difference in total nitrogen content appears to be significant, and this would be interpreted as arising from treatment, when actually it is only an expression of the difference in the original cultures. This is a source of error

that must be constantly guarded against in experiments in which final total growths are taken rather than growth rates. However, in these experiments it was noted that even though replicates might vary considerably in total nitrogen (final growth) the percentage nitrogen was much more stable; frequently the duplicate with the lower total nitrogen had the higher % N, *i. e.*, there is no correlation between total nitrogen and % N if replicates only are considered. On the other hand, under circumstances in which fixation is obviously restricted, *e. g.*, very low pN_2, the percentage nitrogen in the plant is definitely decreased. This suggests an additional criterion for distinguishing between those factors which affect the total nitrogen content through specific effect on the fixation system and those which affect the total nitrogen only through effects on the

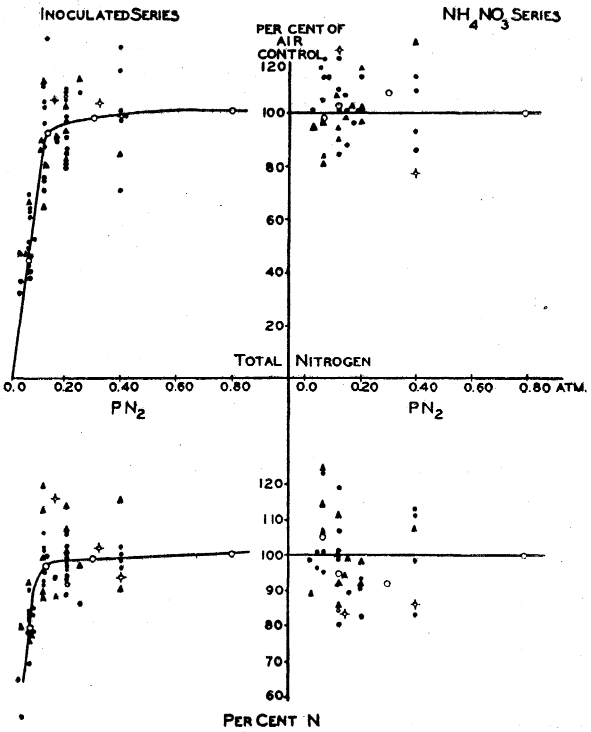

Fig. 1.—Comparison between the pN_2 functions of clover plants using free and combined nitrogen. Value for air controls (pN_2 = 0.80 atm.) taken as 100 in each case. ●, No added gas; ▲, helium; -ϕ-, argon; ○, mean of all points in each pressure group.

general growth of the plant. Thus a partial control is available for experiments in which for technical reasons growth rate studies are not particularly suitable.

Plot of the % N in the plants from 20 experiments on a relative basis confirmed the conclusions drawn from the total nitrogen data. As can be seen in Fig. 1 no consistent change in the % N occurs in inoculated plants until the pN_2 of the atmosphere is decreased to less than 0.10 atm., then a significant decline is observed. The scatter of the points for pressures greater than 0.10 atm. is usually within ±10% of the 100% line. With plants furnished combined nitrogen, % N in the plants did not appear to change significantly with pN_2 over the entire range, although the scatter of the points was greater.

Discussion

The qualitative observations made from a study of the figures were verified by a statistical analysis of the data from the pooled experiments. The different pressures used were grouped as follows: group 1, 0.04 to 0.07 atm.; 2, 0.10 to 0.12 atm.; 3, 0.20 to 0.40 atm.; 4, 0.80 atm.; and the data from the several experiments subjected to analysis of variance.[5] In the inoculated series 11 experiments were available in which all four pressure groups were represented; in the combined nitrogen series groups 1, 2 and 3 (6 experiments) and groups 2, 3 and 4 (7 experiments) were analyzed separately since all four groups were not represented in all experiments. The analyses show: (1) in the inoculated series the observed differences in total nitrogen and in % N among pressure groups 2, 3 and 4 are not statistically significant, but the differences between group 1 and the remainder are highly significant; (2) in the combined nitrogen series all the observed differences could have arisen from random sampling. The principal statistical constants given in Table IV likewise point to this conclusion.

In consideration of the following statistical analysis of the data, it appears that at pressures of nitrogen greater than 0.10 atm. most of the active points of the enzyme system concerned with the fixation are saturated so that the fixation is independent of the pN_2; below this pressure the quantity of nitrogen adsorbed, and hence fixed, is dependent on the pN_2.

TABLE IV

COMPARISON OF MEANS OF DIFFERENT pN_2 GROUPS

Inoculated

Function	No. of expts.	Pressure, mg. 1[a]	2	3	4	Standard error,[b] mg.
Total N	11	10.99	20.60	22.32	22.52	1.615
% N	11	1.61	1.90	1.88	1.94	0.038
			NH_4NO_3			
Total N	6	31.32	33.02	32.93	...	2.770
	7	...	20.80	22.38	20.73	1.315
% N	6	3.28	3.03	2.85	...	0.158
	7	...	3.42	3.33	3.69	.183

[a] Pressures: 1, 0.05–0.07 atm.; 2, 0.10–0.12 atm.; 3, 0.20–0.40 atm.; 4, 0.80 atm.

[b] Of difference between two means, *i. e.*, difference between two means must be twice this before it can be regarded as significant.

Because of variation in the plants it is not possible to characterize definitely the exact nature of the curve in the region in which complete saturation is replaced by partial saturation since relatively large differences are necessary in order that they fall outside the limits of experimental error. Likewise, control of the pN_2 under the experimental conditions described is probably restricted to about ±0.01 to 0.02 atm. In spite of the limitations the data in Table IV show that it is improbable (38:1 odds): (1) that the true mean of the 0.10–0.12 atm. series is less than 18.32 mg. (observed mean minus twice standard deviation) and (2) that the true mean of the air control groups is greater than 24.80 mg. This means that under the most unfavorable assumptions, a 75% saturation at pN_2 of 0.10 to 0.12 atm. is indicated. Considerably higher saturation, (up to 100%) is more probable; this is borne out by consideration of the % N data. The curves for the inoculated series in Fig. 1 were drawn through the mean values for each pressure group with the result that the transition regions are not well defined; it is not improbable that the true curve of the pN_2 function approximates a typical Langmuir adsorption isotherm.

Burk[2,6] on the basis of both total growth (respiration) and rate of respiration has shown that fixation of nitrogen by the *azotase* complex in the free living nitrogen-fixing bacteria *Azotobacter* is a function of the pN_2 until the latter becomes relatively large—up to 5 to 10 atmospheres—and that the rate is almost directly proportional to the pN_2 up to 0.5 atm. The dissociation constant (K_{N_2}, equivalent to substrate concentration at which rate is 50% of maximum) of the enzyme–nitrogen

---

(6) Burk, *J. Phys. Chem.*, **34**, 1195 (1930).

complex was found to be 0.215 ± 0.002 atm., a value which Burk states is somewhat high in comparison with other gases for different enzyme systems. In our own work the data observed were total growth and not growth rates, hence K_{N_2} cannot be precisely determined from these values. However, since under the experimental conditions used, the rate will roughly follow the final observed total growth, an approximation of K_{N_2} is possible. It would appear that K_{N_2} for the symbiotic system is below 0.10 atm. possibly in the neighborhood of 0.05 atm. Whether this difference between the dissociation constants represents a real difference in these two biological nitrogen-fixing systems is still open to question, but further experiments concerned with the character of the enzyme complex should be able to supply an answer.

Summary

The relation of the partial pressure of nitrogen to fixation of the free element by the symbiotic system in red clover has been studied over the range of pN_2 from 0.04 to 1.56 atm. in the presence of no added gas, helium and argon. Statistical analyses of data from 11 experiments indicate that the fixation of nitrogen is essentially independent of pN_2 when the latter exceeds 0.10 to 0.20 atm. but decreases rapidly with pN_2 as the latter is diminished below 0.10 atm. This pN_2 function is characteristic of the nitrogen fixing process since it is not observed in plants supplied with combined nitrogen. The implications of these observations for the mechanism of the symbiotic fixation process are discussed.

The Mechanism of the Dehydration of Calcium Sulfate Hemihydrate

BY HARRY B. WEISER, W. O. MILLIGAN AND W. C. EKHOLM

During the past few years several papers have appeared which reopen the question of the chemical individuality of the so-called calcium sulfate hemihydrate or plaster of Paris and the mechanism of its dehydration. Linck and Jung[1] deduced from dehydration data that plaster of Paris loses its water after the manner of zeolites. Balarew[2] at different times has been on all sides of the question. At first[2a] he claimed that the dehydration isobar would indicate that the water is present in the form of a true hydrate; later[2b] he stated that the dehydration curves show the water to be held in a new way "half-hydratic and half-zeolitic"; finally,[2c] he concluded that the water is lost in the manner of zeolites. Gibson and Holt[3] concluded from pressure–temperature curves that the water is lost continuously as in a zeolite. Parsons[4] claimed that all the water in gypsum may be lost by heating without the intermediate formation of a hemihydrate.

Jung,[5] Ramsdell and Partridge[6] and Caspari[7] reported that the x-ray diffraction pattern of calcium sulfate hemihydrate and its dehydration product[8] are identical, in agreement with the view that the hemihydrate is a zeolite. Onorato[9] and Gallitelli[10] found the hemihydrate and dehydrated hemihydrate to have the same type of structure but recognized minor differences in the powder x-radiograms. Feitknecht[11] likewise observed differences in the two patterns provided care was taken to prevent rehydration of the dehydrated hemihydrate. Feitknecht believed that Jung's dehydrated sample must have rehydrated before x-ray examination was made.

From the above survey it appears to be an open question whether "calcium sulfate hemihydrate" is a true chemical hydrate which gives a definite x-radiogram and decomposes to "dehydrated hemihydrate" which gives a different x-radiogram

[8] It should be pointed out that van't Hoff, Henrichsen and Weigert [*Sitz. akad. Wiss.*, 570 (1901)] prepared a "soluble" form of calcium sulfate by treating gypsum with nitric acid containing 2.38 moles of water per mole of nitric acid, above 50°. This material was named "soluble anhydrite" to distinguish it from the ordinary "insoluble" anhydrite. Although the term "soluble anhydrite" is usually applied to the product formed by the dehydration of calcium sulfate hemihydrate below 200°, Balarew[2b] believes this to be distinct from the "soluble anhydrite" of van't Hoff. Both Balarew and Ramsdell and Partridge[6] prefer to apply the term "dehydrated hemihydrate" to the dehydration product, and this terminology is used in this paper.

or whether the system is zeolitic, yielding upon dehydration a product identical in structure with the hydrated material. In the experimental portion of this paper there will be given the results of isobaric dehydration and x-ray diffraction studies which indicate that calcium sulfate hemihydrate is not a zeolite but behaves in all essential respects like a true chemical hydrate.

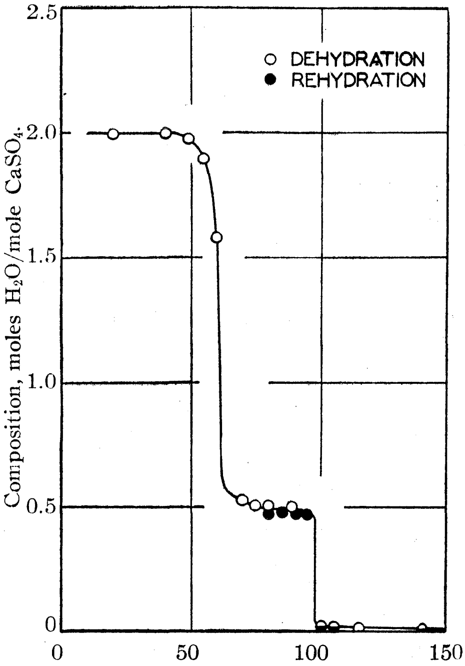

Fig. 1.

Experimental

Isobaric Dehydration.—The source of the calcium sulfate used in the experiments was clear, transparent selenite. Five samples of this material were dehydrated by raising the temperature progressively in an apparatus already described[12] at a constant aqueous vapor pressure of 23.6 mm. (water at 25°). One dehydrated sample was rehydrated by the reverse procedure. The temperature of the oven was maintained constant within ±1° for short periods of time and to within ±2° for longer periods. The samples were held at the various temperatures for days or weeks, weighing at intervals until equilibrium was attained. In some cases, the samples were held as long as five hundred hours at a given temperature. Figure 1 shows the complete dehydration–rehydration isobar for one sample. Figure 2 shows the hemihydrate portion of the dehydration for four samples. The points on the curve represent the average of values which differ by not more than ±0.006 mole of water per mole of calcium sulfate.

X-Ray Diffraction Examination.—A preliminary study was made of the x-ray diffraction patterns for (*a*) $CaSO_4 \cdot 2H_2O$ (selenite); (*b*) hemihydrate prepared by heating (*a*) to 95°; (*c*) dehydrated hemihydrate obtained by heating (*a*) to 145°, in a vacuum; and (*d*) anhydrite. Since the dehydrated hemihydrate is highly hygroscopic,[13] great care must be taken in preparing the samples for x-ray analysis. While still hot the samples were placed in thin tubes of Lindemann glass which were subsequently heated overnight in a vacuum and sealed. The sealed tubes were examined microscopically for possible leaks before placing in the diffraction apparatus. For the preliminary work the General Electric outfit (Kα Mo radiation) was employed. The films were standardized with sodium chloride in the usual way. The results are given in the form of diagrams in Fig. 3. It is apparent that each sample gives a different x-radiogram but the patterns for the hemihydrate and the dehydrated hemihydrate resemble each other rather closely.

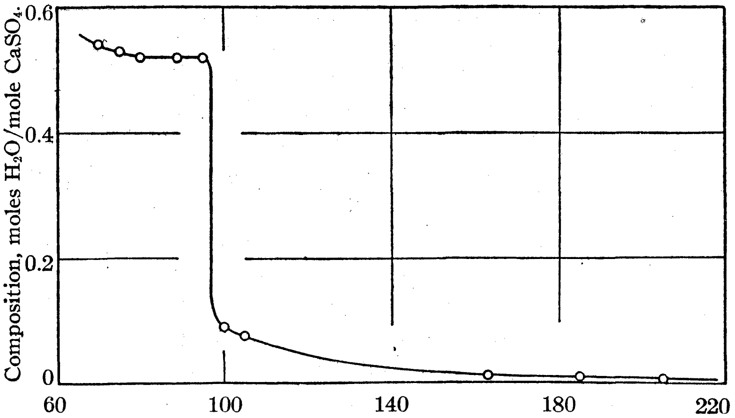

Fig. 2.

In order to make a quantitative study of the differences between the similar patterns of the hemihydrate and dehydrated hemihydrate, diffraction patterns were obtained with a Seemann

crystal analysis apparatus using Kα Cu radiation filtered through nickel foil. A precision Debye–Scherrer camera, 115.3 mm. in diameter, was employed. For purposes of calibration, pure nickelous oxide[14] prepared by igniting nickel nitrate in a current of nitrogen was mixed with the samples.

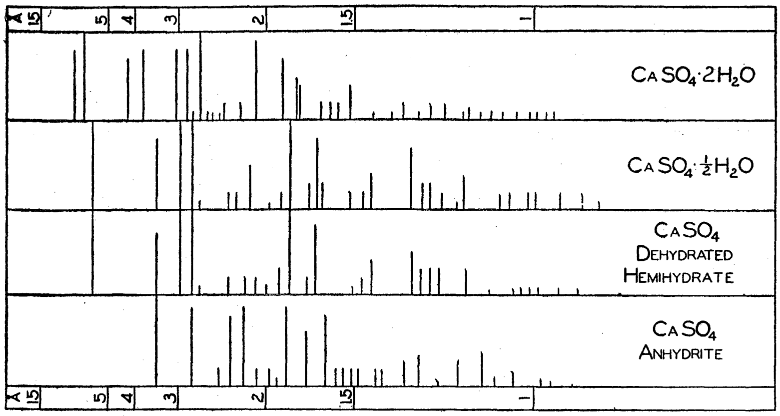

Fig. 3.

Fairly long exposures were required because of the low symmetry of the material, the small primary particle size, the large size and small aperture of the camera, and the need for obtaining a large number of lines. The usual exposure time was thirty to thirty-five hours at 60 m. a. and 40 k. v. Some typical negatives are reproduced in Fig. 4 and the data are shown diagrammatically in Fig. 5.

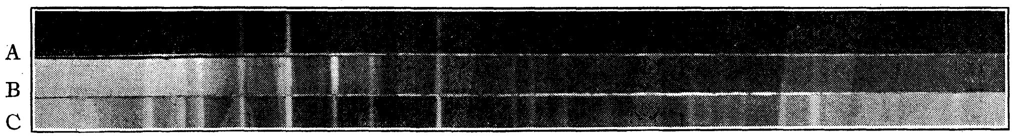

Fig. 4.—A, NiO; B, $CaSO_4\cdot 0.5H_2O$; C, $CaSO_4$ (Dehydrated hemihydrate).

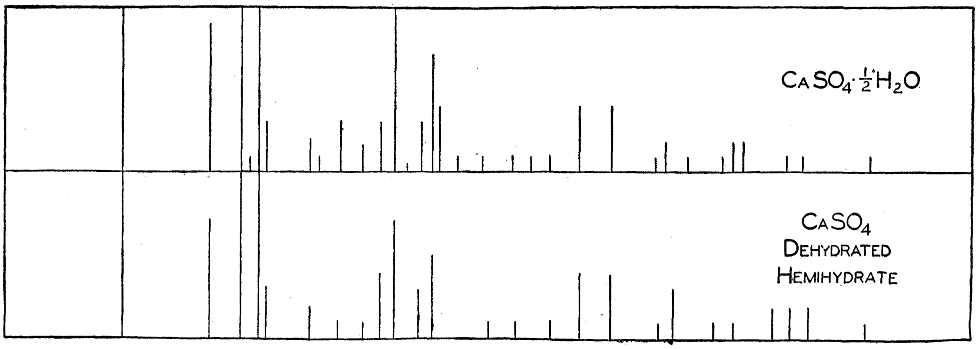

Fig. 5.

For purposes of comparison the corrected data are given in Table I. The interplanar spacings in Å. are denoted by d_{hkl} and the visually estimated, relative intensities by I.

Additional samples for x-ray examination were prepared by dehydrating selenite for twenty-four hours in a vacuum at 134, 159, 180 and 219°. The average composition of these samples was found to be $CaSO_4\cdot\pm 0.01H_2O$. To avoid any possibility of rehydration, the same procedure for filling and sealing the sample tubes was used as described above. All the patterns, using molybdenum radiation, were identical with those for dehydrated hemihydrate. This indicates the absence of any detectable amount of undecomposed hemihydrate or anhydrite. The samples dehydrated at 159 and 219° were allowed to rehydrate in air for several days. The compositions became, respectively, 0.63 and 0.60 mole of water per mole of calcium sulfate. After rehydrating the sample dehydrated to 134°, it was examined by x-rays, giving a pattern identical with that of hemihydrate.

Discussion of Results

The dehydration isobars for calcium sulfate hemihydrate are typical of those for a definite hydrate which adsorbs a small amount of water and gives a dehydration product which likewise adsorbs water. Since the hemihydrate and es-

pecially the dehydrated hemihydrate are known to adsorb water, the evidence seems conclusive that when $CaSO_4 \cdot 2H_2O$ is dehydrated isobarically, a definite hydrate $CaSO_4 \cdot 0.5H_2O$ which adsorbs a small amount of water is first formed and this in turn dehydrates in stepwise fashion to give dehydrated hemihydrate, calcium sulfate, which adsorbs water that is not removed completely at a vapor pressure of 23.6 mm. until well above the decomposition temperature. There is no indication that the water is present in the zeolitic form unless one wishes to apply the term "zeolitic" to the very small amount of water adsorbed first by the very finely divided hemihydrate and later by the resulting dehydrated hemihydrate. The failure of some investigators to obtain a clearly defined reversible step-curve for the decomposition of the hemihydrate is probably due to their failure to wait until equilibrium was established at each temperature.

The conclusions drawn from the dehydration data are supported by the x-ray diffraction studies. Since distinct characteristic differences exist between the x-ray patterns of hemihydrate and dehydrated hemihydrate, it would follow that the two are definite chemical individuals. The close agreement between many strong reflections shows that the type of lattice and the size of the unit cell are similar and that the hemihydrate lattice does not rearrange very much upon loss of the one-half molecule of water. This is the only way in which the hemihydrate resembles a zeolite. The characteristic changes in the pattern which take place on dehydration and rehydration show, however, that the water molecules in the hemihydrate are in a fixed position in the lattice and that the compound is not a zeolite.

The x-ray observations confirm qualitatively those of Feitknecht[11] but since the latter reported his data only in rough graphical form it is impossible to make a quantitative comparison. Since Jung,[5] Ramsdell and Partridge[6] and Caspari[7] believed the patterns of hemihydrate and dehydrated hemihydrate to be the same and Gallitelli[10] and Onorato[9] state that the structures are the same but recognize minor differences in the powder photographs, it would appear that these investigators failed to recognize the existence or the significance of the small but characteristic differences upon dehydration. This may be due to the small size of the cameras employed, the use of molybdenum radiation in some cases, and the failure to use a reference material for standardizing the films. However, there can be no doubt that significant differences exist between the x-radiograms of the two substances when use is made of a relatively large camera, copper radiation, and a standardizing material, and when special care is taken to avoid rehydration of the dehydrated hemihydrate.

Summary

1. Contrary to the conclusions of Linck and Jung, Balarew, Gibson and Holt, and others, the dehydration curve of calcium sulfate hemi-

hydrate gives a definite step indicating that the compound is a true chemical hydrate and not a zeolite.

2. Contrary to the conclusions of Jung, Ramsdell and Partridge, Caspari, Gallitelli, Onorato and others, calcium sulfate hemihydrate and "dehydrated hemihydrate" do not have identical structures. The x-radiograms of the two substances are similar, showing that the structures are similar; but the existence of definite characteristic differences between the two patterns indicates that the water molecules in the hemihydrate occupy fixed position in the lattice. These observations likewise support the view that calcium sulfate hemihydrate is a chemical individual and that the process of dehydration is not zeolitic in character.

Strong Oxidizing Agents in Nitric Acid Solution. I. Oxidation Potential of Cerous–Ceric Salts

BY ARTHUR A. NOYES AND CLIFFORD S. GARNER

Plan of these Investigations

In connection with the recent investigations made by Noyes, Hoard, Pitzer and Dunn[1,2] of argentic salts in nitric acid solution, electromotive force measurements were made by Noyes and Kossiakoff[3] to determine the oxidation potential of argentous–argentic salts (Ag^{I}, Ag^{II}); and the result (1.914 volts) was compared with those of other strong oxidizing agents for which reliable data exist. As these data are rather limited, it seemed desirable to carry out researches on the oxidation potential of other powerful oxidizing substances; and it is the purpose of this series of papers to present the results obtained with cerous–ceric salts (Ce^{III}, Ce^{IV}), with thallous–thallic salts (Tl^{I}, Tl^{III}), and with cobaltous–cobaltic salts (Co^{II}, Co^{III}) in nitric acid solution.

The method of measurement was much the same as that used for argentous–argentic salts by Noyes and Kossiakoff, to whose article reference should be made for certain details of procedure. The conditions are simpler, however, in the case of ceric nitrate or thallic nitrate, in that these substances, unlike argentic nitrate, do not undergo at room temperature spontaneous reduction to cerous or thallous salt.

In this first paper are presented the results of measurements on cerous–ceric cells. Such cells were first measured by Baur and Glaessner.[4] They used cells containing cerous and ceric salts in nitric and sulfuric acid solutions; but carried out the work at "room temperature," and eliminated the liquid potential only to the extent that this is accomplished by inserting a saturated solution of potassium chloride between the cerium and the calomel electrodes. A satisfactory value therefore cannot be calculated for the oxidation potential from their data.

More recently, Kunz[5] studied the formal potential of cerous–ceric salts in 0.5 and 1.0 formal sulfuric acid solutions.

In order to determine the value in nitrate solution, which is likely to form complexes to a less extent, and to eliminate largely the liquid potential, we measured at 25 and at 0° cells of the type

$$\mathrm{Pt} + \mathrm{H_2}\,(1\ \mathrm{atm.}),\ \mathrm{HClO_4}\,(c'),\ \left\{\mathrm{HNO_3}\,(c) + \frac{\mathrm{Ce^{IV}}\,(c_2)}{\mathrm{Ce^{III}}\,(c_1)}\right\},\ \mathrm{Pt}$$

These experiments will now be described.

Apparatus and Materials

Preparation and Analysis of Solutions.—In preparing the stock solutions of cerous and ceric nitrate, C. P. hydrated cerous nitrate was used to make up a solution approximately 0.1 *f* in cerous nitrate and 1 *f* in nitric acid (to prevent subsequent hydrolysis). A 17-cm. layer of this solution gave no absorption spectrum, showing the absence of other rare-earth elements. The solution was then divided into two nearly equal portions.

A solution of ceric nitrate was prepared by electrolytic oxidation of one of these portions with a current of 2 amperes at 6–8 volts, till samples removed and titrated with ferrous sulfate solution showed that the oxidation was nearly complete.

The ceric nitrate solution thus prepared was analyzed as

follows. Samples were weighed out, and, after adding the proper amount of water and sulfuric acid, the solutions were titrated with standard ferrous sulfate solution potentiometrically, using a vacuum-tube voltmeter. The amount of ceric cerium was thus obtained. The total cerium was determined by titration after oxidation of the cerium with ammonium peroxysulfate, using silver nitrate as a catalyst.[6] The nitric acid content was determined, after removing the cerium, by titration with standard sodium hydroxide solution, using phenolphthalein as indicator. To remove the cerium, the sample was shaken with mercury and a little potassium chloride till all the cerium was reduced to the cerous state; then sodium oxalate was added, the mixture was filtered, and the acid determined in the filtrate, tests having shown that no appreciable amount of nitric acid was adsorbed on the precipitate. The solution was diluted by weight to give a stock solution exactly 1.000 f in nitric acid, and check analyses were made. The ceric nitrate stock solution prepared in this manner was 0.1057 f in ceric nitrate and 0.004181 f in cerous nitrate.

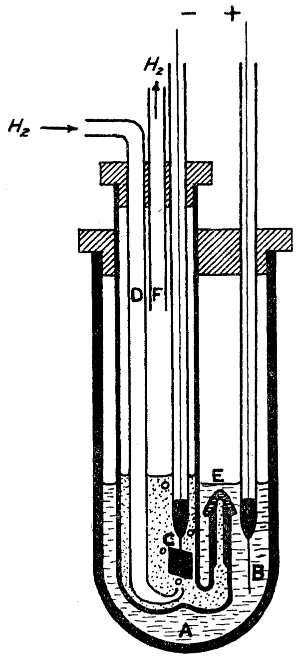

Fig. 1.

The other portion of the original cerous nitrate solution was analyzed in much the same way. It was diluted by weight so as to be exactly 1.000 f in nitric acid, and then again analyzed. The resulting stock solution of cerous nitrate was 0.08292 f in cerous nitrate and contained no ceric nitrate.

The solutions of perchloric acid were prepared by dilution of C. P. 60% perchloric acid, and were standardized against a sodium hydroxide solution.

Tank hydrogen was purified by passing it successively through concentrated potassium hydroxide solution and concentrated sulfuric acid, and over solid potassium hydroxide and an electrically heated platinum wire.

The Electrolytic Cell.—The assembled electrolytic cell is shown in Fig. 1. A large test-tube served as a container A for the cerous–ceric mixture, in which was immersed the hydrogen half-cell and a platinum wire electrode B. Measurements were made with the platinum wire bright and with it platinum-blacked; there was no difference in potential, although the latter electrode came to equilibrium with the solution much more rapidly. The hydrogen half-cell vessel contained the perchloric acid solution into which dipped a platinized platinum foil electrode C and a tube D through which the hydrogen was bubbled in; the vessel was also equipped with a short vertical capillary side-arm provided with a ground glass cap E which prevented liquid diffusion while allowing electrolytic contact. Before entering the half-cell the hydrogen passed through a glass coil and a vessel containing perchloric acid of the same concentration as that used in the half-cell. In addition a small "bubbler" was provided at the hydrogen outlet F to ensure a hydrogen atmosphere in the half-cell. The apparatus was immersed in a thermostat maintained at 25.00 ± 0.01°, or in one kept at 0°.

Method of Potential Measurements.—A Leeds and Northrup Type K potentiometer was used in conjunction with a high-sensitivity galvanometer for the measurements of the electromotive force. The Weston standard cell used was carefully checked at 25° against a new laboratory standard.

Cerous–ceric mixtures containing varying amounts of nitric acid were prepared from the stock solutions and a standard nitric acid solution by weighing. While each mixture was attaining thermal equilibrium in the cell, the hydrogen electrode was checked at 25° against a 1 N hydrochloric acid calomel electrode which had been prepared with purified chemicals in the presence of air.[7] The hydrogen half-cell was then placed in the electrolytic cell, and the potential observed over a period of one to fifty hours. In all cases equilibrium was attained within one hour, and readings were constant thereafter to 0.3 mv. or better; stirring had no effect on the potential. The hydrogen half-cell was checked against the calomel electrode after each run; the calculated value being always obtained to within 0.1 mv.

Calibrated volumetric apparatus, thermometers and weights were employed in this research, and all weighings were corrected to vacuum.

Measurements at 0°.—One of the cells which had been measured at 25° was placed in a 0° thermostat, and measurements of the electromotive force were made over a period of several days. The readings were constant to 0.2 mv., and upon returning the cell to the 25° thermostat, it gave a value for the potential within 0.1 mv. of that previously determined.

The Observed and Computed Electromotive Forces

In Table I are recorded the electromotive forces observed at various concentrations of the substances involved, the corrections computed for reducing these to standard concentrations and eliminating the liquid potential, and the final formal electrode potential thereby obtained.

The first column of the table shows the temperature, 25 or 0°. In the next five columns are given the weight formalities f (the concentrations in formula weights per kilogram of water) of the substances in the cells. In the next two columns are the mean ionic strength μ of the cerous–ceric mixtures, and the observed electromotive forces $E_{\text{obsd.}}$. The activity coefficients α of the two

acids are given below their concentrations, the coefficients being interpolated from the data of Pearce and Nelson[8] for perchloric acid at 25° and from those of Abel, Redlich and v. Lengyel[9] for nitric acid at 25°. In the next three columns are the values of the electromotive force corrections computed as described below, and in the last column are the values of the formal oxidation potential E^0 referred to the standard molal hydrogen electrode H_2 (1 atm.), H^+ (activity 1 m.); by formal oxidation potential being meant the oxidation potential when the total concentrations, represented by Ce^{IV} and Ce^{III}, of the oxidized and reduced cerium (without reference to their ionization) are both 1.0 *f*.

This formal oxidation potential E^0 (for the reaction $Ce^{IV} + E^{-I} = Ce^{III}$) has been derived by adding to the observed electromotive force $E_{obsd.}$ (which is that of the cell formulated in the first section of this paper) the three following quantities:

(1) $E_C = (RT/2F) \ln (c_1/c_2)$, in order to provide for equiformal concentrations of cerous and ceric cerium, their total concentrations c_1 and c_2 being used in this Nernst equation in place of the ion activities.

(2) $E_L = (2T_H - 1)(RT/F) \ln (\alpha c/\alpha' c')$, in order to eliminate the small liquid potential arising from the different ion activities αc and $\alpha' c'$ of the nitric and perchloric acids; it being assumed that the ion mobilities of the two acids are equal in the given concentration range. The mean transference number T_H of the cation of the two acids has been estimated[10] to have the value 0.85 at 25° and the value of 0.86 at 0°.

(3) $E_H = (RT/F) \ln (\alpha' c'/\sqrt{p_{H_2}})$, in order to refer the value to the molal hydrogen electrode standard at 25°, p_{H_2} being the partial pressure of the hydrogen gas in atmospheres.

Discussion and Summary

It is seen from Table I that the formal cerous–ceric oxidation potential E^0 changes only slightly (at most by 1.5 mv.) on varying the ratio Ce^{III}/Ce^{IV} over ten-fold at constant ionic strength. Moreover, varying the acid concentration from 0.5 to 2.0 *f* and the ionic strength correspondingly has only a small effect on the value of E^0. This shows that nitrate complexes are formed only slightly, if at all, and that a hydrolytic reaction such as $Ce^{++++} + H_2O = CeOH^{+++} + H^+$ does not occur appreciably at these concentrations. Hence the value **1.6095** ± 0.0007 volt may be regarded as the cerous–ceric oxidation potential in nitric acid at 25°, independent of the concentration of that acid between 0.5 and 2.0 formal.

---

[8] Pearce and Nelson, THIS JOURNAL, **55**, 3080 (1933).

[9] Abel, Redlich and v. Lengyel, *Z. physik. Chem.*, **132**, 204 (1928).

[10] This estimate at 25° is based on the considerations that the two acids have equal conductances at 2.0 *f*, that the nitric acid solution contains less than 10% as much cerium as acid, so that its conductance does not differ greatly from that of pure nitric acid, and that the latter has the values recorded in "International Critical Tables" (Vol. VI, pp. 241, 310 (1929)). For the 0° measurement, the same activity values were used as at 25°, since none are available at 0°.

The value of this potential at 0° was found to be **1.601** volts (in 1.0 *f* HNO_3).

It is interesting to note that in sulfate solution Kunz[5] obtained much smaller values, namely, 1.461 and 1.443 volts at 25° in 0.5 *f* and in 1.0 *f* H_2SO_4, respectively. This indicates that complex formation between the ceric ion and sulfate ion (or hydrosulfate ion) takes place to a large extent. It is probable therefore that the value obtained in nitric acid represents much more nearly the *molal* oxidation potential of cerous–ceric *ions*.

It may also be noted that the cerous–ceric potential in nitrate solution is of the same order as that (1.59 volts)[11] for the reaction $MnO_4^- + 4H^+ + 3E^- = MnO_2(s) + 2H_2O(l)$. Correspondingly, on adding permanganate solution to a nitric acid solution of cerous nitrate, manganese dioxide was found to form; and on adding ceric nitrate solution to freshly precipitated manganese dioxide, the color of permanganate was developed.

Strong Oxidizing Agents in Nitric Acid Solution. II. Oxidation Potential of Thallous-Thallic Salts

BY ARTHUR A. NOYES AND CLIFFORD S. GARNER

Previous and Proposed Investigations

The thallous–thallic oxidation potential has been studied by several investigators. Its determination was first undertaken by Spencer and Abegg[1] who studied the potential in nitric, hydrochloric and sulfuric acids, and in the presence of various salts with the view of investigating complex-ion formation. Their measurements were made at 25° against a 0.1 *N* calomel half-cell as a reference electrode, and their potentials were not corrected for liquid-junction potentials. Grubb and Hermann[2] later obtained values for the thallous–thallic potential in sulfuric acid solutions. Measurements by them were made at 18° against either a normal calomel electrode or a mercurous sulfate electrode, and liquid-junction corrections were not applied. Partington and Stonehill[3] recently measured at 25° cells of two types

$$\mathrm{Pt}, \left\{ \mathrm{H_2SO_4}\,(c) + \begin{matrix} \mathrm{Tl_2SO_4}\,(c_1) \\ \mathrm{Tl_2(SO_4)_3}\,(c_2) \end{matrix} \right\}, \mathrm{H_2SO_4}\,(c), \mathrm{H_2}\ (1\ \text{atm.}) + \mathrm{Pt}$$

and

$$\mathrm{Pt}, \left\{ \mathrm{H_2SO_4}\,(c) + \begin{matrix} \mathrm{Tl_2SO_4}\,(c_1) \\ \mathrm{Tl_2(SO_4)_3}\,(c_2) \end{matrix} \right\}, \mathrm{Hg_2SO_4}\ (\text{satd.}), \mathrm{Hg}, \mathrm{Hg_2SO_4}\,(\text{satd.}), \mathrm{H_2SO_4}\,(c), \mathrm{H_2}(1\ \text{atm.}) + \mathrm{Pt}$$

These investigations showed that the oxidation potential of thallous–thallic salts varies greatly with the nature of the anion present, doubtless owing to the formation of anion complexes; and as these complexes are probably produced in minimum quantity with monobasic oxyacids, such as nitric acid and perchloric acid, thereby yielding a molal potential approximating most closely that of the simple thallous and thallic ions, we have measured and describe in this paper cells of the type

$$\mathrm{Pt} + \mathrm{H_2}\,(1\ \text{atm.}), \mathrm{HClO_4}\,(c'), \left\{ \mathrm{HNO_3}\,(c) + \begin{matrix} \mathrm{Tl^{III}}\,(c_2) \\ \mathrm{Tl^{I}}\,(c_1) \end{matrix} \right\}, \mathrm{Pt}$$

During the progress of our investigation an article upon the thallous–thallic potential in perchloric acid solution has been published by Sherrill and Haas,[4] thereby making possible a comparison of the potential in the two monobasic oxyacids.

Apparatus and Materials

Preparation and Analysis of the Solutions.—A weighed quantity of c. p. thallous nitrate, dried in an oven at 140°, was dissolved in a definite weight of distilled water, and the resulting solution was divided into two nearly equal portions.

(1) From one of these portions a thallic nitrate solution was prepared by oxidation with a gas mixture containing 5% by volume of ozone (Noyes, Hoard and Pitzer[5]), thereby avoiding the introduction of foreign substances into the solution. To it had previously been added the amount of strong nitric acid (freed from nitrogen dioxide by bubbling air through it) required to leave the oxidized solution 0.5 *f* in nitric acid. It was thought that this acid would suffice to prevent the hydrolysis of the thallic nitrate formed, but during the oxidation dark-brown thallic hydroxide precipitated, and it was necessary to add more nitric acid to the oxidized mixture. The excess of ozone was blown out with oxygen, and the thallic nitrate solution was analyzed in the following way.

To a weighed sample solid potassium chloride and mercury were added, the mixture was shaken for two minutes and filtered through a Jena glass filter. The filtrate with washings was then titrated with standard sodium hydroxide solution to determine the nitric acid content. It was necessary to reduce the thallic salt in this way, since otherwise it separated out as the hydroxide and obscured the end-point. The content in thallic nitrate was determined on separate samples by reducing the thallic thallium to thallous thallium with sulfur dioxide, blowing out the excess of sulfur dioxide with carbon dioxide, and determining the thallium by two independent methods. However, it was found that the large amount of nitrate present interfered with these determinations; so the samples were first fumed with concentrated sulfuric acid to convert the nitrate to sulfate. Two determinations were made by the iodate method using the iodine monochloride end-point,[6] and these agreed to better than 0.1% with two determinations by the bromate method using methyl orange as an oxidation indicator.[7] The absence of thallous thallium in the thallic nitrate solution was proved by making a sample 5 *f* in hydrochloric acid, adding a small amount of iodine monochloride solution and shaking with carbon tetrachloride; no iodine color was perceptible. The thallic nitrate stock solution thus prepared was 0.1835 *f* in thallic nitrate and 2.430 *f* in nitric acid.

(2) To the other portion of the thallous nitrate solution was added enough nitric acid to make the resulting solution of the same acidity as the thallic nitrate stock solution. Analyses for both thallium and acid checked the values obtained by the direct synthesis of the solution. The thallous nitrate stock solution was 0.1284 *f* in thallous nitrate and 2.430 *f* in nitric acid.

The Electrolytic Cell.—The electrolytic cell used for the electromotive force measurements was that described in the preceding paper. The platinum wire electrode gave the same potential whether it was bright or platinum-blacked; however, equilibrium was more rapidly attained in the latter case.

Method of Potential Measurements.—The equipment used and the method of making the electromotive force measurements were those previously described in detail. The potential of a given cell was observed over a period of one to seventy hours. Equilibrium was reached within an hour, and subsequent readings were constant to 0.1 mv., stirring having no effect on the potential.

Measurements at 0°. One of the cells which had been measured at 25° was transferred to a 0° thermostat, and its potential observed over a period of three days. Equilibrium was much more slowly attained than at 25°, and the readings were sensitive only to about 0.5 mv. The cell was afterward returned to the 25° thermostat, and gave substantially the same electromotive force as before. The probable error of the formal potential at 0° is about one millivolt.

The Observed and Computed Electromotive Forces

In Table I are shown the concentration data, the observed electromotive forces, $E_{obsd.}$, the corrections applied to these, and the computed formal oxidation potentials E^0 resulting thereby, all in just the same form in which these quantities are presented in Table I of the preceding article. The activity coefficients α and α' of the two acids are as before taken from the data of Pearce and Nelson[8] and of Abel, Redlich and v. Lengyel,[9] the same values being used at 0° (where data are lacking) as at 25°.

Summary and Discussion

Measurements have been described above of the electromotive forces at 25 and 0° of cells of the type

$$\text{Pt} + \text{H}_2\,(1\text{ atm.}),\ \text{HClO}_4\,(c'),\ \left\{ \text{HNO}_3\,(c) + \frac{\text{Tl}^{\text{III}}\,(c_2)}{\text{Tl}^{\text{I}}\,(c_1)} \right\},\ \text{Pt}$$

From these measurements presented in Table I the formal oxidation potential E^0 of the reaction $\text{Tl}^{\text{III}} + 2\text{E}^{-\text{I}} = \text{Tl}^{\text{I}}$ has been computed to have the value **1.2303** ± 0.0007 volt at 25° and the value **1.193** ± 0.001 volt at 0° in nitric acid solution. This value is shown to remain substantially constant when the ratio $\text{Tl}^{\text{I}}/\text{Tl}^{\text{III}}$ is varied one hundred-fold and when the concentration of nitric acid is varied from 0.5 to 2 *f*. This constancy of the potential shows that neither hydrolysis of the thallic nitrate (by a reaction like $\text{Tl}^{+++} + \text{H}_2\text{O} = \text{TlOH}^{++} + \text{H}^+$), nor formation of nitrate complexes occurs to a considerable extent with thallic salts in nitric acid solutions between 0.5 and 2.0 formal.

This value, 1.230 volts, of the formal potential is slightly lower than those found by Sherrill and Haas[4] for the thallous–thallic potential in perchloric acid solution, who obtained at 25° 1.260 volts for the formal potential in 1.0 *f* perchloric acid and 1.247 volts for the extrapolated molal potential for thallous–thallic ions.

Noteworthy is the fact that the thallous–thallic potential in sulfuric acid solution, determined by Partington and Stonehill[3] to be 1.20 to 1.22 volts, is of about the same magnitude as the potentials in nitric and perchloric acids indicating that the formation of sulfate complexes by thallic sulfate is not very extensive.

The Electron Diffraction Study of Paraldehyde

BY D. C. CARPENTER AND L. O. BROCKWAY

Paraldehyde has been shown[2] to exist as the trimer $(\text{CH}_3\text{CHO})_3$ in the gaseous state and in solution in phenol, and metaldehyde as the tetramer $(\text{CH}_3\text{CHO})_4$ in phenol solution. In the present work the configuration of paraldehyde has been established by electron diffraction methods as a staggered six-membered ring of alternate carbon and oxygen atoms with a hydrogen atom and a methyl group attached to each of the ring carbon atoms, the methyl carbon atoms being approximately coplanar with the ring oxygen. The technique of the electron diffraction method of determining the structure of molecules has been described,[3] and the method now represents one of the most direct and feasible means of determining bond angles and distances.

Experimental

The sample of paraldehyde used in this study was purified by repeated fractional distillation and boiled at 124.0 ± 0.2°. Smits and deLeeuw[4] record the boiling point as 123.7°.

The low vapor pressure of paraldehyde at room temperature prevented the use of the ordinary unheated gas nozzle. In this investigation the sample was placed in a small glass bulb which was sealed to a copper tube leading through an all-metal high vacuum valve and up into the apparatus where it terminated in a nozzle just below the electron beam. The sample bulb, connecting tubes, valve and nozzle were all heated by spirals of resistance wire enclosing the entire path of the vapor. The valve was constructed so that a stiff spring pressing on the valve stem compensated for relative expansion of the valve parts and the valve was vacuum tight both at ordinary and elevated temperatures. Four thermocouples were used to follow the temperatures of the various parts of the assembly. This arrangement for handling vapors at high temperatures differs from those used by other investigators in which the gas stream flows continuously and is regulated by changes of the temperature of the sample holder. Here the gas flow is controlled by a quick-acting valve.

Fifteen photographs of paraldehyde were obtained in three sets with the temperature of the sample ranging from 103 to 115°. The exposure

times were adjusted so that the inner rings could be measured on some photographs and the outer rings on others. The de Broglie wave length of the electrons was 0.0606 Å. as determined by calibration with gold foil. The distance from gas orifice to photographic film was 10.43 cm.

The photographs show seven rings of which the second and fifth are very strong. The fourth is close to the third and weaker than the third and fifth rings. The sixth ring is weaker than the fifth and seventh. Measurements of the diameters were made by two observers and the corresponding values of s (equal to $(4\pi \sin \theta/2)/\lambda$) are given in Table I.

TABLE I

No. of readings	Max.	Min.	Visual intensity	S (obsd.)	S (calcd.)	l_{C-O}

				Weighted mean		1.427

C–O = 1.43 ± 0.02 Å.

Discussion

The estimated intensities of the visual maxima and the corresponding s values were used in the calculation of a radial distribution curve.[5] The data of Table I lead to the curve shown in Fig. 1. This curve shows two pronounced peaks corresponding to the most important interatomic distances in the molecule. The first peak occurs at 1.47 Å., exactly the value which would be predicted for models of the ring type shown in Fig. 2, in which there are six C–O and three C–C single bonds. The covalent radii lead to the values 1.43 and 1.54 Å., respectively. If these values are weighted according to the number and scattering power of the atoms involved, the single peak corresponding to the two unresolved distances should occur at 1.47 Å. the observed value. Accordingly, the single bonded ring structure is very probable.

A determination of the bond angle can be made by use of the second peak which occurs at 2.36 Å. This peak corresponds to the interaction of atoms bonded to the same atom. The ratio 2.36 to 1.47 is 1.61, which leads to the bond angle of 108° in close approximation to the tetrahedral angle of 109°28′. Similar values of the bond angle between carbon and oxygen have been found in other compounds, such as dimethyl ether and dioxane, and we accept the tetrahedral angle as being correct in the calculation of theoretical intensity curves.

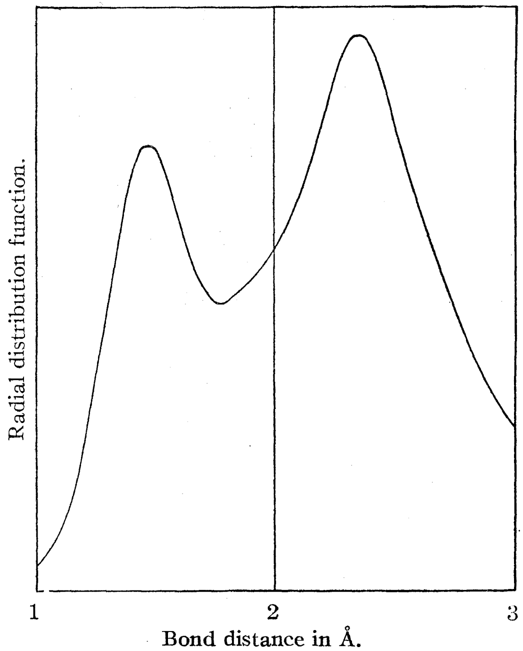

Fig. 1.—Radial distribution curves for paraldehyde.

Four ring models of the paraldehyde molecule are possible, corresponding to elevating the methyl groups successively above the plane of the –C–O–C–ring as shown in Fig. 2. Calculations of the theoretical intensity of scattering, $I = \Sigma_i \Sigma_j Z_i Z_j (\sin sl_{ij}/sl_{ij})$ where $s = (4\pi \sin \theta/2)/\lambda$ were made for each of the four models for s values up to 20. The distances between bonded atoms were taken as follows: C–O, 1.43 Å.; C–C, 1.54 Å.; C–H, 1.06 Å.; and the bond angles were taken as 109° 28′. The calculated curves are shown in Fig. 3. The observed positions of the maxima and minima are indicated at the bottom of the figure. The s values for the maxima and minima of the first theoretical curve (all methyl groups in the plane of the ring) are listed in the sixth column of Table I. The four curves all show the qualitative intensity features observed in the photographs. Particularly characteristic is the strong fifth maxi-

---

[5] L. Pauling and L. O. Brockway, THIS JOURNAL, **57**, 2684 (1935).

mum. Differences in the four models are evident in the fourth and sixth rings. The fourth ring is displaced outward in going from model 1 to model 4, and models 3 and 4 are in definite disagreement with the photographs on this account. Similarly these last two models show an inward displacement of the sixth ring which is not observed.

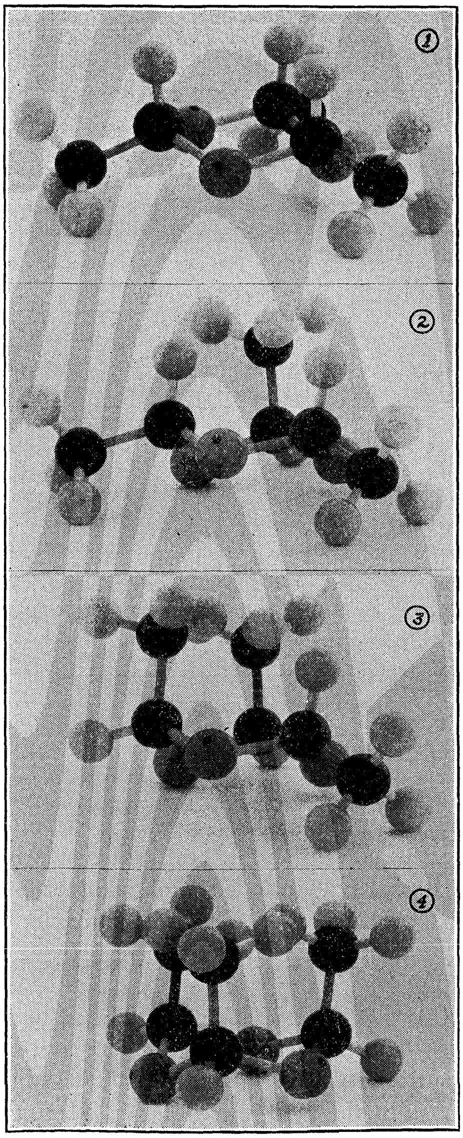

Fig. 2.—Models of paraldehyde molecule.

The values for the C–O distances in the last column of Table I are derived by multiplying the ratio of S(calcd.) to S(obsd.) by the assumed value for the distance. In arriving at the weighted mean value we reject the values from the two innermost rings and from the fourth and sixth maxima. In the former case the contrast effect of the dense central image leads to interatomic distance values which are too small and in the latter case the notable asymmetry of maxima results in the expected shift explained by the St. John effect.[3] While these rings are not suitable for exact determination of the interatomic distances, they are valuable in confirming the ring structure of the molecule since the corresponding theoretical curve and the photographs show the same asymmetric features. The dimensions of the molecule are determined as 1.43 ± 0.02 Å. for the C–O bond distance and 1.54 ± 0.02 Å. for the C–C bond distance with the staggered ring arrangement of six alternating carbon and oxygen atoms well established.

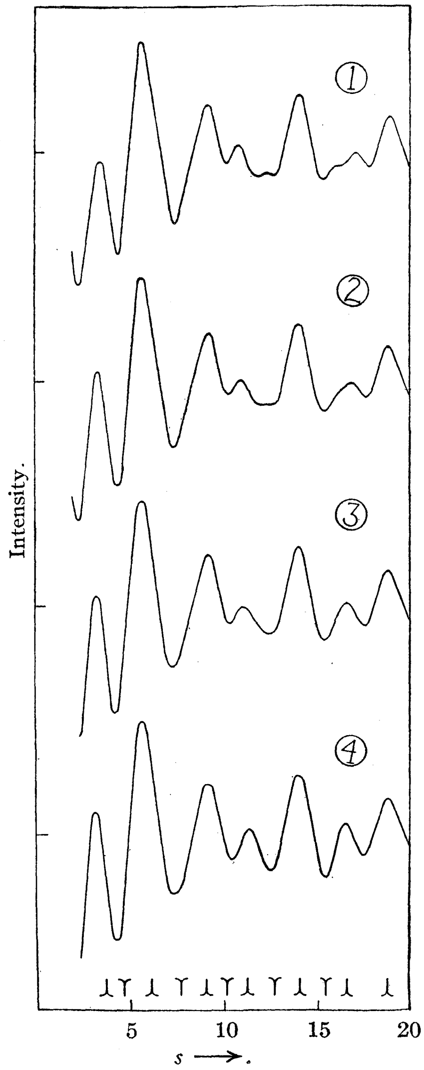

Fig. 3.—Theoretical intensity curves for paraldehyde models.

The close similarity in the theoretical intensity curves corresponding to models 1 and 2 makes it impossible to distinguish on the basis of our data between the model with all of the methyl groups nearly in the plane of the ring and the model having one methyl group above the ring. A comparison can be made with the structure of metaldehyde determined by x-ray crystal studies.[6] Metaldehyde, which is the tetramer of acetaldehyde, has an eight-membered ring of alternating carbon and oxygen atoms with four methyl groups attached to the four carbon atoms and all four of the methyl groups lie in the plane of the carbon atoms in the ring. The molecules are packed together in such a way that the closest approach of methyl carbon atoms on adjacent molecules is 3.90 Å. with an average separation for the intermolecular methyl groups of 4.02 Å. Hydrogen atoms on these methyl groups are separated by 2.14 Å. In models 3 and 4 of paraldehyde which have two and three methyl groups above the ring the calculated separation of methyl carbons is 2.33 Å. and of the methyl hydrogens is 1.85 Å.; comparison of these distances with those observed in the metaldehyde crystals again eliminates these two models of paraldehyde. The observed configuration of the metaldehyde molecules makes model 1 of paraldehyde (all methyl groups nearly in the plane of the ring) seem most probable.

Electron diffraction pictures were taken of the vapor of metaldehyde and the photographs show that the gaseous molecule cannot be represented by any single configuration. This is to be explained by the ease with which the eight-membered ring can be distorted from the configuration found in the crystalline form of metaldehyde without stretching or bending the bonds between adjacent atoms. This labile nature of the ring is not found in the crystal because the interactions between molecules in the condensed state are strong enough to hold the molecules in a single equilibrium configuration. The six-membered ring of paraldehyde does not exhibit any such labile character because of the strains set up in any distortion of the smaller ring.[7]

We are indebted to Professor Linus Pauling for proposing the investigation and for many valuable suggestions and criticisms.

Summary

Paraldehyde has been studied by the electron diffraction method and found to consist of a staggered six-membered ring of alternate carbon and oxygen atoms having a C–O distance of 1.43 ± 0.02 Å. The bond angles are all tetrahedral and the three methyl groups are placed symmetrically about the molecule in nearly the same plane as the ring (*i. e.*, as fixed by the tetrahedral angles) with the possibility that only one of the methyl groups may be elevated above the plane of the ring. The methyl carbon atoms are attached to the carbon atoms of the ring by bonds having a length of 1.54 ± 0.02 Å.

[6] L. Pauling and D. C. Carpenter, THIS JOURNAL, **58**, 1274 (1936).

[7] An electron diffraction study of paraldehyde vapor has been reported by Ackermann and Mayer (*J. Chem. Phys.*, **4**, 377 (1936)). These authors used electrons of only 6400 volts energy corresponding to a wave length of 0.15 Å. and obtained three maxima. While their observed *s* valves for the first and second maxima and minima are from 3 to 10% lower than those reported in this paper the discrepancy may well be due to the differences in technique. As reported above, when the shorter wave-length (0.06 Å.) is used the apparent positions of the innermost rings is affected by the very dense central spot and they lead to unreliable interatomic distance values. This effect is evidently less serious when the inner rings occur at greater angles. The conclusions of Ackermann and Mayer are in fair agreement with the present results based on photographs showing seven maxima.

The Crystal Structure of Metaldehyde

BY LINUS PAULING AND D. C. CARPENTER

Metaldehyde is described by Groth[2] as crystallizing in tetragonal needles with the axial ratio $a:c = 1:0.2761$. A preliminary x-ray investigation of the crystal was carried out by Hassel and Mark,[3] who determined the size of the unit of structure and reported the space group to be either C_{4v}^9 or C_4^5, the location of the atoms in the unit not being found. We have reinvestigated this crystal, finding the space group to be C_4^5—I_4, and making a complete determination of the atomic arrangement. The unit of structure contains two molecules of the tetramer, $(CH_3CHO)_4$, each molecule consisting of an eight-membered –O–C–O–C– ring with H and CH_3 attached to each carbon atom of the ring. The interatomic distances and bond angles were found to be the same as in paraldehyde,[4] $(CH_3CHO)_3$.

The Unit of Structure and Space-Group Symmetry

Metaldehyde was recrystallized from absolute alcohol by the method of slow cooling, and dried on a Büchner funnel. The crystals were in the form of needles with dimensions about 0.5 × 0.5 × 20 mm. Laue photographs taken with crystal orientations differing only by rotation through a multiple of 90° about the needle axis were found to be identical, verifying the tetragonal symmetry of the crystal. Several Laue photographs were prepared with the incident beam in the plane normal to the *c*-axis. Each of these photographs showed a horizontal plane of symmetry, but none showed a vertical plane of symmetry (photographs with the incident beam parallel to [100] and [110] of the unit of structure, among others, were prepared). Consequently the point-group symmetry of the crystal cannot be that of D_{4h}, D_4, C_{4v}, or D_{2d}, but must be instead that of C_{4h}, C_4, or S_4. Of these C_{4h} and S_4 are eliminated by our observation of a strong pyroelectric effect along the needle axis, the liquid-air method[5] being used. The crystal is thus definitely allocated[6] to the point group C_4.

The pronounced prismatic cleavage of the crystal was strikingly shown by its behavior on cooling with liquid air, the strains resulting from temperature gradients during cooling causing each crystal to separate into a large number of fibers.

Oscillation and rotation photographs were prepared with [001] as axis of rotation, Mo $K\alpha$ radiation filtered through zirconia being used. These led to the values $a_0 = 10.40$ Å. and $c_0 = 4.11$ Å. for the edges of the unit of structure, in approximate agreement with the values of Hassel and Mark, $a_0 = 10.34$ Å., $c_0 = 4.10$ Å. All of the reflections on a complete set of oscillation photographs about [001] and on a completely-indexed Laue photograph were found to be compatible with this unit (the axes of which are 45° from those used by Groth). No reflections (hkl) with $h + k + l$ odd were observed; the lattice is accordingly body-centered. Of the body-centered space groups isomorphous with C_4 all but C_4^5 are eliminated by the observation that all types of prism planes give reflections; C_4^5—I_4 is accordingly the space group of the crystal.

The Atomic Arrangement

There are 8 CH_3CHO in the unit of structure (density calculated, 1.31; observed, 1.27). As pointed out by Hassel and Mark, these are formally combined by the four-fold axes into polymers $(CH_3CHO)_4$. It seems highly probable that these groups have a structure closely similar to that of paraldehyde, each oxygen atom being attached to two carbon atoms by single bonds. We made the preliminary assumptions that the interatomic distances have the values C—C = 1.54 Å. and C—O = 1.43 Å. and the bond angles all have the tetrahedral value 109° 28′, as in paraldehyde. There are only two configurations of the molecule compatible with these assumptions. In one of these the four methyl groups are directed along the *c*-axis, and in the other they

[6] Hassel and Mark prepared only complete rotation photographs, and so were unable to distinguish between the point groups C_4 and C_{4v} and the space groups C_4^5 and C_{4v}^9.

are directed outward from the center of the ring. (The four-fold axis eliminates intermediate configurations.) The first of these is at once ruled out by the consideration of interatomic distances in the c direction, in which molecules are only 4.11 Å. apart. The metaldehyde molecule accordingly has the configuration shown in Fig. 1. The atomic arrangement is then completely determined by one additional parameter φ, corresponding to rotation of the molecule about the four-fold axis through its center (see Fig. 6).

The intensity data used in evaluating this parameter and in verifying the assumed values for the others were obtained in the following way. Using the same crystal and the same exposure, oscillation photographs about [001] were prepared with the incident beam covering the ranges 0–15, 15–30, 30–45, 45–60, 60–75, 75–90 and 90–105° with the axis [100] (the first and last photographs being identical). Microphotometer records of the equatorial reflections were then prepared with a Krüss microphotometer, and interpreted in terms of intensities with the aid of similar records of a set of 0–15° photographs taken with different exposure times. The intensity values so obtained for thirty prismatic forms are given in Table I, together with relative values of F calculated from them by use of the equation

$$F_{hkl} = \left(\frac{2I_{hkl} \sin 2\vartheta}{1 + \cos^2 2\vartheta}\right)^{1/2} \qquad (1)$$

in which I_{hkl} is the observed intensity and ϑ the angle of reflection.

TABLE I

EQUATORIAL REFLECTIONS FOR METALDEHYDE

	Intensity of reflection		
hkl	Obsd.	Calcd.	F, obsd.
110	275	230	5.0
200	33	18	2.1
220	78	62	−3.8

2.10.0	9	13	−2.8

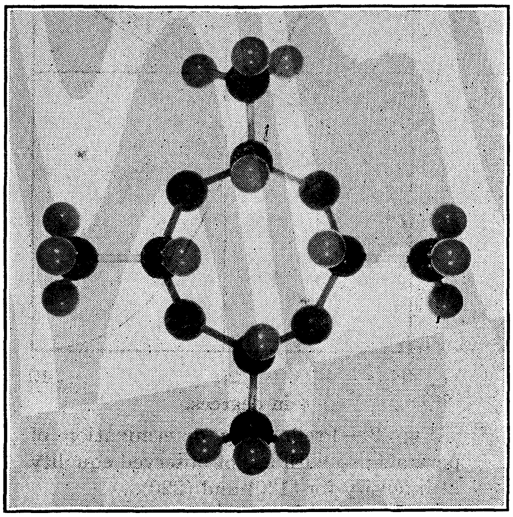

Fig. 1.—Configuration of metaldehyde molecule.

The observed intensity values were compared with intensity values calculated by replacing F_{hkl} in Equation 1 by

$$F_{hkl} = \Sigma_j f_j e^{2\pi i(hx_j + ky_j + lz_j)} \qquad (2)$$

Pauling–Sherman f-values[7] being used for f_j, and the coördinates x_j y_j z_j being calculated as a function of φ for the molecular model described above.

The observed approximate equality in intensity of reflection from {130} and {220} limits φ to values in the neighborhood of 16° (Fig. 2). The comparisons of {150} with {510} ($F_{150}/F_{510} = 0.87$) and {260} with {620} ($F_{260}/F_{620} = 0.63$) shown in Fig. 3, as well as other similar comparisons, lead to values near 16° 40′ for φ.

In order to investigate the possibility that the molecular parameter values differ slightly from those assumed, a two-dimensional Fourier analysis of the distribution of scattering power in the crystal projected on the plane (001) was made, using the equation

$$\rho(x,y) = \text{constant}\ \Sigma_h \Sigma_k F_{hk0} \cos 2\pi(hx + ky) \qquad (3)$$

---

[7] L. Pauling and J. Sherman, *Z. Krist.*, **81**, 1 (1932).

the sum being extended over all planes (*hk*0) for which reflections were observed. The experimental *F*-values for the corresponding forms are given in Table I, together with their assumed algebraic signs, these being as calculated for $\varphi = 16° 40'$ and the original molecular model. The resultant distribution function $\rho(x,y)$ is shown in Fig. 4. It is seen that the function corresponds to well-defined molecules of the type described. In order to obtain some information as to the reliability of the distribution function and especially as to the effect of breaking off the Fourier series, the calculations were repeated three times: first, with use of the *F* values of Table I except for omission of the form {2.10.0}; second, the same except for omission also of the forms {860} and {680}; and third, with inclusion of all forms, the *F*-values of Table I being multiplied by a factor decreasing from 1 for forms with sin ϑ/λ less than 0.75 to 0.20 for the forms with largest sin ϑ/λ, in order to force a gradual termination of the series. The atomic coördinates given by the four treatments deviate from their average values by a mean of 0.002, or 0.02 Å. The average values of the atomic coördinates given by the four treatments are

$$\begin{aligned} \mathrm{O}:&\ x = 0.074,\ y = 0.143\\ \mathrm{C_1}:&\ x_1 = 0.149,\ y_1 = 0.050\\ \mathrm{C_2}:&\ x_2 = 0.291,\ y_2 = 0.091 \end{aligned}$$

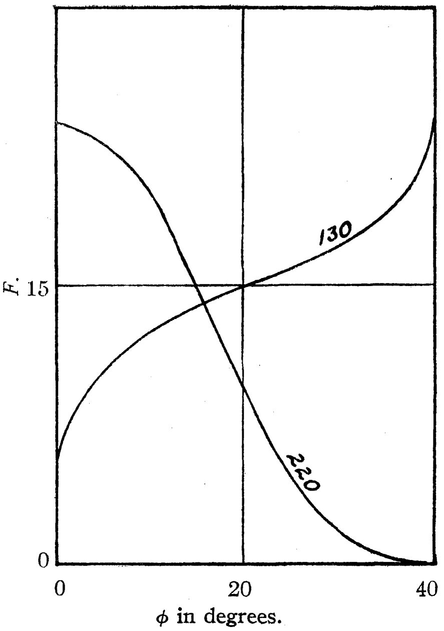

Fig. 2.—Preliminary determination of parameter φ with use of observed equality of intensity for (130) and (220).

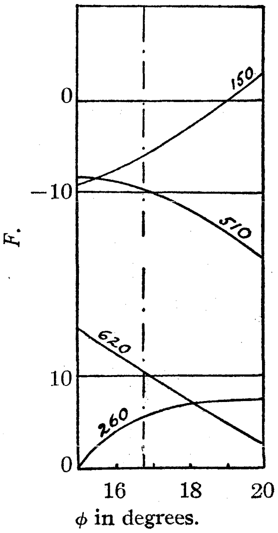

Fig. 3.—Determination of parameter φ.

These correspond to the projected interatomic distances C–O = 1.24 Å. and 1.28 Å. and C–C = 1.53 Å. (all ±0.03 Å.), in excellent agreement with the originally assumed values C–O = 1.27 Å. and C–C = 1.54 Å.

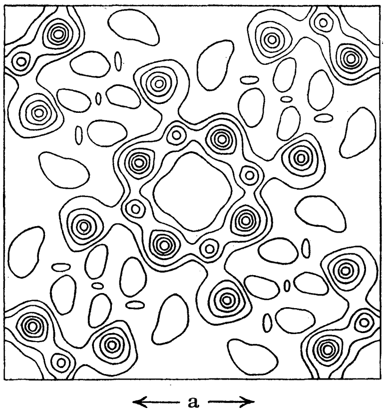

Fig. 4.—Distribution function $\rho(x,y)$ for metaldehyde (projection on (100)).

The value of φ given by the distribution function is about 17° 30′, and that given by our original treatment is 16° 40′. Inasmuch as the projected interatomic distances agree with those originally assumed to within 0.02 Å., we shall accept the original molecular model as verified by experiment, and take for φ the average of the two determined values, 17° 0′ ± 30′. The atomic arrangement of the crystal is then described by the parameters

$$\begin{aligned} \mathrm{O}:&\ x = 0.074,\ y = 0.140,\ z = -0.163\\ \mathrm{C_1}:&\ x_1 = 0.151,\ y_1 = 0.047,\ z_1 = 0.000\\ \mathrm{C_2}:&\ x_2 = 0.293,\ y_2 = 0.090,\ z_2 = 0.000 \end{aligned}$$

The values of the *z* parameters are those corresponding to the original model. Verification of these values is provided by the general agreement of calculated and visually estimated observed intensities of layer-line reflections (Table II).

Description and Discussion of the Structure

The crystal of metaldehyde is found to consist of molecules with the configuration shown in Fig. 1 arranged as shown in Fig. 5. The single-bond distances 1.43 Å. (C–O) and 1.54 Å. (C–C) and the tetrahedral bond angle 109° 28′ for both carbon and oxygen are verified within the accuracy of the investigation (±0.03 Å. and ±3°, respectively). The molecules are piled in columns along the *c*-axis. We expect the forces between adjacent molecules in a column to be large, because of the apposition of the negatively charged face of each molecule (formed by the four oxygen atoms of the staggered ring) to the positively charged face of the next molecule (formed by the hydrogen atoms attached to the ring carbon atoms).[8] On the other hand, the forces between columns are small, the molecules in one column presenting their relatively inactive methyl groups to those of the surrounding columns. In consequence the crystal cleaves easily into fibers.

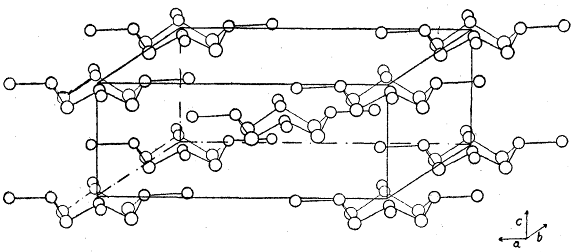

Fig. 5.—Arrangement of metaldehyde molecules in the unit cell.

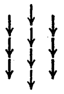
It is interesting that the translation by $c_0/2$ of each column relative to its four nearest neighbors brings the molecule dipole into an electrostatically stabilized configuration



in which the positive poles of one column are closer to the negative poles of neighboring columns than to their positive poles.

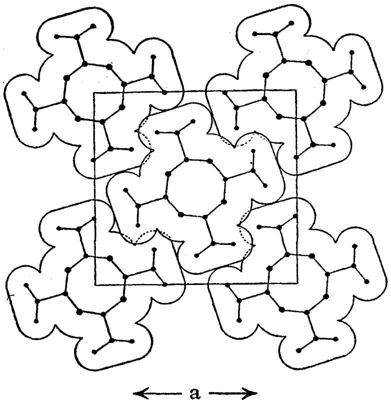


Fig. 6.—Packing diagram of metaldehyde molecules in the unit cell.

The packing of the molecules is shown in Fig. 6, drawn with packing radii of 1.0 Å. for hydrogen and 1.5 Å. for oxygen, the C–H distance being taken as 1.06 Å. and the methyl groups being assumed to rotate about the C–C bonds. Each methyl group is approximately equidistant from eight methyl groups of surrounding molecules, there being two at a distance of 3.90 Å., four at 4.03 Å., and two at 4.11 Å. (directly above and below), corresponding to a packing radius for the methyl group of 2.01 ± 0.06 Å. The variation observed in the methyl–methyl distances is not accidental; it is clearly the result of the shape of the methyl group. Interatomic distances between hydrogen atoms are found to be very closely equal, showing that a hydrogen atom attached to carbon can be assigned a packing radius and con-

---

[8] The parallel dipole moments of the molecules give rise to the observed pyroelectric effect.

sidered to behave as a sphere (so far as contacts in directions away from the carbon atom are concerned). This point of view has been especially emphasized by Mack[9] in connection with his interesting work on the packing of organic molecules. In metaldehyde, assuming rotation of methyl groups, the hydrogen–hydrogen distances corresponding to the methyl–methyl contacts mentioned above are 2.16 Å. (two), 2.15 Å. (four), and 2.11 Å. (two), giving for hydrogen the packing radius 1.07 ± 0.01 Å.

There may also be contact between oxygen and hydrogen atoms. Each oxygen atom is 2.68 Å. from two hydrogen atoms attached to ring carbons of the molecule below, and 2.70 Å. from a hydrogen atom in an adjacent column. These distances correspond to a packing radius for oxygen of 1.6 Å., which is somewhat larger than the ionic crystal radius 1.40 Å.

It is interesting to note that metaldehyde, like paraldehyde, contains no aldehyde groups, the oxygen atoms being ethereal in type.

We are indebted to Dr. S. Weinbaum for much assistance in the course of this investigation.

Summary

The tetragonal crystal metaldehyde is shown by x-ray examination to have a body-centered unit of structure with $a_0 = 10.40$ Å. and $c_0 = 4.11$ Å., containing two molecules of the tetramer, $(CH_3CHO)_4$. The atomic arrangement involves all atoms in general positions of the space group C_4^5–I_4, with the following parameter values: oxygen, $x = 0.074$, $y = 0.140$, $z = -0.163$; ring carbon, $x_1 = 0.151$, $y_1 = 0.047$, $z_1 = 0.000$; methyl carbon, $x_2 = 0.293$, $y_2 = 0.090$, $z_2 = 0.000$. The molecule contains an eight-membered –C–O–C– ring, with the carbon–oxygen distance 1.43 ± 0.03 Å., and methyl groups attached to ring carbon atoms, with the carbon–carbon distance 1.54 ± 0.03 Å. The bond angles of oxygen and carbon have the value 109.5 ± 3°. A discussion of the packing of the molecules and of the packing radii of the methyl group and hydrogen atom is given.

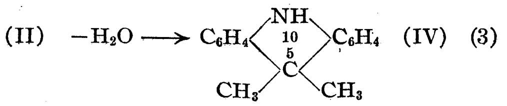
The Preparation of Acridanes by the Grignard Reaction

BY W. L. SEMON AND DAVID CRAIG

In previous publications[1a] *o*-*t*-butyldiphenylamine (III) has been identified as one of the two main products from the reaction of methylmagnesium iodide with methyl N-phenylanthranilate (I). The other product[1b] is shown here to be 5,5-dimethylacridane (IV) formed as indicated in reactions 1 and 3 by the dehydration of *o*-anilinophenyldimethylcarbinol (II).

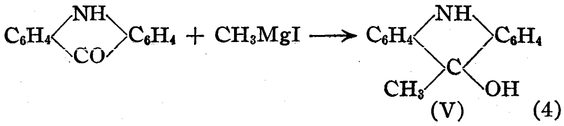
$$C_6H_5—NH—C_6H_4\text{-}o—CO—OCH_3\ (I) + CH_3MgI \longrightarrow$$
$$C_6H_5—NH—C_6H_4\text{-}o—C(OH)(CH_3)_2 \qquad (II) \quad (1)$$

$$(II) + CH_3MgI \longrightarrow$$
$$C_6H_5—NH—C_6H_4\text{-}o—C(CH_3)_3 \qquad (III) \quad (2)$$



$$(II)\quad -H_2O \longrightarrow C_6H_4\langle\overset{NH}{\underset{C(CH_3)_2}{\ }}\rangle C_6H_4 \qquad (IV) \quad (3)$$

The acridane (IV) has not previously been described and identified although some may have been contained in the material isolated following the action of sodium on commercial acridine.[2] The 5,5-diphenylacridane[3] and certain amino derivatives of acridane[4] have been prepared by reactions similar to the ones used here. While this method of formation is strong evidence for the accuracy of the formula assigned to IV, it is not beyond the realm of possibility that the product might have been *o*-isopropenyldiphenylamine. A more conclusive proof for the presence of an *o*,*o*′-carbon bridge was found in the synthesis of IV from compounds such as acridone or 5-methylacridine already containing the heterocyclic nucleus. This was accomplished by reactions 4 and 6



$$C_6H_4\langle\overset{NH}{\underset{CO}{\ }}\rangle C_6H_4 + CH_3MgI \longrightarrow C_6H_4\langle\overset{NH}{\underset{C(CH_3)(OH)}{\ }}\rangle C_6H_4 \qquad (V) \quad (4)$$

$$V + CH_3MgI \longrightarrow IV$$

$$V - H_2O \longrightarrow C_6H_4\begin{matrix}N\\ C\\ CH_3\end{matrix}C_6H_4 \quad (VI) \qquad (5)$$

$$VI + CH_3MgI \longrightarrow IV \qquad (6)$$

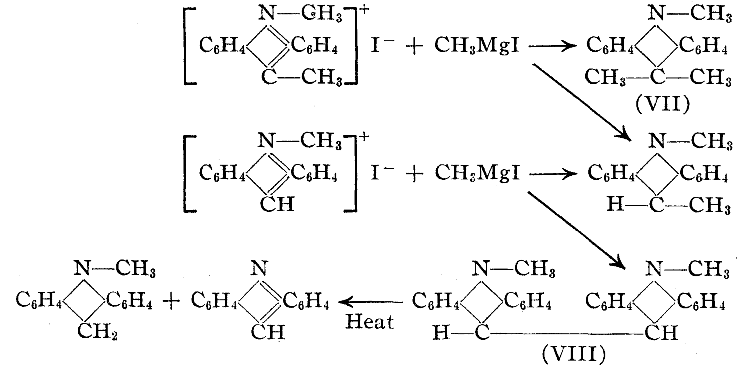
In some respects reaction 4 is similar to reaction 2 and might indicate the direct replacement of oxygen by Grignard reagent;[5] however, a two-stage reaction such as the 1,4-addition of methylmagnesium iodide to an unsaturated intermediate is not precluded[6] as a means for explaining the formation of III, or of IV from reaction 6.

Higher homologs of IV have been prepared by these same reactions. Thus ethylmagnesium bromide reacts with I to yield an oil analyzing satisfactorily for *o*-anilinophenyldiethylcarbinol. On dehydration there is obtained 5,5-diethylacridane and an isomer, possibly *o*-pentenyldiphenylamine. The formation of *o*-*t*-heptyldiphenylamine was not observed. The isolation of the two isomers emphasized the desirability for preparing the acridane by a reaction similar to reaction 4. Both the 5,5-diethylacridane and the 5,5-di-*n*-butylacridane were thus prepared from caridone and the appropriate alkylmagnesium halides.

In all of the cases discussed so far the alkylmagnesium halide has reacted with =NH or –N= to form N-magnesium halides. These have been hydrolyzed to the corresponding NH compounds as is usual in the process of working up such reaction mixtures.[7]

Where the nitrogen has an alkyl group attached as in the 5-alkylacridinium salts, the reaction with alkylmagnesium halide becomes more complex. Freund and Bode[8] reported 5,5-diethyl-10-methylacridane formed by the reaction of 5-ethylacridine methiodide with ethylmagnesium bromide and of 5,10-di-methylacridane by a similar reaction. Further, Stevens, *et al.*,[9] reported 5,5,10-trimethylacridane as a product from the reaction of methylmagnesium iodide with 5-methylacridine methiodide or with 5-cyano-5,10-dimethylacridane. However, the compounds reported were not well characterized and that described as trimethylacridane is probably, in the light of the present work, a mixture of this compound (m. p. 100–102°) and of 5,10-dimethylacridane (m. p. 140–141°). Freund and Bode[8a] failed to mention the formation of acridine from the reaction of methylmagnesium iodide and acridine methiodide and did not record the isolation of any high melting compound. We have subsequently isolated such a material and assigned formula VIII as it is probably the N,N′-dimethyl homolog of diacridane. The melting point of this compound, due to decomposition, varied with the rate of heating and the product of pyrolysis contained acridine and 10-methylacridane, thus behaving in a manner quite similar to the unsubstituted diacridane.[10]

Reaction 7 accounts for the products obtained when acridine methiodide and 5-methylacridine methiodide were treated with methylmagnesium iodide.



(7)

The further observation that the original acridine is reformed when the corresponding methiodide is treated with Grignard reagent indicates the reversible character of the formation of acridinium salts; thus the consumption of alkyl halide by some reagent such as the Grignard favors the decomposition and explains the formation of the ethane which is evolved as a gas in the course of the reaction.

The low yields and many products observed from the reaction of acridinium salts and Grignard reagent indicate that the products may not be formed in a single reaction but rather in a series of concurrent ones. If we generalize in re-

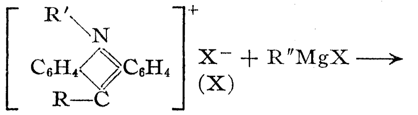
gard to a reaction such as reaction 8, it may be seen that the Grignard reagent may add in two



(8)

different ways in a 1,4-manner and in a larger number of ways if the less likely 1,2-addition is to be considered. The MgX portion may therefore be attached through N or through C. Where the attachment is to N there should be formed 5,5,10-trisubstituted acridane; where the attachment is to C there is formation of a new more complex Grignard reagent along with generation of alkyl halide which may occur in at least two ways. Further, the various Grignards now present may react with the alkyl halides and unsaturates to give a multiplicity of products which may account for the evolution of hydrocarbon noted. Specifically if the C attached MgX derivative reacts with X there is formed a complex salt which gives rise to a diacridane derivative of the type VIII already mentioned. Further, since acridines may be liberated from the acridinium salts by Grignard reagents as previously mentioned the possibility of these reacting further should not be overlooked. Pseudo-salt formation as an alternate for reaction 8 explains all of the products so far isolated but does not predict quite as many products in the case of higher homologs. The extent to which the formation of reduction products was due to unreacted magnesium was not determined.

Properties of 5,5-Dimethylacridane.—5,5-Dimethylacridane (IV) shows the typical reactions of a diarylamine. It dissolves readily in concentrated sulfuric acid and less readily in concentrated hydrochloric acid to form colorless solutions from which the free base precipitates on dilution with water. It forms N-acetyl, N-phenyl, N-methyl and N-metallic derivatives, showing the presence of a secondary amino group. One interesting reaction that indicates its similarity to many other hydrocarbon substituted diarylamines is the formation of 5-methylacridine by heating with hydrochloric acid, an essential reversal of the reaction by which it is formed from methylmagnesium iodide and 5-methylacridine. This reaction also occurs on refluxing IV with its N-sodium salt. The absence of an unsaturated side chain in the molecule is shown by the remarkable stability of IV on prolonged refluxing with aqueous potassium permanganate. 5,5-Dimethylacridane in a manner entirely similar to other diarylamines readily forms fairly stable yellow double compounds with acridine and 5-methylacridine.[11]

Experimental Part

5,5-Dimethylacridane (IV).—This compound prepared as previously described[1a] was reported as melting at 122–124°. After further recrystallization it was found to melt at 125–126°. Addition of 17 g. (0.088 mole) of 5-methylacridine to a solution of 0.3 mole of methylmagnesium iodide in 100 cc. of *n*-butyl ether at 100° produced no apparent reaction. When the mixture was heated to boiling, a vigorous reaction set in. After refluxing for thirty minutes the mixture was poured into ice water containing 30 cc. of glacial acetic acid. A solid precipitated which proved to be 5-methylacridine hydroiodide, yield 11.5 g. The butyl ether layer was separated, dried and upon distillation gave 3.5 g. of a product boiling at 155° at 1 mm. Recrystallization gave 2.5 g. of pure 5,5-dimethylacridane of the same melting point as the material prepared from methyl N-phenylanthranilate. This compound was also prepared by adding 18 g. (0.092 mole) of acridone to 0.3 mole of methylmagnesium iodide in di-*n*-butyl ether. Reaction began at 80° but, due to the insolubility of the acridone, it was not complete even after refluxing for thirty minutes. There were isolated from the crude reaction product, 6 g. of 5-methylacridine and 2.5 g. of 5,5-dimethylacridane or yields of 44 and 17%, respectively, of these compounds based upon the unrecovered acridone (14 g.).

Anal. Calcd. for $C_{15}H_{15}N$: C, 86.07; H, 7.23; N, 6.70. Found: C, 86.0, 86.3; H, 7.28, 7.29; N, 6.96, 6.80.

The acetyl derivative was prepared by reaction of IV with acetyl chloride and crystallization from hexane. It melted at 153–154°. The benzoyl derivative was prepared by reaction with benzoyl chloride and, when crystallized from *o*-dichlorobenzene, melted at 294–297°.

5,5-Dimethylacridane is easily soluble in concentrated sulfuric acid from which it is precipitated by the addition of water. This property is useful for separating IV from other compounds which may be either less soluble in concentrated acid, or soluble and more strongly basic so that soluble, stable salts remain unhydrolyzed on dilution. 5,5-Dimethylacridane dissolves less readily in concentrated hydrochloric acid. A solid hydrochloride is not formed under these conditions. The free base precipitates on the addition of water. The solutions both in sulfuric and in hydrochloric acid are colorless, thereby distinguishing the compound from an acridine. The reaction of IV with iodobenzene according to Goldberg's[12] method gave an N-phenyl derivative, m. p. 123°, after crystallization from alcohol. The mixed melting point of this derivative and of the parent compound was lower than either. 5,5-Dimethylacridane reacted with sodium or sodamide much like diphenylamine and formed the N-sodium derivative.

---

(11) Blum, *Ber.*, **62**, 891 (1929), described the corresponding double compounds of diphenylamine with these acridines as well as the double compound of 5-methylacridine with 5-methylacridane.

(12) Goldberg, *ibid.*, **40**, 4541 (1907).

Forty grams of 5,5-dimethylacridane and 0.5 g. of sodamide were heated gently until the evolution of ammonia was complete. The temperature was then raised to the refluxing point and maintained for forty-five minutes. A combustible gas was evolved slowly. The product was cooled and shaken with 100 cc. of benzene and the mixture extracted with three 50-cc. portions of 5% sulfuric acid. On making the extracts alkaline 2 g. of 5-methylacridine separated. After crystallizing from a mixture of benzene and hexane it melted at 117–119°. Heating a mixture of 5,5-dimethylacridane (0.3 mole), hydrogen chloride (0.15 mole) and diphenylamine (0.45 mole) in an autoclave for three hours at 250° gave 5-methylacridine and a combustible gas, presumably methane. The acid was neutralized and the non-aqueous portion distilled. The bright yellow double compound of 5-methylacridine with 5,5-dimethylacridane separated on crystallization from hexane. The melting point, 124°, was depressed not at all or only a few degrees by the addition of varying quantities of 5,5-dimethylacridane.

Anal. Calcd. for $C_{15}H_{15}N \cdot C_{14}H_{11}N$: C, 86.52; H, 6.52; N, 6.96. Found: C, 86.65; H, 6.51; N, 7.04.

The same compound was also prepared by mixing equimolecular quantities of the components dissolved in hot hexane or alcohol solution and cooling. Plates were secured from alcohol and needles from hexane. The corresponding double compound of 5,5-dimethylacridane with acridine melted at 135–136° when crystallized from hexane. The acridine components can be separated readily from these double compounds by repeated extraction with dilute sulfuric or nitric acid. Hydrochloric acid is less suitable because of the low solubility of the acridine hydrochlorides in water.

5,5-Dimethylacridane showed no signs of reaction with boiling aqueous potassium permanganate during four hours, the starting material being recovered unchanged.

During some experiments on the melting and freezing of 5,5-dimethylacridane it was found that a low melting (m. p. 92–93°) form could be obtained by careful cooling. It was unstable in the presence of the high melting form.

5,5,10-Trimethylacridane, 5,10-Dimethylacridane and Related Compounds.—The trimethyl derivative was prepared by treating the sodium salt of IV with methyl iodide in refluxing toluene. The sodium iodide was washed out with water and the oil fractionally distilled. Unreacted IV was then separated from its N-methyl derivative by crystallizing from a mixture of hexane and benzene. The N-methyl derivative melted at 100–102°.

Anal. Calcd. for $C_{16}H_{17}N$: C, 86.04; H, 7.68; N, 6.28. Found: C, 85.88; H, 7.64; N, 6.49.

In order to repeat the work of Stevens, *et al.*,[9] 0.072 mole of finely powdered 5-methylacridine methiodide[13] (m. p. 265–267°) was added to 0.30 mole of methylmagnesium iodide in 100 cc. of ether during five minutes. Reaction took place rapidly with the disappearance of the red color of the methiodide and with the evolution of a gas. The mixture was refluxed for forty minutes and then hydrolyzed with dilute acetic acid. Benzene (100 cc.) was added and the ether distilled. The residue was filtered, yielding 4.5 g. of solid material that was not identified. The benzene layer was distilled and yielded 10.5 g. of material at 160–170° (1.5 mm.). This on crystallization from a mixture of benzene and hexane gave 1.5 g. of crystals of m. p. 140–141° and 1.5 g. of less pure product of m. p. 138–140°. This product is 5,10-dimethylacridane.

Anal. Calcd. for $C_{15}H_{15}N$: C, 86.07; H, 7.23; N, 6.70. Found: C, 86.05; H, 7.13; N, 6.99.

The mother liquor was extracted with dilute hydrochloric acid to remove colored by-products and on evaporation yielded 1 g. of crystals melting at 92–98°. These on crystallization from hexane melted at 100–102°, alone or mixed with the above described 5,5,10-trimethylacridane.

The 5,10-dimethylacridane just described was identified by mixed melting point with the compound prepared from the addition of 0.1 mole (32.1 g.) of acridine methiodide (m. p. 206–209°, dec.) to a well-cooled solution of 0.3 mole of methylmagnesium iodide in 100 cc. of ether. Reaction occurred with the evolution of a gas, presumably ethane, and precipitation of a solid. The mixture was hydrolyzed with ice and dilute acetic acid in the usual way. A considerable amount of solid (12 g.) was filtered off. From the filtrate there were obtained acridine and 5,10-dimethylacridane; yield 8.5 g. A small amount of impurity in the latter compound may have been 10-methylacridane.[14]

The solid after crystallizing twice from toluene melted with decomposition at about 280°.

Anal. Calcd. for $C_{28}H_{24}N_2$: C, 86.55; H, 6.23; N, 7.21. Found: C, 86.87; H, 6.08; N, 7.43.

Three grams of this solid was heated to reflux for three minutes, during which time the temperature reached 350°. The product was treated with 50 cc. of concentrated hydrochloric acid and filtered to remove a small amount of insoluble matter. Several volumes of water were added. The oil thus precipitated soon crystallized and was then filtered off. Four tenths gram of acridine was recovered from the filtrate by distilling the organic bases precipitated by the addition of sodium hydroxide. The product that was filtered off was dissolved in benzene. In order to remove traces of acridine the benzene solution was extracted repeatedly with dilute hydrochloric acid and finally with water. Distillation of the benzene solution produced 0.7 g. of crude 10-methylacridane. It melted at 91–93° after recrystallizing twice from petroleum ether.

Anal. Calcd. for $C_{14}H_{13}N$: C, 86.11; H, 6.72; N, 7.17. Found: C, 86.10; H, 6.82; N, 7.31.

A reaction of methylmagnesium iodide with acridine hydroiodide under the conditions used for acridine methiodide gave approximately a 15% yield of acridane along with some unreacted acridine. Attempts to isolate 5-methylacridine from the products were not successful.

5,5-Diethylacridane.—Thirty grams (0.132 mole) of methyl N-phenylanthranilate in 150 cc. of ether was added to 0.6 mole of ethylmagnesium iodide in 150 cc. of ether during twenty-five minutes. The heat of reaction caused the mixture to boil. A greenish-yellow color developed and a small amount of precipitate appeared. Stirring was continued for forty minutes during which time more of the precipitate formed. The mixture was allowed to stand at room temperature for three days, hydrolyzed with dilute

[14] Bergmann, Blum-Bergmann and Christiani, *Ann.*, **483**, 80 (1930).

acetic acid in the usual way and distilled. The product boiled at 175° (2 mm.); yield 27 g. (79%).

Anal. Calcd. for $C_{17}H_{21}NO$: C, 79.94; H, 8.30; N, 5.49. Found: C, 79.76; H, 8.39; N, 5.66.

These values are in agreement with the empirical formula of *o*-anilinophenyldiethylcarbinol.

The product was dehydrated by dissolving in concentrated sulfuric acid and pouring into water. Distillation of the oil obtained and crystallization from hexane separated it into a white solid, m. p. 90–91°, and an oil, b. p. 150–155° (2 mm.).

Anal. Calcd. for $C_{17}H_{19}N$: C, 86.02; H, 8.07; N, 5.91. Found for the solid: C, 85.99; H, 8.19; N, 6.08. Found for the oil: C, 86.01; H, 8.10; N, 5.89.

The oil contained a small amount of the solid and was probably largely an *o*-pentenyldiphenylamine. The solid was shown to be 5,5-diethylacridane by its synthesis as follows: 18 g. (0.092 mole) of acridone was added rapidly to 0.3 mole of ethylmagnesium bromide in 150 cc. of *n*-butyl ether at 100°. A vigorous reaction ensued causing the temperature to rise to 120°. The mixture was refluxed and stirred for two hours. When this was poured into water a greenish precipitate separated which was filtered off after the addition of 25 cc. of acetic acid and standing overnight; yield 7 g.; m. p. 250–270°. The ether layer was separated and distilled. A fraction, b. p. 150°(2 mm.)–165° (3 mm.), weighing 11 g. and a residue of 5 g. was obtained. The fraction, b. p. 150°(2 mm.)–165° (3 mm.) gave 7 g. (34% yield) of 5,5-diethylacridane which when recrystallized from hexane melted at 90–92° alone or mixed with the solid product obtained from methyl N-phenylanthranilate.

5,5-Di-*n*-butylacridane.—This compound was prepared in refluxing ethyl ether from 13 g. (0.067 mole) of acridone and 0.4 mole of *n*-butylmagnesium bromide. The initial reaction took place rapidly. After thirty minutes the ethyl ether was distilled off and the mixture refluxed in *n*-butyl ether for thirty minutes. The mixture was hydrolyzed in the usual manner with acetic acid and the product distilled and crystallized from hexane; m. p. 87–88°, b. p. 173–183° (2 mm.). The yield of pure product was 4 g. (24%).

Anal. Calcd. for $C_{21}H_{27}N$: C, 85.94; H, 9.28; N, 4.78. Found: C, 85.96; H, 9.16; N, 4.86.

Summary

1. The preparation of 5,5-dialkylacridanes by the reaction of acridines, acridinium iodides, acridone and methyl N-phenylanthranilate with Grignard reagents is described.

2. The following new compounds were prepared: 5,5-dimethylacridane, 5,5,10-trimethylacridane, 5,5-diethylacridane, *o*-anilinophenyldiethylcarbinol, 5,5-di-*n*-butylacridane and the double compounds of acridine and 5-methylacridine with 5,5-dimethylacridane.

3. The properties of 5,5-dimethylacridane are described in considerable detail.

The Synthesis of Dibenzoyl Disulfide

BY R. S. SHELTON AND T. H. RIDER

Amberg and Brunsting[1] recently investigated the use of dibenzoyl disulfide,[2] and found it of considerable value as an antipruritic. Their favorable preliminary clinical report suggested that a detailed study of the properties and methods of preparing dibenzoyl disulfide might be of interest and value, especially as applied to the commercial production of a medicinally pure product.

A check of the previous literature[3] on this product failed to give a method of preparation which was economically feasible.

It was found early in this investigation that sodium thiobenzoate is easily formed by the reaction of benzoyl chloride with 35% aqueous sodium hydrosulfide. The thiobenzoate was not, however, oxidized to any great extent in the reaction mixture to the desired disulfide. The reaction was tried in alcoholic solution, but without much better result, due to the reaction of the alcohol with the acid chloride.

A further investigation of the oxidation of the thiobenzoate yielded satisfactory results. Engelhardt, Latschinoff and Malyscheff[4] had previously studied the oxidation of thiobenzoic acid by the action of air, cupric sulfate, ferric chloride, potassium triiodide and potassium ferricyanide. These and other oxidation agents were investi-

(2) Dibenzoyl disulfide was referred to in the original clinical report[1] as "benzoyl persulphide," an inaccurate nomenclature since it does not distinguish between the di-, tri- or tetra-sulfides, all of which are known [I. Block and M. Bergmann, *Ber.*, **53**, 961 (1920)].

gated and concentrated hydrogen peroxide was found to give the best results. It was found also that thiobenzoic acid is oxidized more smoothly than the sodium salt, and that oxygen was very useful in aiding the oxidation of the thiobenzoate as it was formed in the reaction mixture. From these preliminary findings, a method was developed,[5] easily applicable to large-scale production, in which thiobenzoic acid is oxidized as completely as possible by air and oxygen at the time of its formation in the reaction mixture, and after acidification the oxidation of the filtrate is completed with concentrated hydrogen peroxide.

$$\mathrm{C_6H_5COCl + 2NaHS \longrightarrow C_6H_5SOSNa + NaCl + H_2S}$$

$$\mathrm{2C_6H_5COSNa\ (also\ C_6H_5COSH) + H_2O_2 \xrightarrow{[O]} C_6H_5COSSCOC_6H_5 + H_2O}$$

Experimental

A 22-liter flask is fitted with a motor stirrer, inlet tubes for oxygen, a tube connected to the water pump to aid in the removal of hydrogen sulfide and a dropping funnel. The flask is placed in an ice-bath, and to it is added 10.6 liters of commercial 35% sodium hydrosulfide solution. The stirrer and suction pump are adjusted, the flow of oxygen started, and through the dropping funnel 7.4 liters of benzoyl chloride are added slowly over a period of five or six hours. The first 500 cc. of benzoyl chloride must be added slowly, allowing sufficient intervals of time for the materials to react completely. Failure to observe these precautions results in a violent reaction which is difficult to control. After the addition of the benzoyl chloride has been completed, an excess of sodium hydrosulfide solution is added to make sure that the reaction has gone to completion. A completed reaction is evidenced by the cessation of hydrogen sulfide evolution. The reaction mixture is then allowed to stand overnight.

The following day the precipitate (about 4700 g.) is filtered, washed thoroughly with water to remove adhering chlorides and dried in a stream of air. Any thiobenzoic acid which has escaped oxidation and which may have adhered to the precipitate is oxidized completely by this process. The filtrate and washings are cooled in an ice-bath, then acidified with concentrated sulfuric acid. Air or oxygen is bubbled through the cool solution, and 1200 cc. of 30% hydrogen peroxide added in 25-cc. portions over a period of three or four days.

It is important that during this time the solution be kept acid, and that the oxidation by means of air and oxygen be continued until no more precipitate is formed. The precipitate is then filtered, washed with about 5 liters of water and added to the original crop of dibenzoyl disulfide. The crude material is then broken up in small portions and air dried for several days.

Many solvents were investigated in a study of the purification of the crude dibenzoyl disulfide, but none was found to give a pure white material from one recrystallization. Purification is best accomplished as follows. The crude dibenzoyl disulfide is dissolved in ethylene dichloride at 60° in the ratio of 3 kg. to 6 liters of solvent. The resulting solution is faintly pink. It is important that the temperature of the solvent at the time of solution be 60° or less since the disulfide assumes a decided permanent pink color above that temperature. One liter of saturated sodium bicarbonate solution is added, and the mixture stirred vigorously for an hour. This is done in the absence of heat, as the prolonged heating of benzoyl disulfide in the presence of alkalies results in its decomposition, *i. e.*

$$\mathrm{C_6H_5COSSCOC_6H_5 + 2NaOH \longrightarrow C_6H_5COSNa + C_6H_5COONa + S + H_2O}$$

The alkali purification removes the benzoic acid which is present as an impurity. It was found that sodium bicarbonate gave less decomposition than dilute sodium hydroxide.[6] The layers are allowed to separate, and the ethylene dichloride layer is filtered. Two liters of alcohol (special denatured formula 3A is satisfactory) are added to the filtrate which is then cooled overnight at a temperature of from 0 to 5°. The precipitate is filtered and washed with about 300 cc. of ether. The filtrate is then cooled to −15° and a second crop is obtained, generally of sufficient purity to be added to the first crop. The total yield of purified dibenzoyl disulfide, after air drying, is about 5.5 kg. (yields of 5.9 kg. were obtained on some runs). Yields of about 80% of crude material were obtained; yields of purified material were about 65 to 70% of the theoretical.

Dibenzoyl disulfide is reported in the literature as a white to faintly pink crystalline solid, but there is lack of agreement as to its melting point. Dibenzoyl disulfide, purified by the method described, is a faintly pink (Norite did not remove this coloration) crystalline solid, melting with decomposition to a pink liquid between 128 and 129°, in a capillary tube preheated to 100°. Further recrystallization from ethylene dichloride or carbon disulfide gave beautiful colorless plates melting at 129–130° in the preheated capillary tube or at 132° on the bar.[7]

Anal. Calcd. for $\mathrm{C_{14}H_{10}O_2S_2}$: C, 61.27; H, 3.67; S, 23.38. Found: C, 60.68; H, 4.21; S, 23.55.

Analytical Degradations of Dibenzoyl Disulfide[8]

In an effort to establish beyond doubt the structure of the product prepared by the above method, we have found that in addition to the routine sulfur analysis, it was advisable to work out a method of analytical degradation by which the benzoic acid could be recovered. While it was found possible to prepare benzanilide quantitatively by simple refluxing with aniline, it was impossible to free the benzanilide completely from sulfur without loss of the benzanilide. Dibenzoyl disulfide was found to be quite resistant to hydrolysis under most conditions, but the following method gave yields of from 98 to 99.2% of benzoic acid.

[5] T. H. Rider and R. S. Shelton, U. S. Patent 2,028,246, January 21, 1936.

[6] Grateful acknowledgment is made to Dr. E. S. Cook for suggesting the use of sodium bicarbonate and for checking the method of preparation and purification.

[7] L. M. Dennis and R. S. Shelton, THIS JOURNAL, **52**, 3128 (1930).

[8] The method described was worked out by E. S. Cook and Karl Bambach.

Procedure for Analytical Degradation of Dibenzoyl Disulfide to Benzoic Acid.—Reflux 1 g. of dibenzoyl disulfide with 30 cc. of 40% w/v potassium hydroxide solution in a 100-cc. round-bottomed flask for three hours. Cool, transfer to a separatory funnel (rinsing out flask with water), acidify with concentrated hydrochloric acid, and allow to cool. Shake the benzoic acid into ether, using five portions (total of 120 cc.) and collect the ether extracts in another separatory funnel. Wash the ether with 25 cc. of approximately 0.1 *N* hydrochloric acid, and then wash this aqueous portion with 15 cc. of ether. Combine the ether extracts and filter through cotton into a beaker, washing the cotton with fresh ether. Evaporate the ether with the aid of a stream of air. (Evaporation may be hastened by placing the beaker in a water-bath at not over 40° until 30 cc. remains; then remove from water-bath and complete removal with air.) Treat the residue with a solution of 1.5 g. of sodium bicarbonate in 50 cc. of water. Warm the mixture and allow it to stand until all the benzoic acid has dissolved; the sulfur will be practically insoluble. Filter the liquid through a coarse filter paper into a separatory funnel and wash the paper thoroughly with water. Acidify the sodium benzoate solution with 10% hydrochloric acid, allow it to cool, and shake out the benzoic acid with chloroform, using five portions (total of 100 cc.). Collect the chloroform extracts in another separatory funnel. Wash the chloroform with 20 cc. of approximately 0.1 *N* hydrochloric acid, and then wash this aqueous portion with 10 cc. of chloroform. Filter the combined chloroform extracts through cotton into a tared beaker and evaporate the chloroform with the aid of a stream of air, placing the beaker in a water-bath at a temperature of not over 40° as before. Dry the benzoic acid overnight in a vacuum desiccator over sulfuric acid and weigh.

Summary

A new practical method for preparing medicinally pure dibenzoyl disulfide is described.

Some N-Aryl Barbituric Acids

BY JOHANNES S. BUCK

In connection with a study of the hypnotic action of certain unsymmetrical alkylaryl ureas,[1] it was desirable to obtain a series of 1-aryl barbituric acids, having the aryl group the same both for the ureas and for the barbituric acids. Two series were therefore prepared, one having 5,5-diethyl groups and the other 5,5-ethyl-*n*-butyl groups, the N-aryl groups in both series being phenyl, *o*-, *m*- and *p*-tolyl, *o*-, *m*- and *p*-anisyl, *o*-, *m*- and *p*-phenetyl, and α- and β-naphthyl. Hjort and Dox[2] have previously described briefly four of the diethyl compounds, but they failed to crystallize the 1-phenyl-5,5-ethyl-*n*-butyl compound, and to obtain the 1-*p*-ethoxyphenyl-5,5-ethyl-*n*-butyl derivative. The complete series (24) is here described. The pharmacological examination will be published in another place.

Experimental

The ethyl diethylmalonate used was purchased. Ethyl *n*-butylethylmalonate was prepared in good yield by butylating ethyl ethylmalonate, in the usual way by means of sodium ethylate and *n*-butyl iodide. The ester boiled sharply at 109° (1.4 mm.) or 125–126° (11 mm.). When prepared by ethylating ethyl *n*-butylmalonate, no sharp boiling point could be obtained.

The barbituric acids were all prepared by the usual reaction. 0.05 mole (10.8 g. and 12.2 g.) of the dialkylmalonate was added to 0.2 atom (4.6 g.) of sodium dissolved in the minimum amount of absolute alcohol; 0.05 mole of the requisite urea was added and the mixture refluxed for four to five hours. The solution was then cooled, diluted with water, made just acid to Congo red, and most of the alcohol removed, by a current of air, on the steam-bath. The residue was extracted with ether and the ether washed three times with saturated sodium bicarbonate solution, to remove hydrolysis products (very little of the barbituric acid was lost). The washed ether was then extracted with 80 cc. of 10% sodium hydroxide solution, water being added if necessary. On acidification of the alkaline solution the barbituric acid separated, usually as an oil, and was extracted with ether or filtered off and recrystallized until pure, alcohol or slightly aqueous alcohol being the solvent, unless otherwise noted. A few of the ethyl-*n*-butyl compounds were very difficult to purify and required elaborate treatment.

The bicarbonate washings contain uncyclized compounds, which are usually small in amount. They can be isolated by acidifying the solution. Some were examined but are not recorded here. The residual ether contains unchanged urea, ester and decomposition products.

The barbituric acids are tabulated below. Variations in the foregoing procedure are indicated in footnotes. The compounds are all white, crystalline and tasteless. They are soluble in cold 5% sodium hydroxide solution, practically insoluble in water, slightly soluble to insoluble in petroleum ether (the low-melting ones are more soluble), moderately to readily soluble in ether, readily soluble to very soluble in alcohol, and from moderately soluble to

[a] Not obtained crystalline by Hjort and Dox.[2] Reaction product was distilled (b. p. 203° at 0.5 mm.), rejecting the white sublimate first over. The distillate (stiff resin) was repeatedly recrystallized from carbon disulfide–heptane at 0°, a very tedious operation. The melting point is unsharp. The compound is very soluble in the usual solvents.

[b] These three compounds have recently been obtained crystalline, without the use of distillation, but distillation is preferable, and is essential in order to obtain seeding crystals.

[c] Repeatedly recrystallized from ether.

[d] As footnote [a]. B. p. 212° (0.6 mm.).

[e] After three recrystallizations from aq. alcohol, the product was partly dissolved in ether and the residue recrystallized from ether.

[f] Benzene used for extractions in place of ether.

[g] The reaction product was distilled (b. p. 225–230° at 1.2 mm.) rejecting the white sublimate first over. The distillate was dissolved in carbon disulfide, precipitated with petroleum ether, and kept at the b. p. (216° at 0.5 mm.) until about one-third had distilled over. The residue was crystallized from carbon disulfide–heptane and recrystallized from heptane, then ether, all at 0°. Many months were needed to obtain crystals.

[h] Hjort and Dox[2] obtained only an uncyclized product.

[i] After three recrystallizations from alcohol, the product was again extracted with ether and the ether extracted with another portion of sodium hydroxide solution. After acidification, the precipitate was recrystallized from alcohol, partly dissolved in ether, and the residue recrystallized from alcohol.

very soluble in benzene. The average yield, after drastic purification, is about one-half the weight of ester used, but considerable additional amounts may be recovered from the crystallization liquors. In general, the *m*-aryl compounds show greatly increased solubility and lower melting points, than the ortho and para isomers. The ethyl-*n*-butyl homologs melt lower than the corresponding diethyl compounds.

The ureas used are mostly described, with appropriate references, by Buck, Hjort and deBeer.[3] *p*-Phenetyl urea was purchased from the Eastman Kodak Co. α-Naphthyl urea[4] and β-naphthyl urea[4a] were made by the nitrourea–alcohol method.[5]

(5) Buck and Ferry, THIS JOURNAL, **58**, 854 (1936).

The analyses (micro-Dumas) were carried out by Mr. W. S. Ide. The melting points are corrected.

Summary

A series of 1-aryl-5,5-diethyl barbituric acids, and a series of 1-aryl-5,5-ethyl-*n*-butyl barbituric acids, have been prepared, the substituent N-aryl groups in both series being phenyl, *o*-, *m*- and *p*-tolyl, *o*-, *m*- and *p*-anisyl, *o*-, *m*- and *p*-phenetyl, and α- and β-naphthyl. The aryl radicals were selected in order that comparisons might be made, pharmacologically, with a series of alkylaryl ureas having these radicals.

Biochemical Studies in the Genus Rhizopus. I. The Production of Dextro-Lactic Acid[1]

By G. E. Ward, L. B. Lockwood, O. E. May and H. T. Herrick

Introduction

The production of lactic acid by microörganisms has, in general, been regarded heretofore as an attribute of bacteria, and not characteristic of the fungi. The prevailing conceptions regarding the relation of lactic acid to microbiological metabolism were summarized by Raistrick[2] in 1932: "It is a striking fact that lactic acid has never been reported as a mould metabolic product, although it is produced in larger or smaller quantities by many bacteria." Raistrick and other authors who have made similar statements have probably had in mind the biochemical activities of organisms of genera such as Aspergillus, Penicillium and Fusarium, which, indeed, have never been known to yield lactic acid. However, several investigators have reported lactic acid production in varying quantities by certain organisms of the genera Rhizopus and Mucor.

Since an accurate summary of the literature has never before appeared, and since some of the work is not conveniently reached or translated, it is briefly summarized here. In 1894, Eijkmann[3] suggested that the small quantity of acid produced by *Mucor rouxii* (*rouxianus*) was probably lactic acid, and Chrzaszcz[4] later confirmed this view. Shortly thereafter there were issued patents[5] which described the production of lactic acid by a mold termed "Lactomyces." The culture was of doubtful authenticity, but was probably a Rhizopus. In 1911, Saito[6] reported that *Rhizopus chinensis* produced *l*-lactic acid when cultivated on glucose solutions, and in 1919, Ehrlich[7] stated that in cultures of certain Rhizopus species which produced principally fumaric acid, there occurred small quantities of *d*-lactic acid, succinic acid, and *l*-malic acid.

Takahashi and co-workers[8] showed that up to 38% of the fermented glucose was converted to *l*-lactic acid by certain species of Rhizopus. Varying quantities of fumaric acid, succinic acid, *l*-malic acid, formic acid, acetic acid and ethyl alcohol were also found in these cultures. In 1933, Takahashi and Asai[9] found that four species of Mucor produced traces of lactic acid, in addition to acetaldehyde, ethyl alcohol, pyruvic acid and succinic acid. Ethyl alcohol was the principal product of these fermentations.

In 1930, Kenji Miyaji[10] reported that a new Monilia species isolated from commercial cultures of soy sauce produced *d*-lactic acid and succinic acid when cultured on artificial media containing glucose.

The highest yields of *d*-lactic acid from carbohydrates by fungi heretofore obtained were recently reported by Kanel,[11] who found that a fungus resembling *Rhizopus japonicus* converted 38 to 40% of the consumed invert sugar or starch to this acid. Fumaric acid accumulated in older

[a] Relatively poor development. Complete analysis not made.

cultures, in addition to small quantities of other unidentified acids.

Discussion

In the course of a survey of the biochemical activities of fungi of the genus Rhizopus conducted in this Division, it was found that certain organisms, when cultivated on a glucose-nutrient medium in the presence of calcium carbonate, induced a vigorous fermentation, with the formation of soluble calcium salts, which were found to consist principally of calcium *d*-lactate, with varying quantities of calcium fumarate. Two of the organisms (*Rhizopus oryzae* 394 and *R. oryzae* 395) were outstanding in their ability to convert glucose to *d*-lactic acid, the yields of up to 62% far exceeding those previously reported for fungi.

Ammonium nitrate, ammonium sulfate, and urea were satisfactory nitrogen sources, but none of the organisms developed well or utilized the glucose to an appreciable extent when sodium nitrate was supplied. When cultivated in the absence of calcium carbonate, the organisms generally utilized only a small quantity of the glucose, and developed in the medium only a slight acidity, usually equivalent to not more than 30 cc. of 0.1 *N* potassium hydroxide per flask (75 cc. of culture solution).

Certain strains (two strains of *Rhizopus sp.*, four strains of *R. nigricans*, one of *R. microsporus* and one of *R. chinensis*) produced very little acid under any of the conditions studied. Some strains, particularly one *R. nigricans* and the *R. chinensis*, formed appreciable quantities of ethyl alcohol when urea was used as the nitrogen source and calcium carbonate was absent.

A summary of the activities of organisms which were noteworthy in acid production is presented in Table I. Calcium carbonate was present in all these cases.

From the data presented, it is evident that several Rhizopi are able to convert the major portion of the glucose substrate to *d*-lactic acid, and that two organisms, *R. oryzae* 394 and *R. oryzae* 395, are outstanding in this respect. Fumaric acid is often formed in small quantities by the good lactic

(12) Shaffer and Hartmann, *J. Biol. Chem.*, **45**, 365 (1921).

acid producers, and is formed in considerable amounts by certain other species, especially by *R. oryzae* 585. It should be mentioned that subsequent work has shown that fumaric acid production by *R. oryzae* 394 and *R. oryzae* 395 is a variable function, and small amounts may or may not be present, dependent upon such factors as temperature, age of the cultures, variations in the components of the medium, etc. Data involving this phenomenon and further physiological studies will be presented in a later communication.

All the products of the fermentation have not been identified. The species listed in Table I develop some acidity due to compounds other than lactic and fumaric acids. Many of the solutions give a positive Denigès test for malic acid, and occasionally there have been obtained traces of an acid melting at 177–180°, which suggests the presence of succinic acid. The acidity due to volatile acids is exceedingly small. It is conceivable that there might exist in these biological systems an equilibrium between succinic acid, fumaric acid, malic acid, and perhaps oxalacetic acid, such as has been the subject of recent intensive investigations of tissue metabolism. The authors are studying this question more fully from the standpoint of fungus metabolism.

The 62% yields of *d*-lactic acid given by *R. oryzae* 395 are not only reproducible, but the authors have occasionally attained a yield of 65 to 67% based on the glucose consumed.

Experimental Part

All the cultures were grown at 30° on approximately 15% solutions of commercial hydrated glucose (91.5% *d*-glucose, 8% moisture, 0.4% dextrins), with other nutrient constituents as $MgSO_4 \cdot 7H_2O$, 0.25 g. per liter; KH_2PO_4, 0.30 g. per liter; NH_4NO_3, $(NH_4)_2SO_4$, $NaNO_3$ or urea as nitrogen sources, to yield 0.5 g. of nitrogen per liter.

Each variation was studied in triplicate using 75 cc. of nutrient solution in 200-cc. Pyrex Erlenmeyer flasks. Each variation of nitrogen source was studied with and without the addition of calcium carbonate at the rate of 4 g. per flask. The calcium carbonate was sterilized separately, and added to the sterile nutrient solution at the time of inoculation.

At the conclusion of the incubation period, the culture liquors were analyzed for residual glucose, calcium ion, lactic acid and fumaric acid, as indicated in Table I.

In addition to the examination of its zinc salt, the lactic acid was also identified by the preparation of ethyl lactate (b. p. 154°) and the vacuum distillation of the acid itself (b. p. 119° at 12 mm.).

By virtue of its favorable partition coefficient, the fumaric acid could be separated qualitatively from lactic acid in the first ether extracts of the acidified culture solution, and could then be purified by recrystallization from water. The melting point (285° dec.), neutralization equivalent (58), and melting point of the *p*-nitrobenzyl ester (150°) proved its identity.

In conclusion, the authors wish to mention that the study of the 14 species of Rhizopus reported here represents only the beginning of an investigation of the biochemical activities of the entire genus. About eighty species of the authors' collection have not yet been investigated, it having been considered desirable to study in more detail the production of *d*-lactic acid by the vigorous organisms already encountered.

Summary

Several species of Rhizopus are able to convert glucose to *d*-lactic acid when cultivated in the presence of calcium carbonate. The yields of 62%, based on glucose consumed, are noteworthy in view of the 40% yields which are the highest previously reported. The lactic acid is accompanied by variable quantities of unidentified acids, and may or may not be associated with variable quantities of fumaric acid.

Tetrachloroethane-1,2-d_2 (*sym*-Dideuteriotetrachloroethane)

BY FRITZ W. BREUER

Studies on organic compounds of deuterium, in progress in this Laboratory,[1] have been extended to the chlorination of acetylene-d_2 to give *sym*-dideuteriotetrachloroethane. A well controlled combination of the gases was effected by a negative catalyst. In common with other deuterium compounds the difference in density ($d^{20}{}_{4}$) 1.6118 as compared with 1.5943 for ordinary *sym*-tetrachloroethane, prepared in precisely the same way in the same apparatus, is most pronounced. Assuming the same molecular volume for the "light" and "heavy" compound the calculated density is 1.6136. The boiling point is about 0.5° higher than that of the ordinary compound, and it was found that the vapor pressures differ considerably.[2] Refractive indices ($n^{20}{}_{\mathrm{D}}$) of the deuterio and known compounds are 1.4824 and 1.4940, respectively. In the Raman spectrum[3] all lines predicted for the new substance are actually observed. The observation of Urey and Price[4] of the slow interaction of aluminum carbide and deuterium oxide finds its analog in the low rate of evolution of "heavy" acetylene from calcium carbide. In the catalyzed reaction of ordinary and deuterioacetylene with chlorine no appreciable difference in rates was noticed.

Experimental Part

Most of the methods described for the synthesis of *sym*-tetrachloroethane were tested for their suitability to small scale preparations involving the least risk of explosions. Finally the industrially used procedure utilizing the combination of acetylene and chlorine on a freshly prepared deposit of certain metal chlorides on a carrier was chosen. It was worked out carefully using ordinary water first.

Apparatus and Procedure.—The general assembly of the apparatus is shown diagrammatically in Fig. 1. The principal parts are an acetylene generating flask (a) with dropping funnel (a′), a storage system of four 500-ml. bulbs (b, b′, b″, b‴) interconnected by three-way stopcocks, and using redistilled mercury as a confining liquid, a leveling bulb with customary air trap; two reaction tubes (c, c′) made of heavy-walled (bomb) tubing, diameter 15 mm, length 15 and 30 cm., respectively, with cap joint for the gas inlets and standard tapered[5] glass joint for the attachment of receivers (d, d′) of the conventional type for the immersion in a cooling bath, and a terminal bubble counter (e). The all-glass chlorine purifying train consisted of a platinized asbestos–manganese dioxide catalyzer tube, heated electrically to 450°, gas wash bottles containing saturated potassium permanganate solution and concd. sulfuric acid, a pressure regulator (f) for the adjustment of the gas velocity and a capillary flow control with bubble counter (g). The catalyst, a mixture of 7.5 parts of ferric oxide, 7.5 parts of reduced iron, 15 parts of aluminum oxide, 5.5 parts of antimony metal (powdered) and 15 parts of clean quartz sand, which components had been either ignited or dried *in vacuo* at 110°, was suspended on ignited asbestos and packed rather loosely in the reaction tubes. They were wrapped with wire gauze and after attaching to the assembly the formation of the metal chlorides was started by a slow stream of chlorine. Part of the more volatile chlorides was expelled.

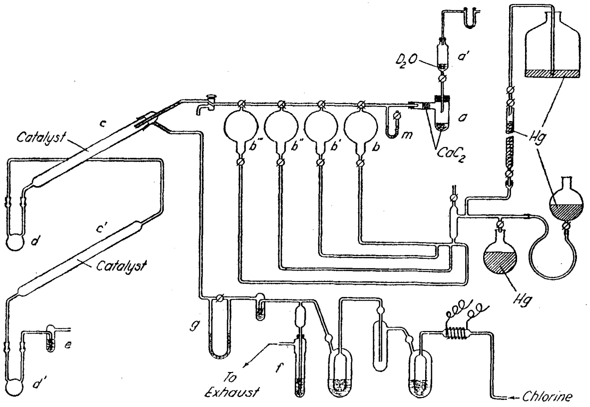

Fig. 1.

A constant and controllable rate of acetylene from the storage flasks to the reaction tubes was secured by a device consisting of a 12-liter carboy, filled with a 7-cm. layer of redistilled clean mercury and a heavy walled siphon tube with a set of two capillary stopcocks for the adjustment and shutting of the mercury flow.

Especially pure calcium carbide kindly supplied by Carbide and Carbon Chemicals Corporation, a light brown material, was crushed with exclusion of moisture and the inner cores powdered in an atmosphere of dry nitrogen. Generator (a) was charged with 8 g. (0.13 mole) of carbide and covered with a 3-mm. layer of ignited quartz sand. In the side-arm a layer of powdered calcium carbide was se-

cured between plugs of glass wool. The thoroughly dried acetylene generating and storage part of the system was outgassed most carefully through three-way stopcock (u), heating the carbide to 250°. Four cc. (0.22 mole) of deuterium oxide (d^{20}_4) 1.1071 was placed in dropping funnel (a′) and permitted to react slowly with the carbide. Formation of "heavy" acetylene and the simultaneous removal of mercury from the storage bulbs were controlled so that the gas pressure was kept close to atmospheric, as indicated by manometer (m). Deuterium oxide was added in small portions whenever no change in pressure was noted during one-half hour. After sixty hours all of the "heavy" water had reacted, while the same volume of ordinary water had been used up in very considerably less time. Unreacted deuterium oxide was expelled by heating the generator to an oil-bath temperature of 170°, and brought into reaction with fresh carbide in the side arm. By simultaneously cooling the bulbs (b, etc.) with dry ice and keeping the generator at 170° most of the gas was transferred in the storage system and a nearly theoretical yield of acetylene-d_2 was obtained.

For the chlorination process a 100-watt incandescent bulb with metal reflector was placed at a distance of approximately 40 cm. from the reaction tube (c) and 16 cc. of chlorine per minute passed through the tubes prior to admitting the acetylene at a rate of 4 cc. per minute. Combination of the gases started immediately as indicated by the warming of tube (c) and the formation of a liquid reaction product. As a matter of precaution tube (c′) was heated slightly by the flame of a wing-top burner. Very little gas passed through the terminal bubble counter (e), until the acetylene storage flasks were emptied (fifteen hours). The reaction products were expelled completely in receiver (d), which was kept at −10°, by repeated heating of tube (c) in a stream of chlorine, finally to the sublimation temperature of ferric chloride. No material had formed in reaction tube (c′). A yield of 14.5 g. of tetrachloroethane-1,2-d_2 (78% of the theoretical amount, based on deuterium oxide) was obtained.

Purification and Physical Constants.—Receiver (d) was attached by standard tapered glass joint to the pot of a partial reflux type fractionating column (length of packed[6] section 37 cm., inner diameter 0.7 cm.) with sealed on pot and multiple receiver, and transferred at 60 mm. pressure. Using a reflux ratio of 10:1 two fractions boiling at 68.8–70.7°, and 70.7° were collected, and the latter refractionated at 89 mm. to give three cuts with boiling ranges of 77.5–79.5°, 79.5–80° and 80°. From the middle fraction (8.5 g.) the density, boiling point, melting range and refractive index were determined by a technique described in an earlier paper.[1b]

	$CDCl_2CDCl_2$	$CHCl_2CHCl_2$
d^{20}_4	1.6118	1.5943
n^{20}_D	1.4924	1.4940
B. p., °C. (737 mm.)	145.7 ± 0.05	145.2 ± 0.05

The melting curves of both deuteric and ordinary compounds indicate that these substances are not quite pure; nevertheless it was found that the "heavy" compound melts 0.2–0.5° higher than its protio analog. Preliminary measurements of vapor pressure differences of the "light" and "heavy" compound, taken at 5° intervals over the range +20–80° indicate that the vapor pressure of the deuteric compound is from 9–6% lower.

Grateful acknowledgment is made to the Carbide and Carbon Chemicals Corporation for the very pure sample of calcium carbide and to Dr. D. H. Rank of the Physics Department of The Pennsylvania State College for the permission to mention some of his as yet unpublished results. Particular thanks are due Dean Frank C. Whitmore of the School of Chemistry and Physics who made possible and greatly encouraged the present work.

Summary

Tetrachloroethane-1,2-d_2 has been prepared and some of its physical constants have been determined.

Vapor Pressures of Saturated Aqueous Solutions. Monoammonium and Diammonium Acid Phosphates

BY EDWARD J. ROEHL

In connection with other current research work, the author has determined the vapor pressure curves for saturated aqueous solutions of monoammonium and diammonium acid phosphates over a temperature range.

A search of the literature failed to reveal data for the diammonium salt, and the only record for the monoammonium salt seems to be that of Edgar and Swan[1] over the limited temperature range of from 19 to 30°.

Experimental Method

The isoteniscope of Smith and Menzies[2] was employed. The bulb of the isoteniscope had a capacity of about 15 ml., and was connected to a 10-liter bottle as reservoir. The manometer was of the closed end type described by Roehl[3] and was read by means of a cathetometer. The usual precautions as to temperature control, stirring, etc., were employed. A saturated solution of the salt was used as the confining liquid. The two ammonium phosphates were prepared by crystallizing commercial C. P. chemicals repeatedly from water. In all cases, duplicate determinations were made upon separate samples, and in several cases other duplicate determinations were made on samples which had been still further purified by recrystallization. The curves were checked for both falling and rising temperatures.

The experimental data for the monoammonium salt were found to fit the equation given over a range of temperature from 19–90°

$$\log P = -2240/T + 8.862$$

with a mean deviation of 0.8% in pressure. The data for the diammonium salt can be represented by the equation given from 19–55°

$$\log P = -2240/T + 8.807$$

with a mean deviation of 0.4% in pressure.

The only available data, those of Warren,[4] give the following values for the ammonia pressure of the solid salts, and which would correspond to the ammonia pressures for the saturated solutions.

PRESSURES IN MM. OF MERCURY

	80.24°	100°	125°
$NH_4H_2PO_4$	....	0.00	0.05
$(NH_4)_2HPO_4$	1.36	5.0	30.0

This indicates that the ammonia pressure over the saturated solution has not reached an appreciable value for the monoammonium salt at 100° and for the diammonium salt at 55°.

It was found that the data for the two salts gave parallel straight lines when plotted as log P against $1/T$, and that the two lines were parallel to the vapor pressure curve for water. A search of the literature was made and all the data possible to locate for saturated aqueous solutions plotted as log P against $1/T$. It was found that all the curves were straight lines and all parallel to the water curve. Thus the data can be represented by the equation

$$\log P = -2240/T + B$$

and in Table I there are given the material, the temperature range, and the values for the constant B.

TABLE I

Material	Temperature range, °C.	Constant B
H_2O[5]	20–100	8.895
Na_2CO_3[6]	30–100	8.800
$NaCl$[6,7]	20–95	8.760
Na_2SO_4[6,7]	20–100	8.835
KCl[1,7]	20–45	8.812
$KClO_3$[6]	55–100	8.864
K_2SO_4[7]	20–55	8.880
$K_2Cr_2O_7$[7]	20–50	8.885

The values obtained from the equations check the observed data with a mean deviation of 1%.

Summary

The vapor pressures for the saturated aqueous solutions of monoammonium acid phosphate have been determined over a temperature range of from 19 to 90°; and for the diammonium acid phosphate from 19 to 55°. Empirical equations were derived to express the data.

On plotting the data and all the data possible to locate in the literature for saturated aqueous solu-

The Synthesis of 3-Hydroxy-2-(3)-benzofuranone and of 4-Hydroxymandelic Acid

BY KURT LADENBURG, KARL FOLKERS AND RANDOLPH T. MAJOR

A number of hydroxy acids were recently investigated in regard to the treatment of urinary infections. Mandelic acid was the most effective of these,[1] and this was due in part to the fact that it was excreted unchanged in the urine. It seemed quite possible that the introduction of a phenolic hydroxyl group into this acid might increase its antiseptic action. 2-Hydroxymandelic acid appeared promising, since salicylic acid has been found to pass through the body into the urine largely unchanged,[2] and because it seemed possible that this hydroxymandelic acid might also be excreted partly unchanged. It was of further interest to determine the influence of the 4-hydroxy group in the bactericidal efficiency of the mandelic acid molecule.

There is but little information on 2-hydroxymandelic acid in the chemical literature. Plöschl[3] treated salicylaldehyde with hydrocyanic acid in solution. The crude 2-hydroxymandelonitrile was then treated with concentrated hydrochloric acid for hydrolysis to 2-hydroxymandelic acid. The acid product was a sirup, which like the nitrile was neither purified, nor analyzed. Later Baeyer and Fritsch[4] obtained crude 2-hydroxymandelic acid by reduction of 2-hydroxyphenylglyoxylic acid with sodium amalgam. They were unable to crystallize the crude sirupy acid, and finally converted it to the crystalline 2-hydroxyphenylacetic acid by further reduction with hydriodic acid. Rosenmund and Schindler[5] mentioned the reaction of 2-hydroxymandelic acid with acetyl chloride to give a diacetyl derivative of m. p. 68°, but gave neither the source nor a description of their 2-hydroxymandelic acid.

Plöschl's preparation of 2-hydroxymandelic acid was repeated carefully several times. The result was always a very small yield of a colored sirup, which would not crystallize. According to Plöschl, the aqueous solution of the acid on evaporation yielded an oil which crystallized, but a description of the solid was not given. This solid, supposed to be the lactone of 2-hydroxymandelic acid (3-hydroxy-2-(3)-benzofuranone),[6] was obtained in these experiments, but in all cases, the products were so impure and unsatisfactory that a more detailed examination of the reactions was made.

2-Hydroxymandelonitrile was found to be an oil, which was stable for only about twelve hours at about 0°. Its distillation under high vacuum was hardly satisfactory due to decomposition. To convert certain nitriles to the acids, it has frequently been advantageous to proceed first to the imino ether hydrochloride, then to the ethyl ester and finally to the acid. Consequently, three experiments were made in which the nitrile was treated with dry hydrogen chloride and ethanol. At the ester stage, only one of the three products could be induced to crystallize partially. The analytical data indicated that the crystals were 3-hydroxy-2-(3)-benzofuranone, the lactone of 2-hydroxymandelic acid.

These results suggested that in the one case the reaction designated as A had proceeded to a greater extent than reaction B so that there was sufficient lactone present to crystallize and be isolated.

If this were true, then the lactone should be isolated without difficulty when ethanol was omitted from the reaction. This contention was verified by experiment, and this reaction has provided an excellent method of preparing the pure 3-hydroxy-2-(3)-benzofuranone.

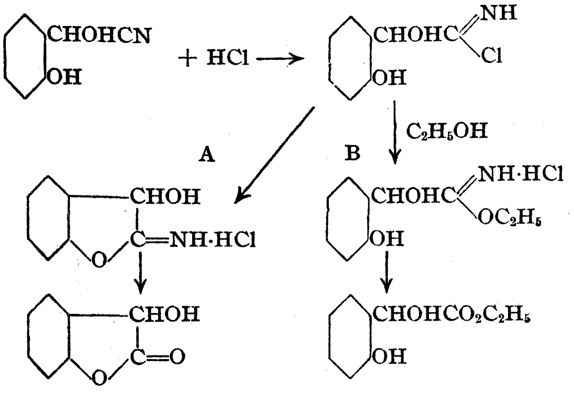
[6] The International Rules numbering has been used for the benzofuran nomenclature.



Certain properties of 3-hydroxy-2-(3)-benzofuranone are described in the experimental section. In particular, and as might be expected, the pure lactone partially hydrolyzed to 2-hydroxymandelic acid when dissolved in water; and when an alkaline solution of the acid was acidified, the lactone was partially formed from the liberated acid.

The isomeric 4-hydroxymandelic acid has been described in the literature, but each of the four methods,[7] by which it was obtained have certain disadvantages. For this research, 4-hydroxymandelic acid was synthesized from 4-hydroxybenzaldehyde through the intermediates: nitrile, imino ether hydrochloride and ethyl ester. This method was found to be quite satisfactory.

Aqueous solutions of 2-hydroxymandelic acid (and its lactone) and 4-hydroxymandelic acid have been tested *in vitro* against *E. Typhi* and *Staphylococcus aureus* by Dr. W. L. Sampson of the Merck Institute for Therapeutic Research. By comparing these two acids with mandelic acid, it was found that the phenolic hydroxyl group did not augment the bactericidal power of the acid.

Experimental

All analyses were micro determinations carried out by Mr. D. Hayman and Mr. S. Adler.

For satisfactory results, the details of the following preparations must be carefully observed.

2-Hydroxymandelonitrile.—Ten grams of pure salicylaldehyde was dissolved in a 10% aqueous solution of 8.6 g. of sodium bisulfite. To this was added 50 ml. of ether, and the liquids were cooled to 0–5° and stirred mechanically. A 20% aqueous solution of 4.1 g. of sodium cyanide was added from a dropping funnel, after which the stirring was continued for one hour. The layers were separated, and the aqueous layer extracted with ether. The combined ethereal solutions were washed twice with 30 ml. of 10% sodium bisulfite solution each time. After removal of the ether *in vacuo* at 20°, *ca.* 35 ml. of dry benzene was added, and then removed *in vacuo* at 20–25°. The residue was pumped out for two to three hours at 1 mm. pressure. The yield of nitrile was 10 to 11 g. (82–90%). It was a light green tinted viscous oil. The yield was increased by further extraction of the aqueous layer.

All efforts to crystallize this oil were unsuccessful. It could be kept only about twelve hours at temperatures of 0 to 10° or lower, and after this the slow decomposition and resinification increased until the oil had become a deep red thick resin. The odor of hydrocyanic acid was noticeable.

A carefully pumped out (1 mm. pressure or lower) analytical specimen of the freshly prepared nitrile gave, on immediate analysis: found, C, 63.71, 63.57; H, 5.01, 5.10; N, 9.0. Calcd. for $C_8H_7NO_2$: C, 64.40; H, 4.73; N, 9.40.

When a sample of the freshly prepared nitrile was placed in a still of the alembic type at a pressure of 10^{-3} to 10^{-5} mm., a few drops distilled on warming the flask to about 50°. However, this slight warming caused a marked increase in the pressure of the system. Hydrocyanic acid was detected and vapors (probably salicylaldehyde) were condensed in the trap. This warming also increased the resinification of the sample. The few drops of distillate on immediate analysis gave, found: C, 64.31; H, 5.28.

3-Hydroxy-2-(3)-benzofuranone (Lactone of 2-Hydroxymandelic Acid).—Ten grams of freshly prepared nitrile that had been well pumped out at 1 mm. was dissolved in 50 ml. of anhydrous ether. This solution was cooled in an ice-bath, and dry hydrogen chloride bubbled through until a little over the theoretical amount was absorbed. The red solution was kept at 10° overnight, and then the ether was decanted from the salt. The flask was placed in a desiccator over sodium hydroxide and evacuated to 5 mm. for four hours. To the imino ether hydrochloride was added 400 ml. of water, and the flask was shaken mechanically until the solution was almost clear. A red lump of tar remained. The solution was filtered and allowed to stand at 25° for five hours. It was again filtered to remove flocculent material, and then extracted with ether five times. The residue that remained after removal of the ether by distillation was pumped out until it crystallized. The lactone was recrystallized from dry benzene until the constant value, m. p. 107–108°, was reached. The yield was 30% (based on salicylaldehyde).

Anal. Calcd. for $C_8H_6O_3$: C, 64.00; H, 4.03. Found: C, 64.23, 64.32; H, 4.27, 4.29.

Titration experiments indicated that 3-hydroxy-2-(3)-benzofuranone partially hydrolyzed when dissolved in warm water. When an aqueous solution of the lactone was treated with the required amount of calcium hydroxide dissolved in a large amount of water, an insoluble calcium salt formed. *Anal.* Calcd. for $C_{16}H_{14}O_8Ca$: Ca, 10.71. Found: Ca, 10.18, 9.97.

When the lactone was dissolved in 0.5% sodium hydroxide solution, and allowed to stand at 25°, a brown insoluble precipitate formed. This precipitate contained only a trace (0.14%) of sodium.

---

(7) (1) The direct hydrolysis of *p*-hydroxymandelonitrile to the acid [Henry, *Chem. News*, **85**, 301 (1902)]. (2) The reduction of *p*-hydroxyglyoxylic acid [Ellinger and Kotake, *Z. physiol. Chem.*, **65**, 409 (1910)]. (3) The reaction of nitrous acid on *p*-hydroxyphenylaminoacetic acid [Fromherz, *ibid.*, **70**, 356 (1910)]. (4) The hydrolysis of 4-α-dibenzoyloxyphenylacetamide [Alay and Rabout, *Bull. soc. chim.*, [4] **11**, 392 (1912)].

Anal. Found: C, 64.17; H, 5.00. The filtrate on acidification, extraction, etc., yielded a red oil.

Anal. Found: C, 60.21; H, 4.23.

When the lactone was dissolved in a 1% sodium carbonate solution and refluxed one hour, hydrolysis was complete, as was evidenced by a lack of extractable material. The alkaline solution, after acidification, extraction, etc., yielded a partially crystalline residue.

Anal. Found: C, 59.48; H, 4.83. Calcd. for the lactone: C, 64.00; for the acid, C, 57.12. Thus, these residues were mixtures of the lactone and the acid.

Obviously, the lactone partially hydrolyzed to the acid in water solution and, conversely, the acid, liberated in solution from its salt, partially formed the lactone.

4-Hydroxymandelonitrile.—Ten grams (0.082 mole) of 4-hydroxybenzaldehyde was dissolved in a warm 10% solution of 10 g. of sodium bisulfite, and cooled to 0°. The solution was covered with 50 ml. of ether, and with mechanical stirring, a 20% solution of 4.2 g. (0.086 mole) of sodium cyanide was added over a period of thirty minutes. After stirring thirty minutes longer at 0°, the layers were separated, and the aqueous one extracted further with ether. The combined extracts were washed with a 10% sodium bisulfite solution, dried over calcium chloride and then distilled at 25° or lower *in vacuo*. The nitrile was dried at 1 mm. for one to two hours. This yield of nitrile was 90%; m. p. 99–102°.[8]

Ethyl 4-Hydroxymandelate.—Eleven grams of the nitrile was dissolved in 50 ml. of anhydrous ether, and 4.6 ml. of absolute ethanol was added. Dry hydrogen chloride was bubbled through the solution at 0–5° until a little over the theoretical amount had been absorbed. After standing overnight at 10°, the ether was decanted from the imino ether hydrochloride. The salt was dried and freed of excess hydrogen chloride in a vacuum desiccator. The yield of the salt was 11.5 g.

The crude imino ether hydrochloride was shaken mechanically with 300 ml. of water until the solution was almost clear. The insoluble material was filtered, and the solution was allowed to stand at 25° for five hours. The solution was then extracted with ether, and on solvent removal, there remained 5.5 g. (34.2% as based on 4-hydroxybenzaldehyde) of ethyl 4-hydroxymandelate of m. p. 124–126°. On recrystallization (with norite) from dry benzene the constant value of m. p. 128.5–129° was obtained.

Anal. Calcd. for $C_{19}H_{12}O_4$: C, 61.19; H, 6.17. Found: C, 61.09; H, 6.25.

4-Hydroxymandelic Acid (Monohydrate and Anhydrous).—Three and one-half grams of the pure ethyl ester was dissolved in 110 ml. of 2% sodium hydroxide solution, and the mixture refluxed for one hour. The light brown solution was cooled and acidified with hydrochloric acid. The first ether extract removed all the colored impurities and about 0.1 g. of the acid (m. p. 79–82°). After twenty more ether extractions, and distillation of the solvent, there remained 2.4 g. (72%) of 4-hydroxymandelic acid monohydrate of m. p. 82–84°. On dissolving in benzene, and reprecipitating with petroleum ether, it melted at 83–84°.

Anal. Calcd. for $C_8H_8O_4 \cdot H_2O$: H_2O, 9.67. Found: H_2O, 9.66.

Anhydrous 4-hydroxymandelic acid (from the monohydrate by warming *in vacuo* at 60°) melted at 109.5–110.5°.[9]

Anal. Calcd. for $C_8H_8O_4$: C, 57.12; H, 4.80. Found: C, 57.42; H, 5.08.

Summary

Pure 3-hydroxy-2-(3)-benzofuranone has been made from salicylaldehyde. When this lactone was dissolved in water, it hydrolyzed partially to 2-hydroxymandelic acid. 4-Hydroxymandelic acid has been synthesized from 4-hydroxybenzaldehyde through the intermediate nitrile, imino ether hydrochloride and ethyl ester.

2- and 4-hydroxymandelic acids were not more bactericidal against *E. Typhi* and *Staphylococcus aureus in vitro* than mandelic acid.

A New Synthesis of Mixed Benzoins. Second Paper

By Richard T. Arnold[1] and Reynold C. Fuson

The new synthesis of mixed benzoins by the condensation of suitable aromatic compounds with arylglyoxals[2] has been extended to a number of new cases, and has been found to be generally useful in the preparation of this type of substance. In Table I are listed the various benzoins which have been made, together with indications as to the conditions employed.

Preparation of the Arylglyoxals

The glyoxals were prepared in good yields by the method of Riley and Gray,[3] with an added modification as follows.

After the oxidation with selenium dioxide, the dioxane solution is decanted from the precipitated selenium and distilled under atmospheric pressure until nearly all of the dioxane has passed over. At this point, 100 cc. of a suitable hydrocarbon[4] is added, and the solution again distilled at atmospheric pressure until the distillate is no longer turbid. At this stage, the solution is transferred to a Claisen flask, and the distillation completed under diminished pressure. This modification was employed to prevent the formation of the glyoxal hydrate which normally contaminates the distillate. By use of this method with commercial xylene (b. p. 137–140°), *p*-bromophenylglyoxal (b. p. 115° (7 mm.); m. p. 51–52°), and *p*-chlorophenylglyoxal (b. p. 123–125° (17 mm.); m. p. 40–42°) were prepared in 64 and 55% yields, respectively. These compounds were identified by conversion into their hydrates which melted at 132°[13] and 121°, respectively.

Preparation of the Benzoins

The optimum conditions for this reaction are typified in the synthesis of *p*-bromobenzoin.

Table I

Benzoin	M. p., °C.	Yield, %	Time, hrs.	Solvent	Analyses, % Calcd. C	H	Found C	H	Diketone
$C_6H_5COC(OH)HC_6H_5$	133	90	20	C_6H_6					95°

$C_6H_5COC(OH)HC_6H_4CH_3$	116[11]	50	15	CS_2					31[10]
$CH_3C_6H_4COC(OH)HC_6H_5$	110[11]	42	15	CS_2					31[10]

Ten and sixty-five hundredths grams of *p*-bromophenylglyoxal was dissolved in 50 cc. of benzene and placed in a 125-cc. separatory funnel.

In a 500-cc., three-necked, round-bottomed flask surrounded with ice and equipped with a mercury-sealed stirrer were placed 200 cc. of dry benzene and 13.3 g. of aluminum chloride. The glyoxal solution was added dropwise to the benzene–aluminum chloride solution. The addition took approximately thirty minutes. The reaction was allowed to run at 0° for fifteen hours. The reaction mixture was then decomposed by adding slowly ice-cold 20% hydrochloric acid solution. The benzene solution was concentrated by removal of the solvent under diminished pressure. The process was performed in the absence of air,

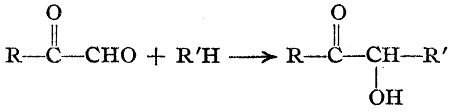
and was continued until the residual solution was reduced to a volume of 30 cc. To this was added 30 cc. of low-boiling petroleum ether, and the solution kept cold overnight. The precipitate was separated by filtration with suction and washed with four 25-cc. portions of cold, low-boiling petroleum ether. The material weighed 10.2 g. (70.2% of the theoretical amount), and melted at 105–106°. After one recrystallization from ethyl alcohol, the benzoin melted at 108–109°.

The general procedure involves the use of the hydrocarbon reactant as the solvent; in some cases, however, carbon disulfide has been found to give very satisfactory results.

The Structure of the Benzoin

In every case where the resulting benzoin is known, our product showed perfect agreement with the published descriptions of the compound anticipated. In cases where both benzoin isomers were prepared, both were oxidized by iodine[14] to give identical diketones. Most of these diketones are known substances.[10] It is important to note that in each instance only one benzoin was obtained, and that in every case the structure of the benzoin corresponded to that to be expected on the basis of the general equation



$$R-\overset{\overset{O}{\|}}{C}-CHO + R'H \longrightarrow R-\overset{\overset{O}{\|}}{C}-\underset{\underset{OH}{|}}{CH}-R'$$

Summary

Twelve benzoins have been prepared by condensation of arylglyoxals with aromatic hydrocarbons or their derivatives. The structures of the mixed benzoins have been shown to be those which would be predicted on the basis of the general equation as indicated above.

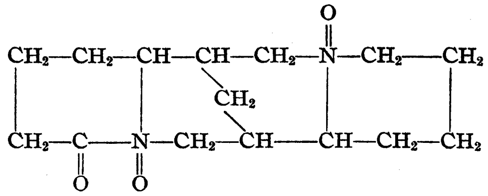
Lupine Studies. XI. The Alkaloids of *Lupinus Barbiger* S. Wats.

BY JAMES FITTON COUCH

In a previous communication[1] the occurrence of sparteine in *Lupinus barbiger* was announced. At that time the presence of two other alkaloids of undetermined identity was indicated. This paper describes the isolation and identification of these alkaloids. *L. barbiger* is a perennial species ranging from Colorado, Utah, Arizona, and California.[2] Two lots of material, one from northern Arizona and one from Utah were examined in the course of this study and no significant differences between them were found.

Three well-defined alkaloids were isolated from this species: sparteine and two hitherto undescribed bases which have been named dilupine and trilupine. Lupinine and lupanine were sought for and found not to be present. The new alkaloids are of unusual interest. Trilupine, $C_{15}H_{24}O_3N_2$, proved to be an amine oxide derived from *d*-lupanine of which it is the di-N-oxide corresponding to the structure



By the action of hydrogen dioxide on sparteine the di-N-oxide of that base has been prepared[3] by a number of workers. Polonovski[4] has shown that geneserine is the amine oxide of eserine and analogous compounds have been prepared synthetically from other bases.[5] This is, however, the first instance in which amine oxides have been discovered in a lupine species. It was found that while gold chloride and platinum chloride would yield the corresponding double salts of trilupine if the mixtures were not heated for more than a short time, other acids and longer heating resulted

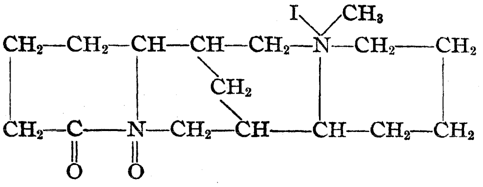
in the formation of salts of *d*-lupanine, the reaction involving removal of the oxide oxygen atoms. Freund and Speyer[5b] were able to prepare crystalline salts of the oxides of morphine, thebaine, codeine and ethylmorphine with mineral acids. When trilupine reacted with methyl iodide in the cold a compound was obtained that contains one oxygen atom less than is required from trilupine methiodide and which appears to be the methiodide of *d*-lupanine mono-N-oxide of the probable structure



Trilupine was converted into *d*-lupanine by treating the dihydrochloride, which is identical with *d*-lupanine dihydrochloride, with alkali, and shaking out the liberated base with chloroform, which yielded an alkaloid identical with *d*-lupanine. The latter was converted into trilupine by the action of calcium dioxide on *d*-lupanine dihydrochloride and the synthetic base agreed with the natural alkaloid in all respects.

The optical activity of trilupine might be expected to throw some light on the problem of the possible asymmetry of the nitrogen atoms in lupanine. The crystallized base had a specific rotation of 63.76° as compared with 84.35° for *d*-lupanine. Correcting for the content of water of crystallization and for the difference in molecular weight the comparable figure for trilupine is 83.12° or sufficiently close to the figure for *d*-lupanine to furnish no support for the view that the nitrogen atoms are asymmetrical.

Dilupine was not obtained in sufficient quantities to permit a thorough study. The analytical figures agree with the formula $C_{16}H_{26}O_2N_2$ for the free base while the analyses of the methiodide and the hydrobromide require a base of the formula $C_{16}H_{26}ON_2$, suggesting that dilupine may be the amine oxide of a C-methyl-lupanine. The base recovered from the hydrobromide was not identical with dilupine but had the nitrogen content required by a methyl-lupanine which supports this view. The question, however, must await further study for complete clarification.

The presence of the di-amine oxide of lupanine in the plant suggested that lupanine should also have been found if only as a decomposition product of trilupine. Careful search failed to reveal that alkaloid even in the residues from vacuum distillations.

Experimental

Material.—The plant material consisted of two lots of plants, one collected on the Kaibab Forest, Arizona, and the second at Hilltop, 10 miles north of Fairview, Utah. The first collection was made during the summer of 1928 and the second on July 11 and August 11, 1931. The plants had not formed seeds at the time of collection. The material was dried, shipped to Washington and ground to a coarse powder for use. The air-dried plant had moisture contents of 8.47 and 7.62% for the two collections. It was identified by W. W. Eggleston as *Lupinus barbiger* S. Wats.

Isolation of the Alkaloids.—The method used in extracting the alkaloids has previously been described;[6] 16.45 kg. of the first collection yielded 1.67% of alkaloid, freed from resinous impurities and calculated to moisture-free plant; 58.09 kg. of the second yielded 1.86%. The alkaloids were treated with an equal volume of ether which dissolved nearly half. The dissolved alkaloids, freed from ether, were then dissolved in petroleum ether, which took up all but a trace of resinous matter. The alkaloidal residue obtained by distilling off the solvent will be referred to as fraction A. The material not dissolved by ether was extracted with benzene which dissolved the larger portion of it. On distilling off the solvent fraction B was obtained. The material not dissolved by benzene was extracted with boiling ethyl acetate and, freed from solvent, the extract furnished fraction C. The undissolved matter was insoluble in a mixture of boiling acetone and 10% alcohol and consisted of resinous substances.

Fraction A was a brownish sirup of strong burnt-wool odor. It weighed 441 g. and gave a strong reaction for sparteine in the modified Grant test. It was submitted to distillation under reduced pressure but could not be separated into its constituents by that method. Fractions were obtained that had nearly the correct index of refraction and optical activity for sparteine, but were evidently contaminated with some other base. Separation was effected by dissolving the fractions that distilled below 195° at 1 mm. in dilute hydrochloric acid and adding aqueous mercuric chloride when the double chloride of sparteine and mercury crystallized and could be purified by recrystallization from hot 20% hydrochloric acid. The alkaloid was recovered from this compound by treating it with ammonia and extracting with chloroform. On distilling off the solvent the base remained as a light yellow sirup which distilled at 185° and 7 mm. with a small residue. It had $n^{27}\text{D}$ 1.5256, $(\alpha)^{30}\text{D}$ 5.95°, and depressed the freezing point of benzene conformably to the molecular weights 241, 244 and 240. The substance was positive to the Jorissen[7] and modified Grant[8] tests for sparteine.

Anal. Calcd. for $C_{22}H_{26}N_2$: C, 76.86; H, 11.19. Found: C, 76.51; H, 11.40.

Salts of Sparteine.—Picrate, m. p. 205–206°, did not depress the melting point of authentic sparteine picrate.

---

[6] J. F. Couch, THIS JOURNAL, **56**, 2434 (1934).

[7] Jorissen, *Ann. chim. anal.*, **16**, 412 (1911).

[8] Couch, *Am. J. Pharm.*, **97**, 38 (1925).

Calcd.: N, 16.18. Found: N, 16.00. The platinum chloride melted at 248° (dec.) and did not depress the melting point of authentic sparteine platinum chloride.

The Dihydrobromide.—Five grams of the base, dissolved in 100 cc. of acetone, was treated with an excess of hydrobromide acid solution. Two layers formed and 1 volume of alcohol was added which produced a homogeneous solution. On standing overnight in an ice box the solution deposited a mass of colorless prisms. Recrystallized from alcohol these melted at 197°.

Anal. Calcd. for $C_{15}H_{26}N_2 \cdot 2HBr \cdot H_2O$; Br, 38.63; H_2O, 4.35. Found: Br, 38.51, 38.50; H_2O, 4.40, 4.54. $(\alpha)^{29}\mathrm{D}$ $-18.33°$ in water, $c = 1.2770$, $l = 4$, $a = 0.93°$. The free alkaloid regenerated from this salt showed $n^{27}\mathrm{D}$ 1.5259 and formed a picrate that melted at 206°. The methiodide readily separated from a mixture of the base with methyl iodide without warming. Recrystallized from alcohol it melted at 239–240°.

Anal. Calcd. for B,CH_3I: I, 33.75; N, 7.45. Found: I, 33.72, 33.63; N, 7.51.

The Zinc Chloride.—Sparteine dissolved in 10% hydrochloric acid (2 moles) treated with excess of saturated zinc chloride solution within a few minutes begins to deposit crystals of the double chloride with zinc.[9] Recrystallized from water and dried in a desiccator these were free from water of crystallization and melted at 316–317°.

Anal. Calcd. for $B2HCl \cdot ZnCl_2$: Cl, 32.09. Found: Cl, 32.01, 31.84. $(\alpha)^{30}\mathrm{D}$ -19.57 in water; $c = 0.9912$, $l = 1$, $a = 0.194°$.

Isolation of a New Lupine Alkaloid, Dilupine.—The highest boiling fraction of the original fraction A distilled at 190–222° and 1 mm. It consisted of a thick reddish oil of strong burnt-wool odor, $(\alpha)^{25}\mathrm{D}$ 69.50°, $n^{24}\mathrm{D}$ 1.5395. It contained some sparteine which was removed by distillation with steam. The non-volatile alkaloid was recovered by shaking the water solution with chloroform and on distilling the chloroform a sirup was obtained that did not react to the modified Grant test for sparteine. On standing the sirup deposited a small quantity of needles which were filtered off and proved to be a third alkaloid which is described in detail below. The sirupy alkaloid was redistilled under reduced pressure several times until it was obtained as light yellow, very thick sirup. It has not been crystallized. The analytical figures agree best with a formula for a C-methyl-lupanine oxide and this is tentatively accepted. Further study of the base is in progress.

Anal. Calcd. for $C_{16}H_{26}O_2N_2$: C, 69.01; H, 9.41; N, 10.07. Found: C, 69.38, 69.31, 69.45; H, 9.81, 9.66, 9.75; N, 10.05, 10.08. $(\alpha)^{26}\mathrm{D}$ 65.59°, in water, $c = 6.5028$, $l = 1$, $a = 4.26°$, $n^{27}\mathrm{D}$ 1.5440.

The Methiodide.—A mixture of equal volumes of the alkaloid and methyl iodide began to deposit crystals within thirty minutes and in twenty hours the mixture had solidified. Recrystallized from boiling alcohol several times the m. p. was 253°. The analytical figures for this compound do not agree with those calculated for a methiodide of a base of the composition assigned to the free alkaloid but require a base with one less oxygen atom. This would indicate that dilupine is an amine oxide.

Anal. Calcd. for $C_{16}H_{26}ON_2 \cdot CH_3I$: C, 50.47; H, 7.17; N, 6.94; I, 31.40. Found: C, 50.47; H, 7.19; N, 6.80, 6.94; I, 31.32, 31.13. $(\alpha)^{32}\mathrm{D}$ 51.10°, in water, $c = 1.409$, $l = 1$, $a = 0.72°$.

The Hydrobromide.—The base, dissolved in alcohol and treated with a slight excess of hydrobromic acid, deposited cubical crystals after several days' standing in an ice box. Recrystallized from alcohol and dried at 115° these crystals melted at 233–234°. As in the case of the methiodide the analytical figures agree better for a less oxygenated base.

Anal. Calcd. for $C_{16}H_{26}ON_2 \cdot HBr$; Br, 23.31. Found: Br, 23.86, 23.83.

Three grams of the hydrobromide was dissolved in water, alkalized with sodium hydroxide, and the liberated base shaken out with chloroform. The solvent was removed and the residual sirup was dissolved in methanol and the solvent boiled off three times to remove chloroform. The base was a reddish sirup.

Anal. Calcd. for $C_{16}H_{26}ON_2$: N, 10.68. Found: N, 10.62. $(\alpha)^{25}\mathrm{D}$ 49.78°, in water, $c = 1.832$, $l = 1$, $a = 0.91$. $n^{25}\mathrm{D}$ 1.5454.

Isolation of a New Lupine Alkaloid, Trilupine.—Fraction B was freed from benzene by warming on the water-bath. An attempt to separate the constituents of this fraction by distillation under reduced pressure resulted in considerable decomposition. On standing several weeks the fraction deposited a mass of prismatic crystals embedded in thick sirup. The crystals were collected by filtering the mass through a porous plate under suction. The sirupy filtrate proved to consist of a small quantity of sparteine, much dilupine, and some of the crystalline alkaloid. The crystals were washed with small quantities of cold acetone in which they were slowly soluble and then were recrystallized from boiling ethyl acetate several times, finally with addition of charcoal. By this means the melting point was raised from 112 to 127° where it was constant. The product was colorless efflorescent needles, soluble in water, alcohol, and chloroform, less soluble in cold acetone and ethyl acetate, and nearly insoluble in ether. They contained 2 moles of crystal water and, when anhydrous, melted at 252°. The aqueous solutions are neutral to litmus.

Anal. Calcd. for $C_{15}H_{24}O_3N_2 \cdot 2H_2O$: C, 56.93; H, 8.92; N, 8.85; $2H_2O$, 11.38. Found: C, 56.71, 56.85, 56.42; H, 9.02, 9.05, 9.15; N, 8.88, 8.79; H_2O 11.07, 11.25. $(\alpha)^{30}\mathrm{D}$ 63.76°, in water, $c = 1.7252$, $l = 1$, $a = 1.10°$.

Certain salts could be prepared from trilupine if the reaction mixtures were not heated for more than a very short time. Heating mixtures of trilupine and acids resulted in salts of *d*-lupanine.

Trilupine Platinum Chloride.—A solution of trilupine (1 g.) and a few drops of dilute hydrochloric acid in 5 cc. of water was treated with platinum chloride solution. No precipitation occurred. The solution was evaporated to dryness in a desiccator over concentrated sulfuric acid. The dried mass was freed from excess platinum chloride by extraction with alcohol and the residue was dried. It melted at 224° (dec.).

Anal. Calcd. for $C_{15}H_{26}O_3N_2 \cdot H_2PtCl_6 \cdot 4H_2O$: Pt, 25.61; Cl, 27.95. Found: Pt, 25.66, 25.66; Cl, 27.78, 27.86.

---

(9) E. J. Mills, *J. Chem. Soc.*, **15**, 1–8 (1862).

Trilupine Gold Chloride.—A solution of the alkaloid in dilute hydrochloric acid treated with gold chloride solution yielded a yellow flocculent precipitate which was redissolved in the mother liquor by gentle warming and set aside. Golden needles were deposited on standing which were collected, washed and dried. The melting point was 188–189° (dec.). The mother liquors on standing deposited much metallic gold.

Anal. Calcd for $C_{15}H_{24}O_3N_2{\cdot}2HAuCl_4{\cdot}4H_2O$: Au, 38.19; H_2O, 6.97. Found: Au, 38.18; H_2O, 6.91.

Trilupine Methiodide.—To a cold solution of trilupine (1 g.) in ethyl acetate (5 cc.) was added 2 cc. of methyl iodide. On standing octahedral crystals slowly separated. These were collected and dried, m. p. 127°. Analysis indicated that this substance contains one atom of iodine and that one oxide oxygen had been replaced by methyl iodide. The substance is, therefore, the methiodide of the mono-N-oxide of *d*-lupanine.

Anal. Calcd. for $C_{15}H_{24}O_2N_2.CH_3I$: I, 31.25. Found: I, 31.47, 31.50.

Conversion of Trilupine into *d*-Lupanine.—Five grams of trilupine dissolved in acetone (100 cc.) and treated with 4 cc. of hydrochloric acid in 4 cc. of alcohol evolved heat. On cooling there was a scanty deposition of colorless crystals. These were collected, washed with acetone and dried. They melted at 163–164°. When mixed with *d*-lupanine dihydrochloride there was no depression of the melting point. This substance lost 16.32% in weight when dried at 120° corresponding to one mole each of hydrochloric acid and water of crystallization. The anhydrous monohydrochloride melted at 252–254° as does anhydrous *d*-lupanine hydrochloride.

Anal. Calcd. for $C_{15}H_{24}ON_2{\cdot}2HCl{\cdot}H_2O$: 2Cl, 20.95; 1 HCl and 1 H_2O, 16.06, 1 Cl, 10.47. Found: Cl_2, 20.46; "moisture" 16.30, 16.34; Cl_1, 10.43.

Recovery of *d*-Lupanine from (Trilupine) Dihydrochloride.—Four grams of dihydrochloride prepared from trilupine was dissolved in 25 cc. of water and alkalized with sodium hydroxide. The precipitated oil was shaken out with chloroform which was separated, evaporated off and the residue was three times treated with methanol and evaporated to remove traces of chloroform. The alkaloid so obtained was a light brown oil with the characters of *d*-lupanine.

Anal. Calcd. for $C_{15}H_{24}ON_2$: N, 11.28. Found: N, 11.27. $(\alpha)^{25}D$ 79.20°, in alcohol, $c = 5.404$, $l = 1$, $a = 4.28°$; $n^{23}D$ 1.5470. Dextro-lupanine prepared from *L. albus* had $(\alpha)^{25}D$ 84.35 in alcohol and $n^{24}D$ 1.5444.

***d*-Lupanine Gold Chloride.**—Trilupine in dilute hydrochloric acid treated with excess of gold chloride solution gave a heavy flocculent precipitate which was redissolved in boiling dilute hydrochloric acid and crystallized on cooling; yellow needles, m. p. 206°. *Anal.* Calcd. for $C_{15}H_{24}ON_2{\cdot}HAuCl_4$: Au, 33.52. Found: Au, 33.33, 33.25.

***d*-Lupanine Perchlorate.**—The dihydrochloride prepared from trilupine (1 g.) dissolved in 5 cc. of water, was treated with 0.5 cc. of perchloric acid and 2 cc. of saturated sodium acetate solution. An immediate crystalline precipitate fell which was recrystallized twice from water, dried, and then melted at 207–209° and did not depress the melting point of *d*-lupanine perchlorate.

***d*-Lupanine Dihydrochloride.**—Since this compound had not been reported it was necessary to prepare it from authentic *d*-lupanine for comparison with the salt derived from trilupine. Seven grams of *d*-lupanine hydrochloride from *L. albus* was dissolved in 30 cc. of alcohol, 3 cc. of hydrochloric acid was added and then enough acetone to produce a slight cloud. The mixture was filtered and set in an ice box. Crystallization began within an hour. After twenty-four hours the crystals were collected, washed, redissolved in 10 cc. of alcohol and treated with 30 cc. of acetone. On standing the substance crystallized. Washed and dried the crystals melted at 161–162° and did not depress the melting point of the dihydrochloride obtained from trilupine. On drying at 120° their behavior was similar to the trilupine derivative.

Anal. Calcd. for $C_{15}H_{24}ON_2{\cdot}2HCl{\cdot}H_2O$: 2Cl, 20.95; 1 HCl and 1 H_2O, 16.06; 1 Cl, 10.47. Found: Cl_2, 20.72; "moisture" 16.05, 16.12; Cl_1, 10.50, 10.44.

Conversion of *d*-Lupanine into Trilupine.—To 10 g. of *d*-lupanine dihydrochloride dissolved in 50 cc. of water was added in small portions 4 moles of calcium dioxide (8.4 g.) with frequent shaking. When the calcium dioxide had all been added hydrochloric acid was added a few drops at a time until the calcium dioxide was nearly all dissolved. The solution was then alkaline to litmus. It was warmed for four hours on the water-bath, let cool and shaken out with chloroform. On distilling off the chloroform after separating it from the aqueous layer there remained a light brown sirup that soon crystallized to a mass of needles embedded in a dark sirup. The mixture was treated with ether, which dissolved the sirup, and the crystals were recrystallized from hot ethyl acetate with a little charcoal; colorless needles, m. p. 125–126°. Mixed with trilupine, m. p. 127°, the mixture melted at 126–127°.

Examination of Fraction C.—The portion of the original crude alkaloid that was not dissolved in ether or benzene proved to contain small amounts of sparteine, some dilupine which was recovered and added to fraction B, trilupine worked up with that alkaloid, much resinous matter, and a quantity of basic matter from which nothing definite has yet been obtained.

Summary

Lupinus barbiger S. Wats. from Arizona and Utah contains three alkaloids, sparteine, dilupine and trilupine, the last two of which were previously undescribed. Dilupine, provisionally $C_{16}H_{26}O_2N_2$, appears to be the amine oxide of a C-methyl-lupanine. Trilupine, $C_{15}H_{24}O_3N_2$, is the di-amine oxide of *d*-lupanine into which it may be converted by the action of acids and heat. It may be prepared by oxidizing *d*-lupanine with calcium dioxide.

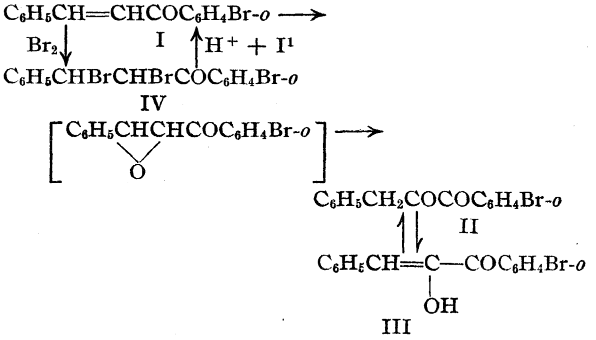
Preparation and Properties of *o*-Bromophenylbenzylglyoxal—Methylation of Alpha Diketones

BY R. P. BARNES AND NOBLE F. PAYTON[1]

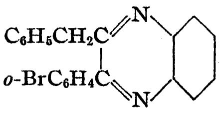
In continuation of the study of the properties of alpha diketones,[2,3,4] it was thought wise to prepare a substituted phenylbenzylglyoxal and study its reactions, since we believe that the glyoxylic acid residue present in the enolic modification of every alpha diketone is intimately related to the methylation reaction. Thus *o*-bromophenylbenzylglyoxal (III) was obtained by the following series of reactions



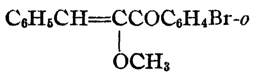
o-Bromoacetophenone was prepared according to the method given by Thorp and Brunskill[5] for *o*-chloroacetophenone. The *o*-bromoacetophenone was condensed with benzaldehyde to benzal-*o*-bromoacetophenone (I), whose constitution was established by converting it into the dibromide (IV) with subsequent reduction to (I). This α,β-unsaturated ketone was in turn oxidized and isomerized to *o*-bromophenylbenzylglyoxal (II). By means of alkali the diketone (II) was converted into the enolic modification (III).

As is the case with the other diketones of this series, *o*-bromophenylbenzylglyoxal differs very markedly from the isomeric series of beta diketones with reference to the extent of O- and C-compound formation.

o-Bromophenylbenzylglyoxal gives a cherry red color with alcoholic ferric chloride, and is 100% enolic in the solid state. It yields a quinoxaline (V) with *o*-phenylenediamine and is quantitatively cleaved to phenylacetic and *o*-bromobenzoic acids by alkaline hydrogen peroxide. Methylation with dimethyl sulfate gives 84.1% of the O-methyl compound (VI), and sufficient unchanged material to indicate that the O-compound is formed exclusively.



V



$$\underset{\displaystyle OCH_3}{C_6H_5CH{=}\overset{|}{C}COC_6H_4Br\text{-}o}$$

VI

Since there was no available information in the literature on the physical constants of *o*-bromophenylglyoxylic acid, it was prepared after the manner described by Russanow,[6] and its ionization constant determined by conductivity measurements. The concentration at which these measurements were made is approximately the same as the upper limit of the range of concentrations on the basis of which the ionization constant for *o*-bromobenzoic acid was determined. Therefore the two ionization constants are excellent criteria for judging the relative strength of the two acids.

The activating effect of carbonyl groups upon alpha hydrogen atoms is common knowledge. A similar effect is observed when one compares the ionization constants[7] of two series of organic acids such as the following.

Acid	*K* (25°)	Acid	*K* (25°)
$C_6H_5CO_2H$	5.86×10^{-4}	$C_6H_5COCOOH$	6.00×10^{-2}
$o\text{-}BrC_6H_4CO_2H$	1.42×10^{-3}	$o\text{-}BrC_6H_4COCOOH$	8.60×10^{-2}[a]
$(CH_3)_3C_6H_2CO_2H$	3.70×10^{-4}	$(CH_3)_3C_6H_2COCOOH$	5.27×10^{-2}[b]

[a] Experimentally determined value reported in this paper.

[b] Breed, Bryn Mawr College Monographs, Vol. I, No. 1, p. 15.

Thus the introduction of the carbonyl tends to increase the extent of ionization.

It is the opinion of the writer that the amount of O-compound formed upon methylation of an alpha diketone in alkaline solution depends very directly upon the acidity of the enol. Every enolic modification of an alpha diketone of the type  $RCOCOCH_2R \rightleftarrows R{-}\underset{\displaystyle O}{\overset{}{C}}\underset{\displaystyle OH}{C}{=}CHR$ may easily be considered as a glyoxylic acid in which the double

bonded oxygen has been substituted by a radical. If on the other hand one considers the enolic modification of the isomeric beta diketone of the type  $RCOCH_2COR \rightleftarrows \underset{OH}{RC}{=}CHCOR$, it is obvious that the acid of which the enol may well be considered a derivative is not a glyoxylic acid. With few exceptions[8] the beta diketones, as well as the beta ketonic esters, yield largely C-methylation products with either methyl iodide or dimethyl sulfate.

Obviously, there are two competing reactions which take place, the relative rates of which determine the extent of O- and C-methylation. One of these reactions is a direct metathesis between the alkali salt of the enol and the alkylating agent, which gives rise to the O-compound—the stronger the acid of which the enol is a conceivable derivative, the greater the amount of O-compound. Whatever the other reaction may involve, it seems to be hindered by substitution on the alpha carbon atom.

The methylation of phenylbenzylglyoxal[2] yields a mixture of O- and C-compounds. Benzhydrylphenyl diketone[3] yields 100% O-compound. Thus it seems that the phenyl group substituted for a hydrogen of phenylbenzylglyoxal offers hindrance to one of the competing reactions with the result that the other reaction preponderates. Mesitylbenzylglyoxal[4] and *o*-bromophenylbenzylglyoxal each yields exclusively the O-compound. As further support of this idea, the alpha ketonic esters of which oxalacetic ester is a good example produce mixtures of O- and C-methylation products.

Experimental Part

Preparation of Benzal-*o*-bromoacetophenone (I).—A solution of 8.4 g. of sodium hydroxide in 65 cc. of water, together with 50 cc. of alcohol, was placed in a 500-cc. wide-mouthed bottle equipped with a stirrer and cooled by an ice-bath. To the reaction chamber was added 30.5 g. of *o*-bromoacetophenone after which stirring was begun. The calculated quantity (17 g.) of benzaldehyde was then introduced. The temperature was maintained between 15 and 20° during three hours of constant stirring. The product was 12.5 g. of a yellow oil distilling at 183–185° (2 mm.).

Anal. Calcd. for $C_{15}H_{11}OBr$: C, 62.7; H, 3.9. Found: C, 62.9; H, 4.0.

Bromination: Dibromobenzal-*o*-bromoacetophenone (IV).—An ethereal solution of 2.0 g. of the α,β-unsaturated ketone was brominated in the usual way, resulting in a quantitative yield of the dibromo product which after crystallization from methyl alcohol melted at 86°.

Anal. Calcd. for $C_{15}H_{11}OBr_3$: C, 40.3; H, 2.5. Found: C, 40.6; H, 2.6.

Reduction: Benzal-*o*-bromoacetophenone (I).—When 1 g. of the dibromoketone was dissolved in 20 cc. of acetone and treated with 10% potassium iodide, a pale yellow color developed. Upon acidification a deep reddish-brown color was produced. Upon dilution a yellow oil separated out. Distillation and analysis of this oil proved that it was identical with the α,β-unsaturated ketone.

Preparation of *o*-Bromophenylbenzylglyoxal (II).—A solution of 7.5 g. of benzal-*o*-bromoacetophenone in 100 cc. of alcohol was treated with 3.5 cc. of 6 *N* sodium hydroxide with stirring. To this mixture was added 7 cc. of 30% hydrogen peroxide. A colorless oil separated out. This oil could not be crystallized. On distilling at 155° (2 mm.) a pale yellow oil was obtained which gave a deep cherry-red color with alcoholic ferric chloride.

Anal. Calcd. for $C_{15}H_{11}O_2Br$: C, 59.4; H, 3.7. Found: C, 59.8; H, 3.6.

Preparation of the Enol of *o*-Bromophenylbenzylglyoxal (III).—To 25 g. of the diketone (II) dissolved in 90 cc. of alcohol, there was added a solution of 14.4 g. of sodium hydroxide dissolved in 30 cc. of water. The mixture generated much heat and boiled on the addition of the sodium hydroxide. The mixture separated into a red upper layer and a colorless alkaline botton layer. The two layers were separated and the red solution was acidified with hydrochloric acid. The solution was largely diluted with water and extracted with ether. The ethereal solution was washed with water, dried over anhydrous sodium sulfate and concentrated. There was obtained a yield of 8 g. of colorless needle-like crystals melting at 107°.

Anal. Calcd. for $C_{15}H_{11}O_2Br$: C, 59.4; H, 3.7. Found: C, 59.2; H, 3.8.

Oxidation.—When 1.0 g. of the alpha diketone was dissolved in 50 cc. of methyl alcohol and treated with an excess of alkaline hydrogen peroxide, cleavage resulted in the production of phenylacetic and *o*-bromobenzoic acids. These products were identified by their melting points and mixed melting points with known pure samples.

Reaction with *o*-Phenylenediamine (V).—A solution of 1.0 g. of the diketone and 1.0 g. of *o*-phenylenediamine in 25 cc. of methyl alcohol was boiled for one hour and allowed to cool. The solution was poured into water, extracted with ether, washed with dilute hydrochloric acid, dried and concentrated. A practically quantitative yield of colorless needles melting sharply at 110° was obtained.

Anal. Calcd. for $C_{21}H_{15}N_2Br$: C, 67.2; H, 4.0. Found: C, 67.5; H, 4.2.

Methylation: Methyl Ether of α-Hydroxybenzal-*o*-bromoacetophenone (VI).—A suspension of 5.0 g. of the powdered enol in 20 cc. of water was treated with 4.2 g. of dimethyl sulfate. To this mixture a 20% solution of potassium hydroxide was added dropwise with vigorous shaking until permanent alkalinity was effected. After extraction with ether, an equal volume of petroleum ether was added to the ethereal layer. This solution was then shaken with successive small portions of 10% potassium hydroxide until the alkaline layer was colorless. The alkaline washings upon acidification gave 0.5 g. of unchanged material. The ethereal solution was dried, filtered

---

(8) Von Auwers, *Ber.*, **45**, 996 (1912).

and concentrated. There resulted a viscous yellow oil boiling at 280–285° (2 mm.). The yield was 4.4 g. or 84.1%.

Anal. Calcd. for $C_{16}H_{13}O_2Br$: C, 60.5; H, 4.1; —OCH_3, 9.8. Found: C, 60.8; H, 4.0; —OCH_3, 10.0.

***o*-Bromophenylglyoxylic Acid.**—This acid was purified by several crystallizations from methyl alcohol and water. The thin colorless needles melted over a range with decomposition as reported by Russanow. For a concentration of 0.03449, molecular conductivity 266.21, and conductivity at infinite dilution 348, the ionization constant at 25° was calculated to be 8.6×10^{-2}.

Summary

The preparation and properties of a new diketone are herein reported in connection with a discussion of the methylation of alpha diketones.

The Hydroxylation of the Double Bond[1]

BY NICHOLAS A. MILAS AND SIDNEY SUSSMAN

The use of osmium tetroxide and chlorates for the addition of hydroxyl groups to the double bond[2] is limited to aqueous solutions, and, at times, to specialized conditions. Similarly, organic peracids which have been used for this purpose are not of general applicability.[3] During the past year and a half we have been engaged in the preparation of tertiary alkyl peroxides and hydroperoxides, and found that anhydrous solutions of hydrogen peroxide and tertiary butyl alcohol are stable at room temperature for long periods of time. Such solutions, however, are perfectly inert toward olefinic double bonds, but in the presence of a small amount of osmium tetroxide, likewise dissolved in anhydrous tertiary butyl alcohol, a reaction proceeds smoothly to yield almost invariably a glycol. For example, from ethylene we obtained ethylene glycol; from tetramethylethylene, pinacol; from cyclohexene, adipic acid; from the ethyl esters of crotonic, maleic and fumaric acids, the corresponding dihydroxy esters. Table I shows some of the quantitative results obtained.

TABLE I

Olefinic substance	Main product	% yield
Isobutylene	Isobutylene glycol	37.6
Trimethylethylene	Trimethylethylene glycol	37.8
Allyl alcohol	Glycerol	60.2
Cinnamic acid	Phenylglyceric acid	56.2
Crotonic acid	Dihydroxybutyric acid	53.8
Maleic acid	Mesotartaric acid	30.3
Fumaric acid	Racemic acid	48.3

While our work was under way Criegee[4] published recently some preliminary results using osmium tetroxide and hydrogen peroxide in ethyl ether, and obtained aldehydes as his main products. In the present research, however, all of the unsaturated substances tried yielded glycols, although in certain cases the latter oxidized further to yield small amounts of by-products. We are now actively engaged in this field and hope to publish in the near future a more extended investigation.

Experimental

Preparation of the Reagent.—To 100 cc. of 30% hydrogen peroxide (Albone C) was added 400 cc. of pure tertiary butyl alcohol and the solution treated with small portions of anhydrous sodium sulfate whereby two layers separated out. The alcohol layer, which contained most of the hydrogen peroxide, was removed and dried with anhydrous sodium sulfate and finally with anhydrous calcium sulfate (Drierite). A solution of 6.32% hydrogen peroxide in tertiary butyl alcohol was obtained, giving a recovery of 93.8%. This solution can easily be concentrated by vacuum distillation of the alcohol at room temperature to any desired concentration without any loss of the peroxide provided an all-glass apparatus is employed. When hydrogen peroxide solutions of this sort were allowed to stand at room temperature for over six months, only a small decrease in hydrogen peroxide concentration was noticed.

The Catalyst.—Osmium tetroxide (Merck osmic acid) dissolves readily in tertiary butyl alcohol and the solution is perfectly stable provided no isobutylene is present, otherwise most of the osmium tetroxide is readily reduced into an insoluble black colloidal oxide which is a very active catalyst for the decomposition of hydrogen peroxide. In aqueous solutions osmium tetroxide destroys hydrogen peroxide in a very short time, whereas in anhydrous tertiary butyl alcohol it decomposes the latter to the extent of 20% in one month's time.

---

[1] A preliminary report of this work was presented before the research conference, M. I. T., December 13, 1935.

[4] Criegee, *Ann.*, **522**, 75 (1936).

Isobutylene Glycol from Isobutylene.—The isobutylene was prepared by the dehydration of tertiary butyl alcohol with oxalic acid. To 4.3 g. (0.0768 mole) of isobutylene dissolved in 36.3 g. of tertiary butyl alcohol was added 39.3 cc. (0.0768 mole) of 6.62% hydrogen peroxide reagent. The mixture was cooled in an ice-bath and to it added 0.75 cc. of a 0.5% solution of osmium tetroxide in tertiary butyl alcohol, and allowed to stand overnight at 0°. The reaction was complete on the following day when the mixture was fractionated and the fraction boiling at 176–178° collected; yield, 2.6 g. or 37.6% of the theoretical. This had a density of 0.999 at 25°. The boiling point and density of isobutylene glycol are recorded in the literature[5] as 176–178° and 1.003 at 20°, respectively.

Trimethylethylene Glycol from Trimethylethylene.—To 7 g. (0.1 mole) of trimethylethylene[6] (b. p. 38.3–38.4°) were added 48.4 cc. (0.1 mole) of 7.03% hydrogen peroxide reagent and 1 cc. of the osmium tetroxide solution catalyst, and the mixture allowed to stand at room temperature for twenty-four hours. At the end of this time the reaction was complete; the mixture was then fractionated whereby 2.9 g. of trimethylethylene was recovered and a fraction boiling at 175° collected; yield, 2.3 g. or 37.8% of the theoretical. This had a density of 0.992 at 25°. The boiling point and density of trimethylethylene glycol are recorded in the literature[7] as 176–178° and 0.989 at 25°, respectively.

Glycerol from Allyl Alcohol.—To 6.1 g. (0.105 mole) of allyl alcohol (Eastman Kodak Company) were added 54.6 cc. (0.1 mole) of 6.3% hydrogen peroxide reagent and 1 cc. of the osmium tetroxide solution catalyst. The reaction mixture warmed up considerably and had to be cooled under running water. At the end of three hours the peroxide was completely consumed and the reaction mixture subjected to fractionation to remove the solvent, the catalyst and the unreacted allyl alcohol (1.7 g.). The glycerol obtained amounted to 4.2 g. or 60.2% of the theoretical. The glycerol was definitely identified as the tribenzoyl ester which was prepared in pyridine from benzoyl chloride and the product obtained. It had a m. p. of 69°. Balbiano[8] gives the m. p. of this derivative as 71–72°.

Phenylglyceric Acid from Cinnamic Acid.—To 3.7 g. (0.025 mole) of cinnamic acid (Eastman Kodak Company) were added 13.6 cc. (0.025 mole) of 6.3% hydrogen peroxide reagent and an equal volume of tertiary butyl alcohol. The mixture was cooled in an ice-bath, to it added 2 cc. of the osmium tetroxide solution catalyst, and allowed to stand overnight at 0°. The reaction was complete on the following day when the solvent was removed by vacuum distillation and the residue taken up with water. The unchanged cinnamic acid (2.4 g.) was removed by filtration and the filtrate distilled under reduced pressure when a semi-solid residue separated out; yield 0.9 g. or 56.2% of the amount of cinnamic acid consumed. The semi-solid phenylglyceric acid was not crystallized, but was found to have a neutralization equivalent of 190 which is in close agreement with the theoretical value of 182 for phenylglyceric acid.

Dihydroxybutyric Acid from Crotonic Acid.—To 4.3 g. (0.05 mole) of crotonic acid (Eastman Kodak Company) was added 27.2 cc. (0.05 mole) of 6.3% hydrogen peroxide reagent. The mixture was cooled in an ice-bath and to it added 1 cc. of the osmium tetroxide solution catalyst, and allowed to stand overnight at 0°. The reaction was complete on the following day when the solvent was removed by distillation under reduced pressure, and the residue taken up with water. The unchanged crotonic acid was then extracted with chloroform following the method of Braun.[9] When the chloroform was evaporated 2.7 g. of unchanged crotonic acid was recovered. The aqueous portion was evaporated under reduced pressure and yielded 1.2 g. of a thick sirup; yield, 53.8% of the amount of crotonic acid consumed. This had a neutralization equivalent of 122, which is in close agreement with the calculated value of 120 for dihydroxybutyric acid.

Mesotartaric Acid from Maleic Acid.—To 2.9 g. (0.025 mole) of maleic acid (Eastman Kodak Company) were added 27.2 cc. (0.05 mole) of 6.3% hydrogen peroxide reagent, 2 cc. of the osmium tetroxide solution catalyst, and the mixture was allowed to stand overnight at room temperature. The reaction was complete on the following day when the solvent was removed under reduced pressure and the residue dissolved in water. The solution was then made ammoniacal, heated to boiling and treated with excess 10% calcium chloride solution, whereby the calcium oxalate and mesotartrate precipitated out. This precipitate was removed, dried and weighed; yield, 1.9 g. To remove the calcium mesotartrate, the precipitate was extracted with 20% sodium hydroxide solution. This separation yielded 1.2 g. of calcium mesotartrate and 0.7 g. of calcium oxalate. The calcium mesotartrate was further purified by reprecipitation and analyzed.

Anal. Calcd. for $C_4H_4O_6Ca{\cdot}3H_2O$: Ca, 16.53. Found: Ca, 16.28.

The filtrate from the calcium precipitation was treated with three volumes of 95% alcohol, and the calcium maleate, which precipitated out, collected, dried and weighed; 2.1 g., equivalent to 1 g. of unreacted maleic acid. From these results the yield of mesotartaric acid was calculated to be 30.3% and that of oxalic acid 14.6% of the maleic acid consumed in the reaction. Obviously the mesotartaric acid formed from maleic acid oxidizes further to oxalic acid.

Racemic Acid from Fumaric Acid.—To 2.9 g. (0.025 mole) of fumaric acid prepared from furfural[2c] were added 27.2 cc. (0.05 mole) of 6.3% hydrogen peroxide reagent, 2 cc. of the osmium tetroxide solution catalyst, and the mixture was allowed to stand for two days at 0°. The solvent was then removed under reduced pressure, the residue taken up with a small volume of water and the unreacted fumaric acid (1.7 g.) removed by filtration. The filtrate yielded 0.3 g. of calcium oxalate precipitated in acetic acid solution, and 1.3 g. of calcium racemate precipitated in ammoniacal solution. These correspond to 9.9% yield of oxalic acid and 48.3% yield of racemic acid. The calcium racemate was then analyzed for calcium.

Anal. Calcd. for $C_4H_4O_6Ca{\cdot}4H_2O$: Ca, 15.38. Found: Ca, 15.26.

Summary

1. It has been found that hydrogen peroxide in anhydrous tertiary butyl alcohol and in the presence of osmium tetroxide reacts with olefinic substances to yield glycols as the main products.

2. Ethylene glycol, isobutylene glycol, trimethylethylene glycol, pinacol, glycerol, phenylglyceric acid, dihydroxybutyric acid, mesotartaric acid and racemic acids have been obtained from their corresponding olefinic substances.

Conversion of Aldoximes to Carboxylic Acids by Means of Hot Alkali. The Elimination of Water from Aldoximes

BY EARL JORDAN[1] AND CHARLES R. HAUSER

The common statement that a β-aldoxime loses water to form a nitrile more readily than its α-isomer has been based presumably on the well-known fact that, in the presence of certain reagents, as for example acetic anhydride followed by alkali, the β-aldoxime forms nitrile, whereas the α-isomer usually gives only negligible amounts of this product. Under these conditions, however, the nitrile is *not* formed by the elimination of water from the β-aldoxime; the latter is first converted to its acetyl derivative which eliminates acetic acid to form nitrile.[2] Apparently there has been no direct evidence that in general, a β-aldoxime loses water more easily than its α-isomer.[3]

In this paper it is shown that certain β-aldoximes in 2 *N* sodium hydroxide solution[4] at 97–100° are slowly converted into mixtures of the corresponding carboxylic acids, ammonia and the α-aldoximes;[5] the latter are more slowly converted into carboxylic acids. The yields of acid and oxime isolated after certain periods of time are given in Table I. It can be seen that after the same periods of time the yields of acid obtained from β-aldoximes are higher than those from the α-isomers. Since these carboxylic acids[6] are probably formed by the hydrolysis of intermediate nitriles produced from the aldoximes by elimination of water, β-aldoximes apparently *do* lose water more readily than their α-isomers; however, this reaction is not recommended for distinguishing a pair of geometrically isomeric aldoximes[7] because, under the conditions used to effect the elimination of water, a considerable portion of the β-aldoxime is converted into the α-isomer.[5]

The rate of conversion[5] of β-3,4-methylenedioxybenzaldoxime into the α-isomer under these conditions is roughly indicated by the melting points of the products recovered after various periods of time. Evidently, complete conversion of the β-aldoxime to the α-isomer requires from sixty to ninety minutes. Likewise, β-4-methoxybenzaldoxime apparently is converted into the α-isomer within four hours. Since practically pure α-benzaldoxime is often obtained as an oil, the products recovered after four hours from both α- and β-benzaldoximes are probably almost pure α-aldoxime. On the other hand, both α- and β-furfuraldoxime apparently are converted into a mixture of the two isomers.[8]

The changes occurring when benzaldoximes in

---

[1] This paper is from a portion of a thesis presented by Earl Jordan in partial fulfilment of the requirements for the Ph.D. degree at Duke University.

[2] For a recent discussion of this reaction see Hauser and Jordan, THIS JOURNAL, **57**, 2450 (1935); Hauser and Sullivan, *ibid.*, **55**, 4611 (1933).

[3] This has been pointed out by Brady, *Science Progress*, **29**, 485 (1935). In this connection it should be mentioned that Hantzsch and Lucus [*Ber.*, **28**, 748 (1895)] have reported that β-mesitylaldoxime with hot alkali gives nitrile whereas the α-isomer is stable under similar conditions; also, Hantzsch [*ibid.*, **24**, 47 (1891)] has reported that β-thiophenaldoxime with hot sodium carbonate gives nitrile. For references to the thermal decomposition of aldoximes see Hurd, "The Pyrolysis of Carbon Compounds," Chemical Catalog Co., N. Y., 1929, p. 659.

[4] Aldoximes in alkaline solutions are quite stable at room temperatures. See Freudenberg, "Stereochemie," Vol. VII, 1933, p. 987. In this Laboratory β-3,4-methylenedioxybenzaldoxime (m. p., 146°), after being kept in 2 *N* sodium hydroxide solution at 30° for thirty-six hours was recovered in a yield of 93% melting at 133–135°; the α-isomer melts at 110°.

[5] It is well known that there is a tendency for the β-benzaldoximes to revert to the α-isomers. See Freudenberg, "Stereochemie," Vol. VII, 1935, p. 988.

[6] It does not seem possible that the carboxylic acids could have been produced by a Cannizzaro reaction since no benzyl alcohol has been found; moreover, in certain cases, the total yields of carboxylic acid and aldoxime recovered amounts to over 90% of the theoretical quantitatives.

[7] These isomers are more readily distinguished by the reactions of their acetyl derivatives with bases; see references 2 and 3.

[8] This is in agreement with the results reported by Brady and Goldstein, *J. Chem. Soc.*, 1959 (1927).

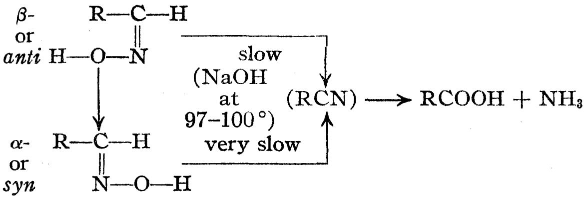
[a] Melting point of α-isomer.

2 *N* sodium hydroxide solution are heated at 97–100° may be represented by the scheme[9]



In order to show that the formation of carboxylic acid is brought about by the presence of alkali, β-3,4-methylenedioxybenzaldoxime was heated at 97–100° with water alone for four hours, and in a solution of dioxane and water for ninety minutes. No nitrile or carboxylic acid could be isolated in either case; the only change observed was the conversion of a portion of the β-aldoxime to the α-isomer.

Experimental

Approximately 2 g. of aldoxime was dissolved in 50 cc. of 2 *N* sodium hydroxide and heated on a boiling water-bath (97–100°). In cases in which considerable acid was produced, ammonia was readily detected in the vapors. After a designated time the solution was cooled and saturated with carbon dioxide. The oxime which precipitated was filtered through a sintered glass crucible. The filtrate was extracted with ether to remove the oxime in solution. The filtrate was then acidified with hydrochloric acid and the precipitated carboxylic acid filtered off; the filtrate was extracted with ether. The products were dried and weighed; they were identified by the mixed melting point method. No other products were found.

Blanks were run with β-3,4-methylenedioxybenzaldoxime at 97–100°: (a), after four hours with water, 99% oxime (m. p. 138–140°) was recovered; (b), after ninety minutes in water–dioxane solution, 95% oxime (m. p. 99–101°) was recovered.

Summary

1. Certain β-aldoximes with 2 *N* sodium hydroxide at 97–100° are slowly converted into mixtures of carboxylic acids and the corresponding α-aldoximes. The latter are more slowly changed to carboxylic acids.

2. These results indicate that a β-aldoxime eliminates water to form nitrile more readily than its α-isomer; presumably, the nitrile undergoes hydrolysis in the presence of hot alkali to form the corresponding carboxylic acid and ammonia.

The Alkaloids of Fritillaria Roylei. I. Isolation of Peimine[1]

BY YUOH-FONG CHI, YEE SHENG KAO AND KOU JEN CHANG

Previous contributions on the alkaloidal content of the plant *Fritillaria Roylei* (Pei-Mu) by Fukuda[2] and Chou[3,4] have shown that it contains the following alkaloids: (A) verticin, $C_{18}H_{33}O_2N$ or $C_{19}H_{30}O_2N$; (B) verticilin, $C_{19}H_{33}O_2N$; (C) peimine, $C_{19}H_{30}O_2N$; (D) peiminine, $C_{18}H_{28}O_2N$; (E) fritimine, $C_{38}H_{62}O_3N_2$; and (F) fritillarin, $C_{19}H_{33}O_2N$. The properties of these alkaloids are recorded in Table I.

TABLE I

Name	Formula	M. p., °C.	Rotation	Pei-Mu source
Peimine	$C_{19}H_{30}O_2N$	223	0°	Chekiang
Peiminine	$C_{18}H_{28}O_2N$	135	−62.5°	Chekiang
Fritimine	$C_{38}H_{62}O_3N$	167	−50°	Szechuen
Verticin	$C_{18}H_{33}O_2N$ $C_{19}H_{35}O_2N$	224–224.5	−10.66°	Japanese
Verticillin	$C_{19}H_{33}O_2N$	Sinters at 130, melts at 148–150, resolidifies at 157–159, decomposes at 212–213		Japanese
Fritillarin	$C_{19}H_{33}O_2N$	130–131		Japanese

This interesting drug (Pei-Mu) finds wide application in medicine and is prescribed in fevers, coughs, dysuria, hemorrhages, deficiency of milk, threatened mammary abscess, lingering labor, rheumatism and diseases of the eye. This plant was identified as *Fritillaria Roylei* by Stuart[5] or *Fritillaria verticillata* by Read and Liu.[6] The part of the plant used in medicine is the starchy corm of this liliaceous plant growing in different parts of China, especially in Chekiang and Szechuen. The material used for this investigation was a Chekiang variety known by the commercial name "Ta Pei," and was obtained from a local drug store or pharmacy. The pharmacological properties of peimine, peiminine and fritimine have been described by Chen.

The alkaloid A, (verticin) recently isolated by us, had the same melting point as C (peimine); but the results of our analyses of the free bases and its salts proved it to have the formula $C_{26}H_{43}O_3N$, instead of $C_{19}H_{30}O_2N$ assigned to peimine by Chou. Judging from the analytical data already known, we conclude this was probably the same alkaloid as peimine, to which the present authors have assigned a different formula.

Experimental Part

Ninety-eight kilograms of the starch corms of *Fritillaria Roylei*, known under the commercial name "Ta Pei" was powdered, and percolated with 95% alcohol. When the solvent had been removed from the alcoholic extract under diminished pressure at 40–45°, the residue was dissolved in 2% hydrochloric acid, and the solution filtered. The crude alkaloid was then liberated from the acid extract with sodium carbonate, and extracted with ether and then with chloroform. After distilling the solvent from the ethereal solution, the ether-soluble alkaloid weighed 48 g., which represented about 0.05% of the total quantity of the crude drug. This crude alkaloid dissolved in benzene, to which some petroleum ether was added just to turbidity, whereupon peimine separated as an amorphous powder. It was then purified by recrystallization from an alcohol–petroleum ether mixture, from which peimine separated in needles, melting at 223–224°.

In some cases, it was better to convert the ether-soluble alkaloids, after solution in dry ether, into their hydrochlorides by passing in dry hydrogen chloride. The mixed hydrochlorides were then separated into peimine hydrochloride and peiminine hydrochloride (to be described in our next paper) by fractional crystallization from an alcohol–ether mixture.

Pure peimine was recovered from its hydrochloride by action of sodium carbonate. It was recrystallized from a mixture of alcohol–petroleum ether, and separated in needles melting at 224°. The yield of pure peimine was 3 g. For analysis, the alkaloid was dried over phosphorus pentoxide at 80° in a vacuum, $[\alpha]^{13}_{D}$ 0°.

The hydrochloride and hydrobromide of peimine were prepared by dissolving in each case 100 mg. of the pure alkaloid in ether, passing in hydrogen chloride or bromide and recrystallizing from an alcohol–ether mixture. The acid sulfate was prepared in similar fashion except that dilute sulfuric acid was employed. The different products were dried for analysis over phosphorus pentoxide at 80° in a vacuum.

The platinichloride and aurichloride were prepared by precipitation in aqueous solution. The former salt was recrystallized from water and the latter from dilute hydrochloric acid. The products were dried for analysis over phosphorus pentoxide at 110° in a vacuum. The results of analyses of the alkaloid and its different salts are recorded in Table II.

Summary

Peimine, melting at 224°, has been obtained in a more pure condition. Its formula is $C_{26}H_{43}O_3N$, instead of $C_{19}H_{30}O_2N$, which was assigned to it by Chou. The present formula is substantiated by the results of analysis of several salts; namely, the hydrochloride, bromide, acid sulfate, platinichloride and aurichloride.

NOTES

An Apparatus for the Determination of the Absorption of Small Quantities of Gas by Solutions

BY H. E. BENT, W. F. GRESHAM AND N. B. KEEVIL

The apparatus illustrated in the figure is designed to measure the absorption of small amounts of gas by solutions contained in sealed glass capsules. The apparatus allows one to break and empty the capsule, measure the amount of oxygen absorbed and make a correction for the amount of oxygen dissolved in the solvent. The sample is contained in a capsule "G" and the oxygen to be introduced is measured in a capillary by means of the scale "B," a small slug of mercury in the capillary serving to confine the gas.

The particular problem which necessitated the construction of this apparatus was the determination of the purity of small quantities of organic free radicals by measuring the quantity of oxygen absorbed. Samples of a half gram or larger may conveniently be studied in the apparatus developed for measuring the heat of the reaction.[1] Frequently, however, it is desirable to analyze with a precision of about 1% a dilute solution of a free radical which will not absorb more than about 1 cc. of oxygen. The details of breaking the capsule and measuring the absorption of oxygen together with typical experimental results are given in the following paragraphs.

The manipulation of the apparatus will be evident from the figure and the following description. "A" is a stopcock through which the apparatus may be evacuated after the capsule containing the solution of the free radical has been placed in the apparatus. "B" is a scale placed behind the capillary (diameter 4 mm.) in order that the volume of oxygen introduced into the absorption bulb may be accurately measured. "C" is a three-way stopcock which connects the capillary tube to the supply of oxygen and to the

---

(1) Bent, Cuthbertson, Dorfman and Leary, THIS JOURNAL, **58**, 165 (1936); Bent and Cuthbertson, *ibid.*, **58**, 170 (1936).

absorption bulb. "D" leads to the oxygen supply and has a blow-off tube below it to permit better control of the pressure. By properly adjusting the pressure a small volume of mercury is introduced into the capillary through "C" before it is filled with oxygen. This slug is blown by oxygen to the top of the capillary. When the cock "C" is carefully turned to introduce oxygen into the absorption bulb which is at a slightly lower pressure the slug of mercury descends and gives a measure of the amount of gas which has been introduced. Provided the tube is clean no difficulty is encountered from the slug's dropping in the capillary. "E" is a thermometer which measures the temperature in the jacket around the absorption bulb. The absorption bulb is just above "F" and at "F" is a reference mark to which the bulb is calibrated. "G" is the capsule which is of rather peculiar design. At the top the capsule is sufficiently blunt to prevent its wedging in the constriction. At the bottom there is a little bulge which permits the glass rod "H" to hold the capsule submerged after it has been emptied. The capsule below the lower bulge is constricted for a short length before drawing down to a capillary. The reason for this is that the capsule cannot easily be emptied unless there is sufficient volume between the lower part of the capsule and the outside tube to hold all of the solution. The contents of the capsule are expelled below the surface of the mercury by warming. If the capsule had not been constricted at the bottom the solution would have come out of the capsule and surrounded the latter, thus making it difficult to expel the contents, as the solution around the outside would have warmed up first and been pushed back into the capsule. The glass rod "H" is connected by a fresh piece of gum rubber tubing. The rubber is connected to a glass tube at such an angle that it is always covered by mercury and does not come in contact with the solution. At the beginning of a run the mercury is lowered and the capsule held by the rod "H." After evacuation the mercury is raised around the capsule and the tip of capsule broken by means of this rod. After emptying the capsule the rod holds the glass down out of the way of the solution while it is absorbing oxygen. "I" is a rubber stopper which is held up by a steel washer which in turn is held securely in place by wires which are not shown. "J" is a pinchcock which permits the mercury to be held at a fixed height in the absorption bulb. "K" is a reservoir of mercury which can be evacuated for removal of mercury from the absorption bulb or may be open to the atmosphere or maintained at any desired intermediate pressure. The pressure in the absorption bulb is measured by means of the mercury column in the tube which is open at the top, a small cathetometer and steel scale, not shown.

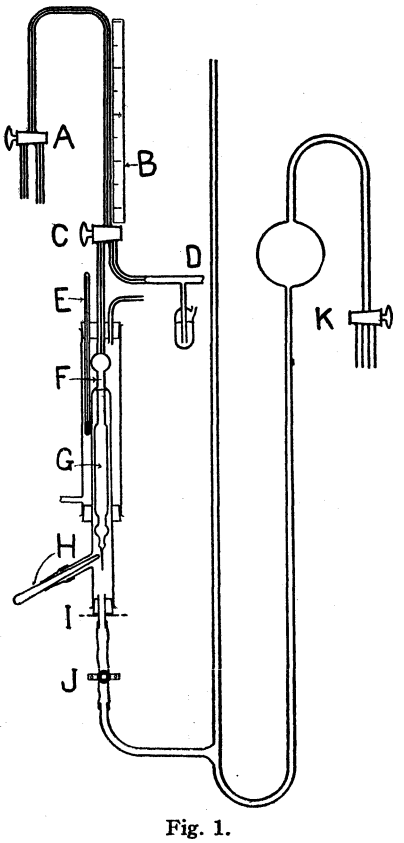

Fig. 1.

In carrying out a run the capsule is first introduced by removing the rubber stopper "I." The pinchcock is closed and the space surrounding the capsule evacuated. Mercury is then allowed to rise, floating the capsule above the rod "H." A correction is made for any trace of residual gas by measuring it before adding the oxygen. The quantity amounted usually to one or two tenths of a cubic centimeter. The pressure is then adjusted, the tip broken and the contents expelled by gentle warming, the broken tip being kept slightly below the surface of the mercury. The pressure is then adjusted to a little less than one atmosphere and an excess of oxygen introduced. The volume of the gas phase is increased to three times that of the calibrated bulb (9.9 cc.), an auxiliary calibration fixing this point, and the solution allowed to stand with occasional shaking in order to come to equilibrium. The ether meniscus is then raised to the graduation on the constriction at "F" and the amount of residual oxygen computed from the total pressure and the vapor pressure of the solvent. A correction is applied for the amount of oxygen dissolved in the solvent at the partial pressure of the oxygen existing at the time equilibrium is being established. The compression of the oxygen, as the solution is raised, increases its solubility. However, the surface of contact is so small at the constriction that the new equilibrium is approached very slowly. Since this is a correction to a correction it is not of importance. When ether is used as a solvent the largest error is due to the changing vapor pressure of ether with slight change in temperature. The table illustrates the accuracy which may be obtained without thermostating the water jacket. Doubtless a more accurate control of the temperature by circulating water at constant temperature through the jacket would still further improve the results. The apparatus was checked by determining the solubility of oxygen in ether using a sample of ether about three times as large as that required in the determination of the purity of a free radical. An error of 10% in determining the solubility of oxygen in ether amounts to about 0.5% in the correction to be applied to a run on a free radical. The data on diphenyl α-naphthylmethyl in the table give an idea of the accuracy of the method.

The Catalytic Oxidation of Carbon

BY HANS M. CASSEL

The activating effect of sodium chloride on the combustion of soot in contact with it, described by R. K. Taylor,[1] has recently been the object of further interesting experiments by Day, Robey and Dauben,[2] using other salts as activating substances. In explaining their observations these authors refer to a theory proposed by H. S. Taylor and H. A. Neville[3] for the heterogeneous reaction of steam with carbon.

It should be taken into consideration, however, that the topochemical relations in the two cases are distinctly different: in the steam experiments the salt particles are imbedded in the carbon surface; in the combustion experiments, on the other hand, the oxygen molecules have to penetrate the soot layer before they can possibly reach the salt surface.[4] It is difficult to see how the contact of the soot with the salt is maintained and continues to be effective once the reaction has started in the interface.

On the basis of the earlier work of Eucken[5] two observations made by me may offer a more satisfactory explanation. Eucken, studying the combustion of graphite under low pressures, observed a rather low rate on smooth surfaces. But after a longer attack by oxygen the carbon surface takes on a velvet-like appearance, accompanied by an acceleration of the reaction. The condition of the surface may, however, be "ironed out" again by a process which Eucken calls "healing." Probably this is due to the reaction $2CO = C + CO_2$ which takes place in the range of not too high temperatures, the formation of CO being the first step of oxidation. According to R. K. Taylor, this process of regeneration seems to occur also in the case of burning soot, for he observed a slowing down of the reaction "presumably because of the more rapid oxidation at first of smaller particles or more active patches on the carbon surface."

I deposited a layer of soot on Pyrex glass by cracking CH_2Cl_2 at about 450°. In burning this by exposing it to a current of oxygen at about 600° the reaction once started generally spreads parallel to the surface, the soot being removed as if swept out by a piston. The fact that the reaction does not visibly proceed perpendicularly to the surface indicates that the carbon deposit is more easily attacked from the sides than from the

surface. This should be expected if the soot particles, as hexagonal crystals,[6] have grown orientated with their cleavage planes lying parallel to the glass surface.[7]

This view is in agreement with the theory of Eucken, which assumes that the adsorption of gas molecules or atoms by graphite takes place preferentially in the planes perpendicular to the cleavage planes of the crystal lattice.[8] The reaction, therefore, should be facilitated wherever two adjacent crystals touch each other or project into the gas phase.

If this is true, and if the soot deposits are always orientated, the combustion of soot deposits should be accelerated when the underlying glass surface is etched or ground. In order to check this the externally ground part of a Jena glass ground joint and the adjacent smooth surface were coated with soot from a natural gas flame and exposed to oxygen at about 600° for a few seconds. This treatment cleaned the ground part perfectly of carbon, while no visible attack took place on the smooth glass surface, a sharp line dividing the two.

Considering that the deposits in the salt experiments naturally have a very coarse structure, it may be concluded that the function of the salts in the case of soot combustion is quite the same as that of the ground glass, in the above described experiment, namely, interrupting the primary growth of large crystals and preventing a secondary regeneration.

From the same point of view the theory of the mechanism of the steam–carbon reaction should be revised. It is known from the experiments of Frankenburger[9] that sodium chloride inserted into iron deposits causes a highly dispersed structure by inhibiting the growth of coherent crystals. Such iron appears remarkably activated. Accordingly the increased activity of the impregnated graphite seems to be due to the opening of the prismatic planes[6] of the crystal lattice combined with the hygroscopic action of the salt ions.

Resin Studies. IV. Sublimed *l*-Abietic Acid

BY DAVID LIPKIN AND W. A. LA LANDE, JR.

l-Abietic acid (and rosin) have been observed to give a "sublimate" when heated under a variety of conditions at a temperature below the distillation point of the acid.[1] We have studied this sublimate carefully and find that it shows certain marked differences from the products obtained by Shaw and Sebrell and by Labatut and Duffour. Dupont[2] considered the sublimate obtained by the latter investigators to be identical with *l*-abietic acid.

To obtain a sufficient quantity of the sublimate the previously described procedure of La Lande[1] was used, except that stirring was eliminated and a large glass tube substituted for the reaction vessel. The yield of dry and colorless product was highest in the range 175–275°; at 330–385° the yield was negligible and the product quite impure due to the rapid decomposition. About 0.5 g. of sublimate was collected during an eight-hour period from a 14-g. charge; none was obtained from various rosins, and air or oxygen could not be substituted for the pure nitrogen.

Fig. 1.—"Sublimed" *l*-abietic acid (× 100).

The product, which is illustrated in the accompanying figure, showed the following properties as compared with a sample of *l*-abietic acid prepared according to Steele.[3]

The rotary power of the sublimate was practically constant regardless of the temperature and its rate of formation. It underwent no change on exposure to the light (including occasional sunlight) and air of the laboratory for a few months,

Studies in the Phenanthrene Series. X. Naphthoquinolines[1]

BY ERICH MOSETTIG AND JOHN W. KRUEGER

The skeleton of morphine consists of a phenanthrene nucleus and a nitrogen-containing ring. Neither in natural nor synthetic products is any other example known of such a condensed ring system as is found in the morphine group. As an approach to the preparation of compounds containing similar ring systems, which might exhibit morphine-like action, we have considered it advisable to include the synthesis of several naphthoquinolines and naphthoisoquinolines.[2]

This communication deals with the synthesis of a naphthoquinoline derived from 3-aminophenanthrene. Since the latter compound has been hitherto prepared practically only through a very tedious detour (phenanthrene sulfonic acid to hydroxyphenanthrene to aminophenanthrene),[3] we sought for a more feasible preparative method. Very recently Bachmann and Boatner[4] described in a preliminary form the preparation of 1-, 2-, and 3-aminophenanthrenes by the Beckmann rearrangement of the oximes of 1-, 2-, and 3-acetylphenanthrenes, emphasizing the practical usefulness of this procedure. We have, independently of these authors, prepared 2- and 3-aminophenanthrenes in the same way. We are withholding the preparative details until comparison with Bachmann and Boatner's procedure can be made.

By application of Skraup's synthesis to 3-aminophenanthrene, a naphthoquinoline of m. p. 106–107° was obtained. In spite of careful search, no other isomer could be found, which indicates that ring closure took place in only one direction. A tetrahydro derivative, obviously hydrogenated in the nitrogen-containing ring, was readily obtained by high pressure reduction, employing Chromite catalyst. By catalytic reduction under ordinary conditions, using platinum oxide catalyst, the same py-tetrahydronaphthoquinoline was formed together with a more highly hydrogenated compound which is most probably an octahydronaphthoquinoline. Since there is still some uncertainty in our minds as to the nature of the substance obtained by the Emde degradation of the methochloride of N-methyltetrahydronaphthoquinoline, the comparison of the degradation product with 2-[3-(dimethylamino)-*n*-propyl]-phenanthrene does not permit any conclusions as to whether the nitrogen-containing ring is attached in the 3,4- or 3,2-positions of the phenanthrene nucleus.

We intend to present this final structural proof together with analogous experiments on the 2- and 9-aminophenanthrenes respectively, in a following communication.

Experimental

Naphtho-(1,2-f)-quinoline or Naphtho-(2,1-g)-quinoline.—For the sake of simplicity we shall refer to this compound as "naphthoquinoline." It was prepared by Cohn's modified method of Skraup.[5] Thirty grams of 3-aminophenanthrene was added to a suspension of 4.5 g. of ferrous sulfate in 30 cc. of nitrobenzene, which was subsequently mixed with a solution of 9.1 g. of boric acid in 46 cc. of glycerol. Finally, 25 cc. of concentrated sulfuric acid was introduced in small portions to the thoroughly stirred mixture. The gray pasty mass was then transferred to an Erlenmeyer flask, kept in a water-bath for three hours, and finally heated on a hot-plate until it turned to

[a] Five grams of finely divided 2-acetylphenanthrene (m. p. 143–144°), 4 g. of hydroxylamine hydrochloride, 80 cc. of alcohol and 2 cc. of pyridine were heated in a pressure bottle for three and one-half hours at 100°. Practically pure oxime crystallized from the cooled reaction mixture; yield, 90%.

[b] The methylation of 3-aminophenanthrene was carried out in 10-g. batches using dimethyl sulfate and potassium hydroxide. The separation of the tertiary and secondary bases was effected by Hinsberg's method with benzene sulfonyl chloride. The quaternary compound was isolated as the methiodide. This, on thermal decomposition, yielded another batch of tertiary amine. The average yield of tertiary amine was 40–50%, of secondary amine, 10%.

[c] Obtained in yields of 60–70% by reduction of the oxime with 2.5% sodium amalgam in alcohol–acetic acid solution.

[d] Ten grams of "naphthoquinoline" suspended in 15 cc. of absolute alcohol with 1 g. of Chromite catalyst was heated to 135° during one hour, and kept at this temperature for one and one-half hours under a hydrogen pressure of 133–144 atm. (apparatus, Adkins and Cramer, THIS JOURNAL, **52**, 4349 (1930), catalyst, 37 KAF, *ibid.*, **54**, 1138 (1932)). The catalyst, together with the crystallized reduction product was filtered, the base (7.5 g., m. p. 70–74°) was separated from the catalyst by extraction with ether in a Soxhlet apparatus. From the alcoholic filtrate 1.5 g. of tetrahydronaphthoquinoline hydrochloride was obtained. No other substances could be obtained. Five grams of naphthoquinoline, dissolved in 125 cc. of glacial acetic acid, was reduced catalytically under ordinary conditions, using 0.25 g. of platinum oxide. Within ten days 1700 cc. of hydrogen was taken up (calcd. for 2 moles, 1100). Three and one-half grams of the octahydro compound was obtained by the aid of its difficultly soluble hydrochloride. When the hydrogenation was interrupted after about two and a quarter moles of hydrogen had been taken up, octahydro- and tetrahydronaphthoquinoline and a considerable amount of oily, undefined products were obtained. The octahydronaphthoquinoline may be prepared more conveniently by catalytic reduction (platinum oxide and glacial acetic acid) of the tetrahydro compound. The tetrahydronaphthoquinoline is rather unstable and becomes dark in solution.

[e] To a suspension of 1 g. of phosphorus pentachloride in 2 cc. of chloroform, 1 g. of finely powdered 2-(3-(dimethylamino)-1-hydroxy-*n*-propyl)-phenanthrene hydrochloride (Mosettig and van de Kamp, unpublished results) was added in small portions, and the mixture was shaken for several minutes. The hydrochloride was precipitated with ether and recrystallized from alcohol; yield, 0.7 g. Its m. p. depends greatly on the speed of heating.

[f] A suspension of 0.075 g. of palladous hydroxide–calcium carbonate catalyst (Pd content 1%), and 0.5 g. of 2-(3-(dimethylamino)-1-chloro-*n*-propyl)-phenanthrene hydrochloride in 10 cc. of alcohol was shaken in a hydrogen atmosphere. The hydrogen absorption was completed in two hours. The catalyst was filtered off, the alcohol was evaporated *in vacuo*, and the residue treated with ether and 10% potassium hydroxide. The brown oily base obtained from the ether layer was distilled in an oil pump vacuum, and converted into the hydrochloride: yield, 30–50%; mol. wt. of free base by micro Rast, calcd. 263; found, 278. In this reduction a white amorphous solid, insoluble in ether and water, was formed, probably according to the equation: $2C_{19}H_{20}NCl \longrightarrow C_{38}H_{40}N_2 + 2HCl$.

a homogeneous liquid which was kept at a gentle boil for nineteen hours. The reaction mixture was steam distilled.

On addition of saturated sodium chloride solution, the naphthoquinoline hydrochloride precipitated in the form of light brown needles. For further purification the base was liberated and taken up in ether. If necessary, a separation from unchanged aminophenanthrene can be effected through the difficultly soluble sulfate of the latter compound. The naphthoquinoline can be purified by high vacuum distillation or by crystallization, and is obtained in the form of long, flat, nearly colorless needles or pale yellow prisms; average yield, 45% of the amount calculated from the aminophenanthrene. The hydrochloride crystallizes in lemon-yellow felt-like needles.

An Improvement on the Quantitative Determination of Radioactivity

BY A. R. OLSON, W. F. LIBBY, F. A. LONG AND R. S. HALFORD

In an investigation of the mechanism by which acetylchloroaminobenzene rearranges into *p*-chloroacetanilide, which is to be published soon, Olson, Porter, Long and Halford used radioactive chloride ion in order to get one datum in addition to the usual kinetic data. It was necessary to determine the radioactivity of the chloride ion remaining in solution at various times as the reaction progressed. The methods which previously have been used for this purpose have utilized solid materials and because of this have had the following defects in common: (a) lack of reproducibility of the sample due to variations in particle size, crystal structure, thickness of the layer, etc., (b) the activity of the sample is at an optimum for a Geiger counter for a time approximately equal to the half-life of the active material.

By dissolving the solid material and introducing the solution into a counter of the type shown in Fig. 1, the errors mentioned in (a) can be eliminated. Then, if the original material is sufficiently radioactive, the time during which the counting can be done in the optimum range can be increased many-fold by utilizing a method of dilution of the original solution.

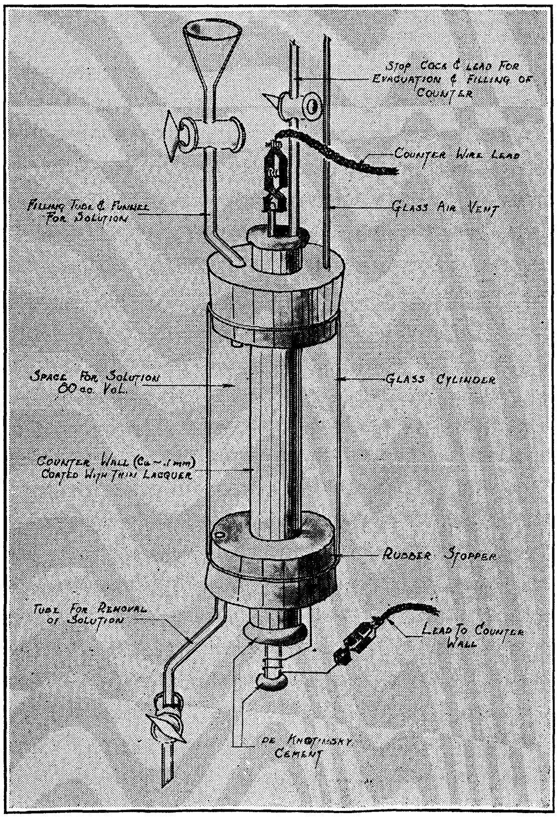

Fig. 1.—Counter assembly for dilution method.

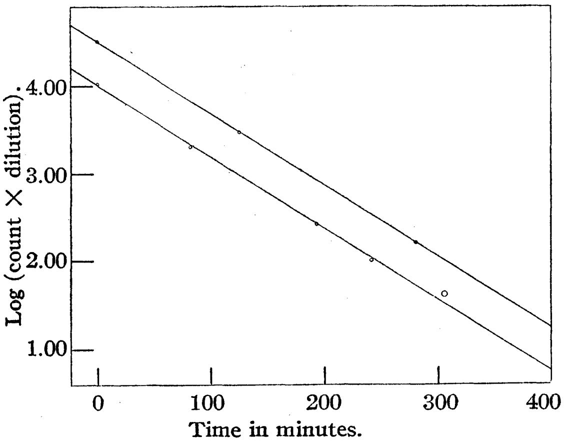

Fig. 2.—Logarithms of the last column of Table I plotted against the time of counting. The circles are these experimental results. The straight lines are calculated under the assumption that the half-life of radioactive chlorine is 37.0 minutes.

Thus in the investigation referred to above, the chloride ion was precipitated as silver chloride, washed and dried. Four-tenth gram of this was dissolved in 15 cc. of five molar ammonium hydroxide and made up to 150 cc. in a volumetric flask with distilled water. This original solution, however, was much too active to be accommodated by the counting apparatus and so 5 cc. of it was used to determine what dilution was necessary to give the optimum counting. The diluent was an ammoniacal solution of silver chloride that differed from the original solution only in that the silver chloride was non-radioactive. From this preliminary experiment and the half-life of radioactive chlorine, it was possible to calculate the most advantageous dilution for any subsequent time. With the strength of the sample of radioactive chlorine that was available to us, it was possible to remain in the optimum counting range for six hours even though the first count was not made until two hours after irradiation of the sample.

In Table I and Fig. 2 we show the data for typical determinations.

TABLE I

Results from two experiments. For both, the solutions were 0.0187 molar silver chloride and 0.5 molar ammonium hydroxide. Each count is the result of a ten minute period of counting.

Sample	Time, min.	Dil.	Net count per minute	Net count times the dil.
1a	0	200	158.8 ± 4.5	31760 ± 900
1b	125	20	147.2 ± 4.4	2944 ± 88
1c	280.5	2	81.2 ± 3.6	162.4 ± 7.2
2a	0	80	134.0 ± 4.0	10520 ± 320
2b	82	20	101.3 ± 3.7	2026 ± 74
2c	193	2	134.0 ± 4.0	268.0 ± 8
2	241	1	102.5 ± 3.7	102.5 ± 3.7
2	305.5	1	41.9 ± 2.8	41.9 ± 2.8

The use of this method for any material that can be brought into solution is obvious. It may be worthwhile to point out that the diluent should be chemically identical with the stock radioactive solution in order to eliminate any errors due to differential absorption.

5,7-Diiodo-8-hydroxyquinoline

BY VIKTOR PAPESCH AND ROBERT R. BURTNER

5,7-Diiodo-8-hydroxyquinoline, which is of therapeutic interest, has been prepared previously by the interaction of iodine and sodium iodide with 8-hydroxyquinoline in alkaline solution.[1] Although the yield is satisfactory, the procedure requires working in rather dilute solution, thus involving the use of large-scale equipment even for semi-commercial production. A different procedure was therefore developed which is distinctly more economical with respect to ease of manipulation and materials required.

A solution of 2105 g. (14.5 moles) of 8-hydroxyquinoline in 5800 cc. of 15% (by weight) hydrochloric acid is added in a slow stream with stirring at laboratory temperature to 4872 g. (30.0 moles) of iodine monochloride dissolved in 6000 cc. of 15% hydrochloric acid. Stirring is continued for four hours longer and the mixture then allowed to stand for twelve hours. The product is washed by decantation with 5% hydrochloric acid to remove excess iodine monochloride, followed by a washing with water and finally with a 2% solution of sodium hydrosulfite to reduce traces of free iodine. An additional amount of product may be recovered by combining the liquors of the first two washings and allowing them to stand for several days. The total yield of product melting at 198–200° is 4900–5300 g. or 83.5–92.5% of the theoretical, the purity of which is approximately 98.5% as determined by iodine analysis.

On a Relation between the Dissociation Constants of Substituted Aliphatic Acids and the Distance between the Dissociating and the Substituted Groups

BY JESSE P. GREENSTEIN

A relationship between the dissociation of a substituted acid and the distance between the carboxyl and substituted groups was suggested by MacInnes[1] in 1928 in which pK_∞ represents the

$$pK = pK_\infty + S(1/d) \qquad (1)$$

value of the dissociation constant for an acid whose substituent is removed an infinite length along the chain, and d has the value 1 for an α-, 2 for a β- and 3 for a γ-substitution. This inverse linear relationship held for the hydroxy and the chloro substituted acids, and was extended by subsequent authors[2–4] to the variously substituted amino acids, diamines, dicarboxylic acids and amino acid esters.

In the endeavor to introduce physical quantities into equation (1), an interesting relation developed. If in place of d in the equation there is substituted the square of the distance, l^2, in Ångströms, from the center of the group dipole to the carboxyl center on the assumption of an extended chain, there is found for the substituted aliphatic acids an inverse linear relationship between pK and l^2.

---

[1] MacInnes, THIS JOURNAL, **50**, 2587 (1928).
[2] Edsall and Blanchard, *ibid.*, **55**, 2337 (1933).
[3] Greenstein, *J. Biol. Chem.*, **96**, 499 (1932).
[4] Schmidt, Appleman and Kirk, *ibid.*, **81**, 723 (1929).

In applying this consideration to substituted aliphatic acids, we may assume tetrahedral symmetry for the carbon atoms, and the estimates of Pauling and Sherman[5] that the interatomic distance from the carboxyl carbon to the two oxygens is 1.29 Å. and the bond angle 124°. The linear component of the carboxyl group will be, therefore, 0.6 Å. In the case of the amino and hydroxyl substituents the mid-point of the dipole may be located in the center of the nitrogen and oxygen atoms, respectively. On the other hand, for the halogen substituents the dipole will lie somewhere along the halogen–carbon bond and we may for all purposes designate its center as midway along this bond. Using the value of the half tetrahedral angle and Pauling's single bond distances,[6] and expressing the straight line distance l from the dipole center to the carboxyl center in terms of Ångströms, there is found for the variously substituted molecules the following data for l^2:

TABLE I

Position	Substituted groups					
	OH l^2	NH_2 l^2	Cl l^2	Br l^2	I l^2	COOH l^2
α	9.18	9.36	6.66	6.97	7.34	13.84
β	18.40	18.66	14.75	15.21	15.76	24.80
γ	30.80	31.14	26.01	26.63	27.35	38.94
δ		46.79	40.45	41.22	42.12	56.25
ϵ		65.61				76.74
ζ						100.4
η						127.2
θ						157.8

Substitution of the above values in the formulation

$$pK = pK_\infty + S(1/l^2) \qquad (2)$$

leads to an excellent linear agreement between pK and $1/l^2$ (Fig. 1), where the values of pK have been derived from Cohn[7] and from Simms.[8]

Examination of the values in Table I suggests the linear integer relation of MacInnes, l^2 for a β-substitution appears to be about twice that for the α-substitution, for a γ-substitution l^2 is about three times that for the α-value, etc. Similar to MacInnes' findings, the lines for the chloro, bromo and iodo acids are identical. Furthermore, within the limits of accuracy of this type of calculation the pK_∞ values derived from either equation (1) or (2) are identical. For the dicarboxylic acids only the value for malonic acid, where both carboxyls are attached to the α-carbon falls widely off the curve and has been omitted from the graph. The inability to fit this acid into any relation involving its higher isomers has been discussed by Gane and Ingold.[9]

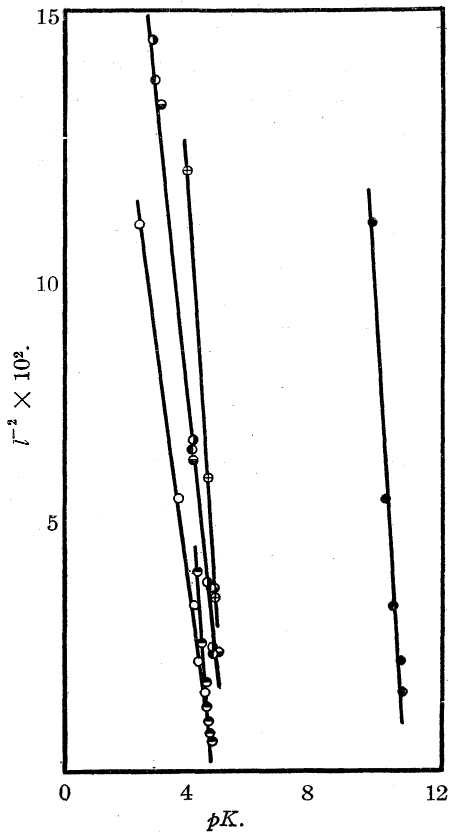

Fig. 1.—Amino acids, pK_1 ○, pK_2 ●; hydroxy acids, ⊕; chloro acids, ◑; bromo acids, ◐; iodo acids, ◒; dicarboxylic acids, ◓.

The constants in equation (2) for the variously substituted acids are gathered in Table II.[10]

TABLE II

[9] Gane and Ingold, *J. Chem. Soc.*, 1594 (1928).

[10] If the interatomic zigzag distance in Ångströms through the chain from the center of the substituent to the center of one of the oxygens of the carboxyl group be considered, an analogous inverse square relation between dissociation constant and distance is revealed in all the cases discussed above. Only malonic acid again provides an exception.

electric moment and θ the angle between d_0 and the dipole axis. It would be difficult, in view of the changes in orientation of the dipole along the chain to derive at present any closer basis of relation other than analogy between the two formulations. It is interesting to note, however, that the value for the slope constant S in equation (2) is practically identical for the three halogen acids. The electric moments of the C–halogen bond for the three halogens are likewise very nearly equal. The relative magnitude of the slope constants, however, bears no obvious relation to that of the electric moments of the substituents.

The Mechanism of the Diene Synthesis

BY EDWIN R. LITTMANN

The observation of Diels and Alder[1] that a yellow color appears during the synthesis of the colorless α-phellandrene-maleic anhydride suggests that the reaction mechanism involves a colored intermediate compound. Such a mechanism would imply a second order followed by a first order process, and in the absence of side reactions the observed reaction rate constants should approach those for a first order reaction as the concentration increases.

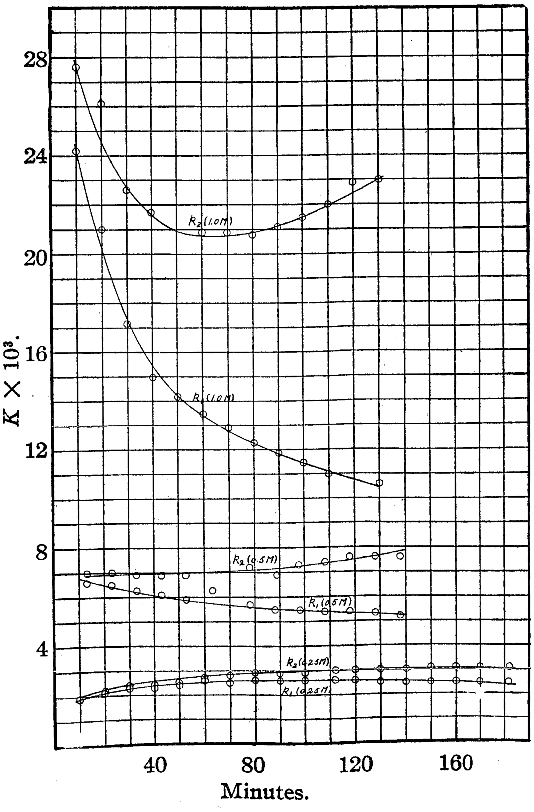

Fig. 1.—Reaction rate constants of α-phellandrene–maleic anhydride.

To test this matter measurements of the rate of reaction between α-phellandrene and maleic anhydride in acetone solutions have now been carried out at 0.25, 0.50 and 1.0 molality.

The α-phellandrene (Schimmel and Company) had the following properties: specific rotation (sodium light), −110.7°; refractive index (white light), 1.4775, and density, both at 20°, 0.856. The maleic anhydride (Eastman Kodak Company) was completely soluble in benzene and was used without further purification. The solutions, cooled to 25°, after thoroughly mixing were transferred to 2-dm. polarimeter tubes and observations of the rotation taken at definite intervals. The temperature of the polarimeter tube was maintained at 25 ± 0.5° by means of an air jet directed on the tube.

The results obtained are given in Fig. 1 in which the rate constants were calculated from the integrated forms of the standard rate equations. The values of the computed constants indicate that the reaction is more nearly unimolecular in the dilute than in the concentrated solutions and therefore it appears either that some other reaction mechanism is involved or that side reactions take place.

In order if possible to isolate the hypothetical polymer formed in the reaction, 6.8 g. of α-phellandrene and 4.9 g. of maleic anhydride were mixed without the use of any solvent and heated to 55–65° whereupon a violent reaction ensued which subsided in a few minutes. After standing for fifteen minutes the mixture was distilled at 3–5 mm. from an oil-bath at 250° until no more distillate was formed. The non-volatile residue was extracted repeatedly with ether, but only a small portion dissolved. The residual white powder when washed with methanol and dried gave, on analysis, 68.7% carbon and 7.27% hydrogen. Its molecular weight by the Rast method was found to be approximately 1220. These data agree with an empirical formula approximating either $C_{46}H_{56}O_{12}$ or $C_{60}H_{74}O_{15}$, giving 69.0 or 69.6% carbon, 7.00 or 7.17% hydrogen, and a molecular weight of 800 or 1034, respectively.

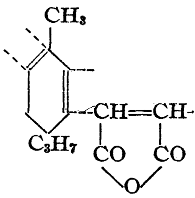
Since α-phellandrene and maleic anhydride were the only substances present, and since the

---

[1] Diels and Alder, *Ann.*, **460**, 98 (1927).

analysis precluded either terpene or maleic anhydride polymers, it seemed highly probable that a polymeric addition product had been obtained in which the average ratio of maleic anhydride to terpene was 4:3 or 5:4. Polymers of probable similar type have been reported by Wagner-Jauregg.[2]

The size of the polymeric α-phellandrene-maleic anhydride molecule and probable excess of anhydride over terpene would seem to exclude any but linear type polymers and would indicate a bifunctional character of the intermediate. An intermediate of the type



would satisfy the requirements of both polyfunctionality and color and would explain the formation of a polymeric material of the type $C_4H_2O_3$ $(C_{10}H_{16}-C_4H_2O_3-)$ $C_4H_2O_3$ in which there is an alternation of terpene and maleic anhydride molecules.

COMMUNICATION TO THE EDITOR

THE DECOMPOSITION OF GASEOUS PARAFFINS INDUCED BY ETHYLENE OXIDE

Sir:

Heckert and Mack [THIS JOURNAL, **51**, 2706 (1929)] obtained evidence that *n*-butane and *n*-pentane were "cracked" in presence of decomposing ethylene oxide at temperatures (—400°) at which the normal rate of decomposition of these paraffins is negligible. We have confirmed this observation in the case of *n*-butane, and have in addition shown that isobutane and propane, but not ethane, also undergo appreciable decomposition under like conditions.

Our method consisted in analyzing the gases, pumped from the reaction vessel, for carbon monoxide (acid Cu_2Cl_2) and for total olefins (bromine water). At a total pressure of about 500 mm. and a temperature of 425°, the following results were obtained.

It will be noted that the relative amount of olefin increases with the complexity of the paraffin; and also (in the case of *n*-butane at least) with the relative amount of paraffin initially present. Since the C_nH_{2n}/CO ratio can exceed unity, it is evident that reaction chains may be set off in the paraffin.

HC.	Initial ratio HC./C_2H_4O	Ratio C_nH_{2n}/CO by anal.
C_2H_6	1.6	<0.05
C_3H_8	1.6	.55
i-C_4H_{10}	1.7	.75
n-C_4H_{10}	1.6	1.2
n-C_4H_{10}	4.1	4.5
n-C_4H_{10}	8.0	12.

The rate of pressure increase falls off rapidly as reaction proceeds, which may indicate that the products of the paraffin decomposition are inhibiting reaction. A similar result is obtained in the uninduced decomposition of paraffins [*e. g.*, Pease and Durgan, *ibid.*, **52**, 1262 (1930)].

The effect of temperature on the C_nH_{2n}:CO ratio is not great.

The accelerated decomposition of acetaldehyde in presence of ethylene oxide noted by Fletcher [*ibid.*, **58**, 534 (1936)] has been confirmed.

This work is being continued.

NEW BOOKS

Grundlagen der Quantenmechanik. (Fundamentals of Quantum Mechanics.) By Dr. H. Dänzer, Assistant at the Physics Institute of the University of Frankfort A.M. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1935. xi + 163 pp. 11 figs. 15.5 × 22.5 cm. Price, RM. 12; bound, RM. 13.

The author aims to present compactly and logically the fundamental content of quantum-mechanical theory, in the forms which may now be regarded as standard. Emphasis is placed upon clear exposition of principles, rather than exhaustive rigor or completeness, so that the book may be useful to those whose specialties lie in other directions, but who require a working knowledge of the subject. The statistical interpretation of wave-mechanics is stressed, and frequent analogies from optics are adduced. The purpose of the book does not include applications to concrete problems, which are discussed only sparingly and by way of illustration.

In the reviewer's opinion, the author has succeeded in accomplishing his aim.

A. S. Coolidge

Molekülspektren und ihre Anwendung auf Chemische Probleme. II. Text. (Molecular Spectra and Their Application to Chemical Problems.) By H. Sponer. Verlag von Julius Springer, Linkstrasse 23–24, Berlin W 9, Germany, 1936. xii + 506 pp. 87 figs. 14.5 × 22 cm. Price, RM. 36; bound, RM. 37.80.

The first volume of this work has already been reviewed in This Journal, **58**, 861 (1936). The present and final volume contains the theory of molecular spectra with many excursions into allied fields and also additional tables of molecular constants, bringing these up to date.

After a brief introduction into atomic spectra and the structure of atoms, the author takes up the theory of quantization of diatomic molecules, with many examples taken from analyzed spectra. Chapters on polyatomic molecules and on the determination from spectroscopic data of such chemically important molecular properties as internuclear distances, heats of dissociation, heat capacities, entropies, etc., follow. Some seventy pages are devoted to the problems of chemical binding and valence, the theories of the homopolar and the ionic bond being discussed in detail. The next chapter deals with different types of inelastic collisions, while the last sixty pages contain remarks on a variety of problems of interest to many chemists, such as photochemical processes, chemiluminescence, etc.

The discussion is carried on in a rather elementary manner and, considering the subject, very few equations will be found in the book. Results and conclusions of various theories are stated without attempts to derive them, but with extensive explanations and illustrations which are well chosen and give the reader some idea of the present status of the theoretical development in this field.

Perhaps if the subject matter were more restricted and instead more details were given occasionally, the book would have been even more useful. It can be recommended, however, as a reference source and should thus find extended use in conjunction with the first volume containing numerical data.

G. B. Kistiakowsky

Über katalytische Verursachung im biologischen Geschehen. (On Catalytic Causation in Biological Processes.) By Alwin Mittasch. Verlag von Julius Springer, Linkstrasse 23–24, Berlin W 9, Germany, 1935. x + 126 pp. 14.5 × 22 cm. Price, RM. 5.70.

This small book represents the reflections of a distinguished chemist, long deeply concerned with catalysis and its industrial applications, on catalytic phenomena in biology. After a brief but penetrating discussion of catalysts in general and of enzymes, the author turns his attention to hormones, vitamines, genes and other constituents of the living organism, and inquires how far their basis of operation may also be catalytic. Finally there is an extensive discussion of the possible relation of such processes to the higher integration of the living organism.

The book bears witness, not only to the author's deep knowledge of his own field, but to a wide acquaintance with many aspects of current philosophical thought. Many of the problems raised lie far beyond the present scope of experimental science, but others have much more immediate application. In the author's words, the book is "a question to the biologist"; it avoids dogmatic pronouncements, and its aim is to stimulate inquiry into regions still unexplored.

John T. Edsall

Collected Scientific Papers of Sir William Bate Hardy. Published under the Auspices of the Colloid Committee of the Faraday Society. Cambridge University Press, The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1936. 922 pp. 18 × 26 cm. Price, $18.00.

This collection is of value for at least two reasons; it makes readily available the many scattered contributions of an unusually stimulating and suggestive investigator; also, by virtue of the chronological arrangement that has been adopted, it discloses the genetic relationships among Hardy's researches and the progressive development of his ideas.

Hardy's initial researches were concerned chiefly with problems of morphology, particularly the morphology of blood corpuscles and other wandering cells in both vertebrate and invertebrate organisms. These researches led him naturally, at about the beginning of the present century, to the study of colloidal solutions and colloidal phenomena in general, and it was in this field that the largest number and perhaps the most important of his investigations were conducted. Although some of these dealt with such inanimate phenomena as adhesion and lubrication, most of them were fundamentally concerned with the physical and chemical processes taking place in the living cell.

Interspersed among the accounts of his experimental investigations and his theoretical speculations are a number of noteworthy summaries and recapitulations, some of them constituting important occasional lectures, namely, the Croonian, the Guthrie and the Bakerian Lectures.

The collection as a whole and these special lectures in particular afford a veritable mine of information, entertainment and stimulation.

ARTHUR B. LAMB

Poggendorffs biographisch-literarisches Handwörterbuch für Mathematik, Astronomie, Physik mit Geophysik, **Chemie,** Kristallographie und verwandte Wissensgebiete. **(Poggendorff's Biographical and Bibliographic Encyclopedia** for Mathematics, Astronomy, Physics, Geophysics, **Chemistry,** Crystallography and Related Sciences.) Vol. VI, 1923–1931, Part I. A–E. Edited by Dr. HANS STOBBE. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 35, Germany, 1936. lxxii + 696 pp. 16 × 25.5 cm. Price, RM. 63.75.

This is the first part of the sixth Volume of this very useful and unique Encyclopedia. The first Volume appeared in 1863 and the following Volumes, II to V, contain the scientific biographies of workers in the field of the exact sciences throughout the whole world during the intervening period.

Volume VI when completed will cover the year 1923 to 1931 and will give biographical data for some eight thousand scientists, together with information as to the books, pamphlets and articles which they have published. The second part is already in print and will be published during the current year; Parts III and IV are to be published in the summer of 1937 and the spring of 1938, respectively.

This Encyclopedia is not only of great current utility but it will also be of permanent value as well, and the scientific community certainly owes a debt of gratitude to the several German Academies of Science who are sponsoring its publication. However, it is unfortunate that in this as in similar monumental bibliographic undertakings, more prompt publication cannot be attained. A delay of five years, such as obtains in this instalment, detracts perceptibly from its current usefulness.

ARTHUR B. LAMB

Annual Tables of Constants (A.T.C.) and Numerical Data, Chemical, Physical, Biological and Technological. Published under the Patronage of the International Union of Chemistry. Volume X (1930), Part II. McGraw-Hill Book Co., Inc., 330 West 42d St., New York, N. Y., 1936. Two parts, about 1800 pages. Price (for subscribers), cloth, $20.00.

This instalment completes Volume X and with it the Second Series of the Tables, except for the Index to Volumes VI–X, inclusive, which is soon to appear.

As the years elapse since the appearance of the International Critical Tables, the continued publication of these Annual Tables becomes even more essential. It is devoutly to be hoped that the gallant efforts of Dr. Marie and the Editors of the Annual Tables receive that international support which is absolutely necessary for their existence.

It should be pointed out that all the texts in the Tables are given in both English and French; also that the full Tables of Contents in each Volume make it easy to locate the information desired.

ARTHUR B. LAMB

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by R. J. MEYER. Eighth edition. System-Number 55, **Uranium and its Isotopes, with an Appendix on Transurania.** Issued by the Deutsche Chemische Gesellschaft. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 35, Germany, 1936. 278 pp. 17 × 25 cm. Price, RM. 34.50.

The publication of this instalment of the Gmelin Handbook is opportune particularly in view of the current interest in the radioactive phenomena connected with uranium; for instance, the new radioactive elements recently discovered by Fermi during the bombardment of uranyl salts with neutrons. Although the nature of these truly synthetic elements is still somewhat obscure, it is certain that they are intimately related to uranium, the element of highest atomic number and atomic weight known to occur in Nature. For this reason it is appropriate that the information relative to these elements should be presented in an Appendix to this volume under the caption "Transurania." It is also appropriate and a striking coincidence that this name should be so similar to that assigned to the planet Neptune after its existence had been deduced but before it had actually been discovered.

The literature on uranium has been covered to the end of 1935 and with this instalment the volume on molybdenum, tungsten and uranium is now completed.

ARTHUR B. LAMB

Mikroskopische Methoden in der Mikrochemie. (Microscopic Methods in Microchemistry.) By Prof. Dr. LUDWIG KOFLER and Dr. ADELHEID KOFLER, with the collaboration of Prof. Dr. ADOLF MAYRHOFER. Emil Haim and Co., Maria-Theresien-Strasse 10, Vienna I, Austria, 1936. vi + 134 pp. 21 figs. + 12 plates. 17.5 × 25 cm. Price, RM. 9; bound, RM. 10.80.

One of a series of monographs in the general field of microchemistry by Austrian writers, this book is intended to acquaint chemists with the extraordinary advantages of applying the microscope to everyday work. It is illustrated by examples of the isolation and identification of a number of organic compounds of pharmacological interest. The first two sections, by L. K., describe the use of a hot stage microscope in the determination of melting points, and in the purification by sublimation, of small amounts of material. The third section, by A. K., deals with the more formidable technique of the measurement of optical constants of crystals by the immersion method; it is addressed to readers without special training in crystallography. The concluding brief section by A. M. treats liquids used with the immersion method.

The subject with which this book is concerned deserves consideration by the generality of chemists such as it has not heretofore received here or abroad. In the examination of any sort of transparent solid material the microscope should be as a matter of practice the first, not the last, resort of the chemist. The limitations of the methods are discussed by the present writers; in section 3 they are overstressed. In the same section reference to some useful American work is absent. An obvious error occurs in the description of potassium nitrate on p. 114.

JOURNAL OF THE
AMERICAN CHEMICAL SOCIETY

VOLUME 58 AUGUST 5, 1936 NUMBER 8

[CONTRIBUTION FROM THE SCHOOL OF CHEMISTRY OF THE INSTITUTE OF TECHNOLOGY, UNIVERSITY OF MINNESOTA]

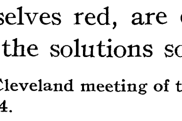
1,2-Diketo-3-phenylhydrindene[1]

BY C. FREDERICK KOELSCH

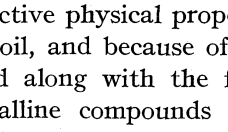
Few α-diketones derived from hydrindene have been studied and some phenomena observed in connection with these compounds have been incorrectly interpreted. These α-diketones may be conveniently divided into three classes corresponding to the number of activated hydrogen atoms they contain: class A having none, B one and C two.

Representatives of class C have been prepared by Perkin and co-workers.[2] No compounds of class A have been described. Since representatives of these two classes do not enolize and since enolization is the main topic investigated in the present research, a discussion of these types will be deferred for later papers.

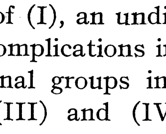
In class B, the compounds represented in the accompanying formulas (I, II, III, IV) have been investigated by v. Braun and co-workers.[3] These substances, themselves red, are easily soluble in aqueous alkalies, the solutions so obtained being deep blue or green. Now 1,3-diketo-2-methylhydrindene, a colorless substance, dissolves in aqueous alkalies to give a deep red solution, and this solution has been shown by Hantzsch[4] to contain a salt of the formula (V). Primarily on the basis of this difference in color between (V) and the enolates of his diketones[5] v. Braun postulated the formula (VI) for the latter.



I, R = CH_3, X = H
II, R = CH_3, X = NO_2
III, R = CH_3, X = $NHCOC_6H_5$
IV, R = CH_2COOH, X = H



V



VI

Since the *o*-quinoid structure is generally unstable,[6] it was decided to investigate this enolate formula more thoroughly. Because of the unattractive physical properties of (I), an undistillable oil, and because of the complications introduced along with the functional groups in the crystalline compounds (II), (III) and (IV), a search was made, ending with 1,2-diketo-3-phenylhydrindene (VII), for a compound not possessing these disadvantages.[7]

---

[1] Presented at the Cleveland meeting of the American Chemical Society, September, 1934.

[2] Perkin, Roberts and Robinson, *J. Chem. Soc.*, **101**, 232 (1912); *ibid.*, **105**, 2405 (1914).

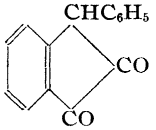
[3] V. Braun and Kirschbaum, *Ber.*, **46**, 304 (1913); v. Braun and Heider, *ibid.*, **49**, 1268 (1916); v. Braun and Fischer, *ibid.*, **64**, 1790 (1931).

[4] Hantzsch, *Ann.*, **392**, 286 (1912).

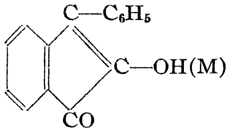
[5] Secondary considerations were the observation that (I) reacted with neither bromine nor ferric chloride. These observations are probably erroneous, the physical character of (I) making visual determination of reaction difficult.

[6] Especially unstable is the *o*-quinomethylene grouping, represented with certainty only by 3,4-benzofuran; *cf.* Koelsch, THIS JOURNAL, **58**, 1331 (1936).

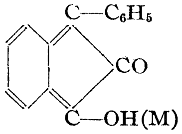
[7] After the present work had been completed, the preparation of diketophenylhydrindene by a different method was carried out by Pfeiffer and de Waal [*Ann.*, **520**, 185 (1935)]. Since a different aspect of the chemistry of the diketone was studied by these investigators, little duplication has taken place. Descriptions of the few similar compounds involved in the two researches check closely.



VII

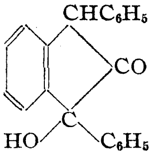


VIII

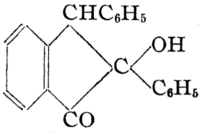


IX

This substance in the crystalline state closely resembles potassium permanganate; like (I) its solutions in organic solvents are red, those in aqueous alkalies deep blue. However, it enolizes to give (VIII) and not (IX). This is clearly shown by the following evidence: the diketone in carbon tetrachloride combines instantly with the calculated amount of bromine; it is mono-phenylated by phenylmagnesium bromide, and the product of this reaction must be (X) and not (XI) since it yields *o*-dibenzoylbenzene on oxidation. To be noted also is the fact that the blue enolate gives a red O-methyl derivative with dimethyl sulfate.[8]



X

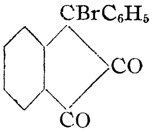


XI

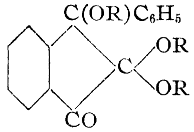
The diketone apparently exists completely in the enolic form: on quantitative treatment with methylmagnesium iodide it reacts with two equivalents of the reagent, liberating one equivalent of gas; and furthermore, as stated above, it combines instantly with the calculated amount of bromine. Also the color of the substance, solid or in solution, indicates that its chromophore is not the α-diketone group (orange) but is the indone nucleus (red). Although the compound gives no color reaction with ferric chloride, this is not evidence against its enolic nature, since it is oxidized immediately by this reagent.

Comparison of 1,2-diketo-3-phenylhydrindene, more properly 2-hydroxy-3-phenylindone, with its β-diketonic isomer and of these with their open chained analogs (Table I) indicates that in the cases of both α and β-diketones of class B, a greater tendency toward enolization is found in the cyclic compounds. That the reverse is true for diketones of class C will be shown in a later paper.

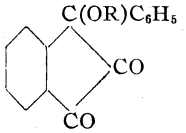
Certain derivatives of 1,2-diketo-3-phenylhydrindene obtained through the replacement of the enolizable hydrogen indicate a considerable reactivity of one of the carbonyl groups. The bromo compound (XII) reacts readily with alcohols giving colorless ether–acetals of the probable structures (XIII).



XII



XIII



XIV

By appropriate treatment, these compounds can be converted into the alkoxy diketones (XIV), whose colors are strikingly different from those of open chain diketones and also from that of the enol (VIII).

Experimental

2-Isonitroso-3-phenylhydrindone.—To a solution of 75 g. of 3-phenylhydrindone in 450 ml. of 95% alcohol is added 75 ml. of butyl nitrite and 10 ml. of concd. hydrochloric acid. The mixture is warmed to 55° for one hour, and after twelve hours at room temperature, the isonitroso compound is removed. The product so obtained (55 g.) is quite pure; crystallization from ethyl acetate–petroleum ether yields faintly yellow prisms that melt at 198–203° with decomposition. The compound gives a yellow-orange solution in aqueous sodium hydroxide.

Anal. Calcd. for $C_{15}H_{11}O_2N$: C, 76.0; H, 4.64. Found: C, 75.8; H, 4.73.

In alkaline solution with methyl sulfate the above oxime yields its methyl ether, which forms pale tan plates that melt at 148–149° after crystallization from alcohol.

Anal. Calcd. for $C_{16}H_{13}O_2N$: C, 76.4; H, 5.18. Found: C, 76.4; H, 5.26.

1,2-Diketo-3-phenylhydrindene (VII).—The maximum yield of the diketone if its monoxime is hydrolyzed in the presence of the usual formaldehyde is 20%, and the product so obtained is difficult to purify. (Optimum conditions developed from many experiments: a mixture of 1 g. of oxime, 10 ml. of 40% formaldehyde, 5 ml. of acetic acid, 5 ml. of water, and 1 ml. of concd. hydrochloric acid is heated at 80–85° for ten minutes.)

The use of pyruvic acid as a hydroxylamine acceptor[9] is very advantageous. A mixture of 50 g. of the oxime, 50 ml. of pyruvic acid, 300 ml. of water, 300 ml. of acetic acid and 50 ml. of concd. hydrochloric acid is boiled for thirty minutes. On standing the solution deposits 29 g. of diketone, and an additional 2.5 g. may be obtained from the mother liquors. In larger runs one-half the proportional amount of pyruvic acid may be used with only a slight reduction in yield. Crystallized from benzene–petroleum

---

[8] It is also of interest in this connection that the red 2-*p*-hydroxyphenyl-3-phenylindone forms a deep purple sodium salt. Postulation of *o*-quinoidation in this case necessitates the assumption of a considerable, and therefore improbable, shifting of the aromatic double bonds.

[9] Suggested by Dr. P. D. Bartlett.

Pechmann, *Ber.*, **23**, 3377 (1890).

ether, the diketone forms violet black needles; from dilute acetic acid, red violet plates. Both forms melt at 140–147°. The diketone decomposes and liquefies on standing in air; the decomposition is complete after about three months.

Anal. Calcd. for $C_{15}H_{10}O_2$: C, 81.0; H, 4.51. Found: C, 81.0; H, 4.58.

Solutions of the compound in organic solvents, polar or non-polar, are dark red. It is readily soluble in cold aqueous sodium hydroxide or in warm carbonate, giving deep blue solutions from which the diketone is precipitated by acids. The solutions in alkali lose their color on long (*ca.* ten minutes) boiling, acidification then giving a small amount of diphenylmethane-*o*,α-dicarboxylic acid together with unworkable oils.

Oxidation.—To a solution of 0.5 g. of the diketone in 10 ml. of 0.5 *N* sodium hydroxide is added 5 ml. of 3% hydrogen peroxide. After the mixture has become colorless (two minutes) it is acidified. The product, diphenylmethane-*o*,α-dicarboxylic acid, forms fine white needles from ethyl acetate–benzene that melt at 171–172° with gas evolution.

Anal. Calcd. for $C_{15}H_{12}O_4$: C, 70.3; H, 4.7. Found: C, 70.1; H, 4.8.

Quinoxaline Formation.—The diketone is condensed with *o*-phenylenediamine in alcohol in the usual way. The product forms colorless needles that melt to a blue liquid at 169–172°.

Anal. Calcd. for $C_{21}H_{14}N_2$: C, 85.6; H, 4.76. Found: C, 85.3; H, 4.82.

Reaction with Ferric Chloride.—The color of an alcoholic solution of the diketone (0.5 g.) rapidly fades when ferric chloride (0.8 g. of $FeCl_3 + 6H_2O$) in alcohol is added. The orange-pink crystalline precipitate (0.45 g.) contains only a trace of iron, and is insoluble in all solvents other than hot nitrobenzene, by which it is altered. It darkens at 180° and melts at 200–205° with gas evolution.

Anal. Calcd. for $C_{30}H_{18}O_4$: C, 81.4; H, 4.1. Found: C, 80.9; H, 4.36.

Bromination.—The diketone (5 g.) in chloroform (30 ml.) is treated with 3.75 g. of bromine in carbon tetrachloride. The halogen is absorbed immediately and hydrogen bromide is given off. The solvents are removed under reduced pressure, and the residue is crystallized from ether–petroleum ether. There is obtained 4.9 g. of 1,2-diketo-3-bromo-3-phenylhydrindone (XII) which forms orange-brown prisms that melt at 77–79°.

Anal. Calcd. for $C_{15}H_9O_2Br$: C, 59.9; H, 3.0. Found: C, 60.1; H, 3.0.

Methylation.—A solution of 28 g. of the diketone in 150 ml. of *N* sodium hydroxide is treated with 15 ml. of methyl sulfate, and the mixture is stirred vigorously for thirty minutes. The solid is filtered and crystallized from methanol, when it is obtained in the form of red prisms and needles (18 g.) that melt at 67–68°. Although it can be distilled without decomposition at 20 mm., the 2-methoxy-

3-phenylindone rapidly (three days) decomposes on standing in air, giving off an odor of formaldehyde and leaving a red resin.

Anal. Calcd. for $C_{16}H_{12}O_2$: C, 81.2; H, 5.1. Found: C, 80.6; H, 5.1.

The oxime of the methyl ether, obtained with hydroxylamine hydrochloride and sodium acetate in alcohol, forms orange prisms that melt to a red liquid at 184–186° and are stable in air.

Anal. Calcd. for $C_{16}H_{13}O_2N$: C, 76.4; H, 5.2. Found: C, 76.0; H, 5.2.

With phenylmagnesium bromide, the methyl ether gives a colorless carbinol which could not be obtained crystalline and could not be converted into a solid methyl ether, but whose solution in acetic acid is colored red-violet by a trace of sulfuric acid.

2-Methoxy-3-phenylindone (15 g.) is reduced when its solution in acetic acid (150 ml.) is treated with zinc dust (15 g.). The solution becomes warm and its color rapidly disappears. The product, 2-methoxy-3-phenylhydrindone, is precipitated by water, distilled at 20 mm. and crystallized from methanol, when it forms colorless prisms that melt at 96–98°.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.7; H, 5.9. Found: C, 80.7; H, 6.0.

Reaction with Grignard Reagents.—Quantitative examination of its behavior in the Grignard machine[10] shows that 1,2-diketo-3-phenylhydrindene reacts with two equivalents of methylmagnesium iodide, liberating one equivalent of gas.

With an excess of phenylmagnesium bromide, the diketone yields 1,3-diphenyl-1-hydroxy-2-ketohydrindene (X), which from ethanol forms white plates that melt at 195–200° with decomposition.

Anal. Calcd. for $C_{21}H_{16}O_2$: C, 83.9; H, 5.3. Found: C, 83.1; H, 5.3.

Oxidized with chromic acid in acetic acid, this hydroxy ketone yields *o*-dibenzoylbenzene (mixed m. p.) nearly quantitatively.

Reduced with hydriodic acid in acetic acid, the hydroxy ketone is converted into 1,3-diphenyl-2-ketohydrindene, which, from acetic acid, forms white needles that melt with decomposition at 169°.

Anal. Calcd. for $C_{21}H_{16}O$: C, 88.6; H, 5.6. Found: C, 88.0; H, 5.7.

With benzylmagnesium chloride, diketophenylhydrindene yields 1-benzyl-1-hydroxy-2-keto-3-phenylhydrindene, white needles that melt at 155–157°.

Anal. Calcd. for $C_{22}H_{18}O_2$: C, 84.1; H, 5.7. Found: C, 84.1; H, 6.1.

Reactions of the Bromo Compound (XII) with Alcohols.—A solution of the crude bromo compound from 5 g. of diketophenylhydrindene in methanol is distilled to a small volume, the methanol is replaced, and the resulting solution is cooled. There is deposited 5 g. of 2,2,3-trimethoxy-3-phenylhydrindone (XIII, R = CH_3), which forms colorless prisms that melt at 102–103°.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.4; H, 6.0. Found: C, 71.9; H, 6.0.

The trimethoxy compound does not react with *o*-phenylenediamine in alcohol even on warming, but the addition of a trace of hydrochloric acid to the mixture causes the immediate precipitation of the quinoxaline of 1,2-diketo-3-methoxy-3-phenylhydrindene.

Anal. Calcd. for $C_{22}H_{16}ON_2$: C, 81.4; H, 4.94; OCH_3, 9.6. Found: C, 81.3; H, 4.96; OCH_3, 9.3.

The trimethoxy compound (0.5 g.) forms a faintly pink solution in acetic acid (8 ml.) which becomes deep crimson on the addition of a drop of sulfuric acid. Dilution with water causes the separation of a crystalline precipitate which can be separated by extraction with cold benzene into a soluble orange compound and a colorless insoluble substance. The orange compound melts at 86–87° and is the methoxy diketone (XIV, R = CH_3).

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.2; H, 4.8. Found: C, 76.3; H, 4.8.

The colorless substance is a hydrate of the methoxy diketone, since at its melting point (115–120°, gas evolution) it is converted into the latter.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.2; H, 5.2. Found: C, 71.2; H, 5.3.

With ethanol, the bromo compound (XII) yields 2,2,3-tri-ethoxy-3-phenylhydrindone (XIII, R = C_2H_5), which forms white plates that melt at 89–90°. This compound is much more easily soluble than its trimethoxy analog, and its quantitative isolation is more difficult.

Anal. Calcd. for $C_{21}H_{24}O_4$: C, 74.0; H, 7.06. Found: C, 74.0; H, 7.09.

Treatment of the triethoxy compound with acetic acid–sulfuric acid converts it into the ethoxy diketone (XIV, R = C_2H_5), which from benzene forms cerise plates that melt at 102–103°. No benzene insoluble substance (hydrate) is formed.

Anal. Calcd. for $C_{17}H_{14}O_3$: C, 76.6; H, 5.26. Found: C, 76.4; H, 5.28.

Summary

It is shown that 1,2-diketo-3-phenylhydrindene exists in the enolic form, and that this enolization does not involve *o*-quinoidation. When enolization is prevented by the replacement of the enolizable hydrogen by alkoxyl, one of the diketonic carbonyl groups becomes active enough to form an acetal.

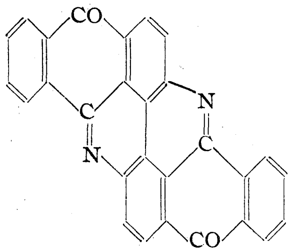
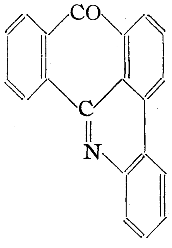
Benzo-semiflavanthrene. I. Reduction

BY C. FREDERICK KOELSCH

The researches of Scholl and his collaborators[1] have cleared up to a large extent the constitutions of the vat dye flavanthrene (I) and of its reduction products. The chemistry of these substances is, however, quite involved. For example Scholl has obtained from flavanthrene nine different reduction products, of which six exist in two forms: one form non-hydrated, the other containing a molecule of water "in a very firm atomically bound condition."



I

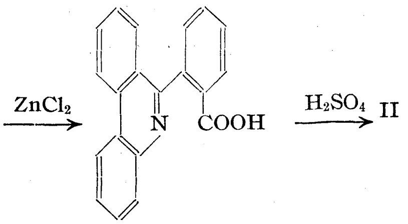


II

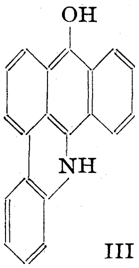
Doubtless still more can be learned about this type of quinone imine by a study of related substances whose structures are less complex. To this end, the substance (II) has been prepared; the name benzo-semiflavanthrene is proposed for this compound to indicate its relation to flavanthrene. Incidentally, benzo-semiflavanthrene appears to hold little promise as a dye, since the color it imparts to fabrics is a very pale yellow.

The preparation of benzo-semiflavanthrene, illustrated by the accompanying formulas, is easily carried out. Each reaction gives a single product in a good yield.

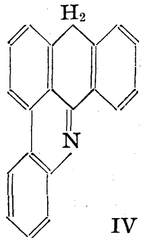
$$o\text{-}C_6H_5C_6H_4NH_2 + C_6H_4(CO)_2O \longrightarrow o\text{-}C_6H_5C_6H_4N(CO)_2C_6H_4$$



Two reduction products have been obtained from benzo-semiflavanthrene: the dihydro compound (III), and a desoxy compound, probably (IV).



III



IV

The reduction product (III), a violet-black substance, separates directly in a crystalline condition when benzo-semiflavanthrene is boiled with alkaline hydrosulfite. It is only weakly acidic and is little soluble in aqueous sodium hydroxide. In such a solution, or dissolved in organic solvents, it is readily oxidized to benzo-semiflavanthrene by air; however, it is quite stable in the solid state. It cannot be acylated, for when it is boiled with acetic anhydride or treated with benzoyl chloride in pyridine, or even when it is boiled with aqueous hydrochloric acid it undergoes disproportionation to benzo-semiflavanthrene and the desoxy compound (IV).

This desoxy compound, a deep red-brown substance, is most readily obtained by the acid reduction of benzo-semiflavanthrene. It, too, is sensitive to air even when dissolved in dilute aqueous hydrochloric acid. Nitrous acid also reconverts it into benzo-semiflavanthrene.

None of the reduction products so far isolated has shown any tendency to form a stable hydrate.

The investigation is being continued.

Experimental

***o*-Xenylphthalimide.**—A mixture of 100 g. of *o*-aminobiphenyl with 88 g. of phthalic anhydride is heated at 200° for ten minutes. The product (175 g.), crystallized from acetic acid, forms colorless prisms that melt at 165–166°.

Anal. Calcd. for $C_{20}H_{15}O_2N$: C, 80.3; H, 4.35. Found: C, 80.3; H, 4.41.

***o*-(9-Phenanthridyl)-benzoic Acid.**—An intimate mixture of 175 g. of *o*-xenylphthalimide with 350 g. of zinc chloride is heated rapidly to 275° and kept at this temperature for one minute; no reaction takes place at lower temperatures and longer heating results in considerable decomposition. The melt is stirred into much water, and the insoluble product is purified by dissolving in 5% aqueous soda and treatment with charcoal. The acid is precipitated by dilute hydrochloric acid as a fine powder which is pure enough for most purposes; yield, 135 g. Recrystal-

---

(1) Scholl and Mansfield, *Ber.*, **43**, 1734 (1910), and previous papers.

lized from ethyl acetate, in which it is very difficultly soluble, it forms colorless prisms that melt at 268–270° with decomposition.

Anal. Calcd. for $C_{20}H_{13}O_2N$: C, 80.3; H, 4.35. Found: C, 80.3; H, 4.38.

The methyl ester obtained from the acid with methanol and sulfuric acid forms prisms from benzene that melt at 150–151°.

Anal. Calcd. for $C_{21}H_{15}O_2N$: C, 80.5; H, 4.8. Found: C, 80.0; H, 4.77.

Distilled with copper acetate (1 g.) *o*-(9-phenanthridyl)-benzoic acid (5 g.) gives 9-phenylphenanthridene (3.5 g.) which melts at 104–106° alone or mixed with a sample of the substance prepared according to the method of Pictet and Hubert.[2]

Benzo-semiflavanthrene.—Ninety grams of *o*-(9-phenanthridyl)-benzoic acid is stirred into 450 ml. of concd. sulfuric acid and the solution is heated for two hours at 160°. The product is isolated by pouring into water. After drying and crystallizing from xylene there is obtained 45 g. of pure benzo-semiflavanthrene which melts at 221–223°.

Anal. Calcd. for $C_{20}H_{11}ON$: C, 85.4; H, 3.96. Found: C, 85.3; H, 3.96.

The Reduction Product (III).—A suspension of 2 g. of benzo-semiflavanthrene in 50 ml. of *N* sodium hydroxide is treated with 4 g. of sodium hydrosulfite, and the mixture is boiled in an inert atmosphere for thirty minutes. Fifteen ml. of acetic acid is added, the precipitate is filtered, washed well with water and dried for a short time at 100°. The product forms black-violet needles that melt at 197°.

Anal. Calcd. for $C_{20}H_{13}ON$: C, 84.7; H, 4.6. Found: C, 84.8; H, 4.46.

The hydroxyamine is little soluble in boiling *N* sodium hydroxide and is completely extracted from the violet solution thus formed by toluene. This solution and the deep red solution in alcohol rapidly become yellow on exposure to air, and deposit yellow needles of benzo-semiflavanthrene. With an excess of acetic anhydride, the reduction product dissolves to give a red solution which becomes deep brown on boiling and deposits benzo-semiflavanthrene, even when air is excluded. From the brown solution, the desoxy compound can be precipitated by dilution with water. A similar result is obtained when the deep red solution of the hydroxyamine in pyridine is treated with benzoyl chloride.

The Desoxy Compound (IV).—A mixture of 1.5 g. of benzo-semiflavanthrene, 5 ml. of hydrochloric acid and 35 ml. of acetic acid is boiled until all of the solid is dissolved. A solution of 3.5 g. of stannous chloride in 5 ml. of hydrochloric acid and 10 ml. of acetic acid is added in one portion, and the boiling is continued until the yellow-green precipitate has become black (thirty minutes to one hour). This black tin double salt is filtered, washed well with acetic acid and water, and boiled for five minutes with 50 ml. of 0.5 *N* sodium hydroxide, excluding air. The red-brown desoxy compound is quite readily attacked by air, even when dry, and in a capillary tube has the same melting point as benzo-semiflavanthrene. Freshly prepared, it is completely soluble in 10% hydrochloric acid; on keeping, even in an evacuated desiccator, it is oxidized, becoming yellow and insoluble in dilute acid. Concordant analytical results could not be obtained. Found: C, 87.5 to 88.2; H, 4.5 to 4.7. $C_{20}H_{13}N$ requires: C, 89.8; H, 4.87.

Summary

This paper reports the preparation of benzo-semiflavanthrene, a quinone imine related in structure to the vat dye flavanthrene. Some experiments on the reduction of the substance are described.

Studies in the *peri*-Naphthindene Series. I. The Condensation of β-Naphthol with Cinnamic Acid

BY C. FREDERICK KOELSCH

Comparatively few derivatives of *peri*-naphthindene have been investigated, but the reactions of these few indicate that the chemistry of this system is quite different from that of the at first sight related indene system.[1] In the present series of papers, the syntheses and reactions of *peri*-naphthindene derivatives will be examined with special reference to the analogous procedures in the indene series.

Phenol reacts with cinnamic acid in the presence of sulfuric acid to give 3,4-dihydro-4-phenylcoumarin.[2] It is now shown that β-naphthol and cinnamic acid behave similarly forming 3,4-dihydro-4-phenyl-5,6-benzocoumarin (I).[3] This lactone is easily hydrolyzed and methylated to give

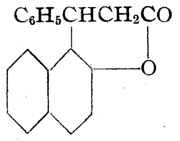
---

[1] Compare, *e. g.*, the ease of formation, stability and basicity of *peri*-naphthindone [Cook and Hewett, *J. Chem. Soc.*, 368 (1934)] with the unknown, presumably easily polymerizable indone, whose derivatives are not basic; the tendency to enolize of 8-phenyl-*peri*-naphthindandione-7,9 [Cesaris, *Gazz. chim. ital.*, **42**, II, 453 (1912)] with the tendency to ketonize of 2-phenylindandione-1,3 [Hantzsch, *Ann.*, **392**, 286 (1912)]; the action of phenylmagnesium bromide on benzanthrone [Allen and Overbaugh, THIS JOURNAL, **57**, 740 (1935)] with its action on fluorenone [Ullmann and v. Wurstemberger, *Ber.*, **37**, 73 (1904)].

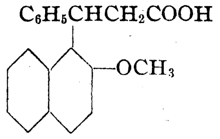
[2] Liebermann and Hartmann, *Ber.*, **24**, 2586 (1891).

[3] The present paper is published in its incomplete form to avoid duplication, a recent article by Miller and Robinson [*J. Chem. Soc.*, 1535 (1934)] having announced a projected investigation of the condensation of α,β-unsaturated carbonyl compounds with phenols.

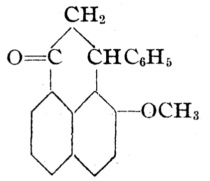
β-phenyl-β-(2-methoxynaphthyl-1)-propionic acid (II), whose chloride, treated with aluminum chloride, is cyclized to 6-methoxy-7-phenyl-7,8-dihydro-9-keto-*peri*-naphthindene (III).



I



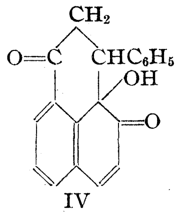
II



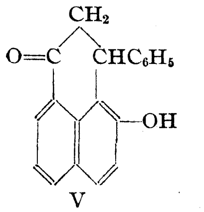
III

In view of the results of Cook and Hewett,[1] who obtained 9-keto-*peri*-naphthindene and not the corresponding 7,8-dihydro compound by the cyclization of β-(naphthyl-1)-propionic acid, it was at first believed that in the present cyclization also hydrogen had been lost. This belief was strengthened by: (a) the yellow color of the product (III), (b) the non-reactivity of it toward phenylmagnesium bromide[4] and (c) the non-formation of a benzal derivative. However, analyses of the ketone (III), its oxime, its demethylation product and its oxidation product indicate that these substances are all dihydro compounds.[5]

The most remarkable reaction of the ketone III is its behavior on oxidation with chromic acid. It is thus converted into a compound which must be 6,9-diketo-7-phenyl-6a-hydroxy-6,6a,7,8-tetrahydro-*peri*-naphthindene (IV) since this oxidation product is easily reduced by alkaline hydrosulfite to (V), the demethylation product of (III).[6]



IV



V

Experimental

3,4-Dihydro-4-phenyl-5,6-benzocoumarin.—A mixture of 250 g. of β-naphthol, 250 g. of cinnamic acid, 700 ml. of acetic acid and 300 ml. of sulfuric acid is boiled for one hour and then poured into water. The resinous precipitate is washed with hot water and boiled with dilute sodium carbonate, enough of the salt being added to cause the red substance to become green. The insoluble material is washed, distilled under reduced pressure and crystallized from alcohol. There is obtained 125–130 g. of the lactone which forms colorless prisms that melt at 115–116°.

Anal. Calcd. for $C_{19}H_{14}O_2$: C, 83.1; H, 5.1. Found: C, 83.2; H, 5.3.

β-Phenyl-β-(2-methoxynaphthyl-1-)-propionic Acid (II).—The lactone (120 g.) is dissolved in 400 ml. of 10% sodium hydroxide by boiling. The solution is cooled and 40 ml. of methyl sulfate is added slowly with stirring. The methylation is completed by boiling for two minutes, cooling, adding more sodium hydroxide (20 g.) and methyl sulfate (20 ml.). The solution is boiled a short time and cooled; the difficultly soluble sodium salt is filtered and decomposed with hydrochloric acid. The precipitate is crystallized from acetic acid, giving 95–100 g. of the methoxylated acid which forms colorless prisms that melt at 168–170°.

Anal. Calcd. for $C_{20}H_{18}O_3$: C, 78.4; H, 5.9. Found: C, 77.9; H, 6.0.

6-Methoxy-7-phenyl-7,8-dihydro-9-keto-*peri*-naphthindene (III).—The methoxylated acid (80 g.) and phosphorus pentachloride (60 g.) are added to 280 ml. of benzene and boiled for five minutes. The solution is cooled and 45 g. of aluminum chloride is added in portions. After boiling a few minutes, the mixture is hydrolyzed and the benzene is removed with steam. The residue is crystallized from acetic acid, giving 66 g. of pale yellow needles that melt at 144–145°. The compound is insoluble in hot sodium hydroxide, and gives a bright red color with sulfuric acid.

Anal. Calcd. for $C_{20}H_{16}O_2$: C, 83.3; H, 5.55. Found: C, 83.1; H, 5.65.

The oxime, obtained by boiling the ketone with hydroxylamine hydrochloride in alcohol for two hours, melts at 207–211°.

Anal. Calcd. for $C_{20}H_{17}O_2N$: C, 79.2; H, 5.6. Found: C, 79.4; H, 5.7.

6-Hydroxy-7-phenyl-7,8-dihydro-9-keto-*peri*-naphthindene (V).—A mixture of 2 g. of the methoxy ketone, 15 ml. of acetic acid and 5 ml. of 40% hydrobromic acid is boiled for three hours. Ether and water are added, the phenol is extracted from the ether with dilute sodium hydroxide, distilled at 20 mm. and crystallized from dilute acetic acid. The compound forms bright yellow needles that sinter at 185° and melt at 191–193°. Its solution in dilute caustic soda is orange-brown.

Anal. Calcd. for $C_{19}H_{14}O_2$: C, 83.2; H, 5.1. Found: C, 83.3; H, 5.1.

6,9-Diketo-7-phenyl-6a-hydroxy-6,6a,7,8-tetrahydro-*peri*-naphthindene (IV).—The methoxy ketone (10 g.) in acetic acid (75 ml.) is treated with 20 g. of chromic acid in dilute acetic acid. When the vigorous reaction is over, the mixture is poured into water and extracted with ether. Sodium carbonate removes very little acidic product; the neutral product is crystallized from dilute ethanol, when it forms bright yellow needles (3.6 g.) that melt with gas evolution at 105–110°.

---

[4] The forced reaction will be described in a later paper.

[5] Compare the cyclization of β-(2-methoxynaphthyl-1)-propionic acid, Barger and Starling, *J. Chem. Soc.*, **99**, 2033 (1911).

[6] Compare the oxidation of 1-methylnaphthol-2. Bargellini and Silvestri, *Gazz. chim. ital.*, **37**, II, 412 (1907).

Anal. Calcd. for $C_{19}H_{14}O_3 + H_2O$: C, 74.0; H, 5.2. Found: C, 73.7; H, 5.4.

The quinol also separates from dilute methanol or dilute acetic acid in needles that contain water. From toluene it is obtained in the form of pale tan prisms which are solvent free and melt at 160–163° with darkening.

Anal. Calcd. for $C_{19}H_{14}O_3$: C, 78.6; H, 4.8. Found: C, 78.4; H, 4.7.

Boiling with sodium hydroxide transforms the quinol into an amorphous brown substance. On boiling with alkaline sodium hydrosulfite it gives a clear orange-brown solution from which acids precipitate the hydroxy compound (V), identified by mixed melting point and by its conversion to the methoxy ketone (III) on methylation with methyl sulfate and alkali.

Summary

The condensation of β-naphthol with cinnamic acid yields a dihydrocoumarin which has been converted into a *peri*-naphthindene derivative. Some reactions of this latter substance are described.

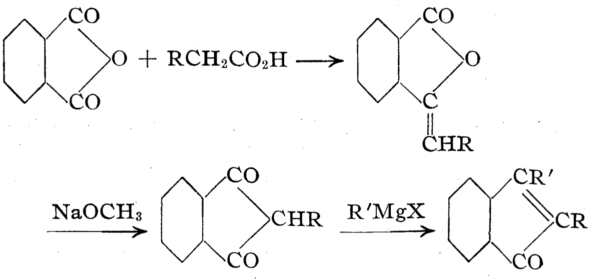
Some Applications of the Rosenmund-v. Braun Nitrile Synthesis

BY C. FREDERICK KOELSCH

When an aromatic bromide is heated in a sealed tube with water, sodium cyanide and cuprous cyanide, the halogen is replaced by carboxyl.[1] Hydrolysis of the intermediate nitrile may be avoided by omitting the water and sodium cyanide, this procedure making the use of a sealed tube or an autoclave unnecessary.[2] The importance of this reaction has been demonstrated in a recent synthesis of phenanthrene-9-carboxylic acid.[3]

In the present research the reaction has been applied to the preparation of some derivatives of 2,3-diphenylindone, and the cyano group has been introduced into each of the three benzenoid rings of this compound. Likewise it has been found that β,γ,γ-triphenylacrylonitrile and β-phenyl-γ-diphenyleneacrylonitrile are readily obtainable from the corresponding vinyl bromides. However, when α-*p*-bromophenyl-β,β-diphenylvinyl bromide is heated with cuprous cyanide under the usual conditions, it is completely resinified; at lower temperatures it is recovered unchanged.

The halogenated indones were prepared by the following series of reactions, the last step of the series constituting a hitherto undescribed diarylindone synthesis.



When 4-bromophthalic anhydride was used, a mixture of benzalbromophthalides was obtained which was converted quantitatively into 1,3-diketo-2-phenyl-5-bromoindane. This with phenylmagnesium bromide gave an easily separable mixture of the isomeric 5- and 6-bromodiphenylindones; thus enolization of this unsymmetrical β-diketone involves either of the carbonyl groups.

It is noteworthy that although solid 2-phenylindandione is obtainable in only the white keto form,[4] the halogenated derivatives of this substance prepared in this research were each easily obtainable in two forms: by crystallization from non-polar solvents in a white modification (keto), and from polar solvents in a violet-black modification (enol).

The structure of 5-bromo-2,3-diphenylindone was proved by oxidation to the known 4-bromo-2-benzoylbenzoic acid, and that of 2-*p*-iodophenyl-3-phenylindone by a separate synthesis according to the scheme[5]

Experimental

Substitution in the 2-Phenyl of 2,3-Diphenylindone

_p_-Iodobenzalphthalide.—_p_-Iodophenylacetic acid was prepared from phenylacetic acid by direct iodination,[6] from _p_-aminophenylacetic acid by diazotization, and from _p_-iodotoluene through _p_-iodobenzyl bromide and cyanide.[7] The last method is much the better.

A mixture of 80 g. of _p_-iodophenylacetic acid, 46 g. of phthalic anhydride and 1 g. of sodium acetate is heated for two hours at 225–235°. The melt is dissolved in hot acetic acid and cooled. The product (70 g.) is deposited in the form of yellow needles. Recrystallized from acetic acid, the compound melts at 172–173°.

Anal. Calcd. for $C_{15}H_9O_2I$: C, 51.7; H, 2.62. Found: C, 51.7; H, 2.58.

2-_p_-Iodophenylindandione-1,3.—A solution of 4.7 g. of sodium in 100 ml. of methanol is added to a suspension of 68 g. of _p_-iodobenzalphthalide in 300 ml. of methanol. After the mixture has been boiled for five minutes, water is added, the diketone is precipitated with hydrochloric acid, dried and recrystallized (64 g.). From acetic acid it separates in red-violet prisms, and from non-polar solvents in colorless needles. Both of these forms melt at 145–146° to a red liquid.

Anal. Calcd. for $C_{15}H_9O_2I$: C, 51.7; H, 2.62. Found: C, 51.9; H, 2.61.

2-_p_-Iodophenyl-3-phenylindone.—A solution of 100 g. of iodophenylindandione in hot benzene is added to a phenylmagnesium bromide solution containing 17 g. of magnesium. The mixture is boiled for one hour and decomposed with iced sulfuric acid. Washing the organic solution with dilute sodium carbonate removes unchanged diketone (17 g.). The neutral product is distilled under reduced pressure and crystallized from acetic acid. There is obtained 61 g. of bright orange-red needles that melt at 141–143°.

Anal. Calcd. for $C_{22}H_{13}ON$: C, 86.0; H, 4.23. Found: C, 86.1; H, 4.35.

2-_p_-Cyanophenyl-3-phenylindone.—Iododiphenylindone (20 g.) and cuprous cyanide (10 g.) are mixed and heated for three hours at 240°. The melt is pulverized and extracted in a Soxhlet with acetone. The product, obtained in a nearly quantitative yield, is distilled at 15 mm. and crystallized from acetic acid, when it forms orange plates that melt at 142–144°.

Anal. Calcd. for $C_{22}H_{13}ON$: C, 86.0; H, 4.23. Found: C, 86.1; H, 4.35.

α,γ-Diphenyl-β-_p_-iodophenylpropanol-β.—This carbinol, obtained from ethyl _p_-iodobenzoate and benzylmagnesium chloride in a yield of about 75%, after crystallization from ether–petroleum ether and then from ethanol, forms white needles that melt at 117–117.5°.

Anal. Calcd. for $C_{21}H_{19}OI$: C, 60.9; H, 4.61. Found: C, 60.9; H, 4.54.

α,γ-Diphenyl-β-_p_-iodophenylpropene.—This hydrocarbon is obtained in a good yield by boiling a solution of the above carbinol in acetic acid containing a little sulfuric acid. It forms colorless prisms from a mixture of ethanol and ethyl acetate that melt at 92–92.5°.

Anal. Calcd. for $C_{21}H_{17}I$: C, 63.6; H, 4.32. Found: C, 63.7; H, 4.25.

1-Phenyl-2-_p_-iodophenylindene.—The above iodotriphenylpropene dissolved in 2.5 times its weight of acetic acid is treated with the calculated amount of bromine, and the solution is boiled for twenty minutes. The product can be separated by crystallization from ligroin into nearly equal amounts of a yellow substance that melts at 165–168° with decomposition (probably α-bromo-α,γ-diphenyl-β-_p_-iodophenylpropene; $C_{21}H_{16}BrI$ requires: C, 53.1; H, 3.4. Found: C, 54.2; H, 3.02) and the indene, which forms microscopic white needles that melt at 184–185°.

Anal. Calcd. for $C_{21}H_{15}I$: C, 63.9; H, 3.83. Found: C, 63.5; H, 3.82.

1-Benzal-2-_p_-iodophenyl-3-phenylindene.—To a suspension of 7 g. of 1-phenyl-2-_p_-iodophenylindene in 70 ml. of absolute ethanol is added 3 ml. of benzaldehyde and a solution of 0.3 g. of sodium in 5 ml. of ethanol. The mixture is boiled for five minutes and cooled, giving 6 g. of the benzal compound. The substance separates from acetic acid in the form of yellow needles that melt at 173–174°.

Anal. Calcd. for $C_{28}H_{19}I$: C, 69.7; H, 3.98. Found: C, 69.9; H, 3.91.

This benzal compound is oxidized by the calculated amount of chromic acid in acetic acid to 2-_p_-iodophenyl-3-phenylindone, which melts at 141–143° alone or mixed with the same substance prepared from iodophenylindandione.

Substitution in the 3-Phenyl of 2,3-Diphenylindone

2-Phenyl-3-_p_-bromophenylindone.—A benzene solution of 2-phenylindandione-1,3 is added to a solution of _p_-bromophenylmagnesium bromide containing 7 g. of magnesium. After boiling for one hour, the mixture is hydrolyzed with iced acid, and the unchanged diketone (20 g.) is extracted with sodium carbonate. The neutral product is distilled under reduced pressure and crystallized from acetic acid and then from toluene. There is obtained 9 g. of the bromodiphenylindone which forms orange prisms that melt at 172–174°.

Anal. Calcd. for $C_{21}H_{13}OBr$: C, 69.8; H, 3.6. Found: C, 69.9; H, 3.82.

2-Phenyl-3-_p_-cyanophenylindone.—The preceding bromodiphenylindone is heated with half its weight of cuprous cyanide at 250° for four hours, the melt is powdered and extracted with acetone, and the product is distilled under reduced pressure and crystallized from acetic acid. The cyano compound forms bright red prisms that melt at 184–187°.

Anal. Calcd. for $C_{22}H_{13}ON$: C, 86.0; H, 4.23. Found: C, 85.6; H, 4.34.

[7] Wheeler and Clapp, _Am. Chem. J._, **40**, 460 (1908).

Substitution in the Indene Nucleus of 2,3-Diphenylindone

2 - Phenyl - 5 - bromoindandione - 1,3.—4 - Bromophthalic anhydride[8] (29 g.) is mixed with phenylacetic acid (17.5 g.) and sodium acetate (1 g.) and heated at 220–240° for three hours. The product (23 g.), a mixture of the two possible benzal bromophthalides, is crystallized from acetic acid, when it melts at 145–170°. This mixture is suspended in methanol and treated with a solution of 2 g. of sodium in the same solvent. The solution is boiled for five minutes, water is added, and the diketone is precipitated with hydrochloric acid. From acetic acid, the product (20 g.) is deposited in the form of violet-black needles, and from benzene in the form of white needles. Both of these forms melt to a red liquid at 166–167°.

Anal. Calcd. for $C_{15}H_9O_2Br$: C, 59.8; H, 2.99. Found: C, 59.4; H, 2.84.

5- and 6-Bromo-2,3-diphenylindones.—The above diketone (19 g.) suspended in benzene is added to a solution of phenylmagnesium bromide containing 4 g. of magnesium. The mixture is boiled for one hour, hydrolyzed, and the unchanged diketone (3 g.) is removed with sodium carbonate. The neutral product is distilled under reduced pressure and fractionally crystallized from ether–petroleum ether. The less soluble part (8.5 g.) is 6-bromo-2,3-diphenylindone, which forms orange-red plates from acetic acid that melt at 192–194°.

Anal. Calcd. for $C_{21}H_{13}OBr$: C, 69.8; H, 3.6. Found: C, 69.7; H, 3.4.

The more soluble part is 5-bromo-2,3-diphenylindone, which forms orange needles from acetic acid that melt at 167–168°.

Anal. Calcd. for $C_{21}H_{13}OBr$: C, 69.8; H, 3.6. Found: C, 69.8; H, 3.4.

The structure of the latter 5-bromodiphenylindone is indicated by its oxidation by chromic acid in acetic acid to 2-benzoyl-4-bromobenzoic acid which melts at 189–191° alone or mixed with a known sample of this same melting point, kindly furnished by Dr. Stephens.

6 - Cyano - 2,3 - diphenylindone.—6 - Bromodiphenylindone is treated with cuprous cyanide and the product is worked up as described for 2-phenyl-3-*p*-cyanophenylindone. The product forms orange red plates that melt at 209–211°.

Anal. Calcd. for $C_{22}H_{13}ON$: C, 86.0; H, 4.23. Found: C, 85.6; H, 4.2.

The Vinyl Compounds

α - *p* - Bromophenyl - β,β - diphenylvinyl Bromide.—An ether solution of benzophenone (28 g.) is added to a solution of *p*-bromobenzylmagnesium bromide containing 7.3 g. of magnesium. The solution is hydrolyzed with iced ammonium chloride, and the product is crystallized from ether–petroleum ether. There is obtained 35 g. of *p*-bromobenzyldiphenylcarbinol, which forms white needles that melt at 124–126°. (Found: C, 68.4; H, 5.0. $C_{20}H_{17}OBr$ requires: C, 68.0; H, 4.7.) This carbinol (7 g.) is dissolved in acetic acid (30 ml.) and treated with bromine (3.2 g.). The bromine is rapidly absorbed, and the solution soon deposits crystals of the vinyl bromide. The product is best purified by distillation under reduced pressure followed by crystallization from acetic acid. It forms colorless needles that melt at 109–110°.

Anal. Calcd. for $C_{20}H_{14}Br_2$: C, 58.0; H, 3.4. Found: C, 57.8; H, 3.4.

Under the usual conditions for the replacement of bromine by cyanogen (240°) this dibromo compound is converted into a black resin. At lower temperatures it is partly resinified and partly recovered unchanged.

Triphenylacrylonitrile.—Triphenylvinyl bromide heated with cuprous cyanide in the usual way gives a quantitative yield of triphenylacrylonitrile which melts at 163–165°.[9]

α - Phenyl - β - diphenyleneacrylonitrile.—α - Phenyl - β-diphenylenevinyl bromide[10] and cuprous cyanide at 240° give a good yield of the corresponding nitrile which forms yellow needles that melt at 188–189°.

Anal. Calcd. for $C_{21}H_{13}N$: C, 90.2; H, 4.66. Found: C, 90.1; H, 4.68.

Summary

The synthesis of some halogenated diphenylindones is described, and it is shown that the Rosenmund–v. Braun method for the replacement of halogen by cyanogen is applicable to these compounds and to certain triarylvinyl bromides.

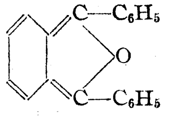
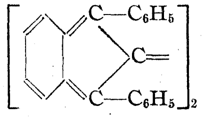
The Attempted Synthesis of Some Compounds Containing the *Iso*-indene Nucleus

BY C. FREDERICK KOELSCH

α,α-Diphenyl-β,β-benzofuran (I) is the only compound known definitely to contain an *o*-quinoid structure similar to that formerly postulated for rubrene (II).[1] That this type of structure is formed with difficulty or once formed is not stable is indicated by the relative ease of oxidation of anthracene as compared with phenanthrene, the radical nature of 2,3,6,7-dibenzanthracene, the immediate rearrangement of *o*-quinone-bisdiphenylmethide and other similar phenomena.

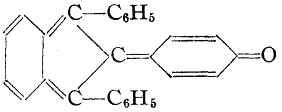


I

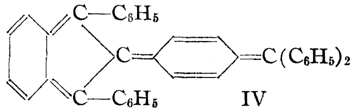


II

The present investigation was undertaken with the object of throwing some light on the structure and possible tautomeric nature of rubrene through a study of the reactions of the compounds (III) and (IV).



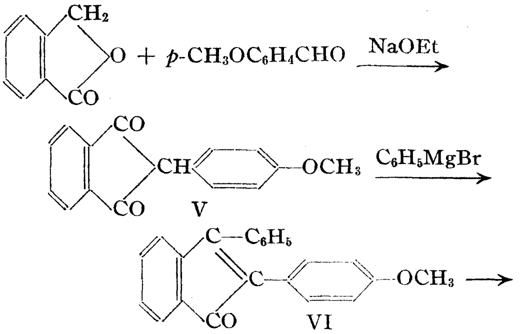
III

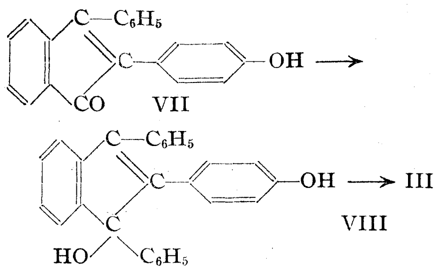


IV

Although these substances could not be prepared, it is believed that the syntheses themselves and what few conclusions may be drawn from such negative results warrant publication.

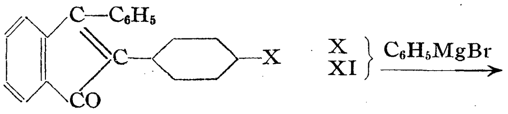
2-(*p*-Quino-)-1,3-diphenyl*iso*indene (III).—The synthesis of this compound was attempted through the following reactions



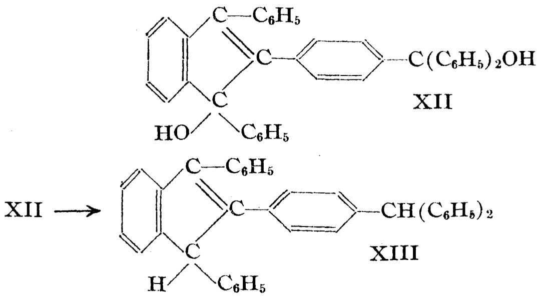


The substance (VIII) could not be dehydrated either by heat alone or by hot acetic acid; when boiled with acetic acid containing a trace of sulfuric acid, it was converted into a white amorphous substance, the reaction being apparently similar to the condensation undergone by 1,2,3-triphenylindenol and 9-phenylfluorenol under like conditions. Similar to Gomberg's easily dehydrated hydroxytriaryl carbinols in that a completely conjugated system connects the phenolic and the alcoholic hydroxyl groups, the compound (VIII) probably owes its resistance to dehydration to the difficulty of forming the necessary *o*-quinoid structure.

2-(*p*-Diphenylmethylenequino)-1,3-diphenyl*iso*indene (IV).—The synthesis of this substance was attempted by the reactions



IX (X = COOH)
X (X = COOR)
XI (X = COC_6H_5)



Neither the glycol (XII), its dimethyl ether, nor its dichloride could be obtained crystalline. The action of metals on the crude dichloride gave intractable orange gums whose solutions were not affected by air.

---

[1] Since this work was completed Dufraisse and Velluz [*Compt. rend.*, **201**, 1394 (1935)] have suggested and proved that rubrene has an entirely different structure.

Experimental

2-*p*-Anisylindandione-1,3 (V).—A mixture of 110 g. of phthalide and 110 g. of anisaldehyde is added to a solution of 20.5 g. of sodium in 400 ml. of absolute ethanol. After boiling for fifteen minutes, the deep red solution is poured into water, the alcohol is distilled and the product is precipitated with hydrochloric acid. After crystallization from acetic acid the diketone forms colorless needles that melt at 152–154°; yield 68 g. The remainder of the anisaldehyde is converted into anisyl alcohol and anisic acid.

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.2; H, 4.8. Found: C, 75.52; H, 4.70.

2-*p*-Anisyl-3-phenylindone (VI).—A solution of 65 g. of anisylindandione in hot toluene is added to phenylmagnesium bromide containing 15 g. of magnesium. The mixture is boiled for one hour and decomposed with iced sulfuric acid. After the unchanged diketone (7 g.) has been extracted with sodium carbonate, the product is distilled at 15 mm. and crystallized from acetic acid. There is obtained 43 g. of red needles that melt at 117–118°.

Anal. Calcd. for $C_{22}H_{16}O_2$: C, 84.6; H, 5.1. Found: C, 85.01; H, 5.21.

2-*p*-Hydroxyphenyl-3-phenylindone (VII).—The methoxy ketone (VI) (30 g.) is hydrolyzed by boiling for six hours with a mixture of 120 ml. of acetic acid and 30 ml. of 40% hydrobromic acid. The product, purified by solution in sodium hydroxide and reprecipitation, separates from acetic acid in red plates that contain acetic acid; m. p. 163–165°.

Anal. Calcd. for $C_{21}H_{14}O_2 \cdot 0.5C_2H_4O_2$: C, 80.4; H, 4.9. Found: C, 80.3; H, 4.9.

Dilute aqueous sodium hydroxide dissolves the phenol, giving a purple solution.

The benzoate, prepared with aqueous alkali and benzoyl chloride, forms red prisms that melt at 145°.

Anal. Calcd. for $C_{28}H_{18}O_3$: C, 83.5; H, 4.5. Found: C, 83.5; H, 4.4.

1,3-Diphenyl-2-*p*-hydroxyphenylindenol (VIII).—A benzene solution of the hydroxydiphenylindone is added to an excess of phenylmagnesium bromide. The mixture is worked up in the usual way, and the product, which like all triarylated indenols shows a tendency to supercool, is purified by recrystallization of its sodium salt. The pure phenol-alcohol crystallizes from ether–ligroin as a colorless powder that melts at 196–197°.

Anal. Calcd. for $C_{27}H_{20}O_2$: C, 86.1; H, 5.3. Found: C, 85.9; H, 5.3.

It is readily soluble in acetic acid and can be recovered unchanged after boiling with this solvent. The acetic acid solution becomes red on the addition of a trace of sulfuric acid and now, on boiling, a white amorphous substance is deposited, which is insoluble in the common solvents.

Hydrolysis of Cyanodiphenylindone.—The cyano compound (0.5 g.)[2] is boiled with a mixture of 5 ml. of sulfuric acid and 5 ml. of water until the originally melted substance has resolidified. The mixture is poured into water; the solid is powdered and extracted with hot sodium carbonate solution. The neutral product, **2-*p*-carbamidophenyl-3-phenylindone,** crystallizes from acetic acid in orange needles (0.15 g.) that melt at 248–254° with decomposition.

Anal. Calcd. for $C_{22}H_{15}O_2N$: C, 81.2; H, 4.6. Found: C, 80.5; H, 4.6.

The acidic product (IX) is precipitated with hydrochloric acid and crystallized from acetic acid, when it forms orange plates (0.35 g.) that melt at 212–214° and can be distilled without decomposition at 15 mm. The acid may also be obtained by boiling the amide with 1:1 sulfuric acid and water.

Anal. Calcd. for $C_{22}H_{14}O_3$: C, 80.8; H, 4.3. Found: C, 80.31; H, 4.3.

On boiling with the appropriate alcohol containing a little sulfuric acid, 2-*p*-carboxyphenyl-3-phenylindone is esterified. The esters (X), obtained in yields of about 80%, are best purified by distillation at 15 mm. followed by crystallization.

The methyl ester, from toluene, forms orange plates that melt at 167–168°.

Anal. Calcd. for $C_{23}H_{16}O_3$: C, 81.2; H, 4.7. Found: C, 81.3; H, 4.8.

The ethyl ester, from ethanol, forms orange needles that melt at 120–121°.

Anal. Calcd. for $C_{24}H_{18}O_3$: C, 81.4; H, 5.1. Found: C, 81.4; H, 5.3.

2-*p*-Benzoylphenyl-3-phenylindone (XI).—The acid (IX) dissolved in benzene is treated with a slight excess of phosphorus pentachloride, and after short boiling, with 2.2 equivalents of aluminum chloride. The solution is boiled for fifteen minutes, decomposed with iced acid and washed with sodium carbonate. The product crystallizes from acetic acid in red-orange prisms that melt at 169–171°. This diketone may be distilled at 15 mm. without decomposition.

Anal. Calcd. for $C_{28}H_{18}O_2$: C, 87.0; H, 4.69. Found: C, 86.6; H, 4.55.

2 - (*p* - α - Oxybenzohydrylphenyl) - 1,3 - diphenylindenol-1 (XII).—The methyl ester, the ethyl ester or the phenyl ketone derived from 2-*p*-carboxyphenyl-3-phenylindone dissolve easily in an excess of phenylmagnesium bromide. Decomposition of these solutions with iced acid followed by steam distillation gives in each case a pale orange glassy substance, easily soluble in acetic acid or in methanol. The solution in acetic acid becomes deep green with a trace of sulfuric acid. The methanol solution, on the addition of a little sulfuric acid, deposits an orange gum easily soluble in ether and nearly insoluble in methanol, but this dimethyl ether (?) cannot be crystallized. The chloride (?) obtained from the glycol with hydrogen chloride in benzene or with acetyl chloride also forms an uncrystallizable oil.

2-*p*-Benzohydrylphenyl-1,3-diphenylindene (XIII).—This hydrocarbon can be obtained from the glycol, the dimethyl ether or the chloride as follows. One gram of granulated zinc is added to a solution of one gram of any of the substances mentioned in 20 ml. of acetic acid. The solution is boiled and a drop of concd. hydrochloric acid is added; boiling is continued until the deep green solution is colorless, when more hydrochloric acid is added.

---

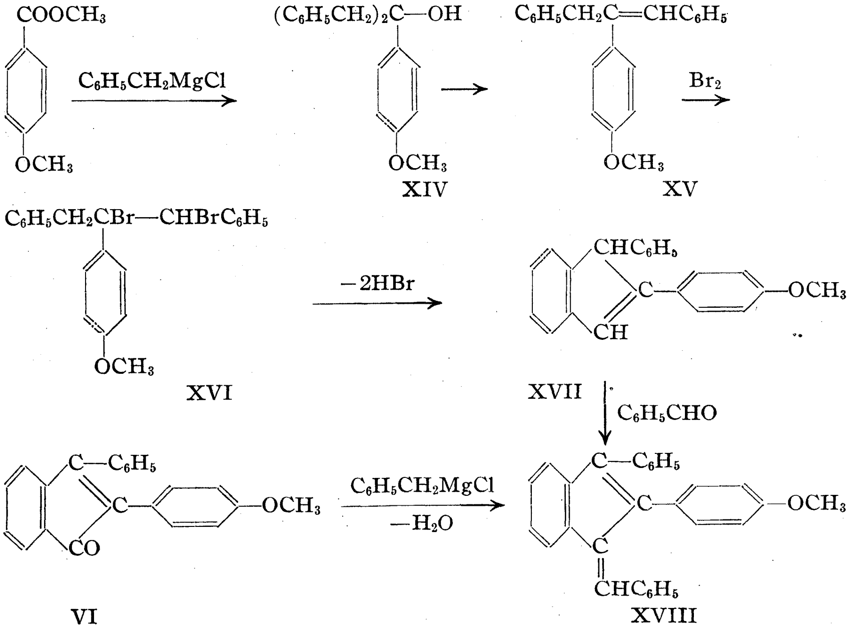
(2) Koelsch, This Journal, **58**, 1328 (1936).

This treatment is continued until the green color is no longer restored by hydrochloric acid. Water and ether are added, the ether solution is freed of acetic acid, dried and evaporated. The product is crystallized from ether–petroleum ether and then from acetic acid, when it forms small colorless flat needles that melt at 173–175°. It may be distilled without decomposition at 15 mm., and this is the most convenient way to purify large quantities (15 g.) of the substance.

Anal. Calcd. for $C_{40}H_{30}$: C, 94.1; H, 5.9. Found: C, 94.4; H, 6.3.

On treating the hydrocarbon in acetic acid with chromic acid, it is oxidized to *o*-dibenzoylbenzene and *p*-carboxytriphenylcarbinol, identified in each case by comparison with an authentic sample.

A Check on the Structure of 2-*p*-Anisyl-3-phenylindone.—In order to make certain of the structure of this compound, the following reactions were carried out



Two products are obtained from the dibromide (XVI), but only the indene (XVII) has been isolated in a pure state.

α,γ-Diphenyl-β-*p*-anisyl-propanol-β (XIV).—This carbinol, obtained in a yield of about 75%, is crystallized from ether–petroleum ether and then from ethanol. It forms white plates that melt at 93–94°.

Anal. Calcd. for $C_{22}H_{22}O_2$: C, 83.0; H, 6.9. Found: C, 83.4; H, 7.0.

α,γ-Diphenyl-β-*p*-anisylpropene (XV).—This substance is obtained in a quantitative yield by boiling the above carbinol in acetic acid containing a little sulfuric acid.

It forms white plates that melt at 82–83° from ethanol.

Anal. Calcd. for $C_{22}H_{20}O$: C, 88.0; H, 6.7. Found: C, 87.7; H, 6.7.

2-*p*-Anisyl-1-phenylindene (XVII).—The propene dissolved in 2.5 times its weight of acetic acid is treated with the calculated amount of bromine, and the solution is boiled for twenty minutes.

The product is distilled under reduced pressure (decomposition of the bromopropene) and crystallized from acetic acid and then from ligroin, when it forms pale orange plates that melt at 120–122°; yield about 35%.

Anal. Calcd. for $C_{22}H_{18}O$: C, 88.5; H, 6.0. Found: C, 87.8; H, 6.0.

1-Benzal-2-*p*-anisyl-3-phenylindene (XVIII).—(a) To a solution of 0.5 ml. of benzaldehyde and 1 g. of the indene (XVII) in 10 ml. of hot *n*-propyl alcohol is added a solution of 0.1 g. of sodium in 2 ml. of ethanol. The benzal compound is rapidly deposited, and on recrystallization from acetic acid forms yellow needles that melt at 188–190° (1.2 g.).

Anal. Calcd. for $C_{29}H_{22}O$: C, 90.1; H, 5.7. Found: C, 90.0; H, 5.6.

(b) A benzene solution of the indone (VI) is added to an excess of benzylmagnesium chloride. Since the resulting carbinol is an oil, it is dehydrated by boiling in acetic acid with a trace of sulfuric acid. The product is identical with that obtained in (a).

Summary

Some unsuccessful attempts to obtain compounds containing the *iso*-indene nucleus are recorded. These failures lend support to the supposition that this nucleus is unstable.

MINNEAPOLIS, MINN. RECEIVED MAY 19, 1936

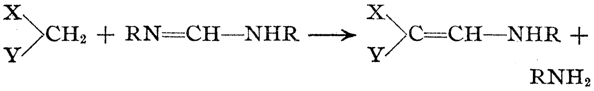
On the Reactions of Certain Methylene Hydrogen Derivatives Containing Cyanide, Thiocyanate or Sulfinate Radicals

BY CLARENCE E. GROTHAUS AND F. B. DAINS

It has been shown previously in a series of papers[1] that compounds containing the methylene hydrogen grouping exhibit the characteristic property of reacting with disubstituted formamidines, forming a carbon to carbon linking and yielding an aminomethylene derivative which may be represented as follows



$$\overset{X}{\underset{Y}{>}}CH_2 + RN{=}CH{-}NHR \longrightarrow \overset{X}{\underset{Y}{>}}C{=}CH{-}NHR + RNH_2$$

These reactions occur in the case of open-chain compounds as acetoacetic ester, benzoylacetic ester, cyanoacetic ester, malonic ester and desoxybenzoin; also heterocyclic compounds as thiazolidones, pyrazolones, isoxazolones and imidazolones are similarly reactive.

The present investigation was carried out with methylene derivatives in which one group was a benzoyl or substituted benzoyl grouping and the other the CN, SCN or *p*-$CH_3C_6H_4SO_2$ radical, ($XC_6H_4COCH_2Y$), in order to ascertain the effect of the latter groups on the reactivity of the methylene hydrogen with the formamidines and in a few cases with benzaldehyde and *p*-nitrosodimethylaniline.

The aminomethylene derivatives obtained in this study were found usually to react with hydrazine, phenylhydrazine and hydroxylamine yielding pyrazole or isoxazole derivatives. However, *p*-phenylanilinomethylenebenzoylacetonitrile failed to give such pyrazole or isoxazole compounds.

Experimental

I. Derivatives of Phenacyl Cyanide

Anilinomethylenebenzoylacetonitrile (III) $C_6H_5COC(CHNHC_6H_5)CN$.—Phenacyl cyanide (6 g.) and diphenylformamidine (8 g.) were heated in xylene solution at 120° for two hours. Anilinomethylenebenzoylacetonitrile (m. p. 159°) and aniline were formed.

Reactions of Anilinomethylenebenzoylacetonitrile with Hydroxylamine.—The nitrile (III) was refluxed in alcohol solution with hydroxylamine hydrochloride, either by itself, in pyridine solution or after neutralization with sodium carbonate. In all cases the same products were obtained, aniline and a compound (XI) melting at 154°, which was insoluble in hydrochloric acid and was recovered unchanged after solution in alkali. It cannot be the expected 2-phenyl-3-cyanoisoxazole which should in the presence of alkali rearrange to benzoylmalonic dinitrile.[2] The compound failed to react with phenylhydrazine, benzoyl chloride, and ethyl iodide and was hydrolyzed only after long boiling with 40% sodium hydroxide. These properties and its inertness point to the probable structure of 4-benzoyl-5-iminoisoxazole (XI) $\underbracket{ON{=}CHCH(COC_6H_5)C}{=}NH$.

With hydrazine.—When this nitrile (III) was refluxed with hydrazine in alcoholic solution, 3-phenyl-4-cyanopyrazole (XII) (m. p. 134°) and aniline were formed.

With Phenylhydrazine.—The anilinomethylene derivative (III) reacted with phenylhydrazine in an analogous manner and gave aniline and 1,5-diphenyl-4-cyanopyrazole (XIII) (m. p. 182°). This product is soluble in most organic solvents but is practically insoluble in either acid or alkali.

Proof of Structure of 1,5-Diphenyl-4-cyanopyrazole.—This was accomplished by hydrolyzing the cyano group to a carboxylic group. Refluxing with 75% sulfuric acid, concentrated hydrochloric acid or sodium hydroxide failed to effect hydrolysis. Concentrated sulfuric acid at 130° hydrolyzed the compound to benzoic acid. The desired carboxylic acid was obtained by heating the pyrazole in a sealed tube with concentrated alcoholic potassium hydroxide at 160 to 170° for three hours, yielding 1,5-diphenyl-4-pyrazolecarboxylic acid (XIV) (m. p. 173°) and ammonia. This acid was found to be identical with that obtained by hydrolyzing the anilide of 1,5-diphenyl-4-pyrazolecarboxylic acid.

The fact that the phenylhydrazone of the phenacyl cyanide failed to react on heating with diphenylformamidine (two hours at 120°) points to this same structure.

4-Dimethylaminoanilinobenzoylacetonitrile (I) $C_6H_5COC({=}NC_6H_4N(CH_3)_2)CN$.—Nitrosodimethylaniline condensed readily with phenacyl cyanide in boiling alkaline alcoholic solution. The blood-red crystals from dioxane melted at 128°.[3]

II. *p*-Bromophenacyl Cyanide and Derivatives

***p*-Bromophenacyl Cyanide (XV).**—*p*-Bromophenacyl chloride (60 g.) was partially dissolved in alcohol (200 cc.). A solution of sodium cyanide (28 g.) was slowly added with continuous stirring, the mixture being cooled with ice. The mixture was then warmed to 60° and the stirring continued for one hour, the color changing from brown to reddish-violet. The cyanide was precipitated by acidifying and was deposited as slightly colored small thick plates (m. p. 159°).

Anilinomethylene-*p*-bromobenzoylacetonitrile (XVI) *p*-$BrC_6H_4COC({=}CHNHC_6H_5)CN$.—This resulted when

[o] Fusion of phenacyl-*p*-tolyl sulfinate and di-*o*-chlorophenylformamidine.

(XV) and diphenylformamidine were fused at 150° and crystallized from benzene in white needles (m. p. 143°).

Reactions of Anilinomethylene-*p*-bromobenzoylacetonitrile.—This compound (and also *p*-bromoanilinomethylenebenzoylacetonitrile) reacted with hydroxylamine to give an isoxazole (XVIII) (m. p. 195°); with hydrazine to give a phenyl pyrazole (XIX) (m. p. 195°); and with phenylhydrazine to give a diphenyl pyrazole (XX) (m. p. 212°). Aniline (*p*-bromoaniline in the case of the bromine derivative) was the other product of these reactions.

III. Derivatives of Phenacyl Thiocyanate

2-Imino-3-phenyl-5-benzoylthiazole (XXI) $SC(NH)-NC_6H_5CHCCOC_6H_5$.—Phenacyl thiocyanate (3.5 g.) and diphenylformamidine (4 g.) were heated at 160° in xylene for one hour. The product was washed with dilute acid and was crystallized from dioxane in fine light yellow crystals (m. p. 257°). Aniline was formed also in the reaction. Anilinomethylenephenacyl thiocyanate was doubtless formed first, but this evidently rearranged to a thiazole. It was not hydrolyzed with concentrated hydrochloric acid, sulfuric acid or alcoholic potassium hydroxide. No hydrolyzable sulfur was indicated by tests with lead plumbite. This derivative gave negative results for the presence of a free thiocyanate grouping in tests using alkaline lead tartrate.[4] It was unreactive to phenylhydrazine. These properties and the work of Kaufmann on thiocyanate derivatives[5] indicate such rearrangement.

Phenacyl thiocyanate was found to react also with di-*p*-bromophenylformamidine and di-*p*-chlorophenylformamidine to give analogous derivatives (XXII and XXIII).

IV. Derivatives of Phenacyl-*p*-tolyl Sulfinate

ω-Benzalphenacyl-*p*-tolyl Sulfinate (XXIV) $C_6H_5COC(CHC_6H_5)SO_2C_7H_7$.—Phenacyl-*p*-tolyl sulfinate and benzaldehyde (excess) were boiled in alcoholic solution to which had been added a few drops of piperidine. On cooling, small white crystals were deposited (m. p. 142°).

Phenacyl-*p*-tolyl sulfinate failed to react with *p*-nitrosodimethylaniline in an analogous manner.

Phenylhydrazone of Phenacyl-*p*-tolyl Sulfinate (XXV) $C_6H_5C(NNHC_6H_5)CH_2SO_2C_7H_7$.—Phenylhydrazine readily reacted with phenacyl-*p*-tolyl sulfinate to form the phenylhydrazone crystallizing in pale yellow short thick plates (m. p. 188°) from dioxane.

Anilinomethylenephenacyl-*p*-tolyl Sulfinate (XXVI) $C_6H_5COC(CHNHC_6H_5)SO_2C_7H_7$.—Phenacyl-*p*-tolylsulfinate (5 g.) and diphenylformamidine (5 g.) were heated together at 180 to 190° for one hour in xylene. The reaction product was washed with dilute acid to remove the aniline formed, and crystallized from dioxane in fine needles (m. p. 208°).

Di-*p*-bromophenylformamidine, di-*p*-chlorophenylformamidine and di-*o*-chlorophenylformamidine were found to react similarly with the sulfinate (derivatives XXVII, XXIX and XXX).

Reaction with Phenylhydrazine.—The anilinomethylene (XXVI) derivative reacted with phenylhydrazine when refluxed in alcoholic solution to give in small yield 1,5-diphenyl-4-(*p*-tolylsulfonyl)-pyrazole (XXVIII) (m. p. 164° from a mixture of alcohol and dioxane). This same pyrazole was obtained from *p*-bromoanilinomethylenephenacyl-*p*-tolyl sulfinate (XXVII) and phenylhydrazine.

Attempted Reactions with Hydrazine and Hydroxylamine.—The anilinomethylene (XXVI) and the *p*-bromoanilinomethylene (XXVII) derivatives failed to react with hydrazine or with hydroxylamine on refluxing in alcoholic solution.

V. Derivatives of *p*-Nitrobenzyl Cyanide and *p*-Nitrophenylacetic Ester

Anilinomethylene-*p*-nitrobenzyl Cyanide (XXXI) *p*-$NO_2C_6H_4C(CHNHC_6H_5)CN$.—This was prepared by fusing *p*-nitrobenzyl cyanide and diphenylformamidine. It formed fine orange-red needles from dioxane (m. p. above 260°). Aniline was split off in the reaction.

p-Nitrobenzyl cyanide was compared with benzyl cyanide in the ease of reaction with formamidines. The former derivative is much more reactive than benzyl cyanide, reacting readily and approaching phenacyl cyanide in reactivity.

The anilinomethylene derivative (XXXI) failed to react with hydroxylamine.

Anilinomethylene-*p*-nitrophenylacetic Ethyl Ester (XXXII) *p*-$NO_2C_6H_4C(CHNHC_6H_5)COOC_2H_5$.—*p*-Nitrophenylacetic ethyl ester and diphenylformamidine were fused together to yield this derivative. It was deposited from alcohol in long yellow needles (m. p. 114–115°). Aniline was split off in this reaction.

p-Nitrophenylacetic ethyl ester failed to react with *p*-nitrosodimethylaniline.

Summary

The methylene hydrogen reactions of phenacyl cyanide, *p*-bromophenacyl cyanide, *p*-nitrobenzyl cyanide, *p*-nitrophenylacetic ester, phenacyl thiocyanate and phenacyl-*p*-tolyl sulfinate with certain disubstituted formamidines have been studied and a number of new derivatives have been synthesized.

Phenacyl cyanide approaches benzoylacetic ester in methylene hydrogen reactivity as does also *p*-bromophenacyl cyanide and *p*-nitrobenzyl cyanide, while phenacyl thiocyanate is less reactive and phenacyl-*p*-tolyl sulfinate reacts with still more difficulty.

The anilinomethylene derivatives studied condense in nearly all the instances tried with hydroxylamine and the hydrazines to form isoxazoles and pyrazoles, respectively. Failures noted: *p*-phenylanilinomethylenebenzoylacetonitrile (no reaction with phenylhydrazine, hydrazine or hydroxylamine); anilinomethylenephenacyl-*p*-tolyl sulfinate (reacted with phenylhydrazine but not with hydrazine or hydroxylamine); *p*-bromoanilinomethylenephenacyl-*p*-tolyl sulfinate (reacted with phenylhydrazine but not with hydrazine or hydroxylamine); anilinomethylene-*p*-nitrobenzyl cyanide (no reaction with hydroxylamine).

Physical Studies of Non-Aqueous Solvates. I. The Solubility of Magnesium Bromide in Ethyl Ether[1]

BY H. H. ROWLEY

The figures on the solubility of magnesium bromide in ethyl ether as given in the "International Critical Tables"[2] are based on the work of Menschutkin.[3] Recently, Evans and Rowley[4] studying the vapor pressures of the ethyl etherates of magnesium bromide demonstrated the existence of a trietherate, stable below +12–13°, that was unknown to Menschutkin. In view of this fact, it was decided to repeat the work of Menschutkin over a temperature range from −20 to +30° and see if the solubility curve also gave indications of a change of phase. At the same time, the preparation of magnesium bromide in ethyl ether solution was studied.

Experimental

Method of Preparation.—The magnesium bromide was prepared according to Zelinsky[5] by treating pure magnesium turnings in ethyl ether with liquid bromine and agitating until the solution was colorless, cooling the flask when necessary to avoid too violent a reaction. As was previously known,[3–5] when the concentration of magnesium bromide reached a value of about 3.5%, an oily, immiscible liquid separated out and, as the reaction proceeded, increased in amount. This immiscible layer was often brown in color, but when properly prepared was almost colorless. When precipitated from a solution of magnesium bromide, saturated at a higher temperature, by cooling, this oily liquid was absolutely colorless. When pure, it crystallized under ether at about +22–23° but was capable of being supercooled 20 to 30° for several hours. However, agitation or seeding with a crystal of magnesium bromide etherate caused it to solidify into a white crystalline mass, which melted under ether above +23° re-forming the heavy layer.

The magnesium turnings were of reagent quality used in the preparation of Grignard reagents. The bromine was taken from a freshly opened bottle of C. P. grade, transferred to a dropping bottle and kept in a desiccator over phosphorus pentoxide. The ethyl ether was kept over calcium chloride for several days, filtered onto freshly cut sodium and kept in a subdued light for at least three or four days. It was then filtered onto fresh sodium and if no reaction occurred was distilled and kept over sodium in subdued light. The first and last fractions of the distillate were discarded and the freshly distilled middle portion used in less than a week. In this way the amount of degradation products present was kept at a minimum.

Determination of Solubility.—The samples were prepared in 150–250-cc. Erlenmeyer flasks as described above and either used directly or recrystallized, depending upon the purity as shown by the first analysis. The flasks, protected with calcium chloride tubes throughout the preparation and analysis, were immersed in a thermostat at the proper temperature held to less than 0.1°. For the determination at 0°, the melting point of ice was used, while at −10 and −20° an acetone-bath cooled with solid carbon dioxide was maintained at the proper temperature with the aid of an iron–constantan thermo element. In most cases, whenever feasible, the solutions were saturated a few degrees above the bath temperature in order that the equilibrium might be reached from supersaturation rather than unsaturation. After placing the samples in the bath, the flasks were agitated at intervals for at least an hour to ensure equilibrium. When the solid phase was crystalline, the oily immiscible layer was first solidified in ice and then melted before placing in the thermostat. After the immiscible layer had once been solidified and then remelted, the amount of supercooling, so characteristic of this substance, was greatly decreased and crystallization occurred rather quickly at temperatures where the crystal phase was stable.

After the solution had come to equilibrium, the flask was removed from the bath and a sample of the clear solution quickly poured into a tared flask and weighed. The weighed solution was then poured into water acidified with dilute nitric acid, the ether removed by evaporation and boiling, and the total bromide concentration determined as silver bromide. All of the solubility measurements were determined by this method and reported in grams of magnesium bromide dissolved in 100 g. of ethyl ether. In a series of experiments, a second sample was weighed in a tared crucible, the ether removed by evaporation on a steam-bath and the residue treated with concentrated sulfuric acid which was later removed by heating on a hot-plate and finally the magnesium sulfate was heated to redness and weighed as such. The determination of magnesium by this method was well suited to the conditions, since the concentrated sulfuric acid destroyed all the organic matter which might interfere with other methods. The disadvantage, aside from the hygroscopic character of anhydrous magnesium sulfate, was that considerable loss of ether from the open crucible occurred before weighing which would lead to higher results than by the bromide method. This was consistently shown in the determinations but, even so, the agreement was quite good.

The results of the analyses are shown in Table I and Fig. 1. The solubility of magnesium bromide at each temperature is the average of at least two individual samples taken from separate preparations. The more important

points such as at 0, +16 and +25° were checked by analysis of five or more samples. During the course of the investigation, well over 150 separate preparations were made. The accuracy of the points is ±0.05 g. of magnesium bromide per 100 g. of ether.

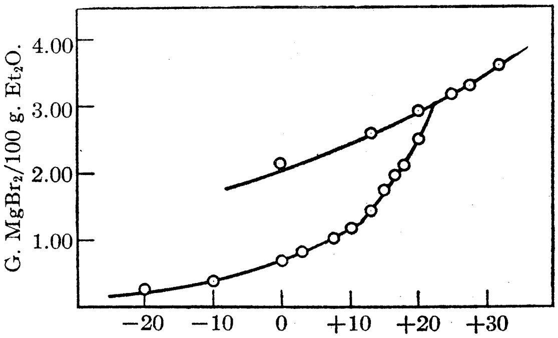

Fig. 1.—Solubility of $MgBr_2$ in ethyl ether.

Factors Influencing Purity

It was found during the investigation that high and inconsistent results were frequently encountered. The possibility of impure reagents was eliminated inasmuch as inconsistent results were often obtained using identically the same materials in successive runs. Since moisture was known to decompose the etherates,[4,6] this was one of the first factors to be investigated.

Effect of Moisture during the Preparation.—Dry, freshly distilled ether was mixed with a known quantity of water and this moist ether was then used in preparing the magnesium bromide solutions in the usual manner. The reaction of bromine on the magnesium was always immediate with moist ether, whereas dry ether required a minute or more before a reaction was visible. With wet ether there appeared to be a gas given off even when the solution was cold. The results of a series of analyses at +24.9° are given in Table II. Small amounts of moisture in the ether during the preparation do not appear to affect the apparent solubility.

Effect of Moisture after the Preparation.—The magnesium bromide was prepared in the usual manner using dry ether. The immiscible layer was crystallized by cooling and the original solution decanted. Ether with a known moisture content was added, the crystals melted and the solution saturated at +24.9°. The amount of magnesium bromide in solution was determined both by the magnesium sulfate and the silver bromide methods. The results of the series are given in Table III and show that the presence of moisture, after the solutions are prepared, definitely raises the apparent solubility of the magnesium bromide.

Table II

Effect of Moisture during Preparation

74	.005	3.51	3.45
71	.01	3.59	3.52
59	.02	3.68	3.57

To overcome this source of error, the apparatus and reagents were carefully dried and the reaction flasks fitted with calcium chloride tubes. During the preparation and recrystallization, the flasks were never opened except in an atmosphere of air dried by calcium chloride and concentrated sulfuric acid.

Effect of Light during the Preparation.—The fact that the solubility of the magnesium bromide could be lowered to a constant value by careful recrystallization from fresh ether, indicated that the apparent high solubilities frequently obtained were due to certain conditions existing during the preparation. There seemed to be good indications that ether, not freshly distilled, caused high results but frequently freshly distilled ether also gave somewhat high values not traceable to moisture. In practically all these cases, when the sample was poured into water and the ether boiled off, there was a more or less strong odor of some organic compound or compounds, frequently lachrymatory in nature, that was difficult to boil out of solution. This organic material caused the silver bromide precipitate to be oily and to stick to the side of the beaker. That the high results were not due exclusively to inclusion of this organic material in the silver bromide, is shown by parallel magnesium determinations which also were high. Since the magnesium sample was evaporated to dryness (residue dark when organic matter is present, white when not) then treated with concentrated sulfuric acid and heated to redness, all the organic matter including the combined ether was destroyed.

Believing that this organic matter might be formed by the action of bromine on ethyl ether in the presence of light, a series of runs was made to test this. The room was partially darkened and the sample exposed to strong light

---

(6) B. N. Menschutkin, *Chem. Zentr.*, **77**, I, 646 (1906).

for definite intervals during the preparations. A 200-watt daylight gas-filled lamp set in a 30-cm. silver reflector was used as a light source and the sample flask held 15 cm. from the bulb. It was noticed that, during the exposure to a strong light, a gas was given off even though the solution was below room temperature.

During several runs when the concentration of bromine was rather high and the reaction was vigorous, the two-layer system would appear normal after the free bromine color had disappeared but almost immediately the heavy immiscible layer would begin to darken. In ten or fifteen minutes it would be a deep purple and the upper ether layer would acquire a light purple color. On further standing for an hour or so, this would fade to a green and finally the immiscible layer would become clear yellow and the ether layer colorless. During these color changes, the liberation of a gas frequently was observed. In all such cases, the analyses were very high and showed the presence of a large amount of high-boiling organic material. The results of the experiments with light are shown in Table IV. When the strong light was not in use, the samples were not in total darkness but were not exposed to any direct daylight.

TABLE IV

EFFECT OF LIGHT DURING THE PREPARATION

ANALYSIS AT +24.9°

61	15–20 min.	3.59	3.61	Color changes

A few rough experiments were performed to determine whether ethyl ether did react with liquid bromine to a certain extent in the presence of light. Ether that had been distilled about six days previously and kept over sodium in semi-darkness was used. In total darkness 50 cc. of this ether and 1.8 g. of bromine still showed a strong bromine color after five days. However, exposure of this sample to a strong light caused the color to disappear in less than two hours. Another 75-cc. portion took up about 0.9 g. of bromine in a few hours in daylight giving a colorless solution and another gram of bromine more slowly on exposure to the 200-watt lamp. When colorless, this sample reacted vigorously with magnesium giving a homogeneous solution. Analysis of this solution showed a concentration of 0.0125 mole of magnesium and 0.0135 mole of bromine per 100 g. of solution. There was considerable organic material in both samples.

Discussion

Examination of Fig. 1 shows two discontinuities in the solubility curve of magnesium bromide, one at about +22.5° the other, less distinct, at about 12°. If it is assumed that the heat of solution remains constant over this temperature range, a plot of the logarithm of the solubility against the inverse absolute temperature should give a straight line as long as the phase in equilibrium with the solution does not change. Plotting in this manner, in Fig. 2, straight lines are obtained and show very distinctly a change of crystal phase between +11 and +12°. The solid phase in equilibrium with the ether solution along the line AB is magnesium bromide triethyl etherate.[4]

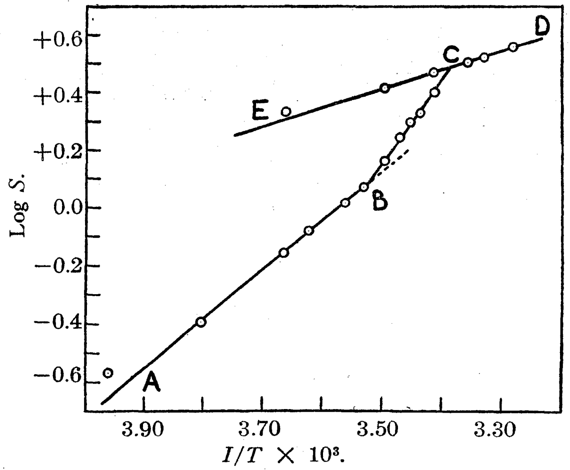

Fig. 2.—Solubility of $MgBr_2$ in ethyl ether.

At approximately +12° (B) the trietherate decomposes to form magnesium bromide diethyl etherate which is the solid phase in equilibrium along BC. The dietherate, which in the absence of excess ether exists to +28°,[3,4] reacts with excess ether at +22.6° (C) and forms an immiscible liquid layer which is the phase in equilibrium along CD. As noted previously, this liquid can be greatly supercooled and the solubility in the metastable state below +22.6° follows along CE.

Though Menschutkin[3] made only a few measurements below +10°, when his data are plotted in the same manner as Fig. 2, a break is also obtained at about +12°. The transition temperature of magnesium bromide triethyl etherate at +12 ± 0.5° as determined from the solubility data agrees very well with the value of +13 ± 0.5° found by Evans and Rowley[4] from vapor pressure measurements. Likewise, the change to a liquid phase of the diethyl etherate of magnesium bromide under ether, as determined in this work, checks Menschutkin's value to within a few tenths of a degree.

From the slope of the lines AB and BC (Fig. 2), the heat of solution of one mole of the crystal phase in an almost saturated ethyl ether solution can be calculated. Thus, the average differential heat of solution is −4.03 kcal. for magnesium bromide triethyl etherate over the temperature range −20 to +10°, while the average differential heat of solution is −6.47 kcal. for the diethyl etherate from +12 to +22°.

The determination at 0° when the immiscible layer is in equilibrium with the solution is known to be somewhat high. It was frequently difficult to obtain absolutely pure samples without recrystallizing the magnesium bromide and since there is little supercooling in a sample that has once been crystallized, the metastable points below +22.6° had to be obtained with fresh samples. Quite a number of samples had to be prepared before the points at +13 and +20° were obtained. Even so, all the values obtained were considerably lower than those found by Menschutkin and reported in the "International Critical Tables"[2] amounting to an average difference of 0.1 g. $MgBr_2$/100 g. Et_2O for the trietherate; 0.2–0.3 g. $MgBr_2$/100 g. Et_2O for the dietherate; and 0.4–0.5 g. $MgBr_2$/100 g. Et_2O for the immiscible layer. Experimental values taken from the smooth curve and compared to the literature values are given in Table V.

TABLE V

SOLUBILITY OF $MgBr_2$ IN ETHYL ETHER

Temp., °C.	G. $MgBr_2$/100 g. Et_2O	Moles % $MgBr_2$ Experimental	"I. C. T."

+10(m)	2.47	0.98	1.14
+20(m)	2.95	1.17	1.36
+30	3.49	1.38	1.56

The effect of moisture on the purity of the sample shows, in Table II, that the presence of a slight amount of moisture during the preparation does not materially affect the result. This might be expected since the free bromine would probably combine with the water to give hydrobromic acid which would react immediately with the magnesium, forming magnesium bromide and free hydrogen.

However, the presence of traces of moisture after the magnesium bromide is prepared affects the apparent solubility as shown in Table III. It is well known that water will displace completely the ethyl ether from etherates.[4,6] Possibly small amounts of water would displace only part of the solvated ether, giving rise to mixed solvates. These mixed solvates might be expected to be somewhat soluble in ether and in turn have little effect on the solubility of unchanged magnesium bromide etherate so that the net result would be an increase of magnesium and bromide in the solution. The analysis of magnesium by magnesium sulfate and of bromide by silver bromide would not distinguish between these two compounds in solution. In all cases when moist ether was used to crystallize the magnesium bromide, there appeared to be a white solid mixed with the immiscible layer. Menschutkin[6] claimed that small amounts of water give $Mg(OH)Br \cdot MgBr_2 \cdot 2(C_2H_5)_2O$ which is practically insoluble in ethyl ether. Possibly this compound is more soluble than he thought.

Summary

1. The solubility of magnesium bromide in ethyl ether was measured from −20 to +30°.

2. Two discontinuities in the solubility curve were found: one at +12 ± 0.5° where $MgBr_2 \cdot 3(C_2H_5)_2O$ decomposes to form $MgBr_2 \cdot 2(C_2H_5)_2O$; the other at +22.5 ± 0.5° where $MgBr_2 \cdot 2(C_2H_5)_2O$ melts under ether to form an immiscible liquid layer.

3. The average differential heat of solution for $MgBr_2 \cdot 3(C_2H_5)_2O$ over the temperature range −20 to +10° was calculated to be −4.03 kcal. The average differential heat of solution for $MgBr_2 \cdot 2(C_2H_5)_2O$ from +12 to +22° was calculated to be −6.47 kcal.

4. The values of the solubility of magnesium bromide were found to be consistently lower than those reported in the "International Critical Tables."

5. The purity of the magnesium bromide prepared in ethyl ether solutions was studied and it was found that traces of moisture during the prepa-

ration had little effect on the solubility values, whereas the presence of very small amounts of water after the preparation was complete caused an increase in the apparent solubility.

6. The effect of light during the preparation was studied and the conclusion reached that bromine reacted to a certain extent with recently distilled ethyl ether in the presence of light giving rise to side reactions and impurities.

A Study of Some Reactions between Dry Inorganic Salts. III*

BY E. B. THOMAS WITH LYMAN J. WOOD

In two previous papers[1,2] the authors have reported results obtained from a study of a few of the possible reactions occurring between the dry alkali halides in the fused state. The remaining 42 of the 60 possible reactions have now been studied and some of the previously reported reactions have been studied in greater detail. Also 12 new salt pairs having a common ion have been examined in order to determine in which cases solid solutions can be formed. These solid solubility relationships as well as the course of the reactions mentioned above have been determined by the method of x-ray crystal analysis.

The general plan of the work was very similar to that followed in the previous work. The material to be examined was melted and held in the molten condition for a short time, after which it was quenched and quickly placed in a desiccator to avoid the possible absorption of water. The mixture was then ground to a fine powder (approximately 200-mesh) and placed in a small, thin-walled glass tube of 0.6–0.7 mm. inside diameter, in which container it was exposed to the x-ray beam. The molybdenum K_α doublet, filtered through zirconia, was used for all exposures, the scattered rays being photographed according to the well-known powder method of Debye, Scherrer and Hull.

Those mixtures which showed a tendency to absorb water were handled in a "Dry Box" to which rubber sleeves were attached, or were ground in a mortar on a hot-plate from which the small tubes were filled. The chloride, bromide and iodide of lithium and the fluorides of rubidium and cesium were found to be extremely hygroscopic, and the fluoride of potassium moderately so.

Results

In order to supplement the table of miscibilities previously published,[2] all the binary mixtures of salts having a common ion, in which the percentage deviation from the mean cube edge is less than 10, have been examined in order to determine in which cases solid solutions are formed. The results obtained are shown in Table I. As is to be seen, no solid solutions have been observed in any case in which the per cent. deviation from the mean cube edge is greater than 8.20.

In Table II are assembled the results for the 42 new reactions not reported in the previous papers. These results were found to be in excellent agreement with the former findings. In each case the reaction goes to completion in such a direction that the average cube edge of the stable pair is less than that of the reciprocal pair. In each case the stable pair has the cation of smaller atomic weight united with the anion of smaller atomic weight, and the cation of larger atomic weight united with the anion of larger atomic weight. In each case the sum of the heats of formation of the stable pair is greater than that of the reciprocal pair. With the exception of the lithium salts one member of the stable pair always has the highest melting point of the four compounds involved.

It should be mentioned that the value for the cube edge of sodium bromide used in this paper is a little larger than the previously used value of 5.940 Å. which is listed by Wyckoff[3] as the favored value. A survey of the literature showed that Davey[4] reported a value of 5.936 Å. for the cube edge of sodium bromide, that Wyckoff[5] reported a value of 5.95 Å., while Ewald's "Structurbericht" lists the value of 5.962 Å. A very careful com-

[a] $(A_1 - A_2) \times 100/0.5(A_1 + A_2)$.

parison of sodium bromide with sodium chloride in our laboratory gave a value very near to 5.951 Å. Because of the greater density of the sodium bromide this value must be smaller than the value that would have been obtained by mixing the sodium chloride directly with the sodium bromide, which of course could not be done since the two salts are known to form solid solutions with each other. Some electrolytic copper was filed to a fine powder and mixed directly with the sodium bromide. Using a value of 3.605 Å. for the cube edge of copper, a value of 5.959 Å. was obtained for the cube edge of sodium bromide. This latter value has been substituted for the previously used value of 5.940 Å.

For reactions 31, 32, 33, 34, 39, 40, 41, 42, 52, 54 and 56, two interference patterns were obtained in each case which corresponded, respectively, to the pure components of the stable pair. In each of these cases it is known that at least one solid solution is formed between one of the components of the stable pair and one of the components of the reciprocal pair. It may be concluded that all of these reactions go to completion, since if such were not the case interference patterns corresponding to solid solutions would have been obtained, rather than the patterns corresponding to the pure components of the stable pair. In this way quite small amounts of unchanged components of reciprocal pairs could have been detected since very small changes in cube edges are easily measured.

The fact that reaction mixtures 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 43, 44, 45, 46, 47, 48, 49, 50 and 51 gave no evidence of becoming moist after fusion, despite the fact that at least one member of the reciprocal pair is definitely hygroscopic, may be regarded as an indication that reaction has proceeded to completion, although such evidence is not nearly as conclusive as that presented above.

No solid solutions are formed between the compounds involved in reactions 35, 36, 37, 38, 53, 55, 57, 58, 59 and 60. However, had reaction not gone to completion in these cases, four patterns should have been obtained instead of only the two which were observed. Although the mere absence of two patterns is not to be regarded as such satisfactory evidence for completeness of reaction as that described in the foregoing cases, it is very unlikely that both patterns (for the reciprocal pair) would be missed if present in even small quantities, since the scattering power of one member of the reactant pair compares favorably in each of these cases with that of one of the members of the stable pair.

Of the eighteen reactions previously reported[2] three reactions (Nos. 10, 14 and 16) were found not to go to completion in the direction of the minimum average cube edge as did the other 15 reactions and as the 42 additional reactions, which have now been studied, have been found to go. Reaction No. 10

$$\mathrm{RbBr} + \mathrm{KCl} \rightleftharpoons \mathrm{KBr} + \mathrm{RbCl}$$

has not been further investigated since the data and discussion previously given appeared to be adequate. In the case of reaction No. 14

$$\mathrm{KBr} + \mathrm{RbI} \rightleftharpoons \mathrm{KI} + \mathrm{RbBr}$$

the interference lines were found to correspond to two phases of which the cube edge of phase I was 6.710 Å. and the cube edge of phase II was 7.165 Å. It has been found possible to calculate the composition of the equilibrium mixture by assuming that 6.710 Å. is the cubic edge of a binary solid solution of potassium bromide and rubidium bromide and 7.165 Å. is the cube edge of a ternary solid solution of potassium iodide, rubidium iodide and rubidium bromide. The calculations were carried out by solving the simultaneous equations

$$6.570\,\frac{x}{1-y} + 6.868\,\frac{1-x-y}{1-y} = 6.710$$

$$7.325\,\frac{x}{1+y} + 7.052\,\frac{1-x}{1+y} + 6.868\,\frac{y}{1+y} = 7.165$$

where x is the moles of potassium bromide in the binary solid solution and y is the moles of rubidium bromide in the ternary solid solution and the numbers 6.570, 6.868, 7.325 and 7.052 are the respective cube edges of potassium bromide, rubidium bromide, rubidium iodide and potassium iodide.

The results of the calculations are shown in Table III. The hypothesis upon which these calculations rest was tested in the laboratory by preparing and melting a mixture having the composition of 47.48 mol % potassium iodide, 45.80 mol % rubidium iodide and 6.72 mol % rubidium bromide. Upon analyzing this mixture the interference pattern indicated the presence of only one

TABLE III

SHOWING THE RESULTS AND CALCULATIONS FOR THE REACTION $KBr + RbI \longrightarrow KI + RbBr$ (REACTION NO. 14)

	Cube edge, Å.	Calculated molecular ratio	Composition in mol, %
Phase I	6.710	0.491:0.437 = KBr:RbBr	KBr 51.00 RbBr 49.00
Phase II	7.165	0.509:0.491:0.072 = KI:RbI:RbBr	KI 47.48 RbI 45.80 RbBr 6.72
Ternary mix having comp. of Phase II	7.172		

component having a cube edge of 7.172 Å., which is to be compared with the value 7.165 Å. which has been assumed to be the cube edge for a ternary solid solution of potassium iodide, rubidium iodide and rubidium bromide (Table III). The composition calculated for the equilibrium mixture is represented by the equation

$$0.491\ KBr + 0.491\ RbI \rightleftarrows 0.509\ KI + 0.509\ RbBr$$

It is quite interesting to note that the equilibrium mixture is very close to an equimolecular mixture of the four kinds of molecules and that there is only 0.02 kcal./mole difference in the sums of the heats of formation of the two reciprocal pairs.

The equilibrium mixture for reaction 16 was previously reported as being approximately

$$0.64\ RbCl + 0.64\ CsBr \rightleftarrows 0.36\ RbBr + 0.36\ CsCl$$

although the agreement between the equilibrium composition when calculated from phase I and when calculated from phase II was not very close. The average cube edge of phase I and phase II is smaller than the average cube edge of the pair RbBr–CsCl and greater than that of the pair RbCl–CsBr indicating that the reaction should probably go to completion in the direction of RbCl–CsBr. Several new laboratory determinations have been made but thus far the results obtained do not deviate from the values previously reported.

At the present time reactions occurring between the dry alkali halides below the fusion point are being studied. The free energy change has been calculated for one such reaction, *viz.*

$$NaBr + KCl \longrightarrow KBr + NaCl$$

and has been found to be

$$\Delta F = \Delta H - T\Delta S = -1.93 \text{ kcal./mole at } 25°$$

This calculation is in agreement with the x-ray evidence previously reported[2] for the reaction occurring between sodium bromide and potassium chloride below the fusion point.

The reaction

$$TlCl + KI \longrightarrow TlI + KCl$$

has been examined by Chernomordik,[6] using thermal methods and has been found to be irreversible in the direction indicated. The average cube edge of the pair TlCl–KI is 5.446 Å. and that of the pair TlI–KCl is 5.239 Å. Furthermore, the large cation is united with the large anion and the small cation with the small anion. This fact as well as the decrease in average cube edge is in agreement with the generalizations described above for 57 of the 60 reactions studied.

Summary

Reactions occurring between the dry halides of lithium, sodium, potassium, rubidium and cesium in the fused state have been studied.

1. Of the 60 possible reactions, 57 have been found to go completely in such a direction that the average cube edge of the stable pair is less than that of the reciprocal pair.
2. In each of these 57 cases the sum of the heats of formation of the stable pair is greater than the sum of the heats of formation of the reciprocal pair.
3. In each case the stable pair has the cation of larger atomic weight united with the anion of larger atomic weight, and the cation of smaller atomic weight united with the anion of smaller atomic weight.
4. In the case of the other three reactions in which there is either no difference in the average cube edge or no difference in the sum of the heats of formation of the stable and reciprocal pairs, equilibrium has been found to be established. In two of the three cases the equilibrium mixture was composed of very nearly equimolecular quantities of the four kinds of molecules involved in the reaction.

An Azeotropic Mixture of Acetylene and Ethane at Atmospheric Pressure

BY WALLACE A. MCMILLAN

During work on the development of precision methods for the analysis of complex hydrocarbon gases, considerable difficulty was encountered occasionally in the separation of ethylene from ethane by ordinary low temperature fractional distillation methods. Continued work on such separations resulted in the isolation of an azeotropic mixture of acetylene and ethane of minimum boiling point. The existence of such a mixture has been established previously[1] for high but not for low pressures. With the increasing use of low temperature fractionation as an analytical method it was felt that constants for the mixture, at atmospheric pressure and low temperature, should be established.

Experimental

Acetylene.—Commercial acetylene was washed successively with distilled water, 40% potassium hydroxide, and 30% sulfuric acid, then passed through soda-lime and dried with anhydrous magnesium perchlorate. The dried gas was condensed by liquid air in the kettle of a special low temperature fractionating column,[2] the fixed gases pumped off, and the acetylene distilled at 1.5 atmospheres, discarding both end fractions. Two subsequent distillations, discarding heads and tails, were made before use. Hydrogenation of the pure material gave a value of 100% for the unsaturation.

Ethane.—Commercial ethylene-free ethane was purified by successive washings through 30% fuming sulfuric acid, and 98 and 79% sulfuric acid, followed by two washings with 43% potassium hydroxide, a soda-lime tower, and dried by anhydrous magnesium perchlorate. It was likewise distilled through a special low temperature column, retaining only the middle portion each time. After four redistillations, the purified material showed a constant boiling point (−88.3°) and the end fractions showed constant vapor pressures when tested in a Shepherd differential manometer.[3] Hydrogenation of the pure material showed no unsaturation.

Mixtures.—Mixtures of the two components were made by blending in the gas phase in an evacuated all-glass system. They were then condensed into the kettle of a special low temperature fractionating column[2] and distilled. The first mixture, containing 70% ethane and 30% acetylene, distilled at −94.5° until 73.5% had come over, at which point the temperature broke sharply to −88.3° and the remainder of the ethane came over at that temperature. In the case of a 70% acetylene–30% ethane mixture, 50.2% distilled at −94.5° at which point the column froze solid with acetylene and it was necessary to go to 1.5 atmospheres to continue the distillation.

When analyzed by catalytic hydrogenation of the acetylene over a reduced nickel catalyst,[4] each of the azeotropic mixtures boiling at −94.5° gave 40.8% acetylene and 59.2% ethane. Check determinations on five additional samples distilled at pressures from 752 to 766 mm. gave a boiling range of −94.5 ± 0.1° and a composition range of: acetylene, 40.75 ± 0.25%; ethane, 59.25 ± 0.25%.

Redistillations of the constant boiling mixtures did not change either the boiling points or compositions.

An azeotropic mixture isolated from reformed refinery gases gave, after redistillation, a boiling point of −94.4° and a composition of: acetylene, 40.7%; ethane, 59.3%; thus checking the existence and identity of the mixture.

Discussion

The isolation and identification of this mixture is of interest inasmuch as reports in the technical literature show acetylene determined by auxiliary reagent methods even though no acetylene had been observed on fractional distillation of the sample.[5] This phenomenon can be accounted for by the analysts disregarding irregularities usually found in Podbielniak distillations, especially when run at accelerated rates. It also explains, at least in part, the appearance of so-called "carbon dioxide plugs" which develop from time to time during ethane separations even though the original gases have been scrubbed with fresh caustic. The white solid which separates in such cases is usually not carbon dioxide but acetylene and can be identified by Ilosvay solution[6] or some other acetylene reagent.

Summary

The existence and composition of an azeotropic mixture of acetylene and ethane at atmospheric pressure have been determined.

Reaction of Esters with Ammonia[1]

By H. E. French, O. H. Johnson and Eula Ratekin[2]

Numerous reports appear in the literature on the effect of structural variations on the reactivities of esters. In this connection it seemed of interest to determine the effect on the ease of reaction with ammonia caused by varying the structure of the alcohol radical of the ester. Preliminary experiments showed no reaction between the esters and gaseous ammonia at 100° and under pressures up to 8 atmospheres. Somewhat milder conditions with small amounts of water also present, likewise failed to cause reaction. It was therefore decided to use an aqueous alcohol solution of ammonia as the reagent, although the presence of the water would undoubtedly cause a certain amount of hydrolysis as a side reaction.

Reagents.—The reagent used was a forty per cent. solution (by weight) of alcohol in water, saturated at 25–30° with ammonia.

The *n*- and *i*-butyl acetates were prepared by refluxing one mole of the alcohol with one and one-half moles of the acid. Six cc. of concentrated sulfuric acid per 100 cc. of the mixture was also present. After six to eight hours of refluxing, the esters were washed with water, dried over anhydrous calcium chloride, over potassium carbonate, then fractionated through a 90-cm. column filled with glass rings.

The *s*-butyl acetate was prepared by refluxing a mixture of acetic anhydride and acetic acid with 0.6 cc. of concentrated sulfuric acid per 100 cc. of the mixture. The ester was purified by the process used with the normal ester.

The tertiary butyl acetate was prepared by refluxing equal volumes of the alcohol and acetic anhydride with one gram of zinc dust for a period of ten to twelve hours. The ester was purified in the manner described above. The boiling points and densities at 25° for the esters were as follows: *n*-butyl acetate, 123.7–123.8° at 737 mm., 0.8734; *i*-butyl acetate, 116.1–116.3° at 741 mm., 0.8683; *s*-butyl acetate, 110.4–111.2° at 740 mm., 0.8627; *t*-butyl acetate, 95.3–95.7° at 737 mm., 0.8654.

Procedure.—Two volumetric flasks of 250-cc. capacity were used for each ester. Twenty-five cc. of ester, measured with a pipet, was placed in each flask, which was then filled to the mark with the aqueous ethyl alcohol solution of ammonia. The reaction mixtures were kept at 25°, and at twenty-four-hour intervals, 50-cc. portions were removed by means of a pipet and diluted with 70 cc. of water. This usually caused the separation of unused ester. In order to remove the excess of ammonia, the solutions were heated to 65–70° on a water-bath and a rapid stream of purified air was bubbled through them till there was no further test with litmus.

The solutions were then diluted to 100 cc. in volumetric flasks and 25-cc. portions were analyzed for ammonium acetate and acetamide in the following manner. Each sample was placed in a Kjeldahl flask, diluted to a volume of 300 cc., and a paste consisting of 2 g. of magnesium oxide in 20 cc. of water was added. The ammonia liberated from the ammonium acetate was distilled into standard acid and the excess acid titrated with 0.1 *N* base. The contents of the Kjeldahl flask were then cooled, again diluted to 300 cc., and 20 cc. of 40% sodium hydroxide solution was added and the solution was boiled. The ammonia liberated by the hydrolysis of the acetamide was distilled into standard acid and determined in the usual manner. This analytical procedure[3] gave results on known solutions of acetamide of less than 0.2% error, indicating but little hydrolysis during the distillation with the magnesium oxide. Each determination was made in duplicate from different original reaction mixtures.

When the samples for analysis were diluted with water, unused ester usually separated. As would be expected, the heating to 65° to remove the ammonia caused additional reaction. In order to correct for this, blank determinations were run. Each sample analyzed contained 5 cc. of ester or the reaction products from that amount. Therefore, samples of 5, 3 and 1 cc. would represent the amounts of ester remaining when reaction had proceeded 0, 40 and 80% toward completion. In making the blank determinations, these quantities, 5, 3 and 1 cc. of each ester were dissolved in

[1] Presented at the Kansas City meeting of the American Chemical Society, April, 1936.

[2] This paper is an abstract of the theses submitted by Mr. Johnson and Miss Ratekin in partial fulfilment of the requirements for the degree of Master of Arts at the University of Missouri.

[3] Pucher, Vickery and Leavenworth, *Ind. Eng. Chem., Anal. Ed.*, **7**, 152 (1935).

enough of the original aqueous ethyl alcohol solution of ammonia to make a volume of 50 cc. (the amount always taken for analysis), then diluted with 70 cc. of water, aerated at 65° and analyzed for acetamide and ammonium acetate. The blanks were run in duplicate, and the averages of the results were plotted. The analysis of any sample from a run indicated the extent of reaction and by reference to the graph the necessary correction could be made. Acceptable results could be obtained from this part of the procedure only by a careful control of conditions, such as the size of the openings in the water-bath, rate of the air current, etc.

The results are summarized in the accompanying graphs. With the exception of the *t*-butyl acetate, the reactions of each ester are represented by two pairs of curves. The lower pair represents the hydrolysis reaction in each case, and the upper pair the ammonolysis reaction. In any pair of curves, the upper curve corresponds to the total reaction as determined by the analyses. The lower curve is obtained by subtracting the corrections as described above, and represents the reaction taking place at 25°. With the *t*-butyl acetate, the corrections, which are not shown on the graph, were of the same order of magnitude as those for the *s*-butyl ester. Each point on each curve is an average of two determinations made from different reaction mixtures, rather than from two samples of the same reaction mixture. The agreement among the check determinations was good, showing a variation in two-thirds of the cases of less than 0.5%. The products from the reactions at 25° from the different esters were distributed as indicated in the table.

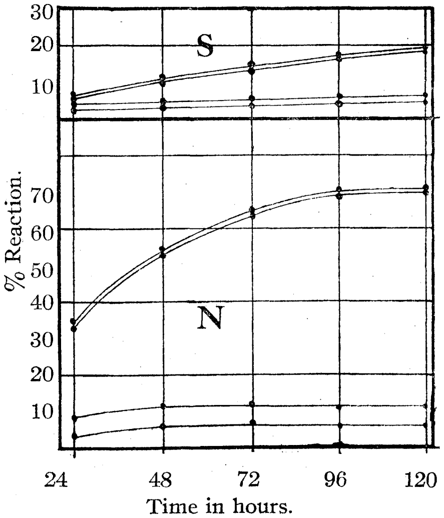

Fig. 1a.—S, *s*-butyl acetate; N, *n*-butyl acetate.

TABLE I

REACTION PRODUCTS FORMED AT 25°

Ester	Hours	% yield amide	% yield salt	Ratio amide : salt[a]
n-Butyl acetate	120	69.7	6.1	11.4:1
Isobutyl acetate	120	68.8	7.7	8.9:1
s-Butyl acetate	120	18.6	4.8	3.8:1
t-Butyl acetate	360	2.9	2.1	1.4:1

[a] These were the ratios at the end of the reaction period.

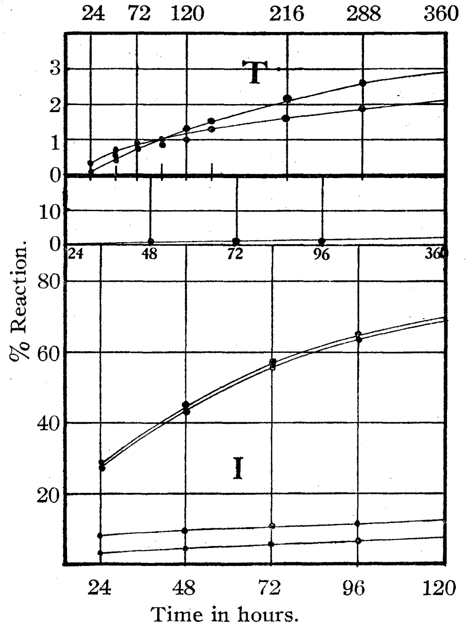

Fig. 1b.—T, *t*-butyl acetate; I, *i*-butyl acetate.

Summary

1. The action of aqueous ethyl alcohol solutions of ammonia on the four butyl acetates was studied.

2. The relative reactivities of the primary, secondary and tertiary butyl acetates toward ammonia was found to be of the order of 24:6:1.

3. A certain amount of hydrolysis took place in each reaction, and increased in importance with the secondary and tertiary butyl acetates.

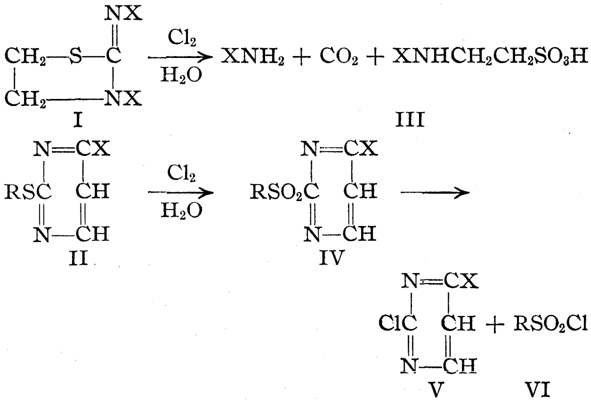
A New Method for the Preparation of Alkyl Sulfonyl Chlorides

BY TREAT B. JOHNSON AND JAMES M. SPRAGUE[1]

2-Imido-4,5-dihydrothiazoles I (X = H, CH_3, etc.) and 2-mercaptopyrimidines II (R = CH_3, C_2H_5, etc., X = H, CH_3, C_2H_5) are characterized by their chemical behavior when subjected to the action of chlorine and bromine in aqueous solution. The thiazoles[2] I undergo complete degradation by the action of either of these halogens with formation of an amine, carbon dioxide, and a taurine derivative III. A mercaptopyrimidine II interacts with chlorine under the same experimental conditions to give the corresponding sulfone derivative IV without degradation of the pyrimidine ring. This reaction with chlorine proceeds still further in the case of certain mercaptopyrimidines leading to replacement of the sulfone grouping by halogen V and formation of an alkyl sulfonyl chloride VI. Furthermore, it has been shown that this oxidation reaction is applicable to both 2- and 6-mercaptopyrimidines[3] yielding the corresponding sulfones, respectively.



Because of the similarity in constitution of the imido-4,5-dihydrothiazoles I and the 2-mercaptopyrimidines II, respectively, and the accepted ammonium structure of the S-alkyl-isothiourea salts[4] VII, the behavior of these latter acyclic substances toward chlorine has now been investigated. We find, when chlorine gas is passed into a cold aqueous solution of these S-alkyl-isothiourea salts VII, that the corresponding alkyl sulfonyl chlorides VI are formed in good yields. In fact, this method of synthesis opens up a new and practical procedure for the replacement of a halogen atom in an aliphatic halide by the sulfonyl chloride grouping ($-SO_2Cl$). If bromine is used instead of chlorine the corresponding sulfonyl bromide ($-SO_2Br$) is formed. This process introduces thiourea in place of phosphorus halide as the key reagent for the preparation of aliphatic sulfonyl chlorides, and also furnishes an interesting and instructive field for further study, which hitherto has received little notice. This program will receive further attention in this Laboratory.[5]

$$\mathrm{RS}\overset{\overset{\displaystyle \mathrm{NH}}{\|}}{\underset{\underset{\displaystyle \mathrm{NH_2}}{\|}}{\mathrm{C}}}\cdot\mathrm{H\ hal}\ \xrightarrow[\mathrm{H_2O}]{\mathrm{Cl_2}}\ \mathrm{RSO_2Cl}$$

Rathke[6] observed the formation of ethylsulfonic acid from S-ethyl-N,N-diphenyl-isothiourea salts by the action of chlorine or bromine. The formation of sulfonic acids from S-alkyl-isothioureas by oxidation with potassium chlorate is also reported in the literature.[7] The direct formation of alkyl sulfonyl halides by the action of halogen on S-alkyl-isothiourea salts has not, however, been previously reported. The cleavage of a carbon–sulfur linkage by chlorine with the formation of an alkyl sulfonyl chloride or sulfonic acid has been observed with other types of sulfur compounds.[8]

The yields of alkyl sulfonyl chlorides obtained from the various alkyl-isothiourea salts are given in Table I. Since bromine also reacts with these salts to form alkyl sulfonyl bromides, it was necessary first to remove the hydrobromic acid when using the hydrobromide salts for preparation of sulfonyl chlorides by treatment with chlorine gas.

[a] The bromine was removed with an equivalent of silver nitrate before treatment with chlorine.

Otherwise a mixture of sulfonyl chloride and bromine was obtained.[9]

With branched alkyl groups, as isopropyl and isobutyl, lower yields of sulfonyl halides were obtained. Both the low (148°) and the high melting (174°) forms of S-benzyl-isothiourea hydrochloride[4a,e] behaved identically on chlorination.

Although the S-alkyl-isothiourea[4] hydrobromides are easily prepared from the alkyl bromides and thiourea, the simple alkyl chlorides react very slowly with thiourea under similar conditions.[10] Since the practicability of the method here described for the preparation of alkyl sulfonyl chlorides depends on the ease of preparation of the S-alkyl-isothiourea salts, an attempt was made to improve the preparation of the hydrochlorides. This may be accomplished by heating the respective alkyl chloride with thiourea in an autoclave (see ethyl and isopropyl, Table II). However, a more convenient process is that used by Stevens[10] for the preparation of S-ethyl-isothiourea hydrochloride. This investigator found that this salt could be obtained by heating thiourea hydrochloride with ethyl alcohol. We have now found that this procedure may be applied with success to the higher aliphatic alcohols.

$$\mathrm{ROH + HCl + NH_2CSNH_2 = \underset{VII}{RSC({=}NH)NH_2 \cdot HCl}}$$

The S-alkyl-isothiourea hydrochlorides VII were not isolated from this reaction but were treated directly with chlorine in aqueous solution. The maximum yields of sulfonyl chlorides were obtained after heating the above reaction mixture for three or four days on a steam-bath. The lower yields of ethyl, isopropyl and isobutyl compounds may be attributed to several factors, such as temperature of the reaction, boiling point of the alcohol, volatility of the alkyl chloride and the effect of a branched chain (compare Table I). The results of this method are summarized in Table II. The yields are based on the amount of thiourea used.

Methyl, ethyl and *n*-heptyl sulfonyl bromides were prepared by the action of bromine on the corresponding S-alkyl-isothiourea salts in yields of 43.5, 64.8 and 36%, respectively.

The identity of the nitrogenous product resulting from the preparation of the alkyl sulfonyl halides from S-alkyl-isothioureas, and the mechanism of these transformations, are being studied further and will be discussed in a future paper from this Laboratory.

---

(9) In our first experiments silver nitrate was employed to replace the bromine ion, thereby forming the corresponding isothiourea nitrate which reacted smoothly with chlorine. This method of precipitation, however, cannot be recommended for practical synthesis and we have found that organic acid salts of isothiourea serve our purpose well when bromine is a conflicting reagent. Very little attention has been paid to the study of this class of salts but we have found in this Laboratory that they can perform a practical service in many operations. Treatment of an alkyl-isothiourea hydrobromide, for example, with potassium acetate leads to the quantitative formation of the acetate of the alkylisothiourea which interacts smoothly with chlorine to give the desired alkyl sulfonyl chloride. Other organic acid salts react in a similar manner and with production of the sulfonyl chlorides in excellent yields. The description of a series of these characteristic organic acid salts is given in a paper from This Laboratory by Dr. John J. Donleavy (THIS JOURNAL, **58**, 1004 (1936)).

Experimental Part

S - Alkyl - isothiourea Salts, $RSC(NH_2)=NH\cdot HCl$.—The following salts which were used in this investigation have been prepared previously: S-methyl-isothiourea sulfate,[4a] S-ethyl-isothiourea sulfate,[4a] S-ethyl-isothiourea hydrobromide,[4c] S-isobutyl-isothiourea hydrobromide,[4d] S,S-ethylenedi-isothiourea hydrobromide,[7] S-benzyl-isothiourea hydrochloride,[4a] nitrate[4a] and sulfate.[4a]

The general procedure for the preparation of the S-alkyl-isothiourea hydrohalide salts is that described by Wheeler and Bristol.[4d] A volume of alcohol equal to the volume of alkyl halide was used, except in the cases of ethylene dibromide and ethylene dichloride. In these cases 3 or 4 volumes of alcohol was used and the insoluble S,S-ethylenedi-isothiourea salts were filtered off. After the thiourea had dissolved completely, the alcohol solutions were heated at water-bath temperature until a sample gave no silver sulfide precipitate with ammoniacal silver nitrate. S,S-Ethylenediisothiourea hydrochloride has been prepared previously from the hydrobromide.[7a]

S-n-Heptyl-isothiourea hydrobromide was obtained in a crystalline form by shaking a concentrated alcohol solution of the salt with ether. S-n-Heptyl-isothiourea acetate was prepared by treating a concentrated aqueous solution of the hydrobromide with a saturated solution of potassium acetate. The precipitated acetate was recrystallized from water. S,S-Ethylenedi-isothiourea acetate was prepared and purified in an analogous manner. S-β-Phenylethyl-isothiourea hydrochloride was recrystallized from concentrated hydrochloric acid.

Ethyl chloride and isopropyl chloride in several volumes of alcohol were refluxed for weeks with thiourea without complete transformation to the corresponding S-alkyl-isothioureas. On heating at 110–120° for six to ten hours in an autoclave there was still unchanged thiourea. However, these crude reaction products were chlorinated and with successful formation of the corresponding alkyl sulfonyl chlorides (Table I). The analytical data on new compounds prepared in this research are recorded in Table III.

Alkyl Sulfonyl Chlorides.—(A) The S-alkyl-isothiourea salts (0.05–1.0 mole) were dissolved in water (50–135 cc.) and the solution cooled to 10°, or below, in an ice-bath. Chlorine gas was conducted into this aqueous solution at such a rate that the temperature did not rise above 15° in order to avoid hydrolysis of the sulfonyl chloride with formation of a sulfonic acid. An occasional rise of temperature to 20° did not seriously lower the yields. The treatment with chlorine was continued until the oil (sulfonyl chloride) had completely settled out and the aqueous layer was distinctly green due to the excess of chlorine. This operation usually required about twenty to thirty minutes. The oil (sulfonyl chloride) was then extracted with ether and the excess of chlorine removed by washing several times with small portions of dilute sodium bisulfite solution (5%). After washing with water the ether extract was dried over calcium chloride and distilled.

Benzyl sulfonyl chloride, $C_6H_5CH_2SO_2Cl$, and ethane-1,2-disulfonyl chloride precipitated as solids directly during the chlorine treatment. They were dried over sulfuric acid and purified by crystallization from chloroform or benzene. However, the melting points of the crude material were only a degree or two lower than those of the purified substances.

The low melting β-phenylethyl sulfonyl chloride ($C_6H_5CH_2CH_2SO_2Cl$, m. p. 32–33°) was occasionally obtained as a solid directly, but usually it was necessary to extract with ether as directed above. On removing the ether a solid was always obtained. This sulfonyl chloride also may be purified by distillation.

The bromine of the S-alkyl-isothiourea hydrobromides was removed by adding an equivalent of silver nitrate and the resulting solution concentrated to the desired volume. Chlorination and ether extraction were carried out as previously described. However, with S-n-heptyl-isothiourea hydrobromide and S,S′-ethylenedi-isothiourea hydrobromide this procedure was unsatisfactory because of the

sparing solubility of the resulting nitrates. The use of a large volume of solution to dissolve the nitrate at the low temperature (10–15°) resulted in a low yield of the sulfonyl chloride. Consequently, in these two cases the acetates were used. These organic salts are more soluble in water than the nitrates. The addition of a small volume of strong hydrochloric acid aids the solution of these salts, (see Table I).

Alkyl Sulfonyl Chlorides.—(B) Seventy-five cubic centimeters of the alcohol containing 4.5–5.0 g. of hydrogen chloride and 7.6 g. (0.1 mole) of finely powdered thiourea were heated on a steam-bath under a reflux condenser for various lengths of time as recorded in the second column of Table II. With frequent vigorous shaking the thiourea dissolved within a few minutes after heat was applied. Some hydrogen sulfide is evolved during the reaction. At the end of the heating period the excess of alcohol was removed under diminished pressure and the viscous residue dissolved in warm water (75–100 cc.). Tests applied to these aqueous solutions with alkaline lead acetate or ammoniacal silver nitrate showed that the thiourea had disappeared completely after seventy-two to ninety-six hours in the case of *n*-propyl-, *n*-butyl and isoamyl alcohol. With ethyl, isopropyl and isobutyl alcohols unchanged thiourea was present after five days of digestion. No attempt was made to isolate the respective S-alkyl-isothiourea hydrochlorides from these reactions. The solution was cooled to the desired temperature and the chlorination operation applied as directed under (A).

That concentrated aqueous hydrochloric acid solution may be used instead of dry hydrochloric acid gas was shown in one experiment: 75 cc. of *n*-butyl alcohol, 10 cc. of concentrated hydrochloric acid and 7.6 g. of thiourea were heated together for forty-eight hours. A yield of 72% of *n*-butyl sulfonyl chloride was obtained as compared to 76% with hydrochloric acid gas. These results are recorded in Table II. The yields given are based on the quantity of thiourea used.

The alkyl sulfonyl chlorides described in (A) and (B) were characterized by chlorine analyses and by melting points of their corresponding acid amides or anilides.[11]

n-Heptyl sulfonamide was prepared by shaking the corresponding sulfonyl chloride with concentrated ammonia. The amide separated in crystalline form and was purified by crystallization from an ether–petroleum ether mixture. β-Phenylethyl sulfonamide was prepared in a similar manner and recrystallized either from dilute alcohol or an ether–petroleum ether mixture.

Ethyl Sulfonyl Bromide, $C_2H_5SO_2Br$.[12]—S-Ethyl-isothiourea hydrobromide (18.5 g.) or sulfate (15.3 g.) was dissolved in 200 cc. of water and the solution cooled to 0–5°. During vigorous stirring 125 g. (0.78 mole) of bromine was added from a dropping funnel during one hour. The temperature was not allowed to rise above 5°, and the solution was stirred for two to three hours at this temperature after the final addition of the bromine. The oil (sulfonyl bromide) was extracted with ether and the excess of bromine removed by washing with 5% sodium bisulfite solution. After washing with water the ether extract was dried over calcium chloride and distilled. The yield was 11.21 g. (64.8%); b. p. 85–86° (18 mm.); n^{25}_D 1.5010. *Anal.* Calcd. for $C_2H_5O_2SBr$: Br, 46.19. Found: Br, 45.93.

The use of a larger amount of bromine did not greatly increase the yield. For example, 150 g. (0.94 mole) gave a yield of 67.6%. However, the use of less than 125 g. of bromine gave lower yields: 108 g. gave a yield of 60% of the sulfonyl bromide. Higher reaction temperatures also reduced the yield. Ethyl sulfonyl bromide decomposes with evolution of sulfur dioxide when distillation is applied at ordinary pressure.

Methyl Sulfonyl Bromide, CH_3SO_2Br.[12]—S-Methyl-isothiourea sulfate (13.9 g.) was treated with 125 g. of bromine as described above except that the stirring period after final addition of bromine was increased to five hours. A shorter period of stirring gave a lower yield. The yield was 6.92 g. (43.5%); b. p. 80–80.5° (22 mm.); n^{25}_D 1.5080. *Anal.* Calcd. for CH_3O_2SBr: Br, 50.27. Found: Br, 50.25.

***n*-Heptyl Sulfonyl Bromide.**—S-*n*-Heptyl-isothiourea hydrobromide (25.5 g.) under the above conditions gave a 36% yield of this sulfonyl bromide of b. p. 135–137° at 9 mm. There was some decomposition on distillation. The sulfonamide melted at 74–75°.

Action of Chlorine on Hydrobromides of S-Alkyl-isothioureas

An aqueous solution of S-ethyl-isothiourea hydrobromide (18.5 g.) was treated with chlorine as described for the preparation of alkyl sulfonyl chlorides. The chlorination was continued until the bromine color had completely disappeared. The resulting oil was then extracted with ether, washed and dried as previously described. There was obtained 14–16 g. of material of b. p. 90–92° at 23 mm., n^{25}_D 1.4960–1.4970. This product contained bromine and a comparison of the refractive index and results of sulfur and halogen analyses indicated a mixture of ethyl sulfonyl chloride (8–12%) and ethyl sulfonyl bromide (88–92%). Ethyl sulfonamide was prepared from the mixture melting at 59°. An aqueous solution of S,S-ethylenediisothiourea hydrobromide on chlorination gave a solid product containing bromine melting at 95–96° after crystallization from chloroform.

Summary

1. S-Alkyl-isothiourea salts interact in aqueous solution at low temperature with chlorine and bromine to form the corresponding alkyl sulfonyl chlorides and sulfonyl bromides, respectively, in good yields.

2. An alkyl halide and thiourea serve as key reagents in this reaction.

3. A method has been developed for preparing alkyl sulfonyl chlorides directly from an aliphatic alcohol and thiourea as key reagents. Advantage is taken here of an old observation made by Stevens for the preparation of pseudothioureas.

4. The new method of synthesis is superior to

Some Alkyl and Aryl Amides and Ureides as Hypnotics[1]

BY E. H. VOLWILER AND D. L. TABERN

A considerable number of simple and substituted acetamides and acetyl ureas have been prepared from time to time and subjected to pharmacologic study. Many have been found to possess distinct hypnotic activity, and at least five, Adalin (bromodiethylacetyl urea), Neodorm (isopropylethylacetamide), Bromural (bromo-isovaleryl urea), Sedormid (allylisopropylacetyl urea), and Novonal (diethylallyl acetamide), are employed in medical practice. In their properties, these compounds appear to stand intermediate between the comparatively powerful barbiturates and the milder bromides, being chiefly used as sedatives in neuropsychic disorders.

Recent studies in the field of barbiturate hypnotics have demonstrated that certain members, particularly those containing secondary amyl groups in addition to ethyl or allyl, possess unique properties. The member most extensively investigated clinically, ethyl-1-methylbutylbarbituric acid, has been found to be characterized by its unusual rapidity of action, and by the fact that while its hypnotic action is intense, it disappears quite rapidly. As has been repeatedly pointed out,[2] this rapidity of recovery from depressant effects, is a valuable property when the drug is to be used as a preanesthetic sedative. Again, clinical reports indicate that in certain of these higher members, the sedative as contrasted to the true hypnotic properties seem to be accentuated.

It seems desirable, therefore, to prepare a series of acetyl ureas and acetamides, and the bromo analogs, containing the 1-methylbutyl and other similar secondary alkyl groups, in order to see whether the typical properties just enumerated are retained.

Experimental

The requisite malonic esters were prepared in the usual way, in absolute alcohol, employing the respective alkyl bromides (in the case of the diethylcarbinyl derivatives the *p*-toluene sulfonyl ester was utilized), and purified by fractionation.

Certain of the higher esters were very difficult to hydrolyze, prolonged refluxing with 40% potassium hydroxide in dilute alcohol being necessary. After removing the alcohol *in vacuo*, the solid mass was dissolved in cold water and carefully neutralized with hydrochloric acid until permanently acid to congo, the organic acids extracted with ether, heated to eliminate carbon dioxide, and distilled *in vacuo*. Bromo acids were synthesized essentially according to the method of "Organic Syntheses."[3]

The acetic acids were then converted to the acid chlorides by a 10% excess of thionyl chloride at room temperature and purified by fractionation *in vacuo*. No attempt was made to secure highest purity.

For the preparation of the amides, a solution of ammonium hydroxide saturated at 10° was prepared and the acid chlorides gradually dropped in at this temperature, or below, ammonia concentration being maintained by passage of a slow stream of ammonia gas. After several hours of stirring, the solid was filtered off, dried and recrystallized either from dilute alcohol, or a mixture of ether and petroleum ether, or in most cases both.

A generally more satisfactory method of preparing the amides lies in the use of the cyanoacetic esters.[4] For example: ethyl cyanoacetate was condensed by sodium ethylate in absolute alcohol by adding somewhat more than one mole of 1-ethylpropyl bromide ($\alpha^{20}\text{D}$ 1.4440) at below 60°. The separation of sodium bromide was rapid. Next morning the mass was heated to boiling and allowed to stand overnight. The ester boiled at 150–160° at 35 mm. This was ethylated by ethyl bromide and sodium ethylate, the reaction again proceeding readily. The ethyl-1-ethylpropylcyanoacetic ethyl ester boiled at 150–155° at 32 mm.

One hundred grams of this ester was refluxed with 100 g. of potassium hydroxide and 200 cc. water for twelve hours or longer. The solvent was distilled *in vacuo*, the cyanoacetic acid liberated by an excess of hydrochloric acid and extracted with benzene. On distillation through a tall column, carbon dioxide was evolved and the redistilled nitrile boiled at 190–200°.

---

[1] The material covered in this paper was presented in part at the Cleveland meeting of the American Chemical Society, September, 1934, and in part at the New York meeting, April, 1935.

[2] (a) Barlow, *Arch. Surg.*, **29**, 527 (1934); (b) Waddy, "The Fear of Anaesthesia," Thesis, University of Manchester, 1934.

[3] "Organic Syntheses," Coll. Vol. I, 1932, p. 108.

[4] See U. S. Patent 1,482,343 (1934).

Sixty grams of the nitrile was refluxed for ten to fifteen hours with 120 g. of potassium hydroxide in 600 cc. of 95% alcohol. The solvent was removed *in vacuo* and ice added. The separated and washed solid was redissolved in methanol. This ethyl-1-ethylpropylacetonitrile hydrolyzed with much more difficulty than most of the cyanides and liquid residues were therefore subjected to further hydrolytic treatment.

All halogen-free amides were colorless solids quite soluble in organic solvents, but relatively insoluble in water. α-Bromoethyl-1-methylbutylacetamide was an oil at room temperature.

We have found that sodamide or finely divided sodium in boiling benzene converts the halogen-free amides quantitatively into sodium salts which are soluble in the solvent and react readily with alkyl halides. The structure of the resultant amides was established by their synthesis from the acid chlorides and the requisite alkylamine.

These N-substituted amides are oils or low melting solids which may be distilled at 15 to 20 mm. They are quite insoluble in water but in the presence of starch or acacia are readily emulsified.

The acetyl ureas were prepared by heating the acid chlorides with a large excess (2.5 moles) of dry urea to 110–135°. After the main reaction, two layers were formed, the lower soon turning solid. After several additional hours of heating, the powdered mass was broken up under dilute alkali and finally recrystallized from dilute alcohol or another appropriate solvent. Another convenient method is to extract with boiling alcohol and pour into cold water kept permanently alkaline by sodium hydroxide. In several instances, appreciable quantities of higher melting substances, insoluble in cold ether, were formed.

A simpler but in general less satisfactory method for the preparation of the acetyl ureas is to heat a solution of the sodium salt of the appropriate barbituric acid in a sealed tube at 100° for several days, filter off the precipitated acetyl urea, and repeat the process.

port the results in detail elsewhere, a few general observations may be indicated here.

The efficiencies of the compounds vary among themselves as much as five-fold, and the toxicities even more widely. Of those active in moderate dosage, particular interest would seem to attach, as had been anticipated, to ethyl 1-methylbutylacetyl urea and the corresponding amide. These have respectively safety margins of 18 and 11, as compared with a range from 2 to 5 for known barbiturates, and 6 for the commercial analog tested allyl isopropylacetyl urea (Sedormid).

In the N-alkyl series it was observed that when the N-substituent group was methyl, prolonged mild sedation was secured. When it was larger, excitement rather than sedation resulted.

A very interesting point is the relatively great analgesic action shown by certain of the amides, this being produced without a correspondingly deep hypnotic effect as in the barbiturates. There are also definite variations among individual members of the series.

Two chemically related substances, diethyl malonic mono-allyl amide and the bis (diethylamide) of ethyl-1-methylbutylmalonic acid, showed no true hypnotic action; the second produced local anesthesia and on oral administration clonic convulsions.

Conclusions

An extended series of simple and substituted alkyl amides and ureas has been synthesized in connection with a study of their use as sedatives and hypnotics. Considered in connection with the N-aryl and N-alkyl barbiturates described in a companion paper the results indicate the wide value of secondary butyl, amyl and hexyl groups in conferring to such compounds valuable therapeutic properties.

N-Alkyl and N-Aryl Substituted Barbituric Acids[1]

By D. L. Tabern and E. H. Volwiler

Although Fischer and Dilthey described several simple N-substituted barbituric acids as long ago as 1904,[2] until recently little systematic study has been made of higher homologs. Dox and his group[3] reported upon certain intermediate members of the series, but did not prepare compounds containing certain secondary butyl, amyl and hexyl groups, which in the simple barbiturates[4] and thiobarbiturates[5] have been found frequently to confer valuable therapeutic properties. Such compounds are among the most effective yet produced and are characterized by a prompt and intense action of short duration.

Apparently the early N-alkyl and aryl barbiturates did not attract attention because preliminary studies failed to reveal anything of especial interest; they are in general but little more active than the analogs derived from urea itself, and in certain members tend to produce pre-anesthetic excitement, paraplegia and convulsions rather than hypnosis.

More recently, however, 5,5-ethylphenyl-N-methylbarbituric acid has been reported to possess a somewhat specific action in epilepsy without the production of pronounced hypnosis, and another, 5,5-methylcyclohexenyl-N-methylbarbituric acid, has been found to have an extremely short but intense period of hypnotic activity. These interesting facts pointed to the need for a more careful study of promising compounds containing one or more secondary alkyl groups in the 5-position with particular reference to rapidity of onset, duration of action, degree of sedation or hypnosis, route and rapidity of elimination, etc. It also seemed of interest to prepare certain members containing secondary and tertiary groups attached to the nitrogen in position "1," none of these ever having been described.

Chemical

The thirty-five barbiturates of this series were prepared by one or more of the following methods: (1) reaction of the dialkylmalonic esters with the appropriate substituted urea in the presence of sodium ethylate at 100–110°; (2) reaction of the dialkyl cyanoacetic esters with a substituted

urea followed by hydrolysis with 15–20% sulfuric acid for ten hours; or (3) the action of allyl bromide on the sodium salt of the simple barbituric acid in water at 100°.[3c] The presence of copper sulfate as a catalyst seems greatly to increase the speed of the latter alkylation. The alkali soluble fraction in each case was extracted and distilled at 2 to 5 mm., passing over below 200°. In the case of reaction 3, there was always a small amount of unchanged dialkyl acid which boiled over 210° under the same conditions and could thus be separated with reasonable accuracy.

The intermediate primary alkyl ureas were best prepared by the action of the corresponding amines upon nitrourea in water or in alcohol at about 80°. After the evolution of nitrogen was at an end, the solvent was removed *in vacuo* and the urea dried and used directly or recrystallized from a suitable solvent, such as acetone or ethyl acetate. Tertiary butyl urea was synthesized by the action of tertiary butyl chloride on urea in the presence of lead carbonate.[6] It was found desirable to carry out the reaction with good stirring, adding the white lead slowly.

Many of the barbituric acids studied were very viscous liquids, insoluble in water but soluble in organic solvents, including petroleum ether; even after long standing, they could not be induced to crystallize and indeed prevented the crystallization of intentionally added portions of the corresponding dialkylbarbituric acids. They are soluble in alkalies, and solid alkali metal salts may be prepared by evaporation *in vacuo* of an absolute alcohol solution. Aqueous solutions of such salts are strongly hydrolyzed and have a *p*H of approximately 10 to 10.5.

Most of the malonic esters have been described previously. The purified barbiturates were analyzed for nitrogen and values obtained agreeing closely with the calculated.

Pharmacologic[7]

While the more promising of the N-substituted derivatives have been studied upon several species and on man, for sake of brevity and uniformity only the results of intravenous injections in rabbits will be indicated here. The figures given represent milligrams per kilogram body weight.

[7] For the tests here described we are indebted to Mr. H. C. Spruth of the Pharmacologic Department of the Abbott Laboratories.

ferior to the secondary substituted thiobarbiturates previously reported by us.[5] Given orally they are relatively ineffective in animals and in man.

In general, most satisfactory compounds are secured where one group attached to the 5-carbon is secondary, the other is methyl, and the N-substituent also methyl. The attachment of large primary or of secondary and tertiary groups on the nitrogen leads to compounds of low hypnotic power. There is some indication that the N-alkyl acts additively in the production of the convulsions characteristic of barbiturates containing certain 6- and 7-carbon atom groups (benzyl, etc.). For instance, methyl-(1,3-dimethylbutyl)-barbituric acid could be given in a dosage of 170 mg./kg. without producing convulsions while both its N-methyl derivative and ethyl (1,3-dimethylbutyl)-barbituric acid produced convulsions in the range of 7 to 15 mg.

Conclusion

A series of N-alkyl and N-aryl barbiturates containing secondary and tertiary groups has been prepared. Pharmacologically, certain members offer some promise as short acting intravenous hypnotics and anesthetics.

The Effect of the Composition of the Medium upon the Growth of Yeast in the Presence of Bios Preparations. I. The Effect of Magnesium Salts[1]

BY ELLIS I. FULMER, L. A. UNDERKOFLER AND JAMES B. LESH

Schopmeyer and Fulmer[2] found that the growth of certain molds on synthetic media, with glycerol or sucrose as substrates, formed materials which accelerated the growth of yeast. Recently, in the study of the growth accelerants produced by *Aspergillus niger* upon sucrose media, attempts were made to separate the active substances into the Bios I and Bios II of Miller and co-workers[3–5] who identified Bios I as *i*-inositol.

The properties of the fractions obtained were determined by their effect upon the growth of yeast in Medium C developed by Fulmer, Nelson and Sherwood.[6] When the activity of the Bios II fraction in Medium C was compared with its activity in Clark's medium, which was used by Miller, it was found that the same amount of stimulant gave a much larger growth in the latter medium. Medium C contains, per 100 cc.: 0.188 g. ammonium chloride, 0.100 g. dipotassium phosphate, and 10 g. of sucrose. Clark's medium contains, per 100 cc.: 0.834 g. of ammonium nitrate, 0.417 g. of potassium dihydrogen phosphate, 0.071 g. of calcium chloride, 0.208 g. of magnesium sulfate and 10 g. of sucrose.

Preliminary results showed that the addition of magnesium sulfate to Medium C had a marked effect upon the growth of yeast in the presence of the bios preparation. The addition of calcium chloride, or the replacement of ammonium chloride by ammonium nitrate had no influence upon the bios activity. The effect of magnesium salts was then further investigated.

The yeast employed was a strain of *Saccharomyces cerevisiae* isolated several years ago from a cake of Fleischmann yeast, and deposited with the American Type Culture Collection as No. 4226. The numbers of cells were determined by means of the Thoma-Zeiss counting chamber. The initial inoculation was made to a count of one (250,000 cells per cubic centimeter) from an actively growing culture. The final counts were made after twenty-four hour incubation at 30°. The Bios II added was equivalent to 2.0 cc. of the original extract per 100 cc. of medium. Inositol, where added, was used in concentration of 3.2 mg. per 100 cc. of medium.

In Table I are given data showing the effect of magnesium sulfate upon the growth of the yeast in several media. The inositol was Eastman's ash-free *i*-inositol. The Bios II preparations were made according to the procedure given by Lucas.[3]

(6) E. I. Fulmer, V. E. Nelson and F. F. Sherwood, *ibid.*, **43**, 191 (1921).

Series A involved Bios II prepared from malt sprouts and in series B the Bios II was prepared from a synthetic medium which had supported the growth of *Aspergillus niger* on sucrose as substrate. It is evident that the addition of magnesium sulfate to Medium C, in the same concentration as that in Clark's medium, very markedly increases the growth of the yeast in the presence of Bios II. The addition of the salt to Medium C, without the bios, does not increase the growth, a result in harmony with previous reports from this Laboratory.[6,7]

TABLE I

The effect of Bios II and of inositol upon the growth of yeast in several media. Series A involves Bios II from malt sprouts; in series B the Bios II was prepared from a medium which supported the growth of *Aspergillus niger*. The control contained neither Bios II nor inositol.

	A	B	A	B	A	B
Control	9	7	9	5	1	6
Control + inositol	8	..	9	...	1	...
Control + Bios II	52	71	191	194	248	255
Control + Bios II + inositol	54	74	284	215	256	311

The data of Table II show that the salt is effective in very low concentrations. The addition of inositol alone does not increase the growth of the yeast, but the growth is increased by the addition of inositol to the medium containing Bios II. This result agrees with the findings of Miller and co-workers.[3-5]

TABLE II

The effect of varying concentrations of magnesium sulfate upon the growth of yeast in Medium C in the presence of Bios II from malt sprouts.

	Count	
Molarity of $MgSO_4 \cdot 7H_2O$	Inositol absent	Inositol present
0	29	34
8×10^{-6}	44	53
8×10^{-5}	150	157
8×10^{-4}	142	147
8×10^{-3}	172	215
8×10^{-2}	192	313

The question at once arises as to whether the above phenomenon is common to all magnesium salts or whether the sulfate radical is involved. Data in Table III show that magnesium chloride and magnesium nitrate are practically without effect, while potassium sulfate gives some increase in growth. The combination of the potassium sulfate with magnesium sulfate is no more effective than is the latter salt alone. In adding the potassium sulfate the concentration of potassium is likewise increased. When ammonium sulfate is substituted for the ammonium chloride, the former salt gives about the same increase in growth as was evidenced by the potassium sulfate. Addition of magnesium chloride or of magnesium nitrate to the medium containing ammonium sulfate gives the same increase in activity of the bios as that shown by magnesium sulfate alone. The above data show that both magnesium and sulfate are involved in the phenomenon.

TABLE III

The effect of several salts upon the growth of yeast in Medium C in the presence of Bios II from malt sprouts.

	Count			
	Medium C		Medium C	NH_4Cl replaced by $(NH_4)_2SO_4$
Salt added (0.017 molar)	Inositol absent	Inositol present	Inositol absent	Inositol present
Control	28	34	47	89
$MgSO_4$	161	257	163	228
$MgCl_2$	30	34	146	204
$Mg(NO_3)_2$	27	31	155	210
K_2SO_4	68	80		
$MgSO_4 + K_2SO_4$	153	228		

Miller and co-workers state that neither Bios I (inositol) nor Bios II produce much increase in the growth of their yeast when used alone, but that the combination gives greatly enhanced growth. It is evident that Bios II alone increases the growth of the yeast employed by us although the effect is further enhanced by the addition of *i*-inositol (Bios I). Lucas,[3] Williams, Warner and Roehm,[8] Stantial,[9] Williams and Saunders[10] and Farrell[11] have called attention to great differences in the response of various strains of yeast toward bios preparations. Preliminary experiments in our laboratory with various strains of yeasts, show that with some yeasts the addition of magnesium sulfate does not increase the activity of the Bios II but actually decreases the growth. However, if inositol be added in the presence of the Bios II a marked increase in growth is evident with all the strains tested. Full details will be published in a later communication.

Summary

For the strain of yeast employed, the presence of magnesium sulfate markedly increases the growth of the yeast in the presence of a bios preparation

[11] Leone N. Farrell, *Trans. Roy. Soc. Can.*, **29**, Sec. III, 167 (1935).

(Bios II). Magnesium chloride or nitrate does not show the above phenomenon while potassium or ammonium sulfate gives some increase in activity. Combinations of magnesium chloride or nitrate with potassium or ammonium sulfate give about the same increase in growth in the presence of the bios preparation as does magnesium sulfate.

Di- and Trialkyl Barbituric Acids

BY H. A. SHONLE AND WILBUR J. DORAN

During the past several years, a number of new dialkyl substituted barbituric acids have been prepared in this Laboratory for the purpose of studying the relationship of the pharmacological action to the chemical structure.[1] Since the intermediate malonic esters were available, it seemed advantageous to extend this study to include certain trialkyl substituted barbituric acids. During the course of the preparation of the trialkyl barbituric acids, several undescribed dialkyl barbituric acids were prepared.

A considerable number of 1-alkyl-5,5-dialkyl barbituric acids have been described since Fischer and Dilthey[2] prepared N-methyldiethylbarbituric acid.[3]

The various malonic esters were made in the usual manner by adding the alkyl halide, usually the bromide, to an absolute alcoholic solution of sodiomalonic ester or sodioalkylmalonic ester, refluxing until the reaction was completed and purifying the malonic ester by fractional distillation *in vacuo*. Table I summarizes some of the physical properties of the malonic esters.

Most of the barbituric acids were prepared by condensing the di-substituted malonic ester with urea, methyl urea, or ethyl urea, in the presence of an alcoholic solution of sodium ethoxide, after which they were precipitated and purified, usually by recrystallization from dilute alcohol. In some instances, however, the barbituric acid was an oil which would not readily crystallize, so that its purification had to be effected by fractional distillation *in vacuo*. Table II summarizes the properties of the various barbituric acids prepared.

TABLE I

	Ethyl malonate	B. p., °C.	Mm.	n^{25}_D
1	3-Methylbutylmethyl[a]	103–104	3	1.4248
2	*n*-Hexylmethyl	125	3.5	1.4280
3	1-Methylpentylmethyl	126	6	1.4323
4	1-Methylpentylallyl	139	5	1.4442
5	2-Ethylhexylmethyl	126	1.5	1.4353
6	*n*-Pentylmethyl	99	8	1.4254
7	1-Methylbutylmethyl	124	10	1.4288
8	*n*-Propyl-2-methylbutyl	100	1	1.4319

[a] Sommaire [*Bull. soc. chim.*, **33**, 189–95 (1923)] describes this ester as boiling at 242–247°.

The di- and trialkyl barbituric acids were converted into their sodium salts by the addition of a 50% solution of sodium hydroxide to an alcoholic solution of the barbituric acid, followed by the removal of the alcohol by vacuum distillation. Solutions of the sodium salts of these barbituric acids were studied pharmacologically on several varieties of laboratory animals. The results obtained by the intraperitoneal injection into white rats are summarized in Table II, wherein the minimum anesthetic dose (M. A. D.) and the minimum lethal dose (M. L. D.) are reported. The detailed pharmacological study will be reported elsewhere.[4] From the pharmacological data, it appears, in general, that the introduction of a third alkyl group lessens the duration of the action. In some instances, alkylating the nitrogen group made the barbituric acids less effective.

We wish to thank Mr. E. E. Swanson and Mr. W. E. Fry for the pharmacological assays, and Mr. John H. Waldo, Miss Anna K. Keltch and Dr. E. C. Kleiderer for assistance in the preparation of several of these barbituric acids.

Some New Local Anesthetics Containing the Morpholine Ring. III. Esters of 2-Alkoxycinchoninic Acids

BY JOHN H. GARDNER AND WARREN M. HAMMEL

Extending the investigation of esters of morpholine alcohols as local anesthetics,[1] a series of esters of 2-alkoxycinchoninic acids has been prepared. These compounds are analogs of the series of alkamine esters prepared from diethylaminoethyl alcohol and 2-alkoxycinchoninic acids by Wojahn.[2]

In this investigation, β-4-morpholineethanol and γ-4-morpholinepropanol were prepared by the method of Gardner and Haenni.[1] 2-Chlorocinchoninic acid was prepared by the method of Camps[3] and this was converted into a series of 2-alkoxycinchoninic acids by reaction with solutions of sodium alcoholates in the corresponding alcohol.[3] From these, the acid chlorides, esters and finally the ester hydrochlorides were prepared.

These ester hydrochlorides have been found to show local anesthetic action when tested on the tongue, but no pharmacological measurements have been made.

Experimental

2-Alkoxycinchoninic Acids.—Methoxy, ethoxy, *n*-propoxy and *n*-butoxycinchoninic acids were prepared. To a solution of sodium in the alcohol, using 40 cc. of alcohol per gram of sodium there was added twice the weight of sodium of 2-chlorocinchoninic acid. The solution was boiled a half hour. The alcohol was evaporated and the residue dissolved in water. Dilute hydrochloric acid was added to the filtered solution to precipitate the 2-alkoxycinchoninic acid. This was filtered out, dried and crystallized from benzene. Yields and properties of the individual acids are given in Table I.

TABLE I

Cinchoninic acid	Yield, %	M. p.,[4] °C.	M. p. (Literature), °C.
2-Methoxy	77	177–178	178–179[a]
2-Ethoxy	82	142.2–143.8	145–146[b]
2-*n*-Propoxy	63	138–139.4	136[b]
2-*n*-Butoxy	60	96.6–97.6	111[b,c]

[a] Mulert, *Ber.*, **39**, 1901 (1906). [b] Ref. 2. [c] *Anal.* Calcd. for $C_{14}H_{15}O_2N$: C, 68.54; H, 6.17. Found: C, 68.35; H, 6.27.

2-Alkoxycinchoninyl Chlorides.—To solutions of the alkoxycinchoninic acids in benzene, using about 7 cc. of benzene per gram of the acid, there was added 4 to 5 g. of thionyl chloride per gram of the acid. The mixture was heated at 55–60° for ten minutes. After cooling, the benzene solution was filtered and the insoluble portion, which was largely 2-alkoxycinchoninic acid hydrochloride, washed well with benzene. The benzene solution was evaporated to dryness in a vacuum desiccator, the residue extracted with ligroin and the filtered ligroin solution evaporated to dryness in a vacuum desiccator. Yields, melting points and analyses of the individual acid chlorides are given in Table II.

TABLE II

Cinchoninyl chloride	Yield, %	M. p., °C.,	Analyses, % Calcd. C	H	Found C	H

(4) All melting points in this paper are corrected.

solid precipitate which had collected on the filter was dissolved in a small amount of water and this solution was added to the hydrochloric acid extract. The ester was precipitated by the addition of sodium carbonate. Melting points and analyses of the individual esters are given in Table III.

Morpholinealkyl 2-Alkoxycinchoninate Hydrochlorides.—Solutions of the esters in benzene were treated with the calculated quantity of a benzene solution of hydrogen chloride. The mixture was allowed to stand for several hours and the precipitated hydrochloride was filtered out, washed with benzene and dried in a desiccator. Yields, melting points and analyses of the individual compounds are given in Table IV.

Summary

1. Eight new morpholinealkyl esters of 2-alkoxycinchoninic acids and their hydrochlorides have been prepared.

2. The hydrochlorides are local anesthetics.

Chemical Studies of the Mechanism of the Narcosis Induced by Hypnotics. II. The Synthesis of Colored Derivatives of Phenobarbital[1]

BY ALAN E. PIERCE AND MARY M. RISING

The pharmacological and histological study of of a hypnotic which shows the property of selectively staining nerve cells may be found to give insight into the mechanism of hypnosis. With the synthesis of such a dye-hypnotic as an object, the work described in this paper consisted of the preparation of several colored derivatives of phenobarbital, or 5-phenyl-5-ethylbarbituric acid, $(C_6H_5)(C_2H_5)\underline{CCONHCONHCO}$, which is itself a white compound. Several investigators[2] have attempted the preparation of physiologically active, colored derivatives of cocaine or procaine with varying degrees of success. It was hoped that phenobarbital would also be suitable for such a study.

In the first paper of this series,[3] the syntheses of four dye derivatives of phenobarbital by means of coupling diazotized 5-*m*-aminophenyl-5-ethylbarbituric acid with various phenolic compounds separately were described. Not one of these products, however, exhibited satisfactory hypnotic properties.

In the present investigation two colored derivatives of phenobarbital were prepared by the coupling of diazotized 5-*m*-aminophenyl-5-ethylbarbituric acid with *m*-phenylenediamine to form 5-*m*-(2,4-diaminophenylazo)-phenyl-5-ethylbarbituric acid, $(NH_2)_2C_6H_3N{=}NC_6H_4(C_2H_5)\underline{CCONHCONHCO}$, and with 5-*m*-hydroxyphenyl-5-ethylbarbituric acid to form *x*-hydroxyazobenzene-*x*,3′-bis-(5-ethylbarbituric acid), $\underline{CONHCONHCOC}(C_2H_5)C_6H_4{-}N{=}N{-}(OH)C_6H_3(C_2H_5)\underline{CCONHCONHCO}$. A third colored derivative is *m*-diazoamino-5-phenyl-5-ethylbarbituric acid, $\underline{CONHCONHCOC}(C_2H_5)C_6H_4{-}N{=}N{-}NHC_6H_4(C_2H_5)\underline{CCONHCONHCO}$. In this synthesis it was hoped by means of linking two ureide nuclei to ensure the preservation of the physiological effect of phenobarbital.

In addition to 5-*m*-nitrophenyl-5-ethylbarbituric acid, obtained by the nitration of phenobarbital, the para nitro compound was isolated in small quantity and identified, but was not used in the syntheses.

For the pharmacological study of the compounds prepared in this work the writers are indebted to several investigators. The work was done in part by Dr. A. L. Tatum, Professor of Pharmacology, University of Wisconsin, and in part by Dr. H. A. Shonle and Mr. E. E. Swanson of the Eli Lilly Company, Indianapolis. Intraperitoneal administration of the sodium salts of the various compounds to rabbits and white mice produced no sedative action without undesirable effects. Neither the three colored compounds nor 5-*m*-hydroxyphenyl-5-ethylbarbituric acid were effective in sub-lethal doses. The 5-*p*-nitrophenyl-5-ethylbarbituric acid was not tested, since the meta isomer has been found to be physiologically inert.[4]

Experimental

5-*m*-Nitrophenyl-5-ethylbarbituric Acid.—The method of Bousquet and Adams[4] was followed in the nitration of

(4) Bousquet and Adams, *ibid.*, **52**, 224 (1930).

phenobarbital. Several recrystallizations of the crude nitrated material from 95% alcohol gave a 60% yield of 5-*m*-nitrophenyl-5-ethylbarbituric acid, m. p. 283–284°. The position of the nitro group in this product has been previously proved.[5]

5-*p*-Nitrophenyl-5-ethylbarbituric Acid.—The alcoholic mother liquors from the recrystallizations of 5-*m*-nitrophenyl-5-ethylbarbituric acid were evaporated to dryness. The residue (7.0 g. from 20 g. crude nitro-ureide) was dissolved in the least possible amount of dilute sodium hydroxide solution, and, with rapid stirring of this solution, enough dilute hydrochloric acid to neutralize three-fourths the alkali used was slowly added to the solution. The white precipitate which formed was brought upon a filter, washed with water, and recrystallized several times, from either 95% alcohol or water, until a product of m. p. 216–217° was obtained. Further crystallization from alcohol, water or toluene did not change this melting point; yield 1.2 g. *Anal.* Calcd. for $C_{12}H_{11}N_3O_5$: C, 51.96; H, 4.00; N, 15.17. Found: C, 52.12, 51.93; H, 4.08, 3.99; N, 15.17, 15.22.

The position of the nitro group in the substance just described was determined through alkaline permanganate oxidation of the material. The pure product (5.0 g.) was dissolved in 300 cc. of 1% potassium hydroxide solution. This solution was refluxed for twelve hours, as 25.0 g. of potassium permanganate was added in portions. When all permanganate color of the reaction mixture had disappeared, the solution was filtered from the manganese dioxide, evaporated to 40 cc., strongly acidified with concentrated hydrochloric acid and chilled. The product which separated was brought upon a filter, washed with water, and recrystallized from hot water with Norite added, yielding 1.2 g. of white crystals, m. p. 239–239.5°. The yield was 40% of the theoretical amount of nitrobenzoic acid. A mixture of the oxidation product and pure *p*-nitrobenzoic acid melted at 239–240°. The oxidation product was reduced with ammonium sulfide, yielding a white crystalline substance, m. p. 186–187°. A mixture of the reduction product and pure *p*-aminobenzoic acid melted at 186–187°.

5-*m*-Aminophenyl-5-ethylbarbituric Acid.—This was prepared by the catalytic reduction of 5-*m*-nitrophenyl-5-ethylbarbituric acid according to the directions of Bousquet and Adams[4]; yield 90%, m. p. 208–209°.

5-*m*-Hydroxyphenyl-5-ethylbarbituric Acid.—Bousquet and Adams[4] attempted to prepare this substance. Our procedure follows. 5-*m*-Aminophenyl-5-ethylbarbituric acid (2.47 g.) was diazotized at 5° in a solution of 5 cc. of concentrated hydrochloric acid in 50 cc. of water, a 10% sodium nitrite solution being used. At the end of the diazotization the excess nitrous acid present was destroyed by the addition of urea. The solution was now heated rapidly and boiled as long as nitrogen was evolved. During this heating the solution assumed a red color. The beaker containing the reaction mixture was vigorously shaken in an ice-bath until a red gummy substance gathered on the sides of the vessel and the liquid itself was practically colorless. At this point the mixture was filtered quickly, and pink crystals soon formed in the filtrate. This product was brought on a filter, washed with water, and recrystallized from hot water with Norite added. The white crystalline material so obtained was a dihydrate, but was easily dehydrated at 110°; yield 77%, m. p. 199.5–200° (anhydrous product). *Anal.* (anhydrous product). Calcd. for $C_{12}H_{12}N_2O_4$: C, 58.04; H, 4.88; N, 11.29. Found: C, 57.96, 58.06; H, 4.93, 4.88; N, 11.27, 11.48. Hydrate, calcd. for $2H_2O$, 12.68. Loss of weight at 110°, 12.68.

5-*m*-(2,4-Diaminophenylazo)-phenyl-5-ethylbarbituric Acid.—5-*m*-Aminophenyl-5-ethylbarbituric acid (2.47 g.) was diazotized in the manner described in the preparation of 5-*m*-hydroxyphenyl-5-ethylbarbituric acid, only 2.5 cc. of concentrated hydrochloric acid being used. To the solution of the diazonium salt was added a cold solution of 1.9 g. of *m*-phenylenediamine dihydrochloride in 20 cc. of water. After this solution was stirred for fifteen minutes a solution of 6.9 g. of sodium acetate in 50 cc. of water was added slowly, the reaction mixture being kept well cooled. After it was stirred for another half hour, the mixture was heated to boiling and filtered. The orange crystals remaining on the filter were purified by solution in hot dilute hydrochloric acid, followed by the addition of sodium acetate to this solution. The tarry material which first formed was separated by quick filtration of the solution. The addition of more sodium acetate to the filtrate caused the separation of the desired product. After a second solution and precipitation in this manner the final product was crystallized from hot water, in which it is slightly soluble. The pure compound consisted of orange crystals, m. p. 221–222°, yield 70%. *Anal.* Calcd. for $C_{18}H_{18}N_6O_3$: C, 58.98; H, 4.96; N, 22.95. Found: C, 58.77, 58.88; H, 5.00, 4.99; N, 22.89, 23.00.

Coupling of Diazotized 5-*m*-Aminophenyl-5-ethylbarbituric Acid with 5-*m*-Hydroxyphenyl-5-ethylbarbituric Acid.—5-*m*-Aminophenyl-5-ethylbarbituric acid (1.0 g.) was suspended in 50 cc. of water and diazotized as previously described, 2.0 cc. of concentrated hydrochloric acid being used. To the solution of the diazonium salt, made just alkaline to litmus with dilute sodium hydroxide solution, was added dropwise with stirring a cold solution of 1.1 g. of 5-*m*-hydroxyphenyl-5-ethylbarbituric acid dihydrate in 25 cc. of water to which just enough alkali had been added to dissolve the ureide. After fifteen minutes, a dye was precipitated from solution by the gradual acidification with normal hydrochloric acid, stirring being continued. The yellow solid was brought upon a filter, washed with water, and purified by solution in dilute sodium hydroxide, and reprecipitation with hydrochloric acid; yield 92%, dec. approx. 280°.

Anal. Calcd. for $C_{24}H_{22}N_6O_7$: C, 56.89; H, 4.38; N, 16.60. Found: C, 56.70, 56.89; H, 4.54, 4.42; N, 16.10, 16.05.

***m*-Diazoamino-5-phenyl-5-ethylbarbituric Acid.**—5-*m*-Aminophenyl-5-ethylbarbituric acid (2.0 g.) was suspended in 100 cc. of water and diazotized as previously described, using 2.0 cc. of concentrated hydrochloric acid. To the solution of the diazotized amine was added a cold solution of 1.9 g. of 5-*m*-aminophenyl-5-ethylbarbituric acid in 75 cc. of water containing 1 cc. of concentrated hydrochloric acid. A solution of 4.9 g. of sodium acetate in 25 cc. of

The Microdetermination of Diazoamino Nitrogen

The method of Houben-Weyl[6] for analyzing diazoamino compounds was modified and adapted to the micro scale. The modified method should be applicable to substances which evolve nitrogen when heated with hydrochloric acid.

The apparatus (Fig. 1) was constructed from a piece of 10-mm. Pyrex glass tubing 15 cm. long. When in use, it was connected to the carbon dioxide generator, at the end near A, and to the azotometer, at the end near B, by flexible connections, each made by joining together several short pieces of 1-mm. capillary tubing with clean rubber connections. A precision microazotometer, described by Pregl,[7] was used.

The sample to be analyzed was deposited in the bulb A and 0.5 cc. of freshly boiled concentrated hydrochloric acid in the bend of the tube at B. The tube was supported in the position shown, connected with generator and azotometer, and thoroughly flushed with a stream of pure carbon dioxide, until the bubble residues in the azotometer were no longer of significant size.[7] The gas stream was adjusted to the rate of one bubble per second, and the apparatus tilted so that the acid in B ran down upon the sample in A. By heating the chamber A, the acid was boiled for a few minutes, decomposing the diazoamino compound with the liberation of nitrogen. The source of heat was withdrawn and the tube swept out with carbon dioxide. The collection and measurement of nitrogen and the subsequent calculation were made according to Pregl's directions.

This micro method was tested by analyzing four diazoamino compounds, whose purity was initially established by duplicate total nitrogen determinations. In the analyses for diazoamino nitrogen the sample size varied between 2.5 and 6 mg. The results are shown in Table I.

Summary

1. In a further attempt to prepare a nerve-cell staining hypnotic derivative of 5-phenyl-5-ethylbarbituric acid, three new colored derivatives of the ureide have been synthesized. These products did not exhibit the desired physiological action. 5-*m*-Hydroxyphenyl-5-ethylbarbituric acid, a white substance used as an intermediate, also was shown to be devoid of hypnotic activity.

2. A method for the microdetermination of diazoamino nitrogen has been devised and tested.

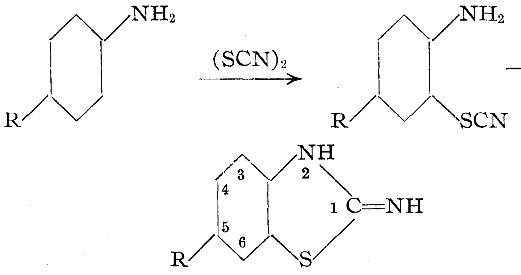
Studies on the Thiazoles Obtained by Direct Thiocyanogenation[1]

BY R. Q. BREWSTER AND F. B. DAINS

Considerable interest has been shown recently in the direct thiocyanogenation of aromatic amines. In the procedure[2] followed by most investigators the amine (1 mole) and ammonium thiocyanate (2 moles) were dissolved in glacial acetic acid and bromine or a chloramide was slowly added. The liberated thiocyanogen substituted in the position para to the amino group or, if that were occupied, in the ortho position. Such ortho thiocyanogenated products were of special interest to us because they automatically rearrange to substituted iminobenzthiazoles similar to others which have been studied previously in this Laboratory.



Our experiments dealing with the extension of this type of reaction and a study of the thiazoles thus produced may be described under four headings as follows:

(A) **General Application of the Method.**—Previous investigators have shown (1) that in the reaction indicated above the group R may be of almost any character (alkyl, halogen, carboxyl, nitro, etc.) but (2) that the reaction fails entirely if the amino group is acetylated or converted to a urethan. Both of these observations have been verified in our experiments. In addition we have found (1) that monoalkylated amines (ethyl-*p*-toluidine, benzyl-*p*-toluidine, etc.) undergo thiocyanogenation smoothly with rearrangement to the alkylated benzthiazoles, (2) that the reaction may also be applied to many disubstituted aminobenzenes such as 3-nitro-4-methylaminobenzene, 2,4-dimethylaminobenzene, 2-bromo-4-methylaminobenzene, and 2-methyl-4-nitroaminobenzene but (3) that the process fails in the case of 2-chloro-4-nitroaminobenzene and 2-nitro-4-methylaminobenzene where "steric hindrance" forces are quite large.

(B) **Alkylation.**—The imino-benzthiazoles undergo alkylation at position 2 upon boiling with alkyl halides for six to eight hours giving products identical with those obtained by direct thiocyanogenation of mono-N-alkylanilines.

(C) **Condensation with Loss of Ammonia.**—Fusion of the iminobenzthiazoles with aniline (or other primary aromatic amines) resulted in evolution of ammonia and production of 1-arylimino-benzothiazoles.

(D) **Formation of Thiazoles from Aryl Thioureas.**—Disubstituted thioureas of the type RNHCSNHR′ react with bromine in chloroform solution giving 1-aryliminobenzthiazoles which in many cases are identical with those obtained by condensation with loss of ammonia as mentioned in the preceding paragraph.

Experimental

A typical procedure for the preparation of one of those iminobenzthiazoles by direct thiocyanogenation is described as follows.

2,4-Dimethylaminobenzene (12.1 g., 0.1 mole) and 16.2 g. (0.2 mole) of sodium thiocyanate were dissolved in 150 cc. of glacial acetic acid, cooled in ice and stirred mechanically while a solution of 16 g. of bromine in 25 cc. of acetic acid was slowly added drop by drop. External cooling was applied throughout the process to keep the temperature below 10° and the stirring was continued for thirty minutes after all of the bromine had been added. The precipitate of 1-imino-3,5-dimethylbenzthiazole hydrobromide[3] was removed by filtration at the pump, dissolved in warm water and the base precipitated with alkali. For purification it was recrystallized from alcohol or ligroin, yield 13 g. The melting points and analyses of this and other benzthiazoles not recorded in the literature which have been prepared by this method are shown in Table I.

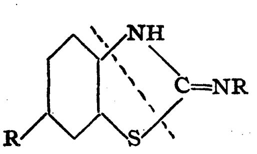
III	1-Imino-3,5-dimethyl	2,4-Dimethylaniline	140	15.93	15.74	15.81
IV	1-Imino-3-bromo-5-methyl	2-Bromo-4-methylaniline	211	11.52	11.50	11.44
V	1-Imino-3-methyl-5-nitro	2-Methyl-4-nitroaniline	280	20.10	20.04	
VI	1-Imino-2-ethyl-5-methyl	Ethyl-*p*-toluidine	106	14.58	14.53	14.60
VII	1-Imino-2-benzyl-5-methyl	Benzyl-*p*-toluidine	80	11.02	11.24	11.14
VIII	1-Imino-2,5-dimethyl	Methyl-*p*-toluidine	51	15.73	15.70	15.81

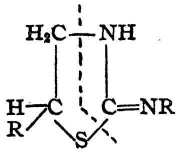
Alkylation of the Benzthiazoles

For these experiments 1-imino-5-methylbenzthiazole was used since it is easily obtained in quantity by thiocyanogenation of *p*-toluidine. 1-Imino-5-methylbenzthiazole (16.4 g., 0.1 mole) when boiled with 10 cc. of ethyl iodide and 50 cc. of ethyl alcohol on the water-bath for ten hours gave 17 g. of the slightly soluble hydriodic acid salt of 1-imino-2-ethyl-5-methylbenzthiazole. Solution of this salt in hot water and addition of alkali gave the free base, m. p. 106°. The location of the ethyl radical at position 2 was established by the fact that a mixture of this substance and compound VI, Table I, showed no depression of the melting point. Analysis of the hydriodic acid salt gave I, 39.50, 39.40. Calculated for $C_{10}H_{13}NSI$: I, 39.68.

Methylation of the 1-imino-5-methylbenzthiazole by the above method using either methyl iodide or methyl sulfate likewise gave a 2-methyl derivative identical with compound VIII. Its hydriodic acid salt is quite insoluble in cold water and analysis showed 41.35% I. Calculated for $C_9H_{11}NSI$: I, 41.53.

Benzylation of the 1-imino-5-methylbenzthiazole by eight hours of boiling with benzyl chloride in ethyl alcoholic solution gave the 2-benzyl derivative identical with compound VII. In none of the alkylations did the alkyl group unite with the nitrogen atom at position 1. Such benzthiazoles (with substituents at position 1) were made by another method shown in a following section. If the hydrogen at either position 1 or position 2 has been replaced by one radical, no further alkylation occurs even upon long heating. Thus 1-*o*-chlorophenylimino-5-methylbenzthiazole (XV) was not ethylated by ethyl iodide either by boiling for several days or by heating in a sealed tube at 150° for six hours. Other compounds in this series behaved similarly. In each case the original benzthiazole (XV) was recovered unchanged. Such difficulty of alkylation is analogous to the behavior of the 2-arylimino-5-alkylthiazolines as observed by Dains and Eberly.[4]

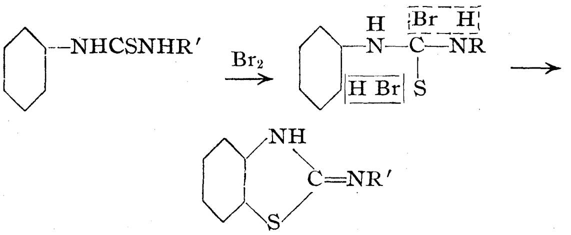




Condensations with Loss of Ammonia.—Fusion of 1-imino-5-methylbenzthiazole (8.2 g., 0.05 mole) with 8 g. (excess of 0.05 mole) of aniline[5] at 220° for thirty minutes resulted in the evolution of ammonia and the production of 11 g. of 1-phenylimino-5-methylbenzthiazole[6] which after crystallization from alcohol melted at 167°. Such condensations are typical of these substances and the following compounds which were prepared by this method and which are not listed in the literature are here reported.

Reduction of 1-*p*-nitrophenylimino-5-methylbenzthiazole (XIII) with tin and hydrochloric acid gave the amino compound  $CH_3C_6H_3\underset{S}{\overset{N}{\lessgtr}}C\text{—}NHC_6H_4NH_2$ which was purified by crystallization from ligroin; m. p. 147°; N, 16.47. Found: N, 16.40, 16.25. It was more conveniently prepared by boiling its acetyl derivative (XIV) with 15% hydrochloric acid for one hour and precipitation of the base with alkali. This compound has a close relation in structure to primuline and its diazotized solution was found to be substantive to cotton cloth and couples on the fiber with phenol or naphthol to give colors of almost the same shade as with primuline.

Formation of Benzthiazoles from Substituted Thioureas and Bromine.—Hugerschoff[7] has shown that thiocarbanilide reacts with bromine in chloroform solution to give the hydrobromide salt of 1-phenyliminobenzthiazole.



This process has heretofore been used only to prepare thiazoles from symmetrical thioureas. We have used unsymmetrical thioureas in order to obtain a check on the constitution of the benzthiazoles shown in Table II. Our observations show that in the conversion of a thiourea of the type RNHCSNHR′ to the substituted benzthiazoles the more positive of the two groups (R and R′) takes the

---

[4] Dains and Eberly, not yet published.

[5] If monomethylaniline is substituted for aniline no reaction occurs.

[6] On heating alone to 270° for thirty minutes, 1-imino-5-methylbenzthiazole evolves 1 mole of ammonia from 2 moles of the benzthiazole giving  $5\text{-}CH_3C_6H_3\underset{S}{\overset{N}{\lessgtr}}C\text{—}NH\text{—}C\underset{S}{\overset{N}{\gtrless}}C_6H_3CH_3\text{-}5'$; m. p. 278°; N, 13.50. Found: N, 13.30, 13.36. This compound is very slightly soluble in the usual solvents and is often a by-product in the formation of the substances shown in Table II.

position 1[8] and the more negative forms the ring closure with the sulfur atom. The results of several experiments are shown in Table III.

Summary

New methods for the preparation of the benzthiazoles and their derivatives have been developed and the properties of these compounds have been studied. In several cases substituted benzthiazoles have been obtained both by the direct thiocyanogenation of aromatic amino compounds and also by the action of bromine upon disubstituted thioureas. The behavior of these substances upon alkylation is also reported.

LAWRENCE, KANSAS

RECEIVED APRIL 10, 1936

---

[8] See table by Kharasch and Flenner, THIS JOURNAL, **54**, 678 (1932). If the two groups (R and R′) are close together in the table, such as phenyl and *p*-tolyl, a mixture of both possible isomeric benzthiazoles results which is practically impossible of separation.

It was also found in this Laboratory that disubstituted thioureas react with ethylene dibromide giving thiazoles in accordance with the same principle as above; *viz.*, the ring closure forming with the more electronegative group. Dains *et al.*, *ibid.*, **47**, 1987 (1925).

The Electron Affinity of Free Radicals. XI. The Free Energy of Addition of Sodium to Ketones and Unsaturated Hydrocarbons

BY HENRY E. BENT AND NORMAN B. KEEVIL

The previous paper of this series[1] describes a potentiometric method for determining the free energy change associated with the addition of sodium to an organic compound. The method has been tested on reactions involving the addition of sodium to several free radicals by comparing the value obtained by the potentiometric method with the value obtained by an analysis of the equilibrium mixture. In order to determine whether or not the potentiometric method may be used in studying other types of compounds, namely, ketones and unsaturated hydrocarbons, the investigation of these reactions by a direct analysis of the equilibrium mixture has been undertaken. In a later paper we hope to compare these results with the results by the potentiometric method. The data are interesting in themselves and shed light on the structure of ketyls.

The experimental procedure is essentially that described in earlier papers of this series.[2] The equilibrium is approached from both sides and the concentrations of the reactants and products determined by analysis. The activity of sodium in the amalgam is adjusted to give a reaction which is approximately 50% complete.

Purification of Materials

Benzophenone was purified by fractional distillation under reduced pressure. The product was recrystallized twice from absolute methyl alcohol, giving large white crystals which melted at 47.7°.

Fluorenone obtained from Eastman Kodak Company was recrystallized from 95% alcohol and stored in a desiccator. The melting point was raised from 180–182 to 183°.

Dibiphenyl ketone, synthesized from phosgene and *p*-bromobiphenyl, melted at 229°.

Tetraphenylcyclopentadienone was prepared in connection with work reported in the fourth paper of this series.

Tetraphenylethylene was very kindly supplied by Mr. E. L. Martin. After recrystallization it melted at 220–221°.

Stilbene and anthracene were used as supplied by Eastman Kodak Company.

Ether was stored either over sodium benzophenone prepared from sodium–potassium alloy, or over sodium fluorenone prepared from dilute amalgam. The latter method of drying the ether does away with the hazard associated with the use of sodium–potassium alloy.

Experimental Results

Benzophenone.—The experimental results are recorded in Table I. Some difficulty was encountered due to the fact that the ketyl sometimes precipitated and was not easily dissolved by repeated washing with solvent. In the latter runs the volume of the solution was considerably increased in order to avoid this precipitation. The equilibrium constant refers to the reaction $(C_6H_5)_2CO + Na = (C_6H_5)_2CONa$. (When we have information on the amount of pinacolate present we will recalculate our results if this becomes necessary.) The concentrations of the ketone and ketyl may be expressed in any units. The activity of the sodium is referred to the pure metal as the standard state. In runs 11 to 15 the ketyl was prepared by shaking benzophenone with 40% amalgam. This leads to the formation of the disodium derivative which was then poured onto a slight excess of ketone, forming the monosodium derivative.[3] This change is accompanied by a change in color from the clear purple of the disodium derivative to the blue of the monosodium derivative. The solution of the monosodium derivative was then poured onto mercury and shaken until equilibrium was established. In run 18 the ketyl was prepared by shaking the ketone with a saturated amalgam (about 1%). Run 13 was carried out at 0° and the rest at 25°. In run 16 benzene was the solvent. The solubility of ketyl in ether seems to be about 10^{-5} moles per liter and in benzene about 5×10^{-3} moles per liter. Exact values cannot be given due to the tendency of the solution to supersaturate, and the slowness with which the precipitate dissolves. The last four runs are probably the best. In approaching the equilibrium by adding sodium directly to the ketone an amalgam was used in which the mole fraction of sodium was 0.0008.

Fluorenone forms a monosodium derivative. The insolubility of the ketyl again introduced some experimental difficulties. In order to avoid error from possible precipitation during the reac-

---

[1] Bent and Keevil, THIS JOURNAL, **58**, 1228 (1936).

[2] Dorfman, *ibid.*, **57**, 1455 (1935).

[3] When the monosodium derivative was prepared by this indirect method the amount of ketone at equilibrium was obtained by evaporation of the solution to dryness and correcting for the amount of ketyl determined by titration.

tion the concentration of ketone was determined by evaporation of the solution to dryness after titration of the sodium as in the case of benzophenone. The various runs are of unequal importance due to the fact that in some cases the concentration of one of the reactants was very low. The large negative value for ΔF for the reaction of addition of sodium to these ketones necessitates working with very dilute amalgams. These ketones exhibit about the greatest stability which can be studied by this method.

Dibiphenyl Ketone.—This ketone behaved in much the same way as the two discussed above, forming a monosodium derivative. In preparing the ketyl for removal of sodium with dilute amalgam a saturated amalgam was used.

Tetraphenylcyclopentadienone.—This ketone is remarkable in that it adds more than one equivalent of sodium even when shaken with very dilute amalgam. The rate of addition of sodium, however, is very slow and we were not able to add as much as two equivalents of sodium even after shaking the ketone with 40% amalgam for fifteen days.

Tetraphenylethylene.—This unsaturated hydrocarbon and the two following compounds exhibit a much smaller tendency to add sodium than any compounds which we have studied hitherto. The sodium derivatives are so unstable as to be completely decomposed by a saturated sodium amalgam. They might be studied by means of solid sodium amalgams but probably better still by means of the potentiometric method. We will

TABLE IV

PRELIMINARY DATA ON UNSATURATED COMPOUNDS

Compound	No.	Procedure	Moles Na in mercury	Moles Na in ether	Moles of mercury	Moles of ether	Moles of ketone at equilibrium	$-\Delta F$
Tetraphenylethylene	1	Out with mercury	2.15×10^{-4}	2.80×10^{-6}	0.3645	0.4413	1.48×10^{-4}	30.2
Tetraphenylethylene	2	Out with mercury	2.49×10^{-4}	3.42×10^{-6}	.6258	.5903	1.77×10^{-4}	30.5
Tetraphenylethylene	3	Out with 1% amalgam	6.61×10^{-3}	1.15×10^{-5}	.7553	.5913	1.96×10^{-4}	28.0
Tetraphenylethylene	4	Out with 1% amalgam	7.72×10^{-3}	6.1×10^{-6}	.1471	.886	2.60×10^{-4}	24.3
Stilbene	1	Out with 1% amalgam	3.29×10^{-3}	2.80×10^{-5}	.0552	.2793	1.66×10^{-4}	24.8
Stilbene	2	Out with 1% amalgam	4.28×10^{-3}	2.84×10^{-5}	.0801	.6572	6.9×10^{-5}	25.5
Anthracene	1	Out with mercury	3.35×10^{-4}	6.10×10^{-6}	.3513	.6134	9.21×10^{-4}	13.7
Anthracene	2	Out with 1% amalgam	8.96×10^{-3}	7.12×10^{-5}	.1787	.9397	4.55×10^{-4}	12.4

reserve comment on these compounds until we have more exact quantitative data. The results reported in Table IV are of interest in indicating the most negative value which ΔF can assume. These are minimum values only, the true value lying nearer to zero. The reaction to which ΔF refers is $2\mathrm{Na} + (\mathrm{C_6H_5})_2\mathrm{C{=}C}(\mathrm{C_6H_5})_2 = (\mathrm{C_6H_5})_2\mathrm{CNaCNa}(\mathrm{C_6H_5})_2$.

Stilbene.—Saturated amalgam did not remove as much of the sodium in the case of stilbene as it did with tetraphenylethylene. It is possible, therefore, that the value in the last column of the table is the correct value for this compound. Since we have not approached the equilibrium from both sides, however, it is safer to consider this a maximum value for $-\Delta F$.

Anthracene.—This compound is remarkable in that it is an unsaturated hydrocarbon and yet differs from the two just discussed in that it will combine with one atom of sodium. This reaction we hope to investigate further and until we have quantitative data will reserve further comment. The values given in the last column of the table are again maximum values for $-\Delta F$. They are approximately half of those given for the two previous compounds since only one atom of sodium is involved and the reaction is written $\mathrm{Na} + \mathrm{C_{14}H_{10}} = \mathrm{NaC_{14}H_{10}}$.

Discussion of Results

The free energy data reported indicate that fluorenone combines with sodium more readily than dibiphenyl ketone, which in turn combines with sodium more readily than benzophenone. This is not the order in which the groups attached to the carbonyl group are effective in promoting dissociation of ethanes but is the order in which free radicals containing these groups combine with sodium. It therefore appears that the problem is not a simple one and that there must be at least two factors involved. It is doubtless too early to state these factors with certainty but since the facts can readily be explained by two factors which must be of importance one is tempted to suggest an explanation. In the first place we will assume that the addition of sodium first forms a free radical, the sodium being attached to the oxygen to give a molecule of the formula $\mathrm{R_2\underset{|}{C}ONa}$. Such a molecule will have a stability which is determined partly by resonance.[4] We would, therefore, expect dibiphenyl ketone to combine more readily with sodium on account of the greater resonance energy of the biphenyl group. In the case of fluorenone, however, we must look for another explanation. Bachman has presented evidence to show that these free radicals double up to form pinacolates of the formula  $\begin{array}{c}\mathrm{R_2CONa}\\ |\\ \mathrm{R_2CONa}\end{array}$. This reaction will not affect the above argument involving resonance if the sodium addition compound is largely in the form of the pinacolate. In the case of fluorenone, however, another factor must be considered. The data on the heat of oxidation and hydrogenation of hexaphenylethane[5] indicate that steric hindrance is an important factor in determining the stability of free radicals. The large association of phenylfluoryl may therefore be due to the fact that the tying together of the two benzene rings decreases the steric hindrance and gives rise to a more stable bond. If this be assumed then it is easy to see why fluorenone combines more readily with sodium than the other ketones. The decreased steric hindrance results in the formation of more pinacolate which removes the product of the reaction and therefore shifts the equilibrium in the direction of formation of the ketyl.

The next point to be discussed is the location of the sodium atom in the ketyl molecule. Recently Wooster[6] has considered the possibility of

the sodium being attached to the carbon, forming an oxygen free radical of the formula  $\begin{array}{l}R_2CO\text{—}\\ \ \ |\\ Na\end{array}$. Our experimental results lead us to the conclusion that the sodium is attached to oxygen and not to carbon. If we compare the free energy of addition of sodium to carbon and to oxygen we find that there is a large difference which is in favor of sodium being attached to oxygen. Thus sodium may be readily removed when attached to carbon free radicals by dilute sodium amalgam while we were not able to remove even a trace of sodium from the oxygen free radical derived from 9-chloro-10-phenanthrol with the aid of mercury.[7] This indicates that the free energy of addition of sodium to a free radical is at least 5 kcal. more negative in the case of the oxygen free radical. Hence we conclude that sodium is much more firmly attached to oxygen than to carbon and that therefore the ketyl should be represented as a carbon free radical with the sodium on the oxygen  $(C_6H_5)_2\underset{|}{C}\text{—}O\text{—}Na$.

Another entirely different approach to the problem leads to the same conclusion. Thus the negative ion formed from the ketyl can be represented by the structures $(C_6H_5)_2\underset{\cdot}{C}:\underset{\cdot\cdot}{\ddot{O}}:$ and $(C_6H_5)_2\underset{\cdot\cdot}{C}:\underset{\cdot\cdot}{\ddot{O}}\cdot$ in which the odd electron may be either on the carbon or the oxygen. Many other structures would have to be included to form the complete wave equation, these structures involving quinonoid rings. The ion must be considered to be the sum of all of these structures with, however, a preponderance of the structure of lowest energy. Since the electron affinity of oxygen is greater than that of carbon,[8] we may expect the first structure given above to be that of greatest importance. This corresponds to the negative charge being localized on the oxygen and hence would lead to an ion pair in which the sodium is attached to oxygen. Finally, a third factor which promotes the addition of sodium to oxygen is to be found in the coulomb interaction of the sodium ion and the electrons which may be considered to give rise to resonance in the molecule as a result of their wandering around in the benzene rings. This coulomb interaction will tend to localize an electron pair in the vicinity of the sodium atom.[9] Here we find a pronounced difference in the effect of such a pair being localized on the carbon or on the oxygen. If the pair is localized on the oxygen the odd electron on the carbon is still free to wander. On the other hand, if the pair is localized on the carbon the free electron on the oxygen is not free to wander and hence this structure would be less stable on account of the smaller amount of resonance energy in the molecule.

The above three lines of evidence lead us to the conclusion that the sodium is attached to oxygen in the ketyl. No shift of the sodium is then required in forming the double molecule.[10]

If our point of view is correct the question arises as to what is the probable answer to each of the lines of evidence which Wooster brings out, leading to the opposite conclusion.

Wooster's first evidence arises from the fact that  $\begin{array}{l}(C_6H_5)_2COC_2H_5\\ \ \ \ \ \ \ \ \ |\\ \ \ \ \ \ \ Na\end{array}$ does not rearrange to give the compound  $\begin{array}{l}(C_6H_5)_2CONa\\ \ \ \ \ \ \ \ |\\ \ \ \ \ \ C_2H_5\end{array}$ and he therefore concludes that the initial product of the reaction of sodium-benzophenone with ethyl bromide is the free radical  $\begin{array}{l}(C_6H_5)_2CO\text{—}\\ \ \ \ \ \ \ \ |\\ \ \ \ \ \ C_2H_5\end{array}$ and that this reacts with a second molecule of ketyl to give  $\begin{array}{l}(C_6H_5)_2CONa\\ \ \ \ \ \ |\\ \ \ \ C_2H_5\end{array}$. We agree that a reaction of the oxygen free radical with sodium benzophenone would be expected as our experiments have shown that sodium cannot be removed from an oxygen free radical by mercury while it can be removed very readily from sodium benzophenone. This difference is due in large measure to the fact that when the sodium is removed from the ketone a single bond between oxygen and carbon is changed into a double bond and it is this process which permits the sodium to be removed so readily from the ketone. Wooster's suggestion that because the ethyl group adds to carbon the sodium must originally have been on the carbon does not seem conclusive in the absence of other evidence. We quite agree with Wooster, however, that the course of the alkylation may be determined by a configuration which is not that of the normal molecule and in this case may be that in which the charge is on the carbon.

The second evidence presented by Wooster has to do with the relative ionization of sodium benzhydrylate, sodium benzophenone and sodium triphenylmethyl. Wooster informs us that he

(8) Glockler, *Phys. Rev.*, **46**, 111 (1934).

(9) There seems to be no way at present of estimating the magnitude of this effect. We hope to study this problem in more detail experimentally.

(10) Bachman, THIS JOURNAL, **55**, 1179 (1933).

expects in the near future to give a different interpretation of these data so that this argument no longer concerns us here. Recent correspondence indicates that Wooster's views and ours are not in complete accord. The question of the degree of localization of the sodium ion in the ion pair is answered by the data of Kraus and Fuoss on the compounds C_6H_5ONa (2.70), C_6H_5SNa (4.95) and $C_{10}H_7ONa$ (2.9–3.1). The values given in parentheses are for the distance "a," multiplied by 10^8, which is characteristic of the distance of closest approach of the two ions. It is apparent that the change from an oxygen to a sulfur atom produces a much greater change in "a," than the addition of several carbon and hydrogen atoms. We therefore conclude that in such an unsymmetrical anion the sodium is localized, in this case near the oxygen or sulfur and the anion cannot be treated as spherically symmetrical. This is the justification for the formulation of the ion pair with the sodium attached to oxygen rather than a more general formula which does not localize it at any point in the molecule.

The third line of evidence suggested by Wooster has to do with the ease with which sodium may be removed from sodium benzophenone and from sodium triphenylmethyl. Wooster gives data to show that these two compounds are about equally stable, the free energy change for the process of transferring the sodium from ketone to the free radical being within 0.5 kcal. of zero. Our data also indicate the free energy change for this reaction is small, from 0.7 to 1.0 kcal. Wooster finds that the sodium is held slightly more firmly by benzophenone while we find that triphenylmethyl has a slightly greater affinity for sodium. The difference is not significant, however, and we may consider the two sets of data in substantial agreement. Wooster concludes from these data that the sodium is attached to carbon in both cases. As we have pointed out above, however, the loss of sodium from the ketone leads to the formation of a double bond between the carbon and oxygen and therefore contributes nearly 100 kcal. to the process. If sodium were attached to carbon in both compounds we would expect (from this factor alone neglecting resonance energy) that it would be liberated from the ketone more easily by 100 kcal. This would mean that the ketyl would not be formed at all. We have calculated the heat of formation of the ketyl assuming the sodium to be on the oxygen, adding up single bond energies and estimating the magnitude of the resonance energies involved. We do not wish to present these figures in detail owing to their very rough qualitative nature, but they give the right order of magnitude for the experimental energy. When one assumes that the sodium is attached to carbon the agreement with the experimental value is very poor, as is indicated above. We, therefore, are led to the conclusion that sodium adds to the benzophenone forming a ketyl with sodium attached to oxygen which then forms a pinacolate.

Summary

1. Data are given for ΔF for the reaction of addition of sodium to benzophenone, dibiphenyl ketone, fluorenone, tetraphenylcyclopentadienone, tetraphenylethane, stilbene and anthracene.

2. The data are correlated with previous experiments which indicate the significance of resonance energy and steric hindrance.

3. Evidence is presented to show that sodium is attached to oxygen in sodium-benzophenone.

Radioactive Manganese as an Indicator in Testing for Possible Equilibria between Several Valences of Manganese[1]

BY MILTON J. POLISSAR

Equilibria Assumed to Exist in a Permanganate–Manganic Oxalate Mixture.—The kinetics of the reaction between permanganate and oxalate ions was studied by Harcourt and Esson,[2] and later by Schilow[3] and Skrabal.[4] Recently Launer[5] has shown that Skrabal's mechanism for the reduction of manganic ion by oxalate ion is not in complete accord with experimental facts. Launer and Yost[6] have proved conclusively that the earlier mechanism for the reactions taking place in a permanganate–manganic oxalate complex mixture is incorrect.

Launer and Yost proposed another mechanism, based on the very plausible assumption that the following equilibria exist in a solution containing permanganate ion and manganic oxalate complex ion

$2MnO_4^- + 3Mn^{++}$ (always present in $KMnO_4$) $+ 16H^+ = 5Mn^{++++} + 8H_2O$ (rapid equilibrium or sum of equilibria) (1)

$Mn^{++++} + Mn^{++} = 2Mn^{+++}$ (rapid, reversible) (2)

$Mn^{+++} + 2C_2O_4^{--} = Mn(C_2O_4)_2^-$ (rapid, reversible) (3)

A little later, Polissar[7,8] has shown that the immeasurably fast reaction taking place on mixing permanganate, oxalate and manganous ions is in need of a new interpretation. He showed that the mechanism of this reaction may be explained with the use of the equilibria assumed by Launer and Yost.

Until very recently there was no other evidence as to the reversibility of reaction (1) in acid solutions. With the discovery of radioactive manganese,[9] it became possible to test for the existence of such equilibria, using marked manganese atoms. The present paper deals with the method of attack used by the writer in carrying out such tests.

The Use of Marked Atoms in Testing for Equilibria.—The method of attack will be illustrated by means of a concrete example. Assuming that it is possible to trace the identity of atoms, one can rewrite equation (1) as follows

$2MnO_4^- + 3{}^*Mn^{++} = 2Mn^{IV} + 3{}^*Mn^{IV}$ (rapid, reversible) (4)

The marked substances are contaminated with radioactive substances chemically identical with them. For the sake of simplicity, the equation is not completely balanced. In this and in the following equations the substances whose exact formulas are not known will be indicated simply by the valence number of the manganese in them. Precipitated manganese dioxide will be represented by the formula MnO_2, even though it is known that the latter is hydrated.

If we start with ordinary permanganate and marked manganous ion, then, provided equilibrium (4) actually exists, the radioactivity should spread into the permanganate, through the operation of the reverse of reaction (4). Thus, we have a means of carrying out a crucial test for the existence of this equilibrium. (1) Mix a *small* amount of marked manganous ion with a *large* amount of ordinary permanganate ion in acid solution. (2) After allowing the mixture to stand for the desired length of time, add enough sodium hydroxide to make the mixture neutral or slightly basic. Filter off the manganese dioxide from the large excess of permanganate ion. If there is a rapid equilibrium, then *most* of the radioactivity should be found in the *filtrate*. On the other hand, if there is no exchange, then *none* of the activity should be found in the filtrate.

All the experiments in this investigation were carried out in the same manner: a highly radioactive filtrate indicates an exchange reaction; an inactive filtrate indicates the absence of an exchange reaction.

Experimental Procedure and Results

The Preparation of Marked Manganous Ion. Analysis for Radioactivity.—Radioactive manganese was prepared by bombarding metallic manganese for about forty-five minutes with a 4-microampere beam of 5.8 m. v. deuterons

$$25^{Mn^{55}} + 1^{H^2} = 25^{Mn^{56}} + 1^{H^1} \qquad (5)$$

The radioactive layer was dissolved in a solution containing perchloric acid and ordinary manganous sulfate. The solution so obtained was analyzed for its total content of manganous ion. Enough sodium hydroxide, ordinary manganous sulfate, and water was added to give 50 cc. of 0.01 M *$MnSO_4$.

The preparation of the various reaction mixtures and the methods of precipitating out one of the valences will be described in connection with the respective experiments. The precipitated manganese dioxide was in each case filtered off rapidly through asbestos, in a Gooch crucible. After separation, the solid phase and the filtrate were each treated with 25 cc. of buffered hydrogen peroxide (approx. 4 M NaAc + 2 M HAc + 0.25 M H_2O_2). The resulting solutions were accurately diluted to 100 cc., a 20.0-cc. portion was removed, and a 20.0-cc. portion of 1 M $MnSO_4$ was added. Thus, all solutions to be tested for radioactivity had approximately the same concentrations of manganous ion, sodium acetate, acetic acid and hydrogen peroxide; they differed only in the concentration of radioactive manganous ion.

The solutions were tested for radioactivity in a special apparatus.[10] If the solution to be tested was found to be too active for measurement, it was diluted with another one containing the proper concentrations of manganous sulfate, sodium acetate, acetic acid and hydrogen peroxide. Frequent measurements were made to check the "background" count of the apparatus.

The experimental results are shown in Fig. 1. The ordinates in the diagram show the number of counts per minute given by each individual solution, corrected for the "background" of the Geiger counter, and for dilution. The abscissas give the time of day at which the respective measurements were made. The four circles marked with short arrows give the measurements on a control solution containing as much marked manganous sulfate as was used in every experiment. The heavy line is the best semi-logarithmic line drawn through these four points, with a slope corresponding to the half-life of radioactive manganese (two hours and forty min.). The lines running parallel to it across the diagram correspond to 80%, down to 0.1% of the activity of the control solution. They make it possible to estimate directly the fraction of the original activity present in a given solution.

The tie lines each connect the two points obtained from a single experiment. In each case the circle corresponding to the filtrate is plain. The circle corresponding to the precipitate is blackened. The radius of each circle is drawn approximately to scale, to indicate the maximum error in the measurement of the radioactivity.

Shortly before 10 P. M. the amplifying circuit of the counter stopped functioning. The last five measurements were made by placing each solution, in an Erlenmeyer flask, over the aluminum window of an electroscope. All five values of the activity, expressed in divisions per minute, were multiplied by a constant factor, selected in such a way as to bring the third control point (11:05 P. M.) on the 100% line.

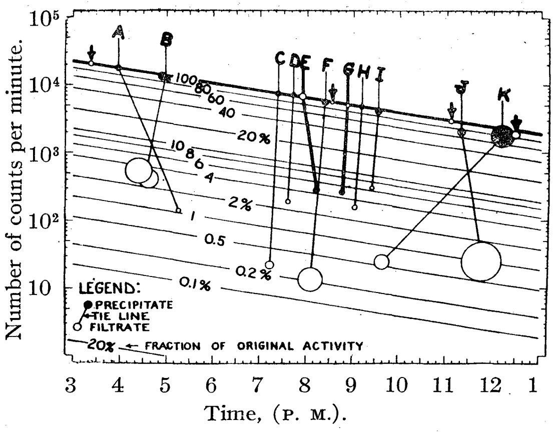

Fig. 1.—Complete record of radioactive measurements. The activities of the solutions obtained from the precipitates (blackened circles) and from the filtrates (plain circles). A very active filtrate indicates an exchange reaction. An inactive filtrate indicates the absence of exchange. Exchange reactions evident in Experiments E and G. In all other experiments no exchange took place. In experiment I the filtrate contained 6.7% of the original activity because of the use of an excess of marked manganous ion in the preparation of the manganese dioxide. The small activity of the filtrates in A, B, C, D, F, H, J and K was due to imperfect filtration.

It will be seen that in all experiments, but J, the sum of the activities of the filtrate and the precipitate was equal to the activity of the control solution, within the experimental accuracy of measuring the activity. In experiment J the deficiency was large, for some unexplained reason. Inspection of the results in experiment K and of Fig. 2 will show, however, that this slight uncer-

---

tainty does not invalidate the conclusions to be drawn from experiment J.

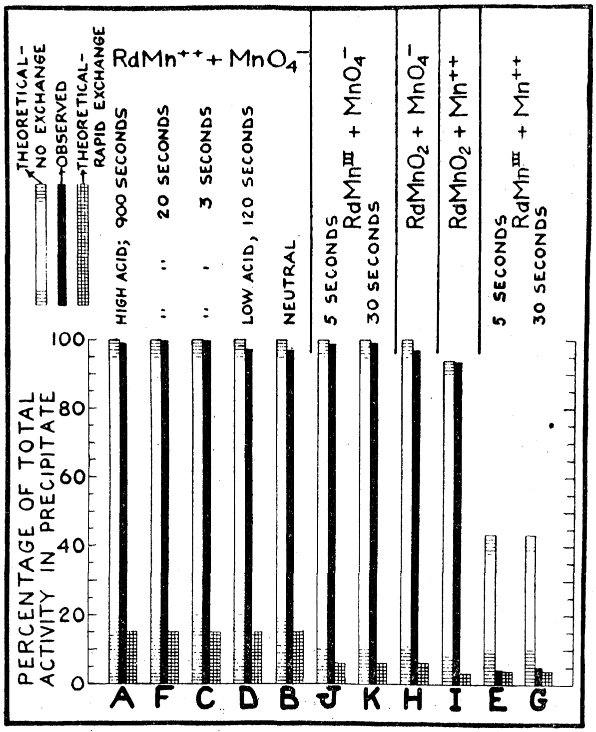

Fig. 2.—Observed activities of the precipitates (black bars) compared with the theoretical values for complete absence of exchange (shaded bars) and for complete exchange (cross-hatched bars). This diagram exhibits more clearly the complete exchange in a solution containing manganic complex and manganous ions (Experiments E and G) and the absence of exchange in the other nine mixtures.

Description of Individual Experiments

Experiments C, F, A, D, B. Marked Manganous and Permanganate Ions.—*Experiment C.*—(10.0 cc. of 0.02 *M* $KMnO_4$ + 1.0 cc. 1 *M* $HClO_4$) was added to (2.0 cc. 0.01 *M* $MnSO_4$ + 10 cc. H_2O). Three seconds later, with the solution still clear and violet, 10.0 cc. of 0.1 *M* NaOH was added. The manganese dioxide precipitated at once. Filtration started about two minutes later. 100% (±6%) of the original activity was found in the precipitate; 0.3% (±0.05%) in the filtrate. (The small amount of radioactivity found in this and in some of the other filtrates is probably not due to a slow exchange. The weight of the precipitated manganese dioxide did not exceed 4.4 mg. in any of the experiments. From visual observations, the writer is inclined to ascribe small activities of the filtrates to imperfect filtration.)

Experiment F.—The same mixture as in C quenched forty seconds after mixing. Just before quenching, the solution was still clear, but definitely reddish, because of the small amount of manganese dioxide formed; 100% (±8.5%) of the original activity found in the precipitate; 0.2% (±0.1%) in the filtrate.

Experiment A.—The same mixture as in C allowed to stand for fifteen minutes. By this time the spontaneous formation of manganese dioxide was practically complete, and it was unnecessary to add sodium hydroxide: 100% (±8%) of the original activity in the precipitate; 1% (±0.05%) in the filtrate.

Experiment D.—(10.0 cc. of 0.02 *M* $KMnO_4$ + 0.1 cc. 1 *M* $HClO_4$) was added to (2.0 cc. 0.01 *M* $MnSO_4$ + 10 cc. H_2O). In this experiment the initial acid concentration was one-tenth as large as in experiment C. The spontaneous formation of manganese dioxide was much faster. In three to four seconds the mixture was definitely red, and in a few more seconds it was opaque. No sodium hydroxide was necessary. Filtered five minutes after mixing: 100% (±6.5%) of the original activity in the precipitate; 3% (±0.18%) in the filtrate.

Experiment B.—The perchloric acid was omitted. The precipitation of manganese dioxide took place on mixing; filtered two minutes later. In this experiment the activities of the two solutions were measured twice: 95% (±6%) of the original activity in the precipitate; 3% (±0.3%) in the filtrate.

Experiments J and K Marked Manganic Oxalate Complex Ion and Permanganate Ion.—*Experiment J.*—Ten cc. of 0.002 *M* potassium permanganate was added to (2.0 cc. 0.01 *M* $^*MnSO_4$ + 10.0 cc. 0.5 *M* $H_2C_2O_4$). Manganic oxalate complex formed on mixing. The solution contained a slight excess of permanganate ion. Two seconds after mixing, 25.0 cc. of 0.02 *M* potassium permanganate was added. Five seconds later the following quenching mixture was added: (5 cc. 3 *M* NH_4OH + 10 cc. 0.5 *M* $CaCl_2$). (The calcium chloride was added to facilitate the decomposition of the manganic oxalate complex into manganese dioxide and manganous ion.) Filtered about two minutes later. In this experiment, and in experiment K, after treating the precipitate with the buffered hydrogen peroxide, it was necessary to carry out a second filtration, since calcium oxalate does not dissolve in the acetic acid buffer solution: 75% (±10%) of the original activity found in the precipitate; 1% (±1%) in the filtrate.

Experiment K.—The same as in J, except that the manganic complex-permanganate mixture was allowed to stand for thirty seconds before adding the quenching mixture: 80% (±24%) of the original activity found in the precipitate; 1% (±1%) in the filtrate.

Experiments E and G. Marked Manganic Oxalate Complex and Manganous Ions.—*Experiment E.*—(2.4 cc. 0.002 *M* $KMnO_4$ + 10 cc. H_2O) was added to (2.0 cc. 0.01 *M*$^*MnSO_4$ + 10.0 cc. 0.5 *M* $H_2C_2O_4$). Marked manganic oxalate complex formed on mixing. Two seconds later 25.0 cc. 0.01 *M* $MnSO_4$ was added. Five seconds later (5 cc. 3 *M* NH_4OH + 5 cc. 2.5 *M* $(NH_4)_2SO_4$) was added. Manganese dioxide precipitated at once; the manganous ion remained in solution. The mixture was filtered two minutes later: 105% (±8%) of the original activity found in the *filtrate;* 4.5% (±0.5%) in the precipitate.

Experiment G.—Procedure the same as in E, except that the quenching mixture was added thirty seconds, instead of five seconds, after the addition of the manganous sulfate: 95% (±7%) of the original activity was found in the filtrate; 5% (±0.25%) in the precipitate.

Experiments H and I. Marked Manganese Dioxide and Permanganate Ion. Marked Manganese Dioxide and Manganous Ion.—*Experiment H.*—(7.0 cc. 0.002 *M* $KMnO_4$ + 10 cc. H_2O) was added to 2.0 cc. 0.01 *M* $^*MnSO_4$. Manganese dioxide formed at once. In this case the excess of permanganate was used advisedly. Two minutes later 25.0 cc. of 0.02 *M* $KMnO_4$ was added. The mixture was shaken and filtered two minutes later: 100% (±6%) of the original activity was found in the precipitate; 3.3% (±0.6%) in the filtrate.

Experiment I.—(6.25 cc. 0.002 *M* $KMnO_4$ + 10 cc. H_2O) was added to 2.0 cc. 0.01 *M* $^*MnSO_4$. Manganese dioxide formed at once. Two minutes later 10.0 cc. 0.1 *M* $MnSO_4$ was added. The mixture was shaken and filtered two minutes later: 95% (±7%) of the original activity was found in the precipitate; 6.7% (±0.35%) in the filtrate.

Attention should be called to the fact that in the preparation of the manganese dioxide a slight excess of the marked manganous ion was used. This accounts for practically the entire activity of the filtrate. Assuming that there is no exchange, the theoretical distribution would be 93.76% in the precipitate and 6.24% in the filtrate.

Sample Calculations

In the following calculations all the amounts have been multiplied for the sake of convenience by the factor 10^6.

Experiments C, F, A, D, B.—The original solution contained 20 moles of marked manganous ion and 200 moles of permanganate ion. The final mixture contained 33.33 moles of manganese dioxide and 186.67 moles of permanganate ion in solution. If there were a rapid exchange between the manganous and permanganate states in the original solution, then the radioactivity of the two ultimate phases would have been proportional to the manganese content of each, namely, 15.1% in the precipitate and 84.9% in the filtrate. In the absence of any interchange, the precipitate should contain all the radioactive manganese.

Experiments E and G. Marked Manganic Oxalate Complex and Manganous Ions.—Subsequent experiments with ordinary manganese yielded the following information, essential for the calculation of the theoretical distribution of radioactivity. (a) In the instantaneous reaction in which manganic oxalate complex was formed, 10% of the oxidizing titer was lost through oxidation of oxalic acid. (b) After this initial reduction, the further reduction of manganic ion was extremely slow, both before and after the addition of the large amount of manganous ion.

The mechanism of the initial 10% reduction is not sufficiently well understood. For this reason it is impossible at present to decide whether the manganous ion formed in this process originated from the marked manganous ion, from the permanganate ion, or from both. The last assumption was made in carrying out the calculation of the theoretical distribution of activity. In other words, it was assumed that the oxidation of the oxalic acid took place *after* the instantaneous formation of trivalent manganese. It should be emphasized, however, that this uncertainty is only of secondary importance. It does not in any way invalidate the conclusions to be drawn from the experimental results, namely, that there is a rapid exchange between the bivalent and trivalent states. On the contrary, if it is assumed that the oxalic acid was oxidized by the permanganate only, the evidence for rapid exchange is strengthened, but only to a small extent.

The mixture was prepared from

$$4.8 \text{ moles } MnO_4^- + 20 \text{ moles } ^*Mn^{++}$$

On mixing, the solution contained the following substances

$$4.8\ Mn^{III} + 19.2\ ^*Mn^{III} + 0.8\ ^*Mn^{++}$$

After the 10% reduction, the mixture contained

$$4.32\ Mn^{III} + 17.28\ ^*Mn^{III} + 2.72\ ^*Mn^{++} + 0.48\ Mn^{++}$$

To this was added 250 moles of ordinary manganous ion. After precipitation, the mixture contained

$$2.16\ MnO_2 + 8.64\ ^*MnO_2 + 11.36\ ^*Mn^{++} + 252.64\ Mn^{++}$$

The preceding material balance was carried out on the assumption that there was no exchange between the bivalent and trivalent states. Under such conditions, the precipitate should contain 8.64/20.0, or 43.2% of the original activity.

On the other hand, if there is a complete exchange between the two valence states, the precipitate must contain only 10.80/274.8, or 3.93% of the original activity.

Discussion of the Experimental Results

The experimentally observed activities are shown in Fig. 1. The fraction of the original activity present in the precipitate and in the filtrate, respectively, can be read directly, with the use of the reference semi-logarithmic lines.

In Fig. 2 the same data are presented in the form of a bar diagram. Before plotting, each pair of activities was multiplied by the same factor, to normalize the total activity to 100%. In each case the observed value of the activity of the precipitate is flanked on both sides by the two theoretical values corresponding to complete exchange and to complete absence of exchange, respectively.

An inspection of the diagram will show that there was no exchange between the two valence states in the first nine experiments. In the last two experiments there was a complete exchange between the two valence states.

The evidence seems to be conclusive that the equilibrium postulated in equation (1) does not actually exist. It does not follow, however, that no other equilibrium exists between permanganate and manganous ions in the same solution. It is possible to postulate other equilibria which would not be in disagreement with the experimental results obtained in the present investigation. The following two will serve as illustrations

$$MnO_4^- + {}^*Mn^{++} = Mn^{VI} + {}^*Mn^{III} \text{ (rapid, reversible)} \quad (6)$$

$$\text{or } 2MnO_4^- + {}^*Mn^{++} = 2Mn^{VI} + {}^*Mn^{IV} \text{ (rapid, reversible)} \quad (7)$$

An inspection of the two equations will show that the radioactivity cannot spread from the bivalent to the permanganate state, provided there is no exchange between Mn^{VI} and Mn^{III}, or between Mn^{VI} and Mn^{IV}, respectively.

The rapid exchange between the manganous and manganic states can be explained easily with the use of the well-known equilibrium shown in equation (2). However, the observed exchange cannot be considered as additional evidence for such an equilibrium. The exchange may have been taking place through the operation of an entirely different reversible reaction, involving no quadrivalent manganese, but involving a direct transfer of an electron from one ion to another

$$^*Mn^{III} + Mn^{++} = {}^*Mn^{++} + Mn^{III} \quad (8)$$

The absence of exchange in experiment I (manganese dioxide and manganous ion) is probably due to the fact that only the surface atoms of the precipitate can be affected by the exchange reaction.

Acknowledgments.—The writer wishes to express his indebtedness to Dr. W. F. Libby, whose lecture on the general topic of Nuclear Chemistry suggested the method of attack used in this investigation, and who contributed liberally of his time in carrying out the radioactive measurements. The writer also wishes to express his gratitude to Professor E. O. Lawrence, who made this investigation possible, and to Dr. R. L. Thornton and Dr. A. H. Snell, who prepared the radioactive manganese.

Summary

1. Radioactive manganese was used as a "tracer" in a search for possible equilibria existing in solutions containing manganese in two valence states.

2. It was found that no exchange takes place in the following pair-systems: (a) permanganate ion–manganous ion; (b) permanganate ion–manganic oxalate ion; (c) permanganate ion–solid manganese dioxide; (d) solid manganese dioxide–manganous ion.

3. A rapid and complete exchange was found to take place in the system (e) manganic oxalate ion–manganous ion.

4. The absence of exchange in system (a) offers conclusive evidence against the existence of a rapidly established equilibrium between permanganate and manganous ions on one hand and some *one* substance of intermediate valence on the other.

5. The absence of exchange in system (a) cannot be taken as evidence against the existence of a rapidly established equilibrium between permanganate and manganous ion on one hand and *two* substances of intermediate valence on the other, provided there is no exchange between the latter two substances.

6. The rapid exchange in system (e) is in agreement with the known existence of an equilibrium between manganic oxalate ion, manganous ion and quadrivalent manganese. However, it may be due to yet another rapid reversible reaction involving the transfer of an electron from a manganous to a manganic ion.

7. The apparent absence of exchange in system (d) is probably due to the fact that only the surface atoms on the solid manganese dioxide can be affected by such an exchange.

8. Work on the mechanism of reduction of permanganate ion is to be continued.

The Rearrangement of Molecules in Plastic Monomolecular Films: Pressure–Area and Potential Relations for Polycyclic Compounds of the Five-Ring Series

BY WILLIAM D. HARKINS, EVERETT F. CARMAN AND HERMAN E. RIES

1. Introduction

Monomolecular films of certain compounds whose molecules contain five benzene rings have been found to exhibit a remarkable phenomenon. That is, a rapid rearrangement of the molecules occurs in the film in such a way that the pressure at the initial area almost disappears. Thus with betuline the initial or immediate pressure at a molecular area of 34.5 sq. Å. is 17 dynes per cm. while after this there is at this area an almost exponential fall of pressure with time to a practically constant value of 1.0 dyne. Nevertheless, a rapid compression to 33.5 sq. Å., or by about $^1/_{34}$ of the area, increases the pressure by 21 times to 21 dynes, or to 4 dynes more than the previous initial compression. At an area of 28 sq. Å. the initial pressure of 40 dynes falls to 5.5 dynes in thirty seconds, but on rapid compression to 26.2 sq. Å. rises to 50 dynes per cm.

The set of six polycyclic compounds was made available through the kindness of Professor Ruzicka. The molecules of these compounds contain a phenanthrene residue (Figs. 1 and 2) as did the *d*-pimaric acids (Fig. 3) investigated in this Laboratory by Harkins, Ries and Carman.[1] A comparison of the surface potentials and force–area relations of the monomolecular films formed by this series (Figs. 4, 5, 6) is of considerable value, since the compounds (supposedly) differ only in their polar substituents.

The writers had the privilege of discussing the proposed structures with Professor Ruzicka (August, 1935), who tentatively assigned the polar groups to the locations suggested in Fig. 1. These proposed structures have not been definitely established, as yet, particularly with reference to the location of some of the polar groups. This fact must be borne in mind throughout the following discussion, as to cite all the possibilities at each reference to structure is not practicable.

2. Apparatus and Procedure

The apparatus is essentially the same as that described by Harkins and Fischer[2] and modified by Harkins, Carman and Ries.[3] The improved method of determining "zero" or clean surface potentials as described by Harkins, Ries and Carman[1] has been used throughout these experiments.

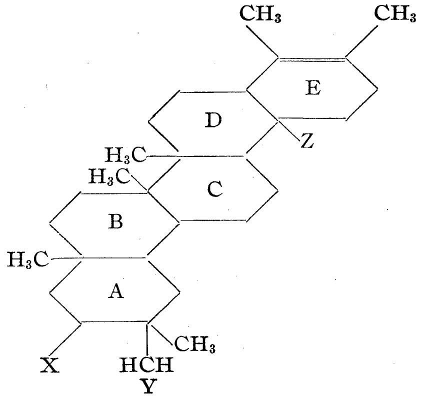

Fig. 1.—General structure of the five-ring compounds.

A modification in the older technique was made to obtain certain effects important in this investigation. As the area of the film was decreased, the torsion wire was turned simultaneously with the movement of the compression barrier. The pressure thus remained balanced during compression and instantaneous pressure readings were obtained. The compression barrier was moved at intervals of one minute and pressure readings taken immediately (unbroken lines) and then thirty seconds later (dotted lines; Figs. 4–6).

The compounds were dissolved in twice distilled chloroform and the films spread on 0.01 molal aqueous hydrochloric acid. The experiments were conducted at room temperature (24–29°) in a metal box covered with a thermal insulation.

3. Pressure–Area Relations

The pressure–area relations for these compounds are shown in Figs. 3–9 and Table I. The condensed films of these substances are of the solid type similar to those of stearic acid. This was demonstrated by the immobility of particles of lycopodium powder on their surface under a jet of air.

β-Amyrine, 5 Betuline, 7 Betuline diacetate, 2

Oleanolic acid, 3 Sumaresinolic acid, 4, or siaresinolic acid, 1

Fig. 2.—Structure of the five-ring compounds (the numbers refer to numbers on the figures).

The compressibility coefficients $\frac{(a_0 - a_1/a_0)}{f_1 - f_0}$, given in Table I are calculated from the slopes of the curves at pressures just below those of collapse. These coefficients range from 0.0033 to 0.0103 (stearic acid = 0.00763), and are normal for solid condensed films with perpendicular orientation of the molecules. The compressibility coefficient for tetrahydro *d*-pimaric acid, which has a three-ring structure, is greater than for any of the five-ring compounds, except betuline diacetate. This was to be expected, as pointed out by Harkins, Carman and Ries,[3] since the compressibility of films of vertically oriented molecules decreases with increasing length while that of horizontally oriented molecules is independent of the length. In betuline diacetate the high compressibility is related to the presence of the ester groups.

It may be noted here that at the lower portion of the curves, especially in the case of oleanolic, sumaresinolic and siaresinolic acids, each of which is supposed to contain a carboxyl group at Z in the upper part of the molecule (Fig. 1), the compressibilities coefficients are very much larger.

CONTRACTED FILMS

Contracted curve								
β-Amyrine	See initial values							
Betuline	24.1	26.2	22.0	44.0	32.8	30.2	36.0	0.00198
Betuline diacetate	See initial values							
Oleanolic acid	47.2	47.0	43.0	29.6	17.0	17.1	18.6	.0030
Sumaresinolic acid	51.8	47.8	39.8	24.0	16.3	17.7	21.2	.00965
Siaresinolic acid	42.2	42.6	35.8	33.6	19.6	19.4	23.1	.0045
Tetrahydro-*d*-pimaric acid	See initial values							

It is interesting to compare the extrapolated areas per molecule at the collapse pressure. The areas for β-amyrine, oleanolic acid and sumaresinolic acid are approximately 43 sq. Å. Betuline gives a much smaller area of about 26 sq. Å. while tetrahydro-*d*-pimaric acid and betuline diacetate give larger areas of about 47 and 48 sq. Å., respectively.

There seems to be some relation between collapse pressure and the number and kind of polar groups in the molecule. Tetrahydro-*d*-pimaric acid with three rings and one carboxyl group has a collapse pressure of about 15.0 dynes per cm.; β-amyrine, which contains one hydroxyl group at X and a double bond in ring E has a higher collapse pressure of about 22 dynes per cm. Betuline, oleanolic acid and siaresinolic acid have collapse pressures of about 48 dynes per cm. while that of sumaresinolic acid is about 45 dynes per cm. All of these compounds which exhibit collapse pressures only slightly below 50 dynes, have either two or three polar groups beside the double bond in ring E (Fig. 1). The fact that the adhesion of the film for the substratum is greatly increased in these latter compounds is undoubtedly related to the addition of polar groups to the molecule. By comparing betuline with betuline diacetate the effect of changing from two hydroxyl to two acetyl groups is very clearly shown in their collapse pressures. Betuline has a collapse pressure of about 48 dynes per cm. while that of betuline diacetate is only 9 dynes per cm. This illustrates the effect of changing from a strongly to a weakly polar group.

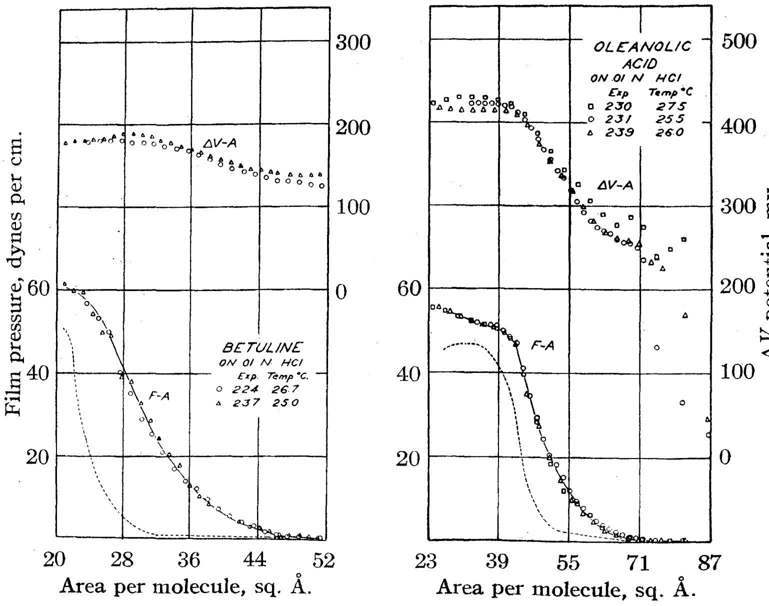

Fig. 4.

4. Molecular Rearrangement in the Films

It has been pointed out in the introduction that films of betuline exhibit a rapid rearrangement of the molecules such that the initial pressure, developed during a compression, almost entirely disappears at lower pressures, and largely disappears at higher pressures.

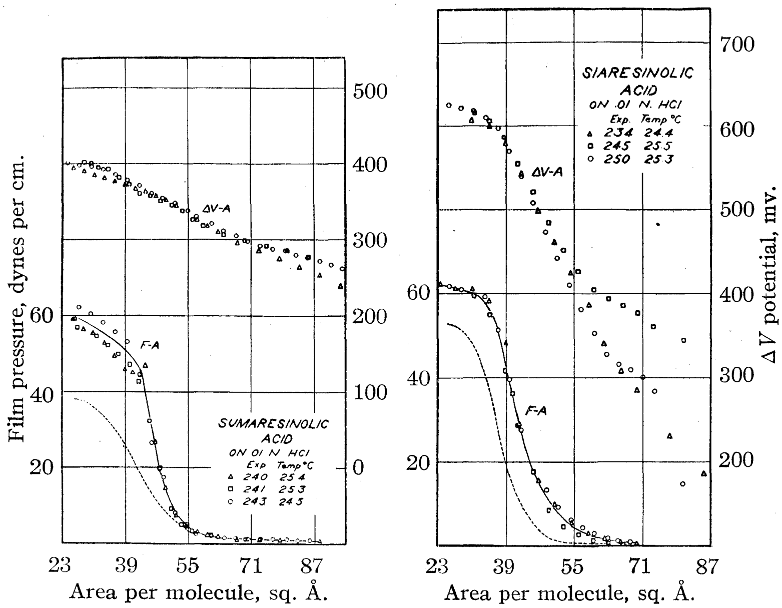

Fig. 5.

After a compression, the film shrinks for about thirty seconds, but the total decrease in area is small. If now the area is restored to its former larger value by the extremely small expansion necessary, the pressure is greatly reduced, as from 30 dynes to 1 dyne, or from 40 dynes to 5.5 dynes. The film is now under a lower pressure, and does not under this lower pressure undergo any further contraction in five minutes. However, if the pressure is kept at the higher value (as 40 dynes) for five minutes, and the area restored to the initial value at the end of five minutes, the pressure is found to be slightly lower than if the pressure had been reduced by adjusting the area at the end of thirty seconds.

Thus the rate of contraction of the film is higher at high than at low pressures. The shrinkage of the film produces a lowering of pressure, when the area is enlarged to the initial value, which is most extreme for betuline, is also great for oleanolic and siaresinolic acids, is large for sumaresinolic acid at high but not at low pressures, and appears with films of β-amyrine and of betuline diacetate only at the higher pressures (Figs. 4–6).

Thus the phenomenon of molecular readjustment and the resultant shrinkage of the film is very pronounced for those molecules of the five-ring type which have two highly polar groups attached to a single ring. These should be oriented toward the water. The removal of one of these groups, as in β-amyrine, or a change from hydroxyl to acetate groups, as in betuline diacetate, causes the phenomenon nearly to disappear. However, with β-amyrine on 0.02 molar hydrochloric acid Askew[4] found a marked contraction of the film up to an initial pressure of 15 dynes per cm.

When the pressure of a film of betuline was adjusted to 16 dynes every five minutes the area decreased in an hour by 18%, but at 1.0 dyne the decrease in area was only 4.5%. If the pressure is kept constant at 16 dynes, the decrease in area occurs more rapidly.

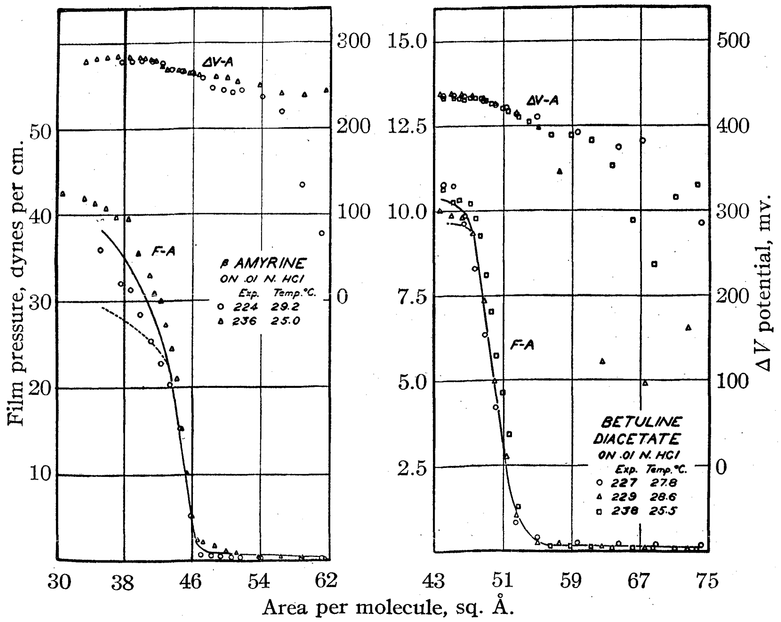

Fig. 6.

---

(4) Askew, *Biochem. J.*, **29**, 472 (1935).

5. Molecular Dimensions and Orientation

Models of the five-ring compounds give a value of about 15 Å. as the length of the molecule, and indicate that the molecular area in a tightly packed film, without water present, should be of the order of 50 sq. Å. The values found at 8 dynes per cm. pressure are of this general order (Table I), with the exception of those for betuline, which seems to give a thickness of film which is anomalous, especially at the highest pressure (48.8 dynes/cm.). This indicates either that the film of this particular substance is not truly monomolecular, or that a part of the betuline has dissolved.

For the three-ring compound the model gives a molecular length of 10 Å., while the apparent film thicknesses are 9.7, 10.2 and 10.7; at zero (extrapolated), 8, and 14.7 dynes/cm., respectively.

These compounds are apparently oriented with the XY ring toward the water, and the presence of a carboxyl group at Z seems to increase the cohesion in the film.

6. Surface Potential Relations

The surface potential (ΔV) of a film composed of molecules of an organic substance is the difference between the contact potential of the aqueous surface and that of the surface when covered by the film. This is defined as positive when of the usual sign.

The data for the contact potentials of the six five-ring compounds are represented by the points of Figs. 4–6. As usual, the spread of the points at low pressures is due to non-homogeneity of the film: that is, islands of condensed film and the adjacent gaseous film are represented. In this region the highest values give the surface potential for the islands.

The shrinkage of the film produces very little effect upon the surface potential, so the data refer to either state.

The mean values for the surface potentials of the condensed films are given in Fig. 7. The surface potentials increase as the concentration in the film increases, that is, as the molecular area decreases, and most rapidly in the case of siaresinolic acid, though almost as rapidly for oleanolic acid.

The values of ΔV per molecule are represented by the values of m, where

$$m = \Delta V/n$$

in Fig. 8. Here n is the number of molecules in one sq. cm. of film. The values of $\mu = m/4\pi$ are also given in order to simplify a comparison with the results expressed by English workers. They assume that μ is the dipole moment of the molecules in the film, even although its values are commonly only one-tenth as large as the true dipole moments. It is recommended that the use of μ be discontinued, since it is the standard symbol for the dipole moment. The equation which has been used for the calculation of μ, is

$$\mu = \Delta V/4\pi n$$

This equation represents a parallel plate condenser with metallic plates, but with the dielectric constant (K) omitted. Even for this simple case the correct equation is $\Delta V = 4\pi\sigma d/K$ which they would write $\mu = \Delta VK/4\pi n$.

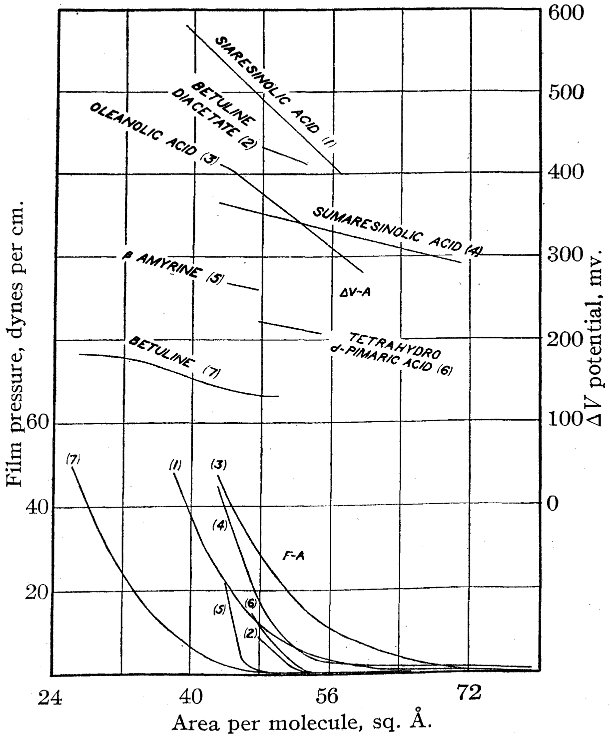

Fig. 7.

If an equation for a condenser could be applied to the case of a film, which is somewhat improbable, the value of μ would depend upon at least three dielectric constants, and the correct constant would not be 4π. It is preferable to use the value of m, which does not assume that the relation to the molecular dipole moments is known.

However, as a preliminary assumption it may be considered that the dipole moments of the molecules of the film contribute to the surface potential, although other factors are involved. It is apparent that the surface potential divided by the number of molecules (*m*) usually decreases slightly as the number of molecules per unit area increases. That is, though the surface potential (ΔV) increases with the concentration in the film, usually the contribution of each molecule to ΔV decreases with the concentration. With siaresinolic and oleanolic acids the variations are more complicated.

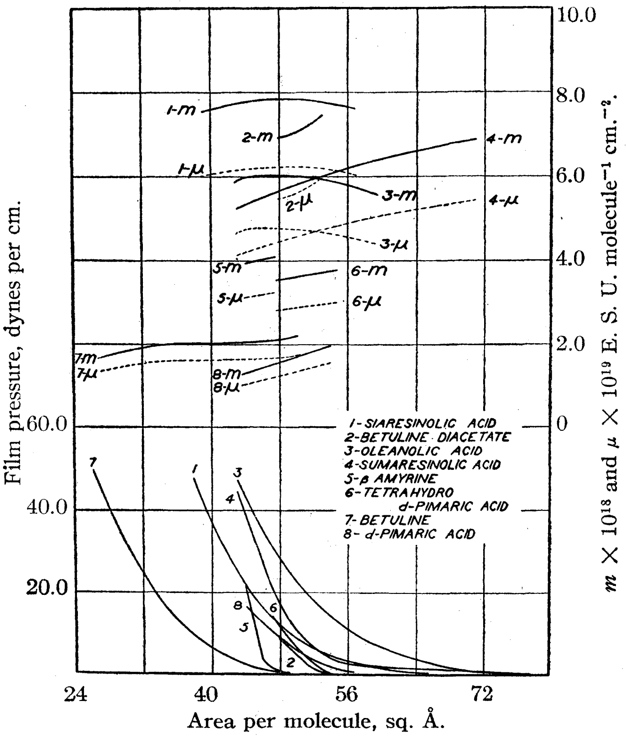

Fig. 8.

These relations are presented in a slightly different way in Table II, which gives the percentage increase in surface density and the corresponding percentage increase of surface potential for a specified range of surface density for the condensed film.

In general, the increase of surface density is more than sufficient to account for the increase of surface potential, but with oleanolic and siaresinolic acid the percentage increase of density is less than that of the potential.

Oleanolic acid is β-amyrine in which a hydrogen atom at Z is replaced by a carboxyl group. While with both compounds the surface potential for the condensed film is about 250 mv., the values for oleanolic acid rise to 415 mv. at 39 Å., while at the same molecular area for amyrine the surface potential is only 280 mv. Thus, when the molecules are closely packed the carboxyl group at Z increases the surface potential by 135 mv. or by about 50%.

The substitution of a hydroxyl group in one of the lower methyl groups (Y) of oleanolic acid to give siaresinolic acid increases the surface potential at low areas from 415 to 625 mv. However, a substitution of a hydroxyl group in the same position in β-amyrine to give betuline lowers the potential by 100 mv. Thus, exactly the same substitution at Y increases the potential by 200 mv. if the carboxyl group is present at Z, and lowers it by 100 mv. if it is not present.

Sumaresinolic acid, which is a stereoisomer of siaresinolic acid, shows widely different surface potential effects. Its potential range, 290 to 400 mv., is considerably lower than that of its isomer (400 to 625 mv.), and is fairly close to that of oleanolic acid, 280 to 430 mv. There is obviously a compensation of the polar groups in the sumaresinolic acid molecule, practically amounting to the complete neutralization of the hydroxyl (Y) group. The striking feature of its potential curve, however, is that the percentage increase of the potential is only 6.67% as compared with its surface density increase of 16.8%. The compensating effect of the dipoles evidently increases rapidly on compression.

The most pronounced compensating effect of the type discussed for sumaresinolic acid was observed for *d*-pimaric acid, by Harkins, Ries and Carman.[1] As shown in Table II, the surface density increases 16.8% while the surface poten-

TABLE II

THE VARIATION OF SURFACE POTENTIAL WITH SURFACE DENSITY

Compound	Surface potential range, total	Increase of surface density, %	Increase of surface potential, %
β-Amyrine	260–285	16.8	7.44
Betuline	130–190	16.8	14.7
Betuline diacetate	410–440	16.8	8.00
Oleanolic acid	280–430	16.8	21.3
Sumaresinolic acid	290–400	16.8	6.67
Siaresinolic acid	400–625	16.8	19.5
Tetrahydro-*d*-pimaric acid	205–225	16.8	8.8
d-Pimaric acid	110–80	16.8	−14.1

The percentage changes are calculated from the straight portions of the $\Delta V - A$ curves, not over the total range, thus the change of surface density of 16.8% corresponds to a decrease of area from 56 to 48 sq. Å. for each compound, except for betuline (40 to 34.3) and β-amyrine (48 to 41.1), since for these two compounds the $\Delta V - A$ curves were not linear in the region between 56 and 48 sq. Å.

tial decreases 14.1% though the saturated compound, tetrahydro-*d*-pimaric acid (one polar group), exhibits normal potential relations.

As mentioned above the magnitude of the potentials of β-amyrine and betuline indicates an electrically oppositional alignment of the two hydroxyl groups in the latter molecule. It is not uncommon for a second polar group to cause a lowering of the surface potential. Similar results were found by us for *d*-pimaric acid as mentioned above and by others for certain sterols.[5] However, too much weight should not be placed on this relationship in the particular case of betuline, since both its $F-A$ and $V-A$ curves are somewhat anomalous.

The high potential, 410–440 mv., of the comparatively weak film of betuline diacetate is of interest. The addition of the two acetate groups to the betuline molecule has apparently produced marked changes in the film.

The surface potentials of the condensed films vary over a large range, from 130 mv. for betuline to 630 mv. as the maximum for siaresinolic acid.

Summary

The solid monomolecular films of four of the six five-ring compounds considered in this paper have been found to give a behavior not previously exhibited, at least not in anything like this high degree. That is, if kept at constant area the pressure almost entirely disappears due to a shrinkage of the film. The behavior is more nearly analogous to that of a wax than to a crystalline solid. Thus for these films the initial pressure seems to be of much more significance than the final pressure. The initial pressures of all of the films and the surface potentials, are exhibited in Fig. 7, while the final pressures and the potentials are given in Fig. 9.

At film pressures of eight dynes per cm. the apparent thickness of the film varies from 14 to 17 Å. for the various compounds, which is about the thickness to be expected if molecules with five rings stand on end.

Derivatives of Tertiary Alcohols. Acid Phthalic Esters

BY W. A. FESSLER[1] AND R. L. SHRINER

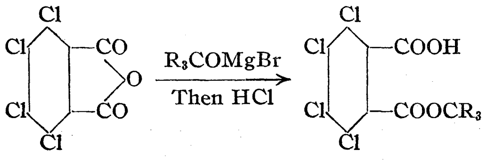
Many reagents are available for the preparation of derivatives of primary and secondary alcohols, but very few of these are applicable to tertiary alcohols. A few urethans and 3,5-dinitrobenzoates of *t*-butyl and *t*-amyl alcohols are reported.[2] The difficulties in obtaining derivatives of tertiary alcohols are due not only to the slowness with which they react, but also to the ease with which replacement of the hydroxyl or elimination of water takes place.

The preparation of solid esters of tertiary alcohols by using the tertiary alkoxymagnesium halide as one reactant seemed to offer a procedure which would avoid the dehydration reaction, since mild conditions could be used. The reaction of alkoxymagnesium halides with acid chlorides was first observed by Grignard[3] as a secondary reaction taking place when ethyl oxalyl chloride was treated with methylmagnesium iodide. Houben[4] later used the reaction with acid chlorides and anhydrides as a general method of esterification for primary and secondary alcohols. Recently Yabroff and Porter[5] prepared *t*-butyl phenylacetate by the action of *t*-butoxymagnesium bromide on phenylacetyl chloride.

In the present work, a study was made of the reaction between *t*-alkoxymagnesium halides and phthalic anhydride and three readily available substituted phthalic anhydrides. In order to determine the best conditions for the reaction and the most suitable anhydride, a series of preliminary experiments were carried out, using *t*-butoxymagnesium bromide prepared from *t*-butyl alcohol and ethylmagnesium bromide. Some of the runs are summarized in Table I.

The addition of dioxane increased the yield of the ester since it is a better solvent for the anhydrides than ether alone. Higher yields of the *t*-butyl ester were obtained at 50–55° than at lower or higher temperatures. The phthalic acid ester melts rather low and the esters of higher alcohols crystallized with difficulty. 3-Nitrophthalic anhydride gave crystalline esters, but the use of this anhydride may give rise to isomeric esters. It was found that ethoxymagnesium bromide reacted with 3-nitrophthalic anhydride to produce the 2-ethyl-3-nitro acid phthalate which melted at 156–158°, and was identical with that previously prepared by direct esterification.[6] It may, therefore, be assumed tentatively that the *t*-butoxymagnesium bromide produces the 2-*t*-butyl-3-nitro acid phthalate. No isomeric ester could be isolated, but it may have been lost during purification.

On the basis of the preliminary experiments, tetrachlorophthalic anhydride (I) seemed to be the most suitable since no isomeric esters are possible and the products crystallized more readily. Accordingly, it was used to prepare the tetrachlorophthalic acid esters (II) of the tertiary alcohols listed in Table II. This table also shows the best time and temperature for the reaction and indicates the best procedure for isolation.



I II

Examination of the data in Table II shows that the tetrachlorophthalic acid esters of tertiary alcohols are satisfactory solid derivatives which may be characterized by their decomposition points and neutral equivalents. Although the yields are not high, the reaction can be used satisfactorily when sufficient amounts of material are available.

The experimental conditions and method of isolation must be varied according to the molecular weight of the tertiary alcohol. For alcohols of low molecular weight a short reaction period at 50° is preferable, whereas the higher alcohols require a long time at a low temperature. The tetrachlorophthalic acid esters of alcohols below tri-*n*-propylcarbinol were soluble in aqueous alkalies, whereas the higher esters were insoluble. The neutral equivalents of these higher esters hence must be determined by titration in acetone solution.

TABLE I

REACTION OF *t*-BUTOXYMAGNESIUM BROMIDE AND VARIOUS PHTHALIC ANHYDRIDES

Anhydride	Reaction solvent	Reaction Temp., °C.	Time, hr.	Dec. point	Yield of ester, %	Neut. equiv. Calcd.	Found
Phthalic	Ether	36	1	85.0–86.0 (melts)	17.5	222	220
Phthalic	Ether–dioxane	50–55	1	85.5–86.5 (melts)	42.8	222	221
3-Nitrophthalic	Ether–dioxane	50–55	1	145 dec.	54.3	267	267
Tetrabromophthalic	Ether	50–55	1	147 dec.	4.1	538	531
Tetrachlorophthalic	Ether–dioxane	50–55	1	142 dec.	54.2	360	360
Tetrachlorophthalic	Ether–dioxane	0	20	142 dec.	15.4	360	358

TABLE II

REACTION OF VARIOUS *t*-ALKOXYMAGNESIUM BROMIDES WITH TETRACHLOROPHTHALIC ANHYDRIDE

Alcohol	Reaction Temp., °C.	Time, hrs.	Yield, %	Dec. point, °C.	Neut. equiv. Calcd.	Found	Procedure[7]
t-Butyl	50–55	1	54.2	142	360	360	A
t-Amyl	50–55	1	38.4	126	374	372	A
Triethylcarbinol	25	2	66.0	145	402	398	A
Tri-*n*-propylcarbinol	0	10	54.3	138	444	443	B
Tri-*n*-butylcarbinol	0	10	36.2	112	486	482	B
Tri-*n*-amylcarbinol	0	20	47.0	102	528	529	B

The reaction with aryl carbinols was also studied. Diphenylcarbinol can be converted into the acid phthalate in 74% yields by use of the alkoxymagnesium bromide, whereas the direct reaction of diphenylcarbinol with phthalic anhydride gave only 18% yields of the ester.

All attempts to prepare acid phthalates of triphenylcarbinol (by varying the experimental conditions) have failed up to the present time.

Experimental

Tertiary Alkoxymagnesium Bromides.—A solution of 0.1 mole of the tertiary alcohol in 50 cc. of anhydrous ether was added dropwise to a vigorously stirred solution of 0.1 mole of ethylmagnesium bromide in 150 cc. of absolute ether in a flask equipped with a reflux condenser.

In the case of *t*-butyl alcohol a white precipitate appeared. With the higher alcohols no precipitate formed. The resulting solution or suspension was used in the following procedure.

In one run with *t*-butyl alcohol the precipitate was filtered, dried *in vacuo* and analyzed. The analysis showed that the precipitate was *t*-butoxymagnesium bromide containing some ether.

Anal. Calcd. for $C_4H_9OMgBr \cdot 0.5(C_2H_5)_2O$: Mg, 11.35; Br, 37.30. Found: Mg, 10.47, 10.57; Br, 35.81, 35.19. Atomic ratio: Mg:Br::1.00:1.02.

Phthalic Acid Esters.—To a vigorously stirred solution of 0.1 mole of the tertiary alkoxymagnesium bromide in 175 cc. of ether was slowly added 175 cc. of anhydrous dioxane (175 cc. of anhydrous ether was substituted on two occasions as noted in Table I). One-tenth mole of phthalic or the substituted phthalic anhydride was then introduced and the reaction flask surrounded by a bath to maintain a constant temperature. After the reaction mixture had been stirred at the temperature and for the time indicated in the tables, the contents of the flask was poured on 500 g. of ice and acidified with 125 cc. of 2 *N* hydrochloric acid. The unreacted anhydride was then filtered, after which the ether layer of the filtrate was separated and the water layer extracted once with a 75-cc. portion of ether. The combined ether layers were then washed with two 50-cc. portions of ice-cold water. Isolation of the acid ester was accomplished by one of two methods, depending upon whether or not it was soluble in a 5% solution of sodium hydroxide. It was found that the tetrachlorophthalic acid esters of the aliphatic alcohols above triethylcarbinol were insoluble in this solution.

Procedure A.—The ether layer was extracted with ice-cold, 5% sodium hydroxide, using a 100-cc. portion followed by a 25-cc. portion. The combined sodium hydroxide layers containing the sodium salt of the acid ester were acidified by slowly stirring in 6 *N* hydrochloric acid until addition of the acid caused no further precipitation. Acid esters separated by procedure A were, in each case, purified by recrystallization from a mixture of ether and low-boiling petroleum ether.

Procedure B.—The ether was evaporated from the ethereal solution of the acid ester by heating on a steam cone. The resultant mass was then placed in a vacuum desiccator over concentrated sulfuric acid for three days. At the end of this time most of the unreacted alcohol had been removed. Purification was completed by dissolving in acetone and precipitating by the addition of water. This was repeated three times, and the product washed with two 50-cc. portions of low-boiling petroleum ether chilled in solid carbon dioxide and acetone.

In each instance, a white amorphous precipitate was formed when dioxane was added to the solution of tertiary alkoxymagnesium bromide in the preparation of the acid ester. In one run with triethylcarbinol this precipitate was separated and found to contain a large and somewhat variable amount of $MgBr_2$ obtained by the effect of dioxane on the probable equilibrium in solution, $2ROMgBr \rightleftharpoons (RO)_2Mg + MgBr_2$.

The properties and neutral equivalents of the esters are recorded in Table II and the analyses in Table III.

Diphenylcarbinyl Acid Phthalate.—Treatment of diphenylcarbinol with ethylmagnesium bromide and subsequent reaction with phthalic anhydride produced this

TABLE III

Compounds	Molecular formula	Calcd., % C	Calcd., % H	Found, % C	Found, % H
t-Butyl acid phthalate	$C_{12}H_{14}O_4$	64.83	6.35	64.60	6.30
t-Butyl acid 3-nitrophthalate	$C_{12}H_{13}O_6N$	53.91	4.90	53.88	4.88
t-Amyl acid 3-nitrophthalate	$C_{13}H_{15}O_6N$	55.49	5.38	55.22	5.06
t-Butyl acid tetrachlorophthalate	$C_{12}H_{10}O_4Cl_4$	39.98	2.80	39.65	3.05
t-Amyl acid tetrachlorophthalate	$C_{13}H_{12}O_4Cl_4$	41.69	3.23	41.58	3.12
Triethylcarbinyl acid tetrachlorophthalate	$C_{15}H_{16}O_4Cl_4$	44.75	4.01	44.47	3.95
Tri-*n*-propylcarbinyl acid tetrachlorophthalate	$C_{18}H_{22}O_4Cl_4$	48.62	4.99	48.49	5.03
Tri-*n*-butylcarbinyl acid tetrachlorophthalate	$C_{21}H_{28}O_4Cl_4$	51.82	5.67	51.64	5.60
Tri-*n*-amylcarbinyl acid tetrachlorophthalate	$C_{24}H_{34}O_4Cl_4$	54.54	6.49	54.41	6.85

ester in 74% yield. The reaction mixture was kept at 0° for twenty hours, and the acid ester separated by procedure A. The product melted at 164–165° and possessed a neutral equivalent of 333. Calcd. for $C_{21}H_{16}O_4$, 332.

By heating equimolar amounts of diphenylcarbinol with phthalic anhydride at 110° for fifteen hours, a yield of 18% of the diphenylcarbinyl acid phthalate resulted.

Summary

The reaction between *t*-alkoxymagnesium bromides and tetrachlorophthalic anhydride produces the *t*-alkyl acid tetrachlorophthalates in 36–66% yields. These solid esters may be characterized by their neutral equivalents and decomposition points.

The acid phthalate of diphenylcarbinol may be prepared in 74% yield by the reaction between phthalic anhydride and the alkoxymagnesium bromide.

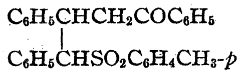
The Michael Condensation. IV. The Active Methylene Group in Sulfones

BY RALPH CONNOR, C. L. FLEMING, JR., AND TEMPLE CLAYTON

Sulfones having the structure RCH_2SO_2R' (in which R is either aryl or another sulfone grouping) are of interest because the methylene group is attached to two activating groups, yet enolization is not possible unless sulfur expands its valence shell. Previous investigators[1] have shown that methylene disulfones form sodio derivatives and may be alkylated by methods similar to those used for the alkylation of 1,3-diketones and that benzyl phenyl sulfone forms a sodio derivative (but may not be alkylated). These are apparently the only characteristic reactions of the active methylene group which have previously been shown to apply to sulfones of this type.[2] This paper demonstrates the ability of benzyl *p*-tolyl sulfone to undergo the Michael condensation.

The product (I) obtained from the condensation of benzyl *p*-tolyl sulfone with benzalacetophenone



$$\begin{array}{l} C_6H_5CHCH_2COC_6H_5 \\ \quad | \\ C_6H_5CHSO_2C_6H_4CH_3\text{-}p \end{array} \qquad \text{(I)}$$

was present in two stereoisomeric forms, m. p. 139–141° and 197–197.5°. The total yield of the pure products was 26%; this does not represent the actual extent of the reaction, however, because of the losses encountered in the difficult separation of the isomers from each other and from unreacted benzyl *p*-tolyl sulfone.

The addition of benzyl *p*-tolyl sulfone to benzalacetophenone is similar to the behavior of the ketonic analog of the former[4] (desoxybenzoin). The analogy between the reactions of ketones and sulfones in the Michael condensation may be carried still further. Both dibenzoylmethane[5] and bis-(phenylsulfonyl)-methane do not condense with benzalacetophenone and both benzyl *p*-tolyl sulfone and desoxybenzoin fail to react with methyl cinnamate. However, the failure of

---

[1] Shriner, Struck and Jorison, THIS JOURNAL, **52**, 2060 (1930).

[2] Aside from active methylene compounds, three other points of similarity may be noted[3] in the behavior of sulfones and their ketonic analogs: (1) the addition reactions of α,β-unsaturated sulfones, (2) the condensation of benzaldehyde with methyl *p*-tolyl sulfone and (3) the reaction of the Grignard reagent with sulfones to give magnesium derivatives similar to those obtained with certain ketones.

[3] Kohler and Potter, THIS JOURNAL, **57**, 1316 (1935).

[5] Connor and Andrews, THIS JOURNAL, **56**, 2713 (1934).

methyl *p*-tolyl sulfone to react with benzalacetophenone is in contrast to the behavior of acetophenone.[6]

Other typical reactions of the active methylene group were tested with these sulfones. The mercuric chloride test[7] for enolic substances was positive with bis-(phenylsulfonyl)-methane and negative with benzyl *p*-tolyl sulfone. All of the other reactions attempted (bis-(phenylsulfonyl)-methane and benzyl *p*-tolyl sulfone with benzaldehyde, *p*-chlorobenzaldehyde, selenium dioxide, nitrous acid and isoamyl nitrite in the presence of sodium ethoxide) were unsuccessful. In all cases the sulfones were recovered unchanged. While the usual caution in interpreting negative results must be observed, these data definitely form grounds for assuming a profound difference in the reactivity (if not in the nature of the reactions) of the methylene group in sulfones and in their ketonic analogs.

As regards the reactivity of benzyl *p*-tolyl sulfone in the Michael condensation and the reactivity of the disulfone with mercuric chloride, the choice between explanations assuming that the enol forms of the sulfones need not be involved or that sulfur may expand its valence shell,[8] is not clear. The former explanation agrees with the fact that it has been shown[5] that the reactivity of an addendum in the Michael condensation is not related to its tendency to enolize. However, the recognized ability of elements other than those of the first period to give transitory reaction intermediates and in some cases stable compounds with expanded valence shells, makes the latter explanation plausible.

Experimental Part

Condensation of Benzyl *p*-Tolyl Sulfone with Benzalacetophenone.—To a solution of 49.2 g. (0.2 mole) of benzyl *p*-tolyl sulfone[1] and 41.6 g. (0.2 mole) of benzalacetophenone in 1700 ml. of dry thiophene-free benzene was added a sodium methoxide solution prepared by dissolving 4.6 g. (0.2 gram atom) of sodium in 60 ml. of absolute methanol. Because of the formation of two liquid phases, the mixture was stirred with a mechanical stirrer. After a reaction period[9] of one week at room temperature 15 ml. of glacial acetic acid was added and the mixture washed with water to remove sodium acetate. The aqueous layer contained an emulsion; this layer, upon separation from the benzene gave, upon standing, 4.8 g. of product which upon recrystallization from benzene gave 2.2 g., m. p. 194–195° (corr.).

The benzene extracts were distilled until 1300 ml. of benzene had been removed. Upon cooling, 16.4 g. (m. p. 164–170°) of solid was obtained, which after recrystallization from benzene gave 9.8 g. melting at 197–197.5° (corr.).

Further concentration of the benzene extracts gave 14.1 g. (m. p. 134–136°) which, upon recrystallization from alcohol gave 11.3 g. of benzyl *p*-tolyl sulfone, m. p. 141–142° (corr.), which suffered no depression of the melting point when mixed with an authentic sample of benzyl *p*-tolyl sulfone.

All of the solvent was removed from the benzene extracts and ether added. The sulfones, which are quite insoluble in ether, are readily separated from benzalacetophenone in this manner. The ether-insoluble residue was washed with ether, giving 29.0 g., m. p. 104–111°, which, after seven recrystallizations from alcohol, gave 7.0 g., m. p. 139–141° (corr.). This product, when mixed with benzyl *p*-tolyl sulfone, gave a mixture melting at 111–113°.

The mother liquors from all the above recrystallizations were combined, concentrated and recrystallized many times from alcohol. The total yields of pure substances, including those mentioned above, finally isolated from the reaction were as follows. There was obtained 13.4 g. (14.7%) of the higher melting condensation product, m. p. 197–197.5° (corr.).

Anal. Calcd. for $C_{29}H_{26}O_3S$: S, 7.0. Found: S, 7.2, 7.2.

In addition to 11.3 g. (23%) of unreacted benzyl *p*-tolyl sulfone (m. p. 141–142°, corr.) there was obtained 10.3 g. (11.4%) of the lower melting isomer of the condensation product, m. p. 139–141° (corr.).

Anal. Calcd. for $C_{29}H_{26}O_3S$: S, 7.0. Found: S, 6.6.

The mother liquors from the crystallizations contained 10.4 g. of a mixture, m. p. 96–118°.

Other Reactions.—Under conditions similar to those described above, the reactions of benzyl *p*-tolyl sulfone and desoxybenzoin with methyl cinnamate, and of bis-(phenylsulfonyl)-methane[10] and methyl *p*-tolyl sulfone with benzalacetophenone were unsuccessful. Using conventional methods, the reactions of bis-(phenylsulfonyl)-methane and benzyl *p*-tolyl sulfone with benzaldehyde,[11] *p*-chlorobenzaldehyde,[11] selenium dioxide,[12] nitrous acid,[13] and isoamyl nitrite[14] (in the presence of sodium ethoxide) were tested. The recovery of unchanged sulfone was above 90% in the majority of the cases and was never below 75%.

Application of the mercuric chloride test[7] gave a positive result with bis-(phenylsulfonyl)-methane but was negative with benzyl *p*-tolyl sulfone.

Summary

The addition of benzyl *p*-tolyl sulfone to benzalacetophenone has been described and certain

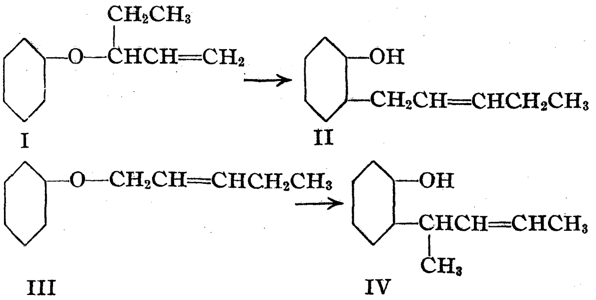
The Rearrangement of Phenyl Allyl Ethers[1]

BY WALTER M. LAUER AND WILLIAM F. FILBERT

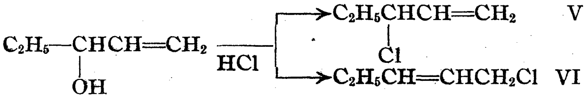
The results of Claisen's investigations dealing with the rearrangement of phenyl allyl ethers are well known. It is sufficient for our present purpose to recall that the migrating allyl group shows a preference for the ortho position and that the point of attachment of the allyl group in the cases hitherto investigated is shifted from the alpha to the gamma carbon atom. The rearrangement of a number of substituted phenyl allyl ethers has been examined,[2] but no study has been made of an isomeric pair of the type, $C_6H_5OCH(R)CH{=}CH_2$ and $C_6H_5OCH_2CH{=}CHR$. This omission presumably is due to the difficulty of obtaining the isomeric halides necessary for the usual synthesis of these ethers. Fortunately, however, Meisenheimer and Link[3] have shown that the action of hydrogen chloride on ethylvinylcarbinol leads to a mixture of $CH_3CH_2CHClCH{=}CH_2$ and $CH_3CH_2CH{=}CHCH_2Cl$, which may be separated by means of a careful fractional distillation. It was therefore considered not without interest to prepare such a pair of isomeric ethers and to study their rearrangement.

The ether I yielded the expected rearrangement product, II, but its isomer, III, quite unexpectedly, yielded IV.



The Isomeric Ethers

The two isomeric chlorides, 3-chloro-1-pentene and 1-chloro-2-pentene, were prepared by the action of gaseous hydrogen chloride upon ethylvinylcarbinol.



$$C_2H_5CH(OH)CH{=}CH_2 \xrightarrow{HCl} \begin{cases} C_2H_5CHClCH{=}CH_2 & \text{V} \\ C_2H_5CH{=}CHCH_2Cl & \text{VI} \end{cases}$$

The two isomeric ethers, I and II, were obtained from these chloropentenes by treatment with phenol and potassium carbonate in the presence of acetone. On account of the possibility of an alpha-gamma transposition, it was especially important to establish the structures of these ethers. This was accomplished by oxidation: I yielded α-phenoxybutyric acid, $C_6H_5OCH(C_2H_5)COOH$, whereas III under similar conditions gave phenoxyacetic acid, $C_6H_5OCH_2COOH$.

The preparation of *1-chloro-2-pentene* (VI) and *3-chloro-1-pentene* (V) was carried out as follows. Ninety-nine grams (1.15 moles) of freshly distilled ethylvinylcarbinol was saturated with dry hydrogen chloride at 0°. After standing for three hours in an ice box, the reaction mixture was again saturated at 0°. This process was then repeated after standing overnight. The total gain in weight was 62 g. Finally after standing for twenty-four hours in an ice box, the lower aqueous layer was separated and the mixed chlorides were placed over anhydrous potassium carbonate for two weeks. The mixture was filtered and then fractionally distilled using a 60-cm. Widmer column. Refractionation gave the following results: (1) $C_2H_5CHClCH{=}CH_2$, b. p. 50–50.2° (150 mm.), 42.1 g.; (2) intermediate, b. p. 50.2–62° (149 mm.), 2.1 g.; (3) $C_2H_5CH{=}CHCH_2Cl$, b. p. 62° (149 mm.) to 63.2° (146 mm.), 43.5 g.; (4) residue 3.7 g.

γ-Ethylallyl Phenyl Ether (III).—A mixture of 18.8 g. of phenol (0.2 mole), 20.9 g. of 1-chloro-2-pentene (0.2 mole), 29.0 g. (0.21 mole) of anhydrous potassium carbonate and 20 cc. of acetone, combined in the order named, was placed in a 200-cc. round-bottomed flask. The reaction mixture was refluxed on the steam-bath for eighteen hours, cooled, taken up in water and 25 cc. of ether added. After separating the aqueous layer, it was again extracted with ether. The combined ether extract was then shaken twice with 15–20 cc. of 20% sodium hydroxide. After drying

the ether solution over magnesium sulfate, it was concentrated and then subjected to distillation at reduced pressure; yield 18.6 g. (57%); b. p. 118.6° (20 mm.); $d^{20}{}_{20}$ 0.9566. Analysis by use of the Grignard machine showed the presence of a negligibly small amount of active hydrogen.

α-Ethylallyl Phenyl Ether (I).—In a 500-cc. flask fitted with a condenser the reagents were placed in the following order and amounts: 28.2 g. of phenol (0.3 mole), 43.5 g. of anhydrous potassium carbonate (0.31 mole), 40 cc. of acetone, and 31.4 g. of 3-chloro-1-pentene (0.3 mole). After standing at room temperature for eighteen hours, the mixture was heated for nine hours and then allowed to stand overnight. Sufficient water to dissolve the precipitate was added and the solution was then extracted several times with ether. The combined ether extracts, after washing with two 25-cc. portions of 20% sodium hydroxide followed by 25 cc. of water, were dried over anhydrous magnesium sulfate. Distillation under reduced pressure using a Widmer column gave the following fractions: (1) chloropentene; (2) b. p. 103–115° (18.5 mm.); (3) b. p. 115–118° (18 mm.). Fraction 2 redistilled yielded 5.6 g. of α-ethylallyl phenyl ether, b. p. 92–93° (15 mm.); $d^{20}{}_{20}$ 0.9465. Likewise fraction 3 gave 9.9 g. of the isomer γ-ethylallyl phenyl ether; b. p. 116–117° (17 mm.); $d^{20}{}_{20}$ 0.9567.

Oxidation of the isomeric ethers was accomplished by means of potassium permanganate in aqueous acetone solution.

(a) **γ-Ethylallyl Phenyl Ether.**—One and two-tenths grams of III, dissolved in aqueous acetone, was treated with 3.2 g. of potassium permanganate dissolved in a small amount of water. After standing overnight, the solution became almost colorless. The reaction mixture was filtered and the solution acidified. About one-half of the solvent was then distilled off to remove most of the acetone. The solution was extracted twice with ether. The ether extract, washed with a small amount of water, then was extracted twice with a 5% solution of sodium carbonate. Acidification of the carbonate solution with dilute sulfuric acid precipitated 0.32 g. of phenoxyacetic acid; melting point and mixed melting point with an authentic specimen of phenoxyacetic acid 98–99.5°.

(b) **α-Ethylallyl Phenyl Ether.**—A 1-g. sample of (I) oxidized in the manner described in (a) yielded an oil which finally crystallized; melting point after two crystallizations from water 80–82°. α-Phenoxybutyric acid prepared according to the directions of Bischoff[4] did not cause any lowering of the melting point when mixed with this oxidation product.

The Rearrangement Products.—The convenient technique of Claisen, which involves heating of the ether in diethylaniline, was adopted after it had been shown that the same rearrangement products were obtained in the absence of diethylaniline. That α-ethylallyl phenyl ether (I) gave *o*-(γ-ethylallyl)-phenol (II) upon rearrangement is indicated by the fact that ozonolysis of the methyl ether of II led to the formation of propionaldehyde. The direct nuclear alkenylation of phenol with 1-chloro-2-pentene, VI, also gave a product which was identical with that obtained by the rearrangement of I. Apparently, this α-monosubstituted allyl phenyl ether follows the rearrangement pattern outlined by Claisen.

The rearrangement of 3-phenoxy-1-pentene (I) was carried out by boiling 5.6 g. of this ether with one-half its weight of diethylaniline in an atmosphere of carbon dioxide. The temperature of the boiling mixture rose from 201 to 225° in three and one-half hours. After cooling, the reaction mixture was taken up in ether and petroleum ether, extracted twice with dilute sulfuric acid to remove the amine, and then three times with 20% sodium hydroxide to remove the phenol. The alkaline solution was acidified with hydrochloric acid and extracted with three 15-cc. portions of ether. After drying with anhydrous magnesium sulfate, the ether solution was concentrated and the residue distilled at reduced pressure. About 1 cc. of higher boiling material remained; yield 4.7 g. (83%); b. p. 131–132.5° (16 mm.); $d^{20}{}_{20}$ 0.988.

The phenylurethan was prepared by the action of phenyl isocyanate on the phenol dissolved in petroleum ether, in the presence of potassium carbonate. After crystallization from petroleum ether and dilute methyl alcohol, it melted at 67–68°.

Anal. Calcd. for $C_{18}H_{19}O_2N$: C, 76.85; H, 6.81. Found: C, 76.65; H, 6.61.

The aryloxyacetic acid was prepared from 1 g. of the phenol by the method of Koelsch[5] giving 0.78 g. of *o*-(2-pentenyl)-phenoxyacetic acid. After crystallization from dilute methyl alcohol, it melted at 108.5–110°.

The methyl ether of the rearrangement product (II) was obtained in 88% yield by treating the phenol with methyl iodide in the presence of a methyl alcohol solution of sodium methoxide; b. p. 143–145° (35 mm.); $d^{20}{}_{20}$ 0.9586. *Ozonolysis* of this methyl ether was carried out using ethyl bromide as solvent. Decomposition of the ozonide was accomplished in a manner similar to that used by Whitmore.[6] The steam distillate contained some brown oil, which was probably a polymer of homoanisaldehyde; it failed to give a semicarbazone. The remainder of the steam distillate was treated with methone (dimethylhydroresorcinol).[7] The precipitated derivative, recrystallized once from alcohol, had a melting point of 120–165°. By washing with cold acetone, a small residue of formaldimethone was obtained. This could have resulted only by deep-seated decomposition of the molecule. The solution from which this mixture of derivatives had been filtered was treated with more methone. The precipitate was crystallized from alcohol, then carbon tetrachloride and finally from dilute acetone; colorless plates, m. p. 152.5–153°. A mixed melting point with propionaldimethone showed no depression.

Anal. Calcd. for $C_{19}H_{28}O_4$ (propionaldimethone): C, 71.2; H, 8.81. Found: C, 71.1; H, 8.62.

The residue from the steam distillation of the ozonide

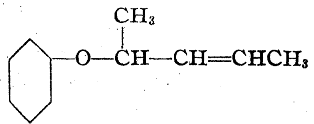
was made alkaline, the precipitated zinc hydroxide filtered off, the filtrate acidified and then extracted with ether. Evaporation of the ether left an oil which finally solidified. This was dissolved in dilute sodium hydroxide and treated with charcoal. By acidification, extraction with ether and evaporation, there was obtained a solid, which when twice crystallized from water showed a melting point of 121–123°. This corresponds to the melting point of *o*-methoxyphenylacetic acid.

Direct nuclear alkylation of phenol with 1-chloro-2-pentene (VI) yielded a product which was identical with that obtained by the rearrangement of I. Sodium (4.6 g.) was dissolved in a solution of phenol (18.8 g.) in benzene (75 cc.). 1-Chloro-2-pentene (20.9 g.) in 25 cc. of benzene was then added and the mixture refluxed on the steam-bath for twelve hours. After standing for twenty-four hours the sodium chloride was dissolved in water, petroleum ether was added and the layers were separated. The petroleum ether–benzene solution was extracted with five portions of Claisen's alkali and then with one portion of water. The alkaline solution was then acidified and extracted with ether. After drying with magnesium sulfate, the ether solution was concentrated and the residue distilled at reduced pressure. A liquid (13.5 g.) boiling at 146°(29)–145° (21 mm.) was obtained. This gave an aryloxyacetic acid that was identical with the one already described.

The rearrangement of γ-ethylallyl phenyl ether (III) led to a product which is identical with that produced by the rearrangement of α,γ-dimethylallyl phenyl ether (VII).



VII

The structures of these isomeric ethers were also established by means of oxidation; VII yielded α-phenoxypropionic acid whereas III gave phenoxyacetic acid. That the rearrangement products of these isomeric ethers are identical is shown by the fact that they gave identical phenylurethans. Structure IV is assigned to this rearrangement product. The transformations outlined in the following diagram will make the reason for this choice clear.

The alternative structure XIII leads to IXa and XIIa, compounds differing in composition from IX and XII.

The rearrangement of γ-ethylallyl phenyl ether (III) was carried out in a small flask fitted with an air condenser. Eight and eight-tenths grams of the ether and one-half its weight of diethylaniline were heated to the boiling point in an atmosphere of carbon dioxide. The temperature rose from 220 to 235° in a period of one and three-quarter hours, after which no further increase of the boiling temperature was noted. After cooling the reaction mixture was taken up in petroleum ether and ether, the solution extracted twice with dilute sulfuric acid to remove the diethylaniline, then three times with 20% sodium hydroxide to remove the phenol. The alkaline solution was acidified with hydrochloric acid and extracted with ether. The ether solution, after drying over magnesium sulfate, was concentrated on the steam-bath and the residual oil distilled at reduced pressure; b. p. 125–127° (16 mm.); d^{20}_{20} 0.9915; yield 7.8 g. (88%).

The phenylurethan, recrystallized three times from petroleum ether and twice from dilute methyl alcohol, melted at 108.5–109.5°.

Anal. Calcd. for $C_{18}H_{19}O_2N$: C, 76.85; H, 6.81. Found: C, 76.80; H, 6.66.

The aryloxyacetic acid (VIII), crystallized from a benzene–petroleum ether mixture and twice from dilute methyl alcohol, melted at 128–130°.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.87; H, 7.33. Found: C, 70.84; H, 7.44.

Oxidation of the Aryloxyacetic Acid (VIII ⟶ IX).—One gram of the aryloxyacetic acid was dissolved in 50 cc. of water containing enough acetone to form a homogeneous solution. To it was added, dropwise and with shaking, a solution of 2.7 g. of potassium permanganate in 100 cc. of water. It was necessary to cool the reaction mixture during the reaction. After standing overnight, the reaction mixture was filtered. The filtrate acidified with dilute sulfuric acid, was extracted with ether. The ether solution, dried over magnesium sulfate, was evaporated slowly. The residual oil was dissolved in benzene and crystallized from this solvent, m. p. 170–171°.

Anal. Calcd. for $C_{12}H_{14}O_5$(IXa): C, 60.5; H, 5.88. Calcd. for $C_{11}H_{12}O_5$(IX): C, 58.9; H, 5.38. Found: C, 59.02; H, 5.39.

Methylation of the Rearrangement Product (IV ⟶ X).—This conversion was brought about by means of (a) methyl iodide and sodium methoxide or (b) dimethyl sulfate. A typical experiment using methyl iodide will be described. To a cooled solution of sodium methoxide prepared in a 200-cc. round-bottomed flask from 0.96 g. of sodium and 30 cc. of methanol there was added 6.8 g. of the *o*-(α,γ-dimethylallyl)-phenol, IV, followed by 5.95 g. of methyl iodide. The reaction mixture was heated for four hours on the steam-bath and then allowed to stand overnight. The alcohol was removed by distillation. Enough water was added to dissolve the sodium iodide, and the oily layer was extracted with ether. The ethereal solution, after washing with dilute sodium hydroxide and drying over anhydrous sodium sulfate, was concentrated on the steam-bath. The residual oil was distilled at reduced pressure collecting the fraction boiling at 134–137° (35 mm.); practically all of it distilled in the range 135–136° (35 mm.) and almost no residue was left; yield 6.5 g. (88%); d^{20}_{20} 0.9633.

Ozonolysis of *o*-(α,γ-Dimethylallyl)-anisole (X).—Two different procedures were used. (a) The anisole (6.2 g.) was dissolved in 50 cc. of ethyl bromide and ozonized by passing a stream of ozonized oxygen (7.5% by weight of ozone) at the rate of 10.6 liters per hour, through the solution in a suitable absorption bottle immersed in an ice–salt mixture. After two and one-half hours (65% excess) the ozonization was discontinued and the solution allowed to stand overnight.

Decomposition was accomplished in a manner similar to that used by Whitmore.[6] The apparatus consisted of a 100-cc. separatory funnel attached by a rubber stopper to a small Claisen flask which contained 60 cc. of water, 2.3 g. of zinc dust, a trace of silver from silver nitrate and a few milligrams of hydroquinone. The distilling flask was attached to a condenser connected by an adapter to a suction flask which, in turn, was connected to a tube reaching to the bottom of a 50-cc. distilling flask containing 45 cc. of methone reagent. The solution of the ozonide was transferred to the separatory funnel and the ethyl bromide was removed as completely as possible by applying suction. A viscous yellow oil remained, which was dropped into the boiling water contained in the distilling flask. Slow distillation took place and a white precipitate appeared in the methone reagent. After all of the ozonide had been added, water was slowly dropped in while the distillation continued until about 75 cc. of distillate had been collected.

There separated, as the bottom layer of the distillate, an oil weighing 2.9 g. This was treated with semicarbazide hydrochloride in the usual way. After twenty-four hours the precipitate was filtered off, crystallized twice from 95% ethyl alcohol and once from 60% alcohol as white needles of m. p. 162.2–162.6°.

Anal. Calcd. for $C_{11}H_{15}O_2N_3$: C, 59.70; H, 6.84. $C_{12}H_{17}O_2N_3$: C, 61.28; H, 7.23. Found: C, 59.91, 60.19; H, 6.79, 6.85.

A mixed melting point with *o*-methoxypropiophenone semicarbazone (m. p. 154–156°) gave a lowering of 25°.

The semicarbazone isolated as a product of ozonolysis was heated on the steam-bath with a small amount of aqueous oxalic acid. The droplet of oil which separated after a few minutes, was washed by decantation with water. It was then treated with 2,4-dinitrophenylhydrazine according to the directions of Allen.[8] The precipitate, after crystallizing from 95% alcohol, melted at 123–125°.

Anal. Calcd. for $C_{16}H_{16}O_5N_4$: C, 55.79; H, 4.69. $C_{17}H_{18}O_5N_4$: C, 56.96; H, 5.07. Found: C, 55.9; H, 4.80.

The distillate was treated with methone solution after separation of the above-mentioned oil. The ether extract left an oil which partially crystallized on standing. The crystals, washed once with cold alcohol, melted at 184–186°. Mixed melting point with formaldimethone showed no depression. The solution in the methone trap after decomposition of the ozonide was filtered. The precipitate melted at 136–137.5°. When mixed with a sample of acetaldimethone of m. p. 139–140°, the melting point was 137–139°.

Decomposition of the ozonide therefore furnished evidence of the formation of formaldehyde, acetaldehyde and a carbonyl compound of composition $C_{10}H_{12}O_2$. The occurrence of formaldehyde along with acetaldehyde is perhaps indicative of deep-seated changes.[9]

(b) The procedure similar to that of Hahn and Wassmuth[10] was also used. The anisole (4.8 g.) was dissolved in 60 cc. of ethyl acetate and the ozonolysis was carried out at a temperature of −10 to −15° using a mixture of air and oxygen containing 1.4% ozone by weight. A 25% excess of ozone was used. After standing overnight, the ozonide solution was subjected to catalytic hydrogenation using 0.2 g. of a 5% palladium–calcium carbonate catalyst which had been reduced in 20 cc. of ethyl acetate. After no further pressure drop, it was assumed that the reduction of the ozonide had been accomplished, and the catalyst was removed by filtration. Water was then added and the ethyl acetate was removed under reduced pressure. Since we were not successful in obtaining satisfactory aldehyde derivatives at this stage, the small amount of oil which separated out was brought into solution with acetone and the solution was subjected to oxidation by the addition of an acetone solution of potassium permanganate. The precipitated manganese dioxide was separated by filtration, the filtrate concentrated to a volume of 15 cc., cooled, acidified with hydrochloric acid and extracted with ether. The ether extract yielded an oil which solidified on cooling. After crystallization with the addition of norite it melted at 100–101°.

Anal. Calcd. for $C_{10}H_{12}O_3$ (XII): C, 66.6; H, 6.72; OCH_3, 17.2. $C_{11}H_{14}O_3$ (XIIa): C, 68.0; H, 7.27; OCH_3, 16.0. Found: C, 66.7; H, 6.71; OCH_3, 17.45.

α,γ-Dimethylallyl phenyl ether (VII) was prepared in accordance with the directions of Claisen.[11] The structure of this compound was established by oxidation as follows. A 2-g. sample was dissolved in a small amount of aqueous acetone and to the solution was added a saturated potassium permanganate solution in 2% excess. The reaction mixture was cooled during the addition. After standing overnight, the manganese dioxide was filtered off and washed with water and acetone. The alkaline filtrate

(10) Hahn and Wassmuth, *Ber.*, **67**, 696 (1934).

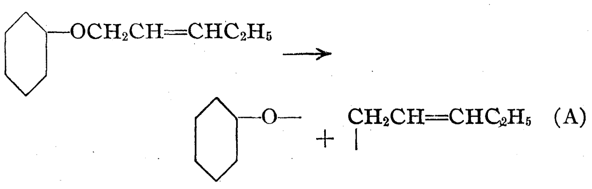
(11) L. Claisen *et al.*, *Z. angew. Chem.*, **36**, 478 (1923); *Ann.*, **442**, 210 (1925).

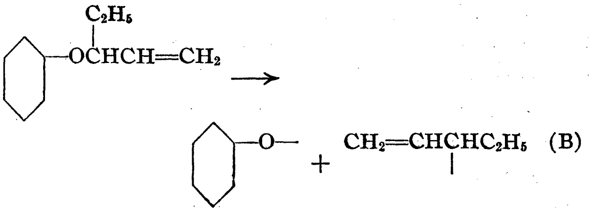
was concentrated to about 25 cc., cooled, extracted with ether, acidified with dilute sulfuric acid and allowed to stand. The solid obtained in this way was crystallized twice from water containing about 5% alcohol, using decolorizing carbon; m. p. 113–114°; yield 0.5 g. A sample of α-phenoxypropionic acid prepared from α-bromopropionic ester and sodium phenoxide according to the directions of Bischoff[4] melted at 114–115°. (Bischoff gives 115–116°, Saarbach 112–113°.) A mixed melting point with the acid obtained by the oxidation of the ether showed no depression.

The rearrangement of this ether was carried out by boiling in diethylaniline in an atmosphere of carbon dioxide. The product (28% yield) boiled at 141–145° at 31 mm.

The phenylurethan of the rearrangement product was crystallized from petroleum ether, dilute methyl alcohol, petroleum ether and finally from dilute methyl alcohol, as colorless needles melting at 107–108.5° (Claisen gives 107–109°). The mixed melting point with the urethan of the phenol obtained by rearranging γ-ethylallyl phenyl ether was 108–109.5°.

The relation of the present results to the mechanism of the phenyl allyl ether rearrangement is not clear. It is evident, however, that the widely held formulation of Claisen must be modified. The view that rearrangement is preceded by dissociation





to yield fragments A and B, one of which isomerizes to the other before combination with  or its benzenoid isomer, leads to the prediction that the two isomeric ethers should give the same rearrangement product. The results of the present study, designed to test this hypothesis, are not in agreement with this prediction. Further work which is in progress has as its aim the accumulation of pertinent facts.

Summary

The three isomeric ethers, α-ethylallyl phenyl ether, γ-ethylallyl phenyl ether and α,γ-dimethylallyl phenyl ether have been rearranged and the structures of their rearrangement products were investigated. The first and third-named ethers rearrange in accordance with the pattern outlined by Claisen, but γ-ethylallyl phenyl ether does not, since it yields a rearrangement product identical with that obtained from α,γ-dimethylallyl phenyl ether.

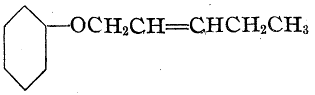
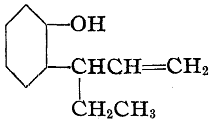
The Rearrangement of Phenyl Allyl Ethers. II. Phenyl Crotyl Ether

BY WALTER M. LAUER AND HERBERT E. UNGNADE

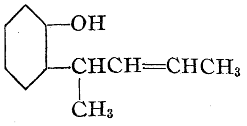
A recent study[1] of γ-ethylallyl phenyl ether (I) led to the conclusion that its rearrangement product was not the expected o-(α-ethylallyl)-phenol (II) but o-(α,γ-dimethylallyl)-phenol (III)



I



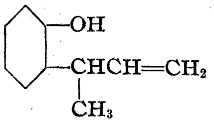
II



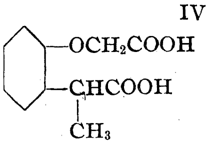
III

The present study was carried out in order to obtain further evidence for the structure assigned to this rearrangement product.

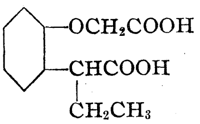
According to Claisen and Tietze[2] phenyl crotyl ether, $C_6H_5O—CH_2—CH=CHCH_3$, when rearranged by heat yields o-(α-methylallyl)-phenol (IV).



IV



V



VI

---

[1] Lauer and Filbert, THIS JOURNAL, **58**, 1388 (1936).

[2] Claisen and Tietze, *Ber.*, **59**, 2344 (1926).

Consequently, oxidation of the aryloxyacetic acid derived from the rearrangement product of phenyl crotyl ether should yield the dibasic acid V. Such a series of transformations has already been described for the rearrangement product of γ-ethylallyl phenyl ether (I) and on the basis of its composition it was concluded that the structure of the dibasic acid was V rather than VI. The present work describes the rearrangement of phenyl crotyl ether and the conversion of its rearrangement product to the dibasic acid and demonstrates the fact that it is identical with the one previously obtained. This supplies additional evidence that III rather than II represents the correct structure for the rearrangement product of γ-ethylallyl phenyl ether.

The work of Claisen and Tietze[2] has shown that direct alkenylation of phenol with crotyl bromide leads to a product differing from that obtained by the indirect method which involves ether formation with subsequent rearrangement. The formation of the dibasic acid V here described incidentally furnishes independent confirmatory evidence pointing to IV, the accepted structure of the rearrangement product of phenyl crotyl ether.

Experimental

Methylvinylcarbinol was prepared by the action of methylmagnesium iodide on acrolein.

Crotyl bromide was obtained from methylvinylcarbinol by treatment with 45% hydrobromic acid according to the procedure of Claisen.[2,3] The directions of Claisen were followed for the preparation and rearrangement of *phenyl crotyl ether*. The rearrangement product was converted to the phenylurethan which melted at 88.5–89° (Claisen gives 89.5–90.5° as the melting point of this compound). The phenylurethan of the rearrangement product was analyzed.

Anal. Calcd. for $C_{17}H_{17}O_2N$: C, 76.38; H, 6.40. Found: C, 76.29; H, 6.45.

Oxidation of Phenyl Crotyl Ether.—Phenyl crotyl ether (1.2 g.) was dissolved in aqueous acetone. A concentrated aqueous solution containing 3.2 g. of potassium permanganate was added and the mixture allowed to stand overnight. The manganese dioxide was filtered off and the filtrate was then acidified with dilute sulfuric acid. The solution was concentrated to one-half its original volume and then subjected to extraction with ether. The ether extract was washed with water and then extracted with 5% sodium carbonate. Acidification of the carbonate solution followed by cooling yielded 0.32 g. of *phenoxyacetic* acid. The melting point and mixed melting point with an authentic sample of phenoxyacetic acid was 97–98°.

The aryloxyacetic acid of the rearrangement product was prepared in accordance with the method of Koelsch.[4] One gram of the *o*-(α-methylallyl)-phenol (IV) was mixed with 3.5 cc. of 33% sodium hydroxide. To this mixture 2.5 cc. of 50% monochloroacetic acid was added slowly with shaking. After heating in a test-tube on the steam-bath for one hour, the solution was acidified with dilute sulfuric acid. The mixture was then extracted with ether and the ether extract washed with water. The product was then extracted with dilute sodium carbonate and after acidification was crystallized from water; m. p. 120–120.5°.

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.87; H, 6.84. Found: C, 69.66; H, 6.74.

Oxidation of *o*-(α-Methylallyl)-phenoxyacetic Acid.—The oxidation was accomplished by dissolving the *o*-(α-methylallyl)-phenoxyacetic acid (1.033 g.) in 50 cc. of water containing sufficient acetone to form a homogeneous solution. Potassium permanganate (2.7 g. in 100 cc. water, *ca.* 8% excess) was added dropwise to the cooled solution and the reaction mixture allowed to stand overnight. After filtration, the filtrate was acidified with dilute sulfuric acid and extracted with one 50-cc. and two 25-cc. portions of ether. The combined ether extracts were dried over magnesium sulfate and then allowed to evaporate spontaneously. The residual oil insoluble in petroleum ether did not solidify at −15°. The oil, dissolved in benzene, was heated on the steam-bath for several hours. After standing overnight, the white crystalline product was collected; m. p. 170–171°; mixed with a sample of the product obtained[1] by the oxidation of *o*-(α,γ-dimethylallyl)-phenoxyacetic acid it melted at 170–171°.

Anal. Calcd. for $C_{11}H_{12}O_5$: C, 58.90; H, 5.40. Found: C, 59.16; H, 5.56.

Summary

Evidence is presented which confirms *o*-(α,γ-dimethylallyl)-phenol and *o*-(α-methylallyl)-phenol as the structures of the rearrangement products of γ-ethylallyl phenyl ether and γ-methylallyl phenyl ether, respectively.

Sugar Alcohols. V. Chemical Constitution and Sweet Taste[1]

BY C. JELLEFF CARR, FRANCES F. BECK AND JOHN C. KRANTZ, JR.

The relationship between chemical constitution and sweet taste has not been elucidated satisfactorily. In a series of investigations[2-5] on the metabolism of sugar alcohols and their anhydrides a large number of these substances were prepared and the authors decided to study the relationship between their chemical constitution and sweet taste. The relative sweet tastes of the simple sugars have been investigated repeatedly, although comparative studies of the sugar alcohols and their anhydrides have not been reported. McGuigan[6] suggests a relationship between intensity of sweet taste and the number of hydroxyl groups in the molecule. This series affords an excellent opportunity to test this hypothesis. In addition, the response of animals and microorganisms to the sugar alcohols is so strikingly different from their response to their anhydrides that this investigation was initiated.

Experimental

Substances of C. P. quality were employed. The mannitol and sorbitol were supplied by the Atlas Powder Co. of Wilmington, Del. The anhydrides were prepared in this Laboratory and their purity and identity established as has been described previously.[2-5,7]

The polygalitol was extracted from *Polygala Amara* by the method of Picard[8] and occurred as colorless crystals, m. p. 142°; $[\alpha]^{16}_{D} + 47.5$. All of the substances were dried in a desiccator for a period of several months and the threshold quantities represent anhydrous material.

Six carefully standardized individuals were used for the determinations and not more than three or four substances were tested on any one day. The threshold quantity of sucrose was determined before each test. After rinsing the mouth with water, 5 cc. of the standard solution was placed on the tongue which was brought in contact with the roof of the mouth and the sensation noted within half a minute. The minimal concentration just producing a sweet taste within one-half to one minute was considered the threshold quantity. Freshly distilled water was used in preparing all solutions. The average of the results for the sugar alcohols is shown in Table I and is compared with sucrose as a standard.

TABLE I

RELATIVE SWEETNESS OF THE SUGAR ALCOHOLS, SUCROSE TAKEN AS 100

Product	Carbon atoms number	OH groups number	Mol. wt.	Ratio
Sucrose	..	..	...	100
Ethylene glycol	2	2	62	130
Glycerol	3	3	92	108
i-Erythritol	4	4	122	238
Pentaerythritol	5	4	136	110
l-Arabitol	5	5	152	100
d-Mannitol	6	6	182	57
d,l-Sorbitol	6	6	182	54
i-Dulcitol	6	6	182	74
Inositol	6	6	180	50

Discussion

The results show no significant relationship between the number of carbon atoms or hydroxyl groups in the molecule and sweet taste. The anhydrides of several of these sugar alcohols, namely, ethylene oxide, epihydrin alcohol, mannitan, mannide, isomannide and dulcitan were devoid of a sweet taste and in most instances exhibited a decidedly bitter taste. It is of interest that these sugar alcohols are metabolized and produce gas with many members of the colon aerogenes group and their anhydrides do not.

Erythritan and polygalitol are the 1,4- and 1,5-anhydrides, respectively, of erythritol and mannitol. These substances possess a sweet taste and polygalitol produces gas and acid with many members of the colon aerogenes group of organisms.

There appears to be no relationship between spatial structure and sweet or bitter taste in this class of compounds. While α- and β-glucose have exactly the same degree of sweetness (ratio of 75), the derivatives of β-glucose are reported to be

uniformly more bitter than those of α-glucose.[9] The isomeric substances mannitol, sorbitol and dulcitol have approximately the same degree of sweetness while the two anhydrides mannide and isomannide are also of about the same degree of bitterness.

Summary

1. The removal of water from a sugar alcohol with the formation of the anhydride as a rule destroys the sweet taste of the former.

2. Erythritan, the first anhydride of erythritol, possesses a bitter taste in high concentrations but a sweet taste in threshold quantities.

3. Polygalitol, the 1,5-anhydride of mannitol, possesses a sweet taste in high concentration and an astringency in high dilution.

4. No relationship between the number of carbon atoms or hydroxyl groups in the molecule or the molecular weight or spatial configuration and sweet taste has been observed in this class of compounds.

Some Derivatives of 1,3-Diketohydrindene

BY W. H. HUNTER AND E. C. YACKEL[1]

Degradation of 2-acyl-1,3-diketohydrindenes by hydrolysis cannot be carried out successfully, and although these substances are converted by oxidation into a monocarboxylic acid and phthalic acid, the reaction does not always proceed smoothly. In connection with studies on the nitration of acyl diketohydrindenes we have found that bromination in acetic acid offers a superior method of degradation, the triketone being cleaved into 2,2-dibromo-1,3-diketohydrindene and a monocarboxylic acid. For example, 2-benzoyl-1,3-diketohydrindene yields dibromodiketohydrindene and benzoic acid. It is noteworthy that this cleavage, otherwise quite similar to the haloform reaction,[2] takes place in the absence of alkalies.

By means of this reaction it has been found that the nitration of 2-benzoyl-1,3-diketohydrindene yields 2-*m*-nitrobenzoyl-1,3-diketohydrindene, since bromination of the product yields dibromodiketohydrindene and *m*-nitrobenzoic acid.

Although the products obtained are too unstable to withstand the hydrolyzing action of the nitrating mixture, it is noteworthy that the O-acetate of 2-carbethoxy-1,3-diketohydrindene may be obtained by the action of acetyl chloride on either the sodium or the silver salt of the diketo ester, while the O-benzoate may be obtained only from benzoyl chloride and the silver salt.[3] The use of the sodium salt in the latter instance gives rise to an as yet unidentified substance, which is not the isomeric C-benzoate.

Experimental

Cleavage of 2-Benzoyl-1,3-diketohydrindene.—A solution of the triketone[4] (3 g.) and bromine (6 g.) in acetic acid (60 ml.) is warmed on a water-bath for two hours. After the bromine color has disappeared the mixture is cooled and diluted. The crystalline product separating melts at 178–179° and is 2,2-dibromo-1,3-diketohydrindene.[5]

Anal. Calcd. for $C_9H_4O_2Br_2$: Br, 52.7. Found: Br, 52.3, 52.7.

Evaporation of the mother liquor yields benzoic acid, purified by sublimation and identified by nitration.

Nitration of 2-Benzoyl-1,3-diketohydrindene.—The triketone (5 g.) is dissolved in sulfuric acid (40 ml.) at −5°, and treated at this temperature with a mixture of fuming nitric acid (1.5 g.) in sulfuric acid. After thirty minutes the solution is poured onto ice. The solid is washed with water and with much hot alcohol and crystallized from chloroform. The product forms microscopic needles that melt with decomposition at 228–229°; yield 70%.

Anal. Calcd. for $C_{16}H_9O_5N$: N, 4.74. Found: N, 4.73, 4.65.

On bromination in acetic acid, the nitrotriketone yields dibromodiketohydrindene and *m*-nitrobenzoic acid, identified by mixed melting points.

Acetylation of Ethyl 1,3-Diketohydrindene-2-carboxylate.—The sodium salt of the diketo ester[6] may be purified by crystallization from water with the aid of charcoal, and

freed of water of hydration by drying at 170° for three hours. The silver salt, obtained by treatment of the sodium salt in aqueous solution with silver nitrate, separates directly without water of crystallization.

The reaction between the sodium salt (10 g.) and acetyl chloride (50 ml.) is completed by boiling the mixture for one hour. The sodium chloride is filtered off, the acetyl chloride is evaporated, and the residue (3.4 g.) is crystallized from ether. Similar treatment of the silver salt yields the same compound (mixed melting point) which forms yellow needles that melt at 77–78°.

Anal. Calcd. for $C_{14}H_{12}O_5$: C, 64.6; H, 4.6. Found: C, 64.7; H, 4.8.

Ethyl 3-acetoxyindone-2-carboxylate is readily hydrolyzed, even on exposure to atmospheric moisture, to 1,3-diketohydrindene.

Benzoylation of Ethyl 1,3-Diketohydrindene-2-carboxylate.—The reaction of the silver salt of the diketo ester with benzoyl chloride in benzene is completed by warming for one hour, and the product is crystallized from benzene and ether. In agreement with the description of Hantzsch and Gajewski,[3] the benzoate forms yellow crystals that melt at 146–148°.

The sodium salt of the diketo ester does not react with benzoyl chloride in boiling benzene. However, if the sodium salt (54 g.) is stirred with benzoyl chloride (60 g.) at 80° for five hours, a reaction takes place. Separated from the sodium chloride with ether and crystallized from benzene, the organic product forms large yellow prisms that melt at 140–141°.

Anal. Calcd. for $C_{14}H_{10}O_4$: C, 69.3; H, 4.1. Found: C, 69.4; H, 4.4.

The substance depresses the melting point of the benzoate. Treated with sodium ethoxide in alcohol it gives a red solution which becomes yellow on acidification. Benzoic acid may be sublimed from the tarry residue obtained by evaporating this solution.

Summary

Bromination is suggested as a method for cleaving 2-acyl derivatives of 1,3-diketohydrindene. Some reactions of 2-benzoyl diketohydrindene and of ethyl 1,3-diketohydrindene-2-carboxylate are described.

Deuterium Exchange Equilibria in Solution and the Quinhydrone Electrode[1]

BY SAMUEL KORMAN AND VICTOR K. LA MER

Introduction

For the elucidation of the isotopic influence of deuterium upon various phenomena in heavy water (deuterium oxide), it is important to know with some degree of precision the magnitude of the equilibrium constants of the exchange processes set up between the protons and deutons in the solvent and solute molecules. For example, the interpretation of acid and base catalysis in D_2O–H_2O mixtures requires a knowledge of the distribution of deuterium and protium between the various substrate, catalyst (*e. g.*, H_3O^+ and D_3O^+) and solvent molecules.[2]

The measurement of the e. m. f. of galvanic cells involving D_2O furnishes a precise means of determining these exchange constants. To exclude the experimental complications and the theoretical uncertainties inherent in galvanic cells with liquid junction potentials, we have restricted our investigation to cells without transference. The experimental difficulties attendant upon the use of the deuterium gas electrode with small quantities of solution make an appropriate substitute highly desirable.

We have found that the quinhydrone electrode[3] establishes equilibrium quickly and is particularly well adapted for the micro technique necessary for heavy water studies. To this end, the following cells were investigated

(I) Pt, $Q\cdot QH_2/HCl\ (0.01\ M)$ in $H_2O/AgCl$, Ag

(II) Pt, $\{Q\cdot QH_2 + Q\cdot QD_2\}/HCl\text{-}DCl\ (0.01\ M)$ in $H_2O\text{-}D_2O/AgCl$, Ag

(III) Pt, $Q\cdot QH_2/\{HA(m_1) + NaA(m_2) + NaCl(m_3)\}$ in $H_2O/AgCl$, Ag

(IV) Pt, $Q\cdot QD_2/\{DA(m_1) + NaA(m_2) + NaCl(m_3)\}$ in $D_2O/AgCl$, Ag

where $Q\cdot QH_2$ and $Q\cdot QD_2$ represent light and heavy quinhydrone, and HA and DA are the light and heavy varieties of a weak acid.

For (I) and (II) the cell reactions may be written

(A) $2HCl\ (0.01\ M) + Q(H_2O) + 2Ag(s) = 2AgCl(s) + QH_2(H_2O);\ E_H$

(B) $2DCl\ (0.01\ M) + Q(D_2O) + 2Ag(s) = 2AgCl(s) + QD_2(D_2O);\ E_D$

---

(2) Hamill and La Mer, *J. Chem. Phys.*, **4**, 294 (1936); **4**, 395 (1936); Urey and Teal, *Rev. Modern Phys.*, **7**, 34 (1935). For a discussion of the importance of exchange reactions see pp. 52, 59, 60.

(3) La Mer and Korman, THIS JOURNAL, **57**, 1510 (1935).

Subtracting (A) from (B)

$$\text{(C)}\quad 2DCl\ (0.01\ M) + QH_2(H_2O) + Q(D_2O) = 2HCl\ (0.01\ M) + QD_2(D_2O) + Q(H_2O);\ (E_D - E_H)$$

Measurements of the solubility of quinone in light and heavy water given below, permit (C) to be rewritten as

$$\text{(D)}\quad 2DCl\ (0.01\ M) + QH_2(H_2O) = 2HCl\ (0.01\ M) + QD_2(D_2O);\ (E_D - E_H)$$

Then

$$\text{(1)}\quad (E_D - E_H) = \frac{RT}{2F}\ln K,\ \text{where}\ K = \frac{(QD_2)\ (HCl)^2}{(QH_2)\ (DCl)^2}$$

From this fundamental exchange constant, by appropriate combination with values obtained from other sources, a number of important exchange equilibrium constants will be derived.

Furthermore, the data on cells (III) and (IV) can be used to obtain the ratio of dissociation constants of weak acids following the method of Harned and co-workers[4] who used the hydrogen electrode. To maintain precision using a micro method, we again substitute the quinhydrone electrode for the gas electrode. The cell reaction then becomes

$$\text{(E)}\quad 2AgCl(s) + QH_2 + 2NaA(m_2) = 2Ag(s) + 2HA(m_1) + 2NaCl(m_3) + Q$$

for which

$$\text{(2)}\quad E - E_0 = -(RT/F)\ \text{in}\ f_H f_{Cl} m_H m_{Cl}$$

where E_0 is the normal electrode potential of cell (I). Since

$$K_{HA} = f_H f_A m_H m_A / f_{HA} m_{HA}$$

we substitute for m_H in equation (2) and rewrite the expression

$$\text{(3)}\quad E - E_0 + \frac{RT}{F}\ln\frac{m_{HA}m_{Cl}}{m_A} = -\frac{RT}{F}\ln\frac{f_H f_{Cl} f_{HA}}{f_H f_A} - \frac{RT}{F}\ln K_{HA}$$

and a similar expression involving D_2O, QD_2, etc., for the deutero acid. The logarithm of the ratio of the activity coefficient products is zero at infinite dilution and varies but little from zero at low ionic strengths. The extrapolation of the right side of equation (3) plotted against ionic strength is linear at temperatures over 15° for ordinary water.[4] Since the dielectric constants of H_2O and D_2O are almost identical,[5] the same extrapolation will be valid in heavy water. Thus the values of K_{HA} and K_{DA} may differ, but their ratio will certainly remain constant to a very good approximation in the dilute range ($\sim \mu = 0.05$). We thus have a method for obtaining the ratios of dissociation constants of weak acids in heavy and light water, which have proved to be valuable in the interpretation of acid catalyzed reactions in heavy water.[2]

Experimental

Materials.—Quinhydrone,[6] constant boiling hydrochloric acid solution,[7] heavy water[8] and silver oxide[9] were prepared according to directions given previously. Acetic anhydride was purified by fractional distillation, while sodium acetate, sodium salicylate and sodium chloride were recrystallized from conductivity water. Salicylic acid was recrystallized from chloroform. Quinone was resublimed twice.

Apparatus.—The micro cell has been described by La Mer and Armbruster.[6] Their preliminary measurements established the reliability of the method as applied to the silver chloride electrode in heavy water, where the quantities of solution available for rinsing are severely limited. The vacuum technique for removing oxygen from the final cell solution, for rinsing the silver chloride electrodes. and for filling the cell, follows closely the method given by Harned and Wright.[10] The cell shown in Fig. 1 was of 4-cc. capacity. Space is provided for duplicate electrodes of each kind, and stopcocks arranged to separate the compartments for rinsing of the silver chloride electrodes.

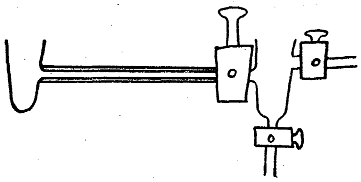

Fig. 1.—Diagram of cell.

Electrodes.—Reproducible quinhydrone electrodes were prepared by immersing several platinum spiral wires, carefully sealed in separate glass tubes filled with mercury contacts, in 0.01 *N* hydrochloric acid solution saturated with quinhydrone, and "short circuiting" them together for about a half hour.[11] They then agreed to within 0.03 millivolt. The electrodes were kept in cleaning solution[12] until another pair was required, whereupon they were rinsed thoroughly with distilled water.

The silver–silver chloride electrodes were the Type 2 described by Harned.[13] Several electrodes made simultaneously were washed repeatedly with distilled water, immersed in 0.01 *N* hydrochloric acid solution, and "shorted" together for twenty-four to thirty hours. They agreed to within 0.05 millivolt. The electrodes so prepared were protected against light.

[13] Harned, *ibid.*, **51**, 416 (1929); Güntelberg, *Z. physik. Chem.*, **123**, 199 (1926).

Preparation of Cell Solutions.—The limiting factor in the precision of the measurements is the accuracy with which the composition of the cell solution is known. In the preparation of the buffer solutions, the equivalent amounts of sodium chloride and the sodium salt of the weak acid were transferred from weighing bottles to a 50-cc. ground glass-stoppered flask containing the water sample.[14] The final concentration of the cell solution was corrected for the water lost in the evacuation process.

Characteristics of the Micro Cell.—Equilibrium was attained within from twenty to forty-five minutes at 25°, and was maintained to within 0.05 millivolt for two to four hours, followed by a slow drift to higher values, due probably to the formation of chlorohydroquinone. There is a definite lag in attainment of equilibrium when the temperature is raised, while equilibrium is reached almost immediately in proceeding from a higher to a lower temperature.

Results and Precision of the Measurements

Hydrochloric Acid Solutions.—E (0.01) in Table I is calculated on the basis of mols/55.3 mols D_2O-H_2O. Figure 2 is E (0.01) plotted against $N_{D_2O} = 9.377\ \Delta S - 1.01\ (\Delta S)^2$, where ΔS is the excess specific gravity of the solvent over ordinary water. The fourth column gives the average deviation from the mean, and the fifth column gives the precision measure for each experiment. This takes into account the deviation of the mean, the weighing error and the difference in electrodes. It will be seen that the average δ for this set of results does not exceed 0.06 millivolt, while the average deviation does not exceed 0.03 millivolt, a result which is about twice as precise as has been obtained with the hydrogen gas electrode, and ten times as precise as has been obtained with the deuterium gas electrode.[15] The precision with the weak acid solutions is about the same, and corresponds to that reported by Harned and Ehlers.[4]

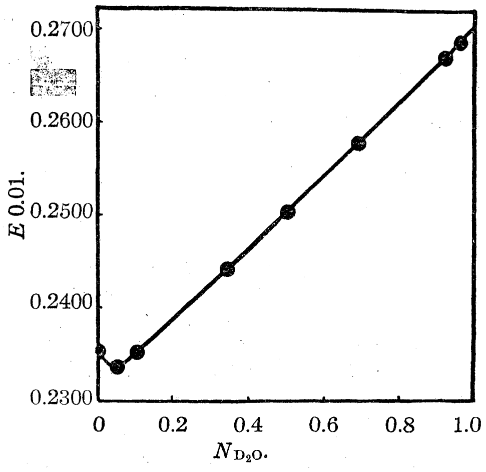

Fig. 2.—Quinhydrone electrode in heavy water.

[a] The results, for N_{D_2O} = 0.1030, were obtained in 1934 by Dr. M. H. Armbruster in a preliminary investigation.

The curve in Fig. 2 has an unexpected but definite minimum at N_{D_2O} = 0.05, corresponding qualitatively to the flat minimum at N_{D_2O} = 0.6 for the cell $Pt,H_2\text{-}D_2/HCl\text{-}DCl$ in $H_2O\text{-}D_2O/AgCl,Ag$, studied by Abel, Bratu and Redlich.[15] These data appeared during the progress of our investigation. No discussion or claim was given concerning the presence of a minimum in the curve for the gas electrode. The experimental difficulties inherent in the deuterium gas electrode prevented these authors from obtaining the precision which we have obtained with the quinhydrone electrode. They mention, however, that as a result of the large value of the constant for the exchange reaction (No. V, Table II below), the concentration of deuterium gas at the electrode was greater than they had supposed at the time the measurements were made. It is likely that their data for mixtures of H_2O and D_2O represent steady state values rather than true equilibrium values with the bulk of the solution since the exchange reaction occurs only on the platinum black at the surface of the electrode. This surface equilibrum will determine the e. m. f., but the e. m. f. will be disturbed depending upon the rate of convection and diffusion of acid and water from the bulk of the solution in H_2O-D_2O mix-

---

XI	$D^+ + OD^- + H_2O = H^+ + OH^- + D_2O$	.0233	6.13	$^1/_2$(VII + IV)

tures. The deuterium content of the gas phase was always greater than that determined by the exchange equilibrium set up on the surface of the electrode between the gaseous H_2–D_2 mixture and the HCl–DCl and the H_2O–D_2O. Since an excess of hydrogen in the cell solution occurred in all the intermediate mixtures which were used, Abel, Bratu and Redlich's measurements can be considered only as indicative of the presence and position of a minimum. Their value for pure D_2O and the pure deuterium gas electrode obtained by short extrapolation, however, should not be affected appreciably by any disturbance of the equilibrium mixtures.

The substitution of the quinhydrone electrode results not only in greater precision, but in contrast to the two-phase gas electrode, the exchange equilibria in cell (II), since they occur entirely in the cell solution, are homogeneous. This circumstance establishes our measurements in mixtures as true equilibrium values. Our results show conclusively that the e. m. f. curve of the quinhydrone electrode, when plotted against the D_2O content of the solvent, has a minimum value, which we may reasonably suppose will be true for the analogous deuterium electrode, although the position of the minima will be different.

Exchange Equilibrium Constants

K of equation (I) may now be evaluated, and may be combined with constants derived in a similar way from the data on the deuterium electrode,[15] and from the exchange reaction

$$\text{(F)}\quad QH_2 + D_2O = QD_2 + H_2O$$

studied by Hamill and La Mer.[16] Table II lists the values of the constants obtained in this way.

The value of the constant for No. V is in excellent agreement with the values which have been calculated from other data by use of the following equations[17]

$$\text{(G)}\quad H_2 + D_2 = 2HD;\ K_1 = (HD)^2/(H_2)(D_2) = 3.27$$

$$\text{(H)}\quad H_2O + D_2O = 2HDO;\quad K_2 = (HDO)^2/(H_2O)(D_2O) = 3.27$$

$$\text{(J)}\quad H_2O + HD(g) = HDO(l) + H_2(g);\ K_3'$$

$$\text{(L)}\quad H_2O(l) + D_2(g) = D_2O(l) + H_2(g);\quad K_4' = (D_2O)(H_2)/(H_2O)(D_2) = (K_3')^2K_1/K_2 = (K_3')^2$$

From Table II, $K_4' = 11.8$; therefore our value of $K_3' = (11.8)^{1/2} = 3.44$. The values of K_3' obtained from other sources are as follows.

TABLE III

VALUES OF K_3' AT 25°

K_3'	Catalyst	Observer
3.8	Pt black	Bonhoeffer and Rummel[18] Horiuti and Polanyi[19]
2.95	Pd black	Farkas and Farkas[20]
3.24	B. coli	Farkas, Farkas and Yudkin[21]
3.44	(e. m. f.)	La Mer and Korman
Av. 3.36		

The exchange constants listed in Table II may also be interpreted as ratios of dissociation constants. For example, process VI is the ratio for the dissociation equilibria

$$\text{(M)}\quad QH_2(s) = Q(s) + H_2(g);\quad K_{QH_2}$$

$$\text{(N)}\quad QD_2(s) = Q(s) + D_2(g)\quad K_{QD_2}$$

K_{QH_2} has the value $10^{-23.65}$.[22] Since $K_{QH_2}/K_{QD_2} = 11.26$, then $K_{QD_2} = 10^{-24.70}$. Processes I and XI, Table II, can be treated as ratios of dissociation constants for weak acids. If we assume that the activity of the chloride ion is the same in both

and equals 6.13 at 25°.

Salicylic and Acetic Acid Solutions.—The data for cells (III) and (IV) for salicylic and acetic acids are given in Table IV, with the ratios K_{HA}/K_{DA}. To obtain this ratio for acetic acid at 12.5 and 37.5°, we employ the equation of Harned and Wright[10]

$$(4)\quad E_0 = -0.47745 + (91.02 \times 10^{-6})(\ -25) - (3.008 \times 10^{-6})(t-25)^2$$

In the absence of a similar equation for the corresponding heavy water cell, we have assumed that the coefficients for the temperature terms are the same for both waters. The E_0 values are given in Table IV. Figure 3 shows R log (K_{HAc}/K_{DAc}) plotted against $(1/T)$. The slope of the curve is a measure of the difference $(\Delta H_H - \Delta H_D)$ of the heats of dissociation between proto- and deutero-acetic acids. From these preliminary measurements, there appears to be a maximum in the curve. The indication that this quantity changes sign, as a function of temperature, suggests that the temperature coefficient of the dissociation constant of deutero-acetic acid be subjected to a more detailed investigation to eliminate the assump-

The Solubility of Quinone, Hydroquinone and Deuteroquinone in H_2O and D_2O.—The errors in the determination of solubility in heavy water by ordinary analytical methods, *viz.*, titration, become greatly magnified when the quantity of solvent is severely limited, so it is scarcely feasible when dilution with ordinary water is undesirable. Furthermore, distillation of the solvent and weighing of the residue is not permissible with volatile substances like quinone.

Although the Zeiss interferometer has long been used for the accurate determination of the concentration of dilute solutions encountered in precision cryoscopic work, the capabilities of the instrument apparently have never been exploited for the precise determination of solubility on small samples. We present some illustrative data necessary for the interpretation of the e. m. f. results upon the quinhydrone electrode in heavy water.

The Method.—A Zeiss–Löwe–Haber portable liquid interferometer was employed. The description of this instrument and the principle upon which its use in determining concentrations of binary mixtures is based is given by Adams.[24]

Deuteroquinone was prepared by dissolving an excess of hydroquinone in 92% D_2O and separating by a vacuum distillation. The dry sample was kept in a vacuum desiccator.

About 5 g. of heavy water is weighed into a glass-stoppered 25-cc. flask and a quantity of solute just insufficient for saturation is added. About 0.15 cc. of the solution is sufficient for a reading in the interferometer when a special 10-mm. cell containing a 9-mm. glass block, producing a film of solution 1 mm. thick, is employed. Pure solvent is placed in the comparison chamber. For solutions more colored than saturated benzoquinone, 1 mm. is about the maximum thickness which will pass sufficient light.

If desired the aliquot may be returned to the flask with a micro-pipet. In any case the flask and solution remaining are reweighed, a small but accurately weighed additional quantity of solute dissolved and a new reading made with the interferometer. Finally, when a saturated solution has been produced, a considerable excess of solute is added. The solution is momentarily heated several degrees above 25°, and returned to the thermostat with constant swirling. Aliquots are removed at convenient (ten-minute) intervals, until an almost constant reading with the interferometer is obtained indicating an equilibrium state. The solution is then momentarily cooled below 25° and the procedure is repeated at convenient intervals. The average of the asymptotes of the two converging time–concentration curves is taken as the interferometer reading for the saturated solution. Obviously these observations can be repeated very readily upon the same sample if satisfactory results are not obtained at first.

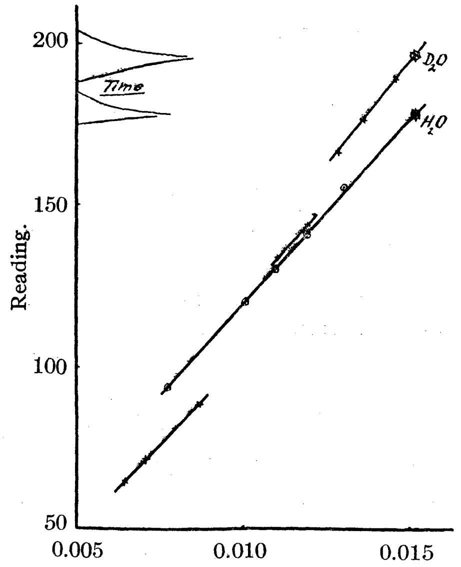

Fig. 4.—Solubility of quinone in H_2O and D_2O.

The tables and figures show that the interferometer readings are linearly proportional to the concentration at least near the saturation point, and that the intersection of the time–concentration asymptotes and the concentration calibration curve yield a value for the concentration of the saturated solution which is precise to about 0.1 mg. per g. of solvent. For a 5-g. sample this

Dissociation Constants of Weak Acids in H_2O–D_2O Mixtures.—The preliminary experiments with acetic and salicylic acids in 91.7% D_2O have established the feasibility of the microtechnique and the quinhydrone electrode in heavy water, as a method for determining dissociation constants of light and heavy acid mixtures. To extrapolate the dissociation constant obtained in H_2O–D_2O mixtures to pure D_2O, we define a constant for weak acid solutions in H_2O–D_2O mixtures by summing the various activities stoichiometrically[25]

$$K_{\text{H,D}} \equiv \frac{[(\text{H}^+) + (\text{D}^+)]\ (\text{A}^-)}{[(\text{HA}) + (\text{DA})]}$$

The fractions of deuterium ion and undissociated deutero-acid are

$$F_{\text{D}^+} \equiv \frac{(\text{D}^+)}{(\text{H}^+) + (\text{D}^+)};\quad F_{\text{DA}} \equiv \frac{(\text{DA})}{(\text{HA}) + (\text{DA})}$$

Then

$$K_{\text{H,D}} = \frac{[(\text{D}^+)/F_{\text{D}^+}]\ (\text{A}^-)}{[(\text{DA})/F_{\text{DA}}]} = K_{\text{DA}}\frac{F_{\text{DA}}}{F_{\text{D}^+}}$$

To evaluate the fractions at various values of $N_{\text{D}_2\text{O}}$, we utilize the constants for the exchange equilibria

$$\text{(S)}\quad \text{HA} + \text{HDO} = \text{DA} + \text{H}_2\text{O};\quad K = \frac{K_{\text{HA}}}{K_{\text{DA}}} \times \frac{1}{7.1}$$

$$\text{(T)}\quad \text{D}^+ + \text{H}_2\text{O} = \text{H}^+ + \text{HDO};\quad K = (15.3 \times 3.27)^{1/2} = 7.1$$

By so doing, we take account of the essential exchanges which must be postulated for H_2O–D_2O, HA–DA mixtures. Then

$$\frac{K_{\text{H,D}}}{K_{\text{HA}}} = \frac{K_{\text{DA}}}{K_{\text{HA}}}\left[\frac{1 + 7.1\,\dfrac{(\text{H}_2\text{O})}{(\text{HDO})}}{1 + 7.1\,\dfrac{K_{\text{DA}}(\text{H}_2\text{O})}{K_{\text{HA}}(\text{HDO})}}\right] \tag{5}$$

The water ratios may be calculated from the equilibrium

$$\text{(U)}\quad \text{H}_2\text{O} + \text{D}_2\text{O} = 2\text{HDO};\quad K = 3.27$$

If, then, we stipulate a value for $K_{\text{HA}}/K_{\text{DA}}$, we may determine the behavior of the constant $K_{\text{H,D}}$ over the range of H_2O–D_2O concentrations. The values for $K_{\text{H,D}}/K_{\text{HA}}$ given in equation (5) are

---

(25) Abel, Bratu and Redlich (ref. 15) have employed a similar definition for the ion product of water in mixtures.

plotted in Fig. 6 as a function of K_{DA}/K_{HA}. It will be noted that the extrapolation is practically linear above 90% D_2O for most ratios. Since measurements must frequently be made in D_2O concentrations less than 100%, a reasonably accurate value for pure D_2O should be obtained by a method of successive approximations. Thus $K_{HA}/K_{H,D} = 2.96$ for acetic acid in 92% D_2O becomes $K_{HA}/K_{DA} = 3.3$ for pure D_2O. Since for most acids so far investigated this ratio lies between 3 and 6, the above method justifies our belief that extrapolations of $K_{H,D}$ from measurements over 90% D_2O are fairly reliable.

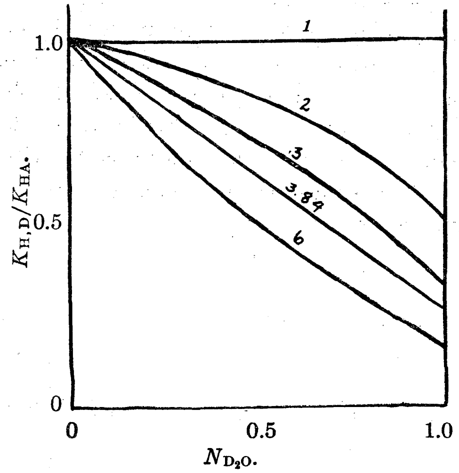

Fig. 6.—Dissociation constant, ratios in H_2O–D_2O mixtures.

Halpern[26] has predicted that K_{HA}/K_{DA}, the ratio of the dissociation constants of a weak acid in pure H_2O and pure D_2O, should increase as K_H decreases. Our studies upon hydroquinone and acetic acid, together with the ratio of the water constants, indicate that this prediction is probably correct. The somewhat anomalous ratio for salicylic acid will serve to indicate that certain conditions must be satisfied before a rigorous comparison of weak acids can be attempted. The constitution of the anion must not be affected by the change of solvent medium for H_2O to D_2O. A complicating factor may be introduced by the exchange of protium and deuterium atoms at points in the acid molecule other than those corresponding to the measured ionization. Thus, the exchange which occurs in the hydroxyl group of the salicylate ion may effectively alter the character of the ion, depending upon the isotopic composition of the medium.

Summary

The free energy changes for a number of important deuterium exchange reactions in aqueous solution have been investigated, using the quinhydrone, silver chloride–silver electrodes and a semi-microtechnique on hydrochloric acid and weak acid buffer systems. The dissociation constants of the weak acids salicylic, acetic, hydroquinone and water in light and 92% heavy water have been measured. With the exception of salicylic acid, the ratio of these dissociation constants in light and heavy water decreases as the constant increases. An equation has been developed which affords a controlled extrapolation of this ratio to 100% D_2O from a single measurement above 90% D_2O.

The quinhydrone electrode yields reliable results of greater precision than have been obtained with the deuterium gas electrode. The superiority of the quinhydrone electrode is due not only to the simplicity of manipulation, but to the fact that the equilibrium between the proto- and deutero-forms of quinhydrone, of water and of acid is established promptly in a homogeneous solution. With the gas electrode the exchange reactions are established only at the surface of the electrode, which equilibrium can be disturbed by convection and diffusion from the bulk of the solution, if the gas has been generated by the complete decomposition of a portion of the water employed.

The temperature coefficients of the e. m. f. indicate that the difference in the heats of ionization of the proto- and deutero-acetic acids may change sign in the neighborhood of 25°.

The solubilities of quinone, hydroquinone and deuteroquinone in small quantities of light and heavy water, necessary for the interpretation of the e. m. f. data, have been determined precisely by an interferometer method. Hydroquinone is 20% more soluble on a mole ratio basis than deuteroquinone at 25°, whereas quinone suffers no change in solubility.

NEW YORK, N. Y. RECEIVED JUNE 6, 1936

---

[26] Halpern, *J. Chem. Phys.*, **3**, 456 (1935). Halpern's treatment can have the status only of an approximate theory, since he consciously omits a detailed consideration of the specific contributions of moments of inertia, mass ratios and interaction effects, leaving the contribution of the vibrational frequencies of the proton and deuton bonds as the only significant factor in determining the ratio.

Photochemical Studies. XXIII. The Photochemical Decomposition of Acetone Vapor near 1900 Å. A Comparison with the Decomposition at Longer Wave Lengths

BY JOHN P. HOWE[1] AND W. ALBERT NOYES, JR.

Acetone, in common with other ketones and aldehydes, exhibits an absorption region beginning at wave lengths somewhat longer than 3000 Å. and extending down to about 2200 Å. On the long wave end some structure has been noted[2] and fluorescence has been observed in this region.[3] Whether or not fluorescence is excited by wave lengths below those for which discrete structure is obtained seems to be the object of some disagreement.[4]

It seems generally agreed that the main products of photochemical decomposition in this near ultraviolet region of the spectrum are carbon monoxide and ethane, although small amounts of other substances may be formed.[4a,5] The quantum yield is a function of wave length, increasing slightly as the wave length is decreased. While the general aspects of the photochemical decomposition of acetone in this region of the spectrum seem quite well established, experiments have not been carried out over a sufficient range of intensities, pressures of acetone and pressures of foreign gas to make it possible to present a mechanism free from criticism.

Recently the ultraviolet absorption spectrum of acetone has been investigated.[2c] In addition to the absorption region near 3000 Å., one additional region is susceptible of investigation with apparatus made of quartz. This region consists of discrete bands extending from about 1995 to about 1820 Å., probably overlaid with a faint continuum. Manning[6] has developed a method of gas analysis applicable to the products of acetone decomposition and studied the gases produced upon illuminating acetone vapor with polychromatic radiation transmitted by fluorite.

A complete understanding of the photochemistry of acetone can be based only on a thorough study of as many different excited states as possible over a wide range of experimental conditions. It is for this reason that the present investigation at wave lengths near 1900 Å. was carried out. A consistent picture of the results is possible.

I. Experimental Procedure and Results

The following primary processes and subsequent steps are possible in any dissociation such as that of acetone (I represents quanta absorbed per second, A represents an acetone molecule, A_1 represents an excited acetone molecule, D represents dissociation products, M represents a molecule of foreign gas):

Reaction	Rate	
$A + h\nu = D;$	I_1	(1)
$A + h\nu = A_1;$	I_2	(2)
$A_1 = A + h\nu_1;$	$k_1\ (A_1)$	(3)
$A_1 = A_2;$	$k_2\ (A_1)$	(4)
$A_1 = D;$	$k_3\ (A_1)$	(5)
$A_1 + A = 2A;$	$k_4\ (A_1)(A)$	(6)
$A_1 + A = D + A;$	$k_5\ (A_1)(A)$	(7)
$A_1 + M = A + M_1;$	$k_6\ (A_1)(M)$	(8)
$A_1 + M = D + M;$	$k_7\ (A_1)(M)$	(9)

If it can be shown that the dissociation products, D, do not react with each other to reform acetone, the quantum yield, ϕ, is found to be

$$\phi = (I_1/(I_1 + I_2)) + (I_2/(I_1 + I_2))(k_3 + k_5(A) + k_7(M))/ (k_1 + k_2 + k_3 + (k_4 + k_5)(A) + (k_6 + k_7)(M)) \quad (10)$$

providing the molecule A_2 either does not dissociate or has a very long life. The quantities in parentheses may be expressed either in pressure units or in numbers of molecules per cubic centimeter.

---

(1) Jesse Metcalf Fellow, 1935–1936.

(2) This structure seems to have been observed first by Herzberg, see (a) Scheibe, Povenz and Linström, *Z. physik. Chem.*, **B20**, 297 (1933), for mention. It has been confirmed subsequently by other workers: (b) Crone and Norrish, *Nature*, **132**, 241 (1933); (c) Noyes, Duncan and Manning, *J. Chem. Phys.*, **2**, 717 (1934).

(3) Norrish, *Nature*, **133**, 837 (1934).

(4) (a) Damon and Daniels, THIS JOURNAL, **55**, 2363 (1933); (b) Fisk and Noyes [*J. Chem. Phys.*, **2**, 654 (1934)] have studied the fluorescence excited by monochromatic 3130 Å. radiation of mercury. They found the fluorescence to follow a Stern–Volmer mechanism at the pressures used (50 to 190 mm.). They did not investigate the effect of wave length. Recently Mr. Fisk and one of us (J. P. H.) using a crystal quartz monochromator and a quartz capillary arc have observed fluorescence to be produced by all of the mercury lines from 3130 to 2536 Å., but apparently not by the weak lines at still shorter wave lengths. These results are in agreement with those of Damon and Daniels.

(5) Norrish, Crone and Saltmarsh, *J. Chem. Soc.*, 1456 (1934).

(6) Manning, THIS JOURNAL, **56**, 2589 (1934). Monochromatic radiation was not used in Manning's experiments and moreover no attempt was made to remove mercury resonance radiation. In the present article it is shown that the effect of the latter is quite appreciable, particularly at low acetone pressure. Also Duncan [*J. Chem. Phys.*, **3**, 131 (1935)] has shown that acetone absorbs strongly still shorter wave lengths which would be transmitted by fluorite. In view of these facts the results of Manning, which generally showed relatively large amounts of hydrogen to be produced, should not be viewed as being in disagreement with the results reported in the present article.

The detailed description of the effect of radiation on the acetone molecule involves, therefore, the proof that the dissociation products do not reunite to give acetone, decision as to whether step (1) or step (2) or both must be considered, the evaluation of the constants k_1–k_7 and decision as to the nature of the molecule, A_2.

(a) The Nature of the Absorption Process.—The source of radiation used in these experiments was a spark between slowly revolving aluminum disks excited by two 1-kva. 25,000-volt transformers connected in parallel. The method of focal isolation was used to obtain monochromatic radiation and the purity of the radiation was tested spectroscopically using a small fluorite prism spectrograph. The following lines were transmitted with sufficient intensity to be photographed: 1854.7, 1858.2, 1862.5, 1862.9, 1930.3, 1935.2, 1989.8. The following bands lie near these exciting lines (intensities in parentheses):[2c] 1866.7 (3), 1868.9 (6), 1870.3 (3), 1872.4 (6), 1921.1 (4), 1923.0 (3), 1925.3 (3), 1926.4 (3), 1927.2 (4), 1938.9 (6), 1939.8 (6), 1941.1 (6), 1942.1 (6), 1943.9 (6). Only bands lying within 10 Å. of an exciting line have been listed. These bands have quite sharp edges, indicating the possibility that rotational structure might be observed with sufficient resolution. No bands lie very close to the group of lines 1854.7–1862.9; moreover these lines are relatively weak from the source due to the absorption by quartz and by the relatively long air path. The 1989.9 line falls in a region in which acetone is quite transparent. Most of the absorption must be due to the two lines at 1930.3 and 1935.2 Å.

In addition to the above lines this type of spark emits a faint continuum which cannot be ignored since it leads to some excitation of mercury vapor to the 2^1P_1 state through absorption of the 1849 Å. line. After this effect was discovered a chamber practically free from air circulation and containing mercury vapor was inserted between the second lens and the reaction vessel. This produced a noticeable decrease in the amount of decomposition at low acetone pressures and the evidence indicated convincingly that this error was removed in this way. The absorption coefficient of the 1849 line by mercury vapor is exceedingly high and even a temperature of −77° does not remove mercury vapor well enough to prevent practically complete absorption in the path length used.

Since absorption takes place in a banded region overlaid with a faint continuum, the spectroscopic evidence might indicate that both equations (1) and (2) should be considered. However, as will be shown, the data indicate that a molecule with a relatively long life is produced and that hence equation (1) may be omitted from consideration.

The fraction of the radiation absorbed by the acetone was determined by means of a photoelectric cell with quartz envelope. The following equation using two absorption coefficients was found to be obeyed (see Table I).

$$I/I_0 = 0.868 \exp. (-0.975P) + 0.132(1 - 0.0114P) \quad (11)$$

(I = transmitted intensity, I_0 = incident intensity, P is pressure in millimeters. The path length was 7.5 cm.)

TABLE I

ABSORPTION OF RADIATION BY ACETONE VAPOR

Pressure, mm.	I/I_0 calcd.	I/I_0 obsd.
0.295	0.786	0.791
.583	.627	.642
1.14	.422	.434

8.60	.122	.117
12.8	.113	.115
19.3	.103	.103

(b) Fluorescence.—A fluorescence cell was constructed with a window so placed that any fluorescence could be observed at right angles to the incident beam. Scattered and reflected radiation was reduced by tapering the ends of the tube and painting the entire cell except the windows with black paint. No visible fluorescence could be observed and attempts to produce blackening of ultraviolet sensitive plates gave negative results.[4b] If fluorescence exists it must either be very weak or the emitted radiation must lie in a region of the spectrum which could not be detected by the methods used.

(c) The Determination of Quantum Yields.—As shown by Manning[6] at low acetone pressures (below 0.03 mm.) approximately one molecule of carbon monoxide is produced per molecule of acetone disappearing (the average ratio was 1.03). In the present experiments no hydrogen was found and at low acetone pressures, as shown in Table II, carbon monoxide constituted very nearly 50% of the gases produced during decomposition. There seems to be no doubt, therefore, that the decomposition proceeds almost solely by the reaction

$$(CH_3)_2CO = C_2H_6 + CO \qquad (12)$$

At higher acetone pressures some of the ethane seems to dissolve in the acetone upon condensation with liquid air, as found by Norrish and coworkers.[5] The number of molecules of acetone disappearing is based, therefore, on an analysis for carbon monoxide.[6]

TABLE II

PERCENTAGE OF CARBON MONOXIDE IN REACTION PRODUCTS

Pressure of acetone, mm.	Total pressure of products, mm.	Carbon monoxide pressure, mm.	Carbon monoxide in products, %

1.78	.0210	.0102	48.7
8.35	.0191	.0098	51.3
		Average	49.9

For determinations of the absolute values of the quantum yield a hydrogen bromide actinometer was used. For this the production of one molecule of hydrogen (uncondensed by liquid air) per absorbed quantum was assumed.[7] The hydrogen bromide cell was about 15 cm. in length and pressures of hydrogen bromide of 10 to 15 mm. were employed. Under these conditions over 99% of the radiation was absorbed by the actinometer.

The hydrogen bromide cell was placed directly in back of the cell containing the acetone vapor, one window (of fused quartz sealed to the actinometer vessel) being in common between the two cells. The transmission of this window was measured subsequently after cutting off the end of the cell. The hydrogen bromide cell was made entirely of quartz and no wax was present in this system. The crystal quartz front window of the acetone cell was attached with picein wax.

In making a run the acetone was frozen with liquid air and the hydrogen bromide decomposition determined, a photoelectric cell being used to detect any variations in the over-all intensity of the spark. The acetone was then vaporized and the decomposition of the hydrogen bromide again determined. Corrections were made for variation in intensity between the two parts of the experiment. For this purpose the ultraviolet intensity was assumed to vary directly with the over-all intensity of the spark. This is not strictly true, but since intensity variations were always small the error introduced by the assumption would be negligible.

Table III presents the absolute values of the quantum yield as determined with the hydrogen bromide actinometer.

TABLE III

ABSOLUTE QUANTUM YIELDS OF ACETONE DECOMPOSITION

Acetone pressure, mm.	Time, min.	Quanta absorbed $\times 10^{-17}$	Molecules of CO produced $\times 10^{-17}$	Incident quanta per sec. $\times 10^{-13}$	Quantum yield, ϕ	Quantum yield, calcd. eq. (15)
6.00	120	2.19	1.163	4.19	0.53	0.57
2.20	38	0.605	0.361	4.87	.60	.61
2.20	60	1.57	.873	7.51	.56	.61
3.2	60	2.11	1.28	8.93	.61	.60
11.1	60	2.60	1.44	9.39	.56	.54
25.1	30	2.45	1.25	15.9	.51	.52

The complete determination of the mechanism of the decomposition involves the evaluation of the constants k_4–k_7. Quantum yields must be determined, therefore, with some precision over a wide range of experimental conditions and for this purpose the hydrogen bromide actinometer is not suitable. In particular the actinometer method lacks accuracy when the pressure of acetone is low and the percentage of the radiation absorbed small.

Relative quantum yields were obtained using a photoelectric cell to measure the incident intensity and calculating the amount of absorbed radiation from equation (11). A quantum yield of 0.55 at a pressure of 9.32 mm. (the average value at the average pressure in Table III) was assumed for the purpose of converting the relative quantum yields into absolute values. Table IV gives the values of the quantum yield obtained in this way.

TABLE IV

RELATIVE QUANTUM YIELDS OF ACETONE DECOMPOSITION

(d) The Effects of Added Gases.—The constants k_6 and k_7 will be expected to vary from one

---

[7] Warburg, *Sitzber. preuss. Akad. Wiss.*, 314 (1916).

added gas to another. Three different gases were used: carbon dioxide, nitrogen and ethane. The experimental difficulties were least with the carbon dioxide which could be condensed with liquid air completely enough to permit easy removal of the decomposition products of acetone. This difficulty was particularly great with nitrogen and frequent circulation of the gases through the liquid air trap was necessary to remove all of the acetone vapor. Within experimental error none of these gases absorbed the radiation used. There is some slight possibility of decomposition of the ethane and carbon dioxide sensitized in some way by the acetone.

Table V shows the results obtained with added gases.

TABLE V

EFFECT OF ADDED GASES ON QUANTUM YIELD OF ACETONE DECOMPOSITION

Acetone pressure, mm.	Foreign gas pressure, mm.	Quantum yield	Quantum yield without added gas	Added gas
1.82	9.8	0.81	0.61	Carbon dioxide
1.81	9.8	.85	.61	
1.72	18.4	.88	.62	
2.12	2.23	.69	.61	Nitrogen
2.12	3.78	.81	.61	
2.34	7.38	.74	.61	Ethane
2.32	7.13	.75	.61	
2.30	12.30	.80	.61	

(e) The Effect of Excited Mercury.—The presence of excited mercury raised the apparent quantum yield as shown in Table VI. It is evident from the results that solid carbon dioxide–chloroform mixtures do not remove mercury vapor completely enough to prevent this effect.

TABLE VI

EFFECT OF EXCITED MERCURY ON APPARENT QUANTUM YIELD

Acetone pressure, mm.	Apparent quantum yield	Quantum yield, calcd. eq. (15)	Remarks
1.51	0.73	0.62	Resonance radiation present
0.155	.72	.65	Trap in CO_2–$CHCl_3$
.124	.88	.65	
.134	.81	.65	
20.4	.53		Resonance radiation present
20.4	.53		Resonance radiation removed
9.9	.55	.55	Resonance radiation present

It is quite obvious from the results in Table VI that at high acetone pressures the fraction of the reaction due to excited mercury is too small to be significant. This is not true, as would be expected, at low pressures.

II. Discussion of Results

It is important first to show that the dissociation products do not react with each other to reform acetone. Two lines of evidence may be brought to bear on this point. (1) In Table III it is seen that the incident intensity was varied by a factor of nearly four and in Table IV the maximum variation is somewhat over seven-fold. In neither table is any significant variation of quantum yield with intensity apparent, whereas if a homogeneous gas phase recombination reaction were taking place the quantum yield should decrease as the intensity increases. (2) Methyl groups do not react with carbon monoxide, at least with any rapidity, when the carbon monoxide pressure is low and the temperature about 25°.[8] This means that if two methyl groups and normal carbon monoxide are produced almost simultaneously, as Norrish suggests at longer wave lengths,[5] the reverse reaction may be neglected. There still remains some slight possibility of a wall recombination between free radicals of the type of CH_3CO and CH_3. However, CH_3CO is probably not very stable and in the thermal decomposition of acetone its recombination with methyl groups does not seem to be important.[9] The evidence against free radical recombination is, therefore, not conclusive but is about as good as one can ever obtain in a photochemical reaction.

In arriving at an equation which will express the quantum yield as a function of the various variables, it is necessary to decide whether the quantum yield approaches unity at zero pressure. Experiments were carried out at pressures down to 0.2 mm. and at this pressure the yield is far from one. Experimental difficulties prevented the execution of precise experiments at still lower pressures. However, it may be stated definitely that the mechanism outlined in equations (2) to (9) inclusive will lead to a quantum yield of unity at zero pressure only if equations (3) and (4) are omitted. The omission of both of these equations results in disagreement between the quantum yield expression and the data, whereas the inclu-

---

[8] Some experiments were carried out by one of us (W. A. N., Jr.) in which lead tetramethyl was illuminated by radiation from a zinc spark in the presence of carbon monoxide. A two per cent. acetone solution used as a color filter effectively removed any radiation which would be absorbed by acetone vapor. Leighton and Mortensen [THIS JOURNAL, **58**, 448 (1936)] have shown that methyl groups are produced when lead tetramethyl is illuminated. No significant reaction between methyl groups and carbon monoxide could be detected.

[9] Rice and Herzfeld, *ibid.*, **56**, 286 (1934).

sion of either one or both makes an agreement possible providing the molecule A_2 is of such a nature that it is always deactivated before dissociating.

We seem forced to one of the following conclusions: (1) fluorescence is emitted; (2) the primarily excited state A_1 changes into another state (or states) without collision, this reaction being necessarily reversible by the principle of microscopic reversibility; (3) the reaction products (especially CO) exert an unexpectedly large effect in deactivating excited acetone molecules; (4) the molecule A_2, for some reason, is stable or is always deactivated without dissociating.

These possibilities will be discussed in order.

(1) Omitting equation (4) and in the absence of foreign gases the quantum yield becomes

$$\phi = (k_3 + k_5(\mathrm{A}))/(k_1 + k_3 + (k_4 + k_5)(\mathrm{A})) \quad (13)$$

If it is assumed that collisions must produce either deactivation or dissociation, $(k_4 + k_5)$ must represent the total number of collisions per excited acetone molecule per second at unit pressure (1 mm.). This number of collisions at 25° is

$$z = 4.78 \times 10^{21}\sigma_1^2 = 1.2 \times 10^7 \quad (14)$$

if σ_1 (the distance between centers at closest approach) is taken as 5×10^{-8} cm.[10] If the quantum yield is 0.65 at zero pressure, the following values of the constants in equation (13) are obtained: $k_1 = 2.56 \times 10^7$; $k_3 = 4.74 \times 10^7$; $k_4 = 0.59 \times 10^7$; $k_5 = 0.61 \times 10^7$. With these values equation (13) fits the quantum yield well within experimental error.

It is now possible to show that 27% of the absorbed quanta should be reëmitted as fluorescence at 1 mm. pressure and about 8% at 10 mm. Since the fraction of the radiation reëmitted decreases with pressure whereas the amount of radiation absorbed per unit path length increases there will be an optimum pressure for observing the phenomenon. With the incident intensities available the intensity of the fluorescent radiation would not exceed the limit of visibility by a wide margin even if all of the fluorescence occurred in the visible spectrum. A lack of visual observation is not adequate proof of the absence of fluorescence. However, the intensity should be high enough to affect a photographic plate with exposures of thirty to sixty minutes providing the plate is sensitive to the wave lengths reëmitted. If fluorescence exists the failure to observe it must be ascribed to this cause, although the plates used should be sensitive to the region from 6000 to 1800 Å.

The question of the existence of fluorescence therefore must be left open.

(2) The introduction of two or more states which may change into each other reversibly without loss of energy makes it possible to derive an equation which will fit the data and still give a quantum yield of unity at zero pressure. The complete evaluation of all of the constants in such an equation is impossible from any experimental data, although conclusions may be drawn with regard to the values of certain ones. The rate of change of A_1 into A_2 and *vice versa* must proceed much more rapidly (at least 100 times) than the spontaneous dissociation of either one and the constant for spontaneous dissociation of the one of longest mean life must be twenty to one hundred times smaller than the number of collisions per second at unit pressure. This means that the mean life must be of the order of 10^{-5} to 10^{-6} sec., although this figure could be reduced somewhat by using a different collision diameter. Obviously any mechanism which will fit the experimental data and still permit the quantum yield to be unity at zero pressure must involve states with long lives.

(3) The reaction products may exert a deactivating effect on excited acetone molecules. However, ethane raises the quantum yield, so that the responsibility would have to be placed on the carbon monoxide. The decomposition was never allowed to proceed very far and the carbon monoxide pressure was usually not greater than 0.01 mm. at the end of an experiment. While fairly good resonance might be expected with carbon monoxide, here again either a long mean life for excited acetone or unreasonably large collision diameters would have to be used to fit the facts.

(4) If the molecule A_2 is stable and does not change back into A_1, the following equation (similar to (13)) is obtained

$$\phi = (k_3 + k_5(\mathrm{A}))/(k_2 + k_3 + k_4(\mathrm{A}) + k_5(\mathrm{A})) \quad (15)$$

The numerical values of the constants will be the same as for equation (13) except that k_2 will replace k_1. The calculated values in Tables III and IV were obtained from equation (15).

---

(10) The various radii used in this discussion are as follows: acetone 2.5×10^{-8} cm., carbon dioxide 1.83×10^{-8} cm., nitrogen 1.58×10^{-8} cm., ethane 2.0×10^{-8} cm. These are estimated from tables and from interatomic distances and are admittedly very crude values. The results should be taken as verifying one of the general pictures presented to explain the experimental facts rather than as signifying an exact numerical agreement.

From the constants for either equation (13) or equation (15) the mean life of the excited acetone molecule is found to be 1.4×10^{-8} second, which is large enough so that a discrete spectrum should be observed.

The theoretical difficulties involved in introducing a metastable molecule of long life will be considered in the next section. However, since either equation (13) or equation (15) fits the experimental data over the range of observations, they will be used in discussing the effects of added gases.

One observes that the effect of added gases is in each case to cause an increase in the quantum yield. By taking into account the constants already evaluated one finds for the ratio of quantum yield with added gas to that without

$$\phi/\phi_0 = \frac{1 + k_7 P_2/(k_5(8.13 + P_1))}{1 + (k_6 + k_7)P_2/(k_4 + k_5)(6.1 + P_1)} \quad (16)$$

where ϕ is the quantum yield at foreign gas pressure of P_2 mm. and acetone pressure of P_1 mm., while ϕ_0 is the quantum yield when $P_2 = 0$. $(k_6 + k_7)$ will be the number of collisions per excited acetone molecule per second at unit pressure of added gas. An examination of the data in Table V reveals the fact that k_6 seems to be small compared to k_7. If one assumes $k_6 = 0$, the following equations are obtained (radii are given in Ref. 10): for carbon dioxide

$$\phi/\phi_0 = (1 + 1.62P_2/(8.13 + P_1))/(1 + 0.79P_2/(6.1 + P_1)) \quad (17)$$

For nitrogen

$$\phi/\phi_0 = (1 + 1.68P_2/(8.13 + P_1))/(1 + 0.82P_2/(6.1 + P_1)) \quad (18)$$

For ethane

$$\phi/\phi_0 = (1 + 2.00P_2/(8.13 + P_1))/(1 + 0.98P_2/(6.1 + P_1)) \quad (19)$$

Table VII shows the applicability of equations (17), (18) and (19) to the data of Table V.

TABLE VII

COMPARISON OF OBSERVED WITH CALCULATED EFFECTS OF FOREIGN GASES

Acetone pressure, mm.	Foreign gas pressure, mm.	ϕ/ϕ_0 obsd.	ϕ/ϕ_0 calcd.	Foreign gas
1.82	9.8	1.33	1.31	CO_2
1.81	9.8	1.39	1.31	
1.75	18.4	1.42	1.41	
2.12	2.23	1.13	1.12	N_2
2.12	3.78	1.33	1.18	
2.34	7.38	1.21	1.30	C_2H_6
2.32	7.18	1.23	1.30	
2.30	12.30	1.31	1.39	

With the exception of one run the agreement between observed and calculated values is satisfactory in the cases of carbon dioxide and nitrogen, thus indicating that practically every collision between an excited acetone molecule and a molecule of these gases leads to dissociation. For ethane the observed values are always lower than the calculated values. Agreement may either be obtained by using 3.4×10^{-8} cm. as the value of σ or by assuming that approximately 10% of the collisions lead to deactivation. In reality the two points of view do not differ materially, since the efficiency factor and the radius cannot be calculated separately. Ethane does possess some bonds similar to those in acetone and hence one should expect a better chance of resonance upon collision than with the other two gases. The fact that ethane is less efficient in producing dissociation than either carbon dioxide or nitrogen agrees with prediction.

III. Theoretical Discussion

As has been shown in the preceding section, many of the aspects of the photochemical decomposition of acetone in the neighborhood of 1900 Å. may be explained on the basis of a simple kinetic picture. The chief difficulty is connected with the fact that the quantum yield, in the apparent absence of fluorescence, does not rise to unity at zero pressure. Several explanations of this fact are possible. There remains the problem of correlating the spectroscopic and photochemical data for the two regions so far investigated.

Mulliken[11] has studied the various electronic states of ketones and aldehydes. The symmetry of the acetone molecule may be taken as C_{2v}, the same as formaldehyde, if the rotation of the methyls is considered. The normal state cannot be formed from two methyl groups and carbon monoxide in its ground ($^1\Sigma$) state. There are several reasons for believing that this is so: (1) the value of ω_e for normal carbon monoxide[12] is 2167.4 cm.$^{-1}$ which does not correspond to the frequency of about 1700 cm.$^{-1}$ observed for all molecules containing the carbonyl group;[13] (2) the carbon–oxygen distance in carbon monoxide corresponds most nearly to that of a triple bond and the electronic configuration of this molecule may best be described in this way.[14] One would

---

(14) See Mulliken, *ibid.*, **9**, 373 (1931).

expect a system of two methyl groups and normal carbon monoxide to be repulsive.

The only state of carbon monoxide which has a value of ω_e approximately corresponding to that of the Raman frequency of the carbonyl group is $a^3\Pi$ with a frequency of 1739.3.[12] If this state is split into C_{2v} symmetry by bringing up two methyl groups one can arrive at Mulliken's configuration for the acetone molecule.

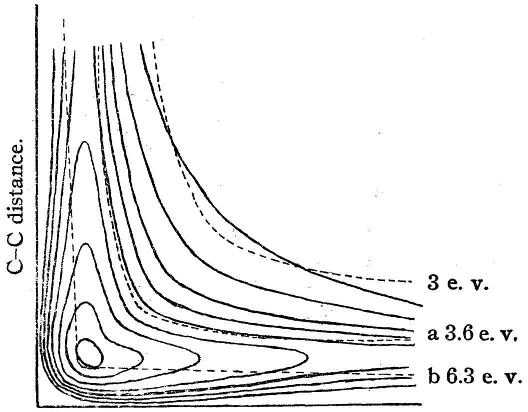

Fig. 1.

Excited states of the acetone molecule must exist which would separate adiabatically into other states of carbon monoxide and normal methyl groups, since the absorption is concerned mainly with electrons in the carbonyl group. Thus there is an excited electronic state of carbon monoxide with $\omega_e = 1182$,[15] which lies 7.13 electron volts above the ground state. Several observers have found upper state frequency differences in aldehyde and ketone absorption corresponding to 1180 to 1200 cm.$^{-1}$ [2c] in the absorption region around 3000 Å. In the bands between 1800 and 2000 Å., strong bands separated by 1049 and 1194 cm.$^{-1}$ were found and one of these frequencies is probably a carbon–oxygen frequency. The corresponding state of carbon monoxide is less definite here because no ω_e value is given for the $d^3\Pi$ state.

There are too many degrees of freedom in the acetone molecule to permit a diagram in two dimensions to represent them all. However, one may, for purposes of discussion, hold the energies in the carbonyl group and in the methyl groups constant and furthermore keep the angle between the carbon–carbon bonds constant. With these restrictions it is possible to represent the acetone molecule by a contour map after the method of Eyring[16] (Fig. 1). The two carbon–carbon distances are represented by ordinates and abscissas and energy differences are represented by contours. These diagrams may be made only semi-quantitatively since all of the necessary facts for the complete description of the acetone molecule are not known. The stable configuration of acetone will be represented by a point at the bottom of the valley and on the line bisecting the angle between the x and y axes. If Fig. 1 represents the surface for the first excited state of acetone, then the dotted lines may be taken to represent the repulsive state formed from normal $^1\Sigma$ carbon monoxide and two normal methyl groups. Since this state is assumed to be repulsive the surface representing it must be rising fairly steeply and will touch the surface for the upper state (at about 4.1 electron volts) at a point lying on the line bisecting the angle between the x and y axes. From the upper state, therefore, the easiest way of egress would lead to the simultaneous splitting off of two methyl groups as postulated by Norrish.[5] However, since the "point" of intersection is in reality a "surface" when one considers all degrees of freedom, there should be some chance of splitting off one methyl group alone, although the "pass" over which the molecule would have to go would be somewhat higher than for the other process. It is easily seen that thermal dissociation should occur with the splitting off of one methyl group as postulated by Rice and Herzfeld.[9] The heat of activation for this process should be the heat of dissociation of the carbon–carbon bond less the energy contained in the various degrees of freedom of the molecule; 70,000 calories is the value chosen by Rice and Herzfeld.[9]

Figure 2 is a vertical cross section cutting across all of the energy levels, keeping both the angle between the carbon–carbon bonds constant and the two carbon–carbon distances equal to each other. This diagram resembles that of a diatomic molecule, but it should be kept in mind that many more degrees of freedom are involved. From spectroscopic information, known heats of dissociation and the photochemical facts one can deduce the vertical distances quite accurately. The manners in which the various curves inter-

---

(15) *Cf.* Ref. 12. Henri [*Compt. rend.*, **199**, 849 (1934)] has assigned the states of the carbonyl group in much the same way as that indicated here.

(16) Eyring, *Naturwissenschaften*, **18**, 914 (1930); Eyring and Polanyi, *Z. physik. Chem.*, **12B**, 279 (1931).

sect are in agreement with these facts, but the horizontal distances are schematic.

I represents the normal state of acetone and II the upper state for the bands near 3000 Å. Fluorescence should be most strong on the long wave end of this band system. There are two reasons for drawing the upper curve displaced horizontally with respect to the curve of the ground state: (1) the maximum intensity of absorption is displaced toward short wave lengths from the band chosen as the (0,0) band.[2c] (2) The maximum intensity of fluorescence is in the green. The curves are drawn to account semi-quantitatively for these facts. Dissociation takes place by a transition from II to the repulsive state IV, but there should be some chance of fluorescence in the entire region.

In discussing the near ultraviolet region of the spectrum it must be emphasized that a consistent explanation of the published results is impossible. It has been shown that practically all of the absorbed energy may be accounted for[4b] by (1) fluorescence, (2) dissociation, (3) deactivation by collision. In order to arrive at this balance it was assumed that the dissociation followed equation (5). However, it has been shown that the quantum yield probably decreases with pressure at 3130 Å.[4a] A mechanism fitting these facts may be derived by assuming that $k_3 = 0$ and that dissociation of an activated molecule occurs only upon collision. Thus it is seen that the relatively small amount of fluorescence is incompatible with a quantum yield approaching zero at zero pressure. To explain some of the facts in this region Norrish[5] has introduced the idea of "degradation to heat," which is equivalent to postulating a molecule formed spontaneously from the originally activated molecule, but incapable of dissociation in a time even considerably greater than the time between collisions. It is seen that a difficulty seems to exist in the near ultraviolet similar to that encountered at 1900 Å., but the experimental data, particularly in the former region, are not accurate enough at present so that one is justified in stating whether the difficulties are apparent or real.

Curve III represents the upper state for the spectral region discussed in the present article. Curve IV must lie fairly close to curve III so that there is a fairly high probability of transition to the repulsive state. In general the transition must occur after a period of time longer than that required for one rotation (between 10^{-10} and 10^{-11} sec.) or the bands would not appear to have sharp edges at low pressures. The mean life of about 10^{-8} second is not in disagreement with this statement. It may be pointed out that the perturbation caused by a collision would be of the right nature to cause a transition to the repulsive level.

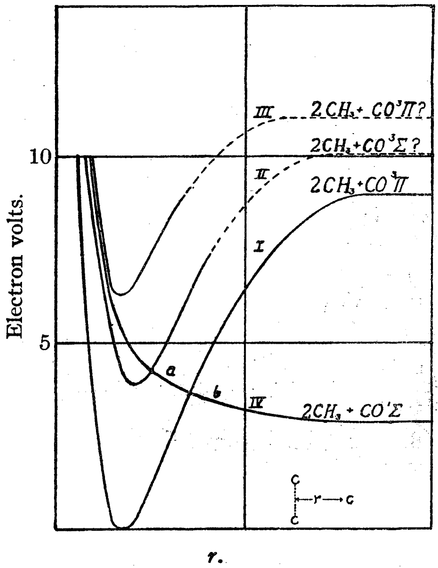

Fig. 2.

Since many of the photochemical facts seem to require the assumption of a state of long life formed spontaneously from the initially excited state, some speculation concerning this matter is in order.

At a first glance one might expect that once a molecule had transferred to the repulsive state IV its lifetime would be less than one period of vibration, about 10^{-13} sec. However, curve IV will not be continuous, but both I and IV will be broken at their intersection, the two upper parts and the two lower parts joining, respectively, to form two new continuous curves.[17] The probability of transition from the upper to the lower of these two new curves may be small enough to increase the mean life of the excited molecules by a large factor. Of course the proper selection rules must be obeyed for a perturbation of this type to occur. Whether or not the mean life would be long enough to account for the photochemical results is an open question, although so many different configurations may be assumed by the molecule that this is not impossible.

Once the molecule is on curve I there will be the

---

[17] *Cf.* Eyring and Stearn, *J. Chem. Phys.*, **3**, 778 (1935).

possibility of dissociation into CH_3CO and CH_3. Damon and Daniels[4a] do note a decrease in quantum yield at high intensities. Most of the known facts for the 3000 Å. region may be explained by assuming a recombination reaction between CH_3CO and CH_3 which takes place largely on the walls but partially in the gas phase. Thus the yield may be made to approach zero at zero pressure even though the fluorescence is small. Dissociation would follow collision, supporting the increase in yield with pressure,[4a] and might be partially into 2 CH_3 and CO and partially into CH_3CO and CH_3. The chief arguments against this explanation are: (1) the supposed instability of the CH_3CO radical;[9] (2) the fact that the photochemical formation of diketones has not been observed.

Any CH_3CO radical produced by the dissociation of a molecule excited in the 1900 Å. region would possess so much energy that it should spontaneously dissociate. It seems very unlikely, therefore, that a recombination reaction can be responsible for the low yield in this part of the spectrum.

At least one other repulsive surface must exist, namely, that between normal carbon monoxide and normal ethane. However, ethane can be produced in one step only if the angle between the carbon–carbon bonds is varied and hence this surface cannot be represented on the diagrams. Moreover, there will be steric effects which will prevent transitions to this state from being very probable.

Certain relationships to the pictures for formaldehyde, acetaldehyde and methyl ethyl ketone may be stated. In formaldehyde there will be no steric effect to prevent transition to the repulsive surface formed by normal hydrogen and normal carbon monoxide and the observed quantum yield is unity.[18] A molecule with sufficient energy might dissociate in other ways. The methane–carbon monoxide surface must be important in acetaldehyde, since the steric effect would be considerably less than in acetone.[19] However, some decomposition in this case must be by way of the methyl–carbon monoxide–hydrogen atom surface since free radicals have been detected to some extent in this case. In methyl ethyl ketone several other repulsive surfaces must intervene and several products are observed upon illumination.

In conclusion the authors wish to express their appreciation to the Chemistry Department of the Johns Hopkins University for the loan of the rotating spark gap.

Summary

1. The quantum yield of acetone decomposition with approximately monochromatic radiation from the aluminum spark about 1900 Å. has been investigated. It is (a) independent of intensity over quite wide limits; (b) dependent upon acetone pressure, increasing at low pressures, the limiting value appearing to be about 0.65; (c) increases with the addition of nitrogen and carbon dioxide and to a lesser extent with the addition of ethane; (d) is apparently increased by the action of excited mercury unless precautions are taken to avoid this error.

2. No fluorescence could be detected.

3. Some difficulty is encountered in explaining the low quantum yield at low pressures, but otherwise the facts fit a simple kinetic picture.

4. The photochemical decomposition of acetone near 3000 Å., the decomposition near 1900 Å. and the various facts of spectroscopy and fluorescence may mostly be correlated with the use of potential energy surfaces.

The Solubility of Thorium in Mercury[1]

BY W. GEORGE PARKS AND GEORGE E. PRIME

Very few alloys of thorium have been prepared. The only reference in the literature to a thorium amalgam is the work of Kettembeil,[2] who was unable to prepare an amalgam by the electrolysis of an aqueous solution of a thorium salt using a mercury cathode. Insoluble basic compounds were always formed during the electrolysis. This investigation was undertaken to see whether an amalgam could be prepared and, if so, what its possibilities are for use in galvanic cells to determine the thermodynamic properties of tetravalent thorium salts.

Experimental

Mercury.—Redistilled mercury was stirred under a dilute nitric acid–mercurous nitrate solution for three days. It was then redistilled three times in a slow current of air (15 mm.) by the Hulett[3] method, and finally under high vacuum.

Thorium.—Crystalline thorium prepared by the electrolysis of fused thorium chloride was kindly supplied by the Kemet Laboratories, Cleveland, Ohio. This metal analyzed 99.75% Th, by the oxalate method.[4] It contained small amounts of thorium oxide, silicon, iron and chromium due to the method of preparation. However, the amounts present are negligible for our purpose. It should be pointed out that very pure metallic thorium entirely free from thorium oxide has never been prepared; commercial samples rarely analyze better than 98.50%.[5] The samples for analysis were first fused with potassium bisulfate because when the metal is treated with acids, either singly or in combination, considerable oxide is formed which does not dissolve even in concentrated acids.[6]

Thorium Salts.—The best grade of C. P. thorium chloride, nitrate and sulfate were secured from Kahlbaum and were not further purified.

The preparation of a thorium amalgam was attempted by two methods. (1) Weighed quantities of thorium and mercury were heated together at 400° in small transparent fused quartz tubes for approximately eight hours. A higher temperature, although desirable, could not be employed due to shattering of the tubes. Furthermore, at elevated temperatures the thorium attacked the quartz badly. (2) An extensive series of experiments was carried out to determine the conditions under which an amalgam could be prepared electrolytically. These experiments included: electrolysis of thorium nitrate, sulfate and chloride in aqueous solution; $Th(NO_3)_4$ and $ThCl_4$ in 95% ethyl alcohol, and $ThCl_4$ in 12 N hydrochloric acid. Both the test-tube and H-type cell vessel were employed using a mercury cathode. The mercury was stirred slowly during all experiments. The concentration of salts, current density, length of time electrolyzed, temperature and acidity were varied over a wide range. The results may be summarized as follows: in all aqueous solutions insoluble basic salts were formed causing the current to decrease gradually with no detectable amalgam formation. In the alcoholic solutions, the purpose of which was an attempt to prevent the formation of the basic compounds, no amalgam could be formed. The basic compounds still precipitated. The only electrolysis which appeared to have some degree of success was carried out in a saturated solution of thorium tetrachloride in 12 N hydrochloric acid. A current of 0.5–1.0 amp. sq. cm. was passed through the solution for twenty-four hours. The H-cell was cooled continuously by running water.

The amalgams prepared by either method were placed in an oil-bath at 25 ± 0.01° and shaken for several days. The liquid mercury saturated with thorium was then separated for analysis by means of the special filter pipet previously described.[7] The analysis of mercury saturated with thorium offers very serious difficulties on account of the large quantity of mercury and relatively small quantity of thorium present. None of the ordinary methods of separation were found applicable. For example, no reagent could be found that would precipitate one without precipitating the other. It was found that hydrochloric acid would not react completely with the amalgam in the ordinary manner. The potassium permanganate oxidation method of Irvin and Russel[8] did not give satisfactory results. The distillation method also proved useless for quantitative work. The method finally adopted, although not entirely satisfactory, at least gives the order of magnitude of the solubility. For a more exact value an electrometric instead of a chemical method will have to be employed.

The samples to be analyzed were weighed carefully and then exposed to the atmosphere for at least two weeks in order that the thorium might separate from the mercury. This procedure has been found to be satisfactory for the separation of lanthanum and aluminum amalgams.[9] After standing the two weeks an excess of standard 0.5 N hydrochloric acid was added and after shaking well the excess acid was determined by titration with standard carbonate-free sodium hydroxide using phenol red as an indicator. The sodium hydroxide was standardized against Bureau of Standards potassium acid phthalate. The analytical weights and burets employed were calibrated and corrections applied where necessary.

Results and Discussion

The solubility of thorium in mercury at 25° is summarized in Table I. The data given represent the average of three determinations on five different amalgams. The second and fourth amalgams were prepared by method (1) while the others were prepared by method (2). The atomic per cent. was calculated from the weight per cent. by the graphical method of Ölander.[10]

TABLE I

THE SOLUBILITY OF THORIUM IN MERCURY AT 25°

Weight, %	Atomic, %
0.0158	0.0140
.0157	.0139
.0156	.0138
.0145	.0128
.0154 ± 0.0005	.0136

There are many factors which must be considered in the determination of the solubility of a sparingly soluble metal in mercury. The solubility may or may not be a definite quantity. Some metals like copper and zinc or lead[11] are known to form aggregates not only with themselves but also with mercury. This means that until the particle size in the amalgam has been determined the term solubility must be a loose one. A method other than filtration must be found for determining a homogeneous phase. Furthermore, we are not absolutely certain that all the thorium separates from the mercury on standing two weeks in contact with the atmosphere. The reproducibility of our results, however, leads us to place confidence in them. The amount of mercury that dissolves when the hydrochloric acid is added was found to be negligible at the concentration employed.

These data may be interpreted in terms of internal pressures and the metallic solution theory of Hildebrand.[12] The mutual solubility of thorium and mercury should follow from their position in the table of internal pressures provided that there is no compound formation. The physical constants necessary for calculating the internal pressure of thorium are not accurately known. However, if we adopt the method of Gilfillan and Bent[13] thorium is placed next to tin in the table given by Hildebrand, Hogness and Taylor.[14] This position indicates a large difference in the internal pressure of thorium and mercury and is in fair accord with the solubility found in this investigation. Joyner[15] found the solubility of tin in mercury to be 1.24 atomic per cent. at 25.4°. The mutual solubility of thorium and tin has not been determined.

According to the relationship between the melting point of a metal and its solubility in mercury as developed by Tammann and Hinnüber[16] our results are too high. However, this relationship is only an approximation. Considering all factors which enter into a problem such as this, we feel that our results indicate a very low solubility with our value as a maximum. This low solubility together with the difficulty of preparation leads to the conclusion that this amalgam is unsatisfactory for precise e. m. f. measurements. Further work on the amalgamation of thorium is in progress.

Identification of Phenolic Ethers as Picrates

BY O. L. BARIL AND G. A. MEGRDICHIAN

The derivatives most frequently employed in the identification of phenolic ethers are those obtained by bromination, nitration and oxidation. The instructions for the preparation of these derivatives are variable, and the original article must be consulted for each individual ether. The products obtained vary from a mono- to a trinitro derivative, and from a mono- to a pentabromo derivative. In many cases, mixtures are obtained. The oxidation of ethers is limited to those containing a side-chain, and the length of the side-chain cannot be determined by this method.

The picrates of phenolic ethers have never been fully studied as a means of identification. In our study of the picrates of phenolic ethers, we arrived at a uniform method of procedure, whereby any phenolic ether can be identified from its picrate. These picrates can be precipitated conveniently, their forms are quite diverse and characteristic and were found to be constant after repeating the crystallization.

Experimental

All phenolic ethers used were Eastman pure, excepting the *p*-nitrophenyl benzyl ether which was prepared in our laboratory. Chemically pure

PICRATES OF CERTAIN PHENOLIC ETHERS

Ether	Color	Crystalline structure	M. p., °C.	Nitrogen, % Calcd.	Found
Anethole[a,b]	Orange-red	Long needles	69–70	11.14	11.60
Anisole[a]	Bright yellow	Tabular crystals	79–81	12.46	12.62
Benzyl	Orange-yellow	Prism clusters	77–78	9.83	9.91
Benzyl methyl	Cream	Square plates	115–116	11.96	11.99
n-Butyl phenyl[a]	Light yellow	Hexagonal plates	110–112	11.08	11.79
Catechol diethyl[a]	Red-brown	Rhombic crystals	69–71	10.63	10.76
o-Tolyl methyl	Light yellow	Short prisms	118–119.5	11.96	11.82
m-Tolyl methyl	Orange-yellow	Medium prisms	113–114	11.96	11.44
p-Tolyl methyl	Yellow-orange	Long prisms	88–89	11.96	12.32
o-Tolyl ethyl	Light yellow	Short prisms	117.5–118.5	11.57	11.23
m-Tolyl ethyl	Orange-yellow	Medium prisms	114–115	11.57	11.44
p-Tolyl ethyl	Yellow-orange	Long prisms	110–111	11.57	11.90
Eugenol	Brown-red	Long blades	62–63	10.68	10.45

Safrole	Orange-red	Long blades	104–105.5	10.74	10.62
Iso-safrole	Dark red	Thick needle clusters	74–75	10.74	10.89
Triphenylcarbinol methyl	Light yellow	Cubes	90–91	8.35	8.70
Veratrole[e]	Red-orange	Six-sided prisms	56–57.5	11.44	11.13

[a] Unstable on exposure to air. [b] Beilstein, Vol. VI, 4th ed., 1923, p. 568. [c] *Ibid.*, p. 956. [d] *Ibid.*, p. 770. [e] *Ibid.*, p. 771.

picric acid was dried in an oven at 100° for six hours. One millimole of the phenolic ether was dissolved in 10 cc. of warm chloroform. One millimole of picric acid plus 5% in excess (0.241 g.) was dissolved in 10 cc. of warm chloroform. The chloroform solution of the phenolic ether was then poured into the picric acid solution while stirring the mixture. This mixture was then set aside and allowed to crystallize in a 100-cc. beaker. The picrate was recrystallized from the smallest amount of warm chloroform. The form or habit of the crystals was then determined by means of a binocular microscope using a magnification of about seven.

The picrates of the four phenolic ethers found in the literature were reported by the investigators as being equimolecular addition products. Melting points were determined by the method of Mulliken[1] in which a thermometer calibrated by the Bureau of Standards was employed. All temperatures given are uncorrected. In the determination of nitrogen, Campbell and Gray's[2] modification of the Dumas method was used.

Discussion of Results

The molecular composition of all the picrates was found to be of the general type 1:1. All the stable picrates of the phenolic ethers can be prepared and recrystallized from 95% ethyl alcohol. The melting points of the picrates thus prepared correspond exactly to the melting points of the picrates prepared from chloroform. The instability of the unstable picrates is manifested by a loss of color upon exposure to air, a rise in melting point, and the amorphous form of the residual picric acid. The melting points of all the unstable picrates must be taken as soon after crystallization as possible, unless kept in a sealed container.

Anethole picrate is decomposed by ethyl alcohol, and the anethole polymerizes to di-anethole in the hot alcohol. The picrates of eugenol, iso-eugenol, eugenol methyl ether and iso-eugenol methyl ether form astatic liquid crystals from ethyl alcohol. The use of methyl alcohol as a solvent prevents this, but several days are required for crystallization. The picrates of anisole, phenetole and *n*-butyl phenyl ether are all decomposed by ethyl alcohol. Methyl alcohol prevents this to a certain extent. The picrates of the isomeric ethers are all darker, and possess lower melting points than the picrates of the normal ethers. The picrates of the α-naphthyl ethers are darker and possess higher melting points than the picrates of the β-naphthyl ethers.

The preparation and recrystallization of all the unstable picrates of phenolic ethers is possible through the use of chloroform as a solvent, thereby affording a general and uniform method of procedure in the preparation of all the picrates of the phenolic ethers. As optical crystallographic data are very important in the final identification of an organic compound, it is hoped to be able to report on the refractive indices of these picrates in a future communication.

Summary

1. The picrates of thirty-five phenolic ethers have been prepared and were found to be suitable derivatives for identification purposes.

2. The procedure is uniform and requires no special degree of skill.

3. The picrates are highly crystalline solids, easily purified and possessing sharp melting points.

Reduction of Nitroguanidine. VI. Promoter Action of Platinic Chloride on Raney Nickel Catalyst

BY EUGENE LIEBER AND G. B. L. SMITH

Introduction

While investigating the effect of small amounts of impurities on the activity of the Raney nickel catalyst for the hydrogenation of nitroguanidine,[1] the further results of which will be reported in another paper, it was found that platinic chloride had a very marked enhancing action.

Nickel catalysts have been rather extensively studied with respect to the promoter action obtained when foreign substances are introduced into the catalyst mass and are summarized by Ellis.[2] Combinations of the platinum and nickel group catalysts have received attention as well as platinum and palladium deposited on other metals.[3] Of these Ginsberg and Ivanov[3e] have prepared active catalysts by adding *in situ* solutions of platinum or palladium chloride (the latter as Na_2PdCl_4) to powdered non-catalytically active metals. More recently, Delépine and Horeau[4] have described the enhancement of the activity of Raney nickel catalyst by platinum deposited from a solution of "alkaline platino-chloride" on the Raney nickel. The enhanced activity was manifested (for the reduction of ethyl acetoacetate) only after the addition of alkali.

In the hydrogenation of nitroguanidine it was observed that the addition of small quantities of platinic chloride very greatly increased the rate of reduction. It was in general found that this effect could be extended with even more marked results to other organic types. Table I summarizes these results, the details of which are given in the experimental section.

TABLE I

ADDITION OF PLATINIC CHLORIDE TO RANEY NICKEL

Hydrogen acceptor	Absorption rate, ml. H_2/min. Raney Ni	Raney Ni + $PtCl_4$
Nitroguanidine	28.4	51.4
Castor oil	35.8	125.8
Linseed oil	24.4	67.0
Nitrobenzene	18.4	165.6
Benzaldehyde	10.2	67.6

Experimental

Method.—The catalytic hydrogenations were carried out at one atmosphere pressure and at room temperature; the general procedure was the same as used previously.[1] The test mixtures were as follows: 5.2 g. (0.05 mole) of nitroguanidine, suspended in water as a solvent, 2.5 g. (or multiple of that quantity) of Raney nickel catalyst or non-catalytic metal powder. Just prior to the beginning of the hydrogenations, varying volumes of an aqueous solution of platinic chloride were added. The hydrogen adsorption rates were followed for a period of thirty minutes.

Concentration of Platinic Chloride.—Keeping the ratio of catalyst to hydrogen acceptor constant, the concentration of platinic chloride was varied from 0.034 to 0.680 g. (0.1 to 2.0 millimoles) per 100 ml. of solvent. The results are summarized graphically in Fig. 1.

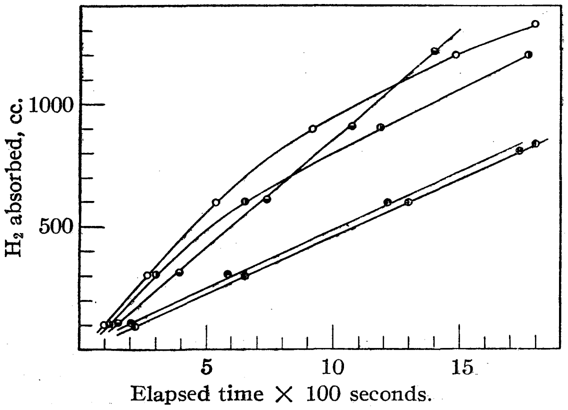

Fig. 1.—Variation in $PtCl_4$ concentration: ◓ Raney; ○ Raney + 2 millimoles $PtCl_4$; ◑ Raney + 1 millimole $PtCl_4$; ◒ Raney + 0.25 millimole $PtCl_4$; ◐ Raney + 0.13 millimole $PtCl_4$.

Variation in Catalyst Mass.—In this series of experiments the concentration of platinic chloride was maintained at 0.075 g. (0.25 millimole) per 100 ml. of solvent and the ratio of catalyst to nitroguanidine was varied from 0.25 to 1.0. It was found here that the greatest effect was with the smallest ratio of catalyst to nitroguanidine. The effect of adding 0.25 millimole of platinic chloride (48 mg. of platinum) to 0.50 g. of Raney nickel catalyst per gram of nitroguanidine gives a rate of hydrogenation equal to that obtained when the ratio of catalyst to nitroguanidine is 1.12.

The Reaction between Raney Nickel Catalyst and Platinic Chloride.—Certain facts concerning the promoter action of platinic chloride on Raney nickel catalyst are

[4] Delépine and Horeau, *Compt. rend.*, **201**, 1301 (1935); see *C. A.*, **30**, 1776 (1936). This paper came to the attention of the authors after this article was prepared for publication but before submission to the Editor.

revealed in the following experiments. Absorption of hydrogen in ml. of hydrogen in thirty minutes by 5.2 g. of nitroguanidine in 100 ml. of water and the catalyst (a) 1 millimole (0.337 g.) of platinic chloride alone, (b) an amount of Adams platinum oxide catalyst equal to 0.337 g. of platinic chloride, (c) a mixture of 2.5 g. of Raney nickel and platinum oxide equal to 0.337 g. of platinic chloride, (d) 2.5 g. of Raney nickel catalyst and (e) 2.5 g. of Raney nickel and 0.337 g. of platinic chloride, are (a) 0, (b) 537, (c) 796, (d) 851 and (e) 1222. These data indicate that platinic chloride is without activity and that the addition of Adams catalyst in an amount equal to the platinic chloride does not increase the activity of Raney nickel.

Thirty-four hundredths gram of platinic chloride was added to a suspension of 2.5 g. of Raney nickel catalyst in 100 ml. of water and the mixture was allowed to stand with occasional shaking for forty-five minutes. The mixture became opalescent during the first few minutes of contact but on standing the colloidal material settled and a clear green supernatant solution resulted. The clear solution was decanted, the remaining "catalyst" mass was washed several times by decantation, and the combined solutions were diluted to a volume of 200 ml. The nickel was determined in aliquot portions by weighing as nickel dimethylglyoxime: found 0.23, 0.25 g.; calcd. on the basis of equation

$$3Ni + PtCl_6^{=} + 2H^+ \longrightarrow Pt + 3Ni^{++} + H_2 + 6Cl^- \quad (I)$$

0.20 g. The solution was strongly acid and contained *no platinum.* The catalyst mass treated as described above had an activity *no greater* than the ordinary Raney nickel catalyst without platinum.

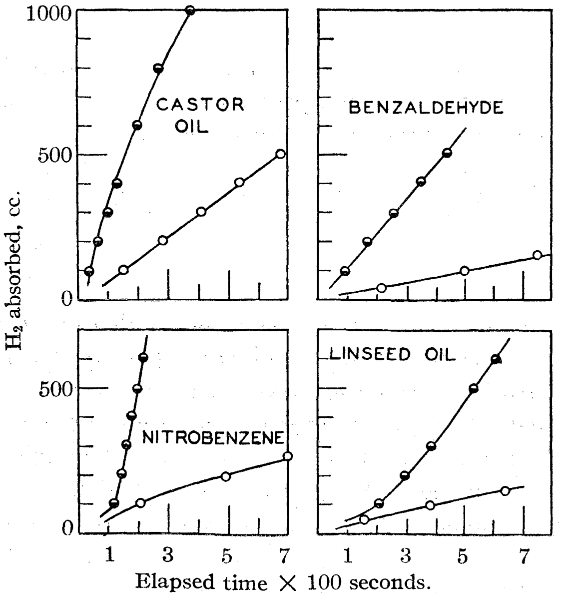

Fig. 2.—Promoted hydrogenations: ○ Raney nickel; ◒ promoted Raney nickel.

In order to determine the possible effect of the several components present the following experiments were performed. In each case 5.2 g. of nitroguanidine was suspended in 100 ml. of water.

	Catalyst	Adsorption ml. H_2/min.
1	2.5 g. Raney nickel	28.4
2	2.5 g. Raney nickel and 0.34 g. $PtCl_4$ added just before start of reduction	51.4
3	0.34 g. of $PtCl_4$ deposited as Pt on 2.5 g. Raney nickel and catalyst mass washed free of ions	29.0
4	As (3) with addition of 3 millimoles of nickel as Ni^{++}	22.7
5	As (3) with addition of 2 millimoles of HCl	26.6
6	2.5 g. of Raney nickel with 2 millimoles of HCl	5.4
7	2.5 g. of Raney nickel with 1 millimole of Ni^{++}	9.1

The addition of alkali (potassium hydroxide) sufficient to neutralize the acidity, produced in catalyst (2) above, decreased its activity 50–60%.

The nickel catalyst, which consists of nickel dispersed on kieselguhr, was prepared according to the method of Adkins and Cramer[5] and was tested for its catalytic activity with and without the addition of platinic chloride. There was no promotor action due to platinic chloride.

Platinic Chloride and Non-Catalytic Metal Powders.—The non-catalytic metal powders tested comprised Raney alloy (50% nickel), iron, aluminum and tungsten, using 0.337 g. (1 millimole) of platinic chloride the absorption rates obtained in ml. of H_2 per minute were 15.4, 8.0, 13.9 and 0.0, respectively. Using 0.075 g. (0.25 millimole) of platinic chloride with non-catalytic Raney alloy and catalytic Raney nickel the hydrogen absorption rates were 3.0 and 51.4 ml. of H_2 per minute, respectively.

Platinic Chloride Promotor Action on the Hydrogenation of Castor Oil, Nitrobenzene, Benzaldehyde and Linseed Oil.—In this series of experiments the solvent was 100 ml. of 95% ethanol; 0.25 g. of Raney nickel per gram of hydrogen acceptor (except for raw linseed oil where 0.1 g. of Raney nickel per gram of material was used) and 0.075 g. (0.25 millimole) of platinic chloride added just prior to the start of the reduction. The quantities of substances hydrogenated were 25 g. of castor oil, 25 g. of linseed oil, 12.5 g. of nitrobenzene and 10.5 g. of benzaldehyde. The reductions were carried out first with Raney nickel alone and then Raney nickel with platinic chloride. The data are summarized in Fig. 2 and Table I.

Discussion of Results

The action of platinic chloride on Raney nickel catalyst is open to several interpretations. It may be defined as a promoter action based upon the definition of Pease and Taylor[6] as the "activation of a catalyst by a small quantity of a relatively active substance." The examination of the reaction between platinic chloride and Raney nickel shows that we are dealing with reaction (I) and it is possible that the observed rates of hydrogenation are the result of the simultaneous activity of nickel and platinum. However, this re-

---

[5] Adkins and Cramer, THIS JOURNAL, **52**, 4349 (1930).

[6] Pease and Taylor, *J. Phys. Chem.*, **24**, 241 (1920).

action apparently must take place during the reduction with hydrogen, *i. e.*, the promotor effect is manifested when platinic chloride is added just before the hydrogenation is started. The interpretation of the results is further complicated by the fact that in adding platinic chloride, poisons for the nickel catalyst are added, although it should be pointed out that using non-catalytically active metals, or completely plating out the platinum and removing the poisons resulted in completely reduced activity. Further, the type of catalytically active nickel appears to be a factor. On a weight basis, reduced nickel on kieselguhr is hundreds of times as active as is Raney nickel,[7] however, addition of platinic chloride to such a catalyst under the same conditions as Raney catalyst (temperature, pressure of hydrogen and ratio of catalyst to hydrogen acceptor) had no effect on its activity.

On the other hand, however, the effect is not limited to the hydrogenation of a single substance (nitroguanidine), as is often the case in promoter catalysis. It has, indeed, been applied even more successfully to the hydrogenation of castor oil, linseed oil, nitrobenzene and benzaldehyde.

The application of the Raney nickel–platinic chloride catalyst to the hydrogenation of various types of organic compounds, as well as a more detailed investigation of the effects involved particularly with respect to other noble metal salts, is in progress in this Laboratory and will be reported in a subsequent paper.

Summary

Small amounts of platinic chloride added to Raney nickel catalyst immediately before the beginning of the hydrogenation have a definite and pronounced enhancing action which is not limited to the hydrogenation of nitroguanidine but is apparently applicable to the reduction of many types of organic compounds.

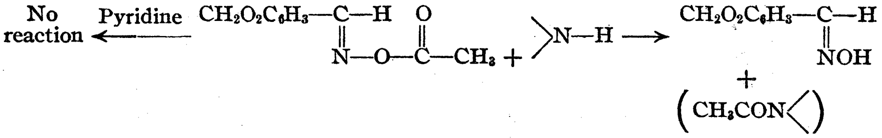
The Reactions of Aldoxime Derivatives with Bases. III. The Reactions of Geometrically Isomeric Acetyl-3,4-methylenedioxybenzaldoximes with Certain Amines

BY CHARLES R. HAUSER AND EARL JORDAN[1]

In continuation of our investigations[2] of the reactions of acyl-aldoximes with bases, a study has been made of the reactions of the two isomers of acetyl-3,4-methylenedioxybenzaldoxime with certain primary, secondary and tertiary amines.

It has been found that when the α-isomer is dissolved in *n*-butylamine, aniline, piperidine or diethylamine, and allowed to stand for a short time, it is converted into the corresponding α-aldoxime in yields of 90–99%; apparently these reactions are quantitative. On the other hand, the acetyl-α-aldoxime may be heated in pyridine solution at 97–100° for an hour and then recovered practically unchanged; also, it is relatively stable in triethylamine solution. The yields of aldoxime and recovered acetyl-α-aldoxime are given in Table I.

The reaction of acetyl-α-3,4-methylenedioxybenzaldoxime with a primary or secondary amine may be represented as an aminolysis,[3] thus[4]



$$\text{No reaction} \xleftarrow{\text{Pyridine}} \begin{array}{l} CH_2O_2C_6H_3—\underset{\|}{C}—H \quad \overset{O}{\underset{}{\|}} \\ \qquad\qquad\quad N—O—C—CH_3 \end{array} + \;>N—H \longrightarrow \begin{array}{c} CH_2O_2C_6H_3—C—H \\ \| \\ NOH \\ + \\ \left(CH_3CON\!<\right) \end{array}$$

The tertiary amines have no hydrogen atom attached to nitrogen and consequently are not capable of bringing about this reaction. The other possible decomposition, the elimination of acetic acid from the acetyl-α-aldoxime to form nitrile,[5] might occur very slowly in triethylamine solution at the boiling point of the

---

(1) This is from a portion of a thesis presented by Earl Jordan in partial fulfilment of the requirements for the Ph.D. degree at Duke University.

(2) See (a) Hauser and Sullivan, THIS JOURNAL, **55**, 4611 (1933); (b) Hauser and Jordan, *ibid.*, **57**, 2450 (1935); (c) Hauser, Jordan and O'Conner, *ibid.*, **57**, 2456 (1935).

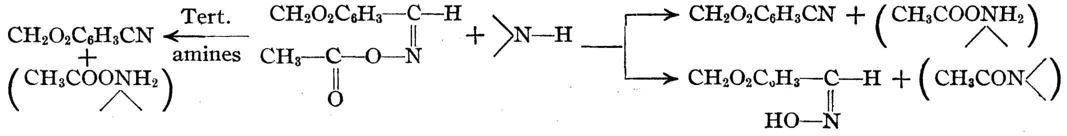
(3) This reaction is analogous to an ammonolysis of an ester; it is possible that the primary or secondary amine attacks the carbonyl group of the acetate, perhaps forming an intermediate addition compound which decomposes to form aldoxime and amide; the latter, however, has not been isolated.

(4) For references to evidence that α-aldoximes have the *syn* configuration, see note 2b.

(5) Although the acetyl-β-aldoxime in the presence of a base eliminates acetic acid to form nitrile much more readily than the α-isomer, it is possible for the latter, under certain conditions, to form nitrile or the corresponding acid; see reference 2b.

amine,[6] but this reaction does not occur in pyridine solution, at least not to an appreciable extent within an hour even at 97–100°.

The reactions of acetyl-β-3,4-methylenedioxybenzaldoxime with amines have been carried out under several different sets of conditions. In general, with primary or secondary amines this isomer gives partly nitrile by elimination of acetic acid, and partly the corresponding β-aldoxime presumably by aminolysis;[3] but with tertiary amines it gives only nitrile. These reactions may be represented as follows



The yields of nitrile and aldoxime obtained from the acetyl-β-aldoxime with a primary or secondary amine depend upon the relative rates of the two competing reactions. Similar to the reactions with alkali,[2b] an elevation of temperature accelerates the elimination of acetic acid to form nitrile more than the aminolysis to form oxime; also, these reactions are apparently dependent upon the basic strength of the amine used. In Table II are given the yields of products obtained by adding the acetyl-β-aldoxime in small portions to *n*-butylamine and to the much weaker base, aniline, at various temperatures. It can be seen that with *n*-butylamine the acetyl-β-aldoxime gives, below 0°, practically only oxime, between 20 and 45°, both oxime and nitrile; but at 78°, apparently only nitrile, no oxime being isolated at this temperature. With aniline at 25–30°, the acetyl-β-aldoxime gives apparently only oxime, and even at 97–100° this is the main product, the yield of nitrile being only 11%.

The difference in degree of reactivity of acetyl-α-, and acetyl-β-3,4-methylenedioxybenzaldoximes with various amines should be pointed out. Whereas the α-isomer merely dissolves in the amines listed in Table I without generating a noticeable amount of heat, the acetyl-β-aldoxime reacts vigorously with *n*-butylamine, piperidine, and diethylamine. When a few cubic centimeters of these amines are added, in 1-cc. portions, to gram samples of the acetyl-β-aldoxime, the reaction mixtures become hot immediately, producing high yields of nitrile and no appreciable amounts of oxime; however, when the relatively weak base, aniline, is added to the acetyl-β-aldoxime in a similar manner, the latter dissolves without a noticeable rise of temperature, giving a high yield of oxime and no appreciable amount of nitrile. The yields of products obtained with these primary and secondary amines under these conditions are given in Table III. In this table are included also the yields of nitrile obtained with the tertiary amines, pyridine and triethylamine; with the latter the reaction mixture becomes warm. The formation of nitrile from the acetyl-β-aldoxime and these tertiary amines is presumably quantitative over a considerable range of temperatures.

The yields of products obtained from the reactions of the acetyl-β-aldoxime with 1 *M* solutions of certain amines in water and in dioxane and with ammonia solutions, at 0 or 30°, are given in Table IV. It can be seen that with *n*-butylamine or piperidine both nitrile and oxime are obtained; in the reaction with aqueous piperidine the yield of nitrile is greater, and that of oxime correspondingly smaller at 30°, than at 0°.

It should be noted that with pyridine even in the presence of water the acetyl-β-aldoxime apparently gives only nitrile, whereas with triethylamine and water a small yield of oxime is obtained in addition to nitrile. In the latter case the formation of oxime presumably is due to the presence of hydroxyl ions since no oxime is found when the reaction is carried out in anhydrous dioxane solution; the concentration of hydroxyl ions in aqueous pyridine is apparently too small to produce an appreciable amount of hydrolysis before the acetyl-β-aldoxime is completely converted to nitrile.

Hantzsch[7] has previously reported that acetyl-β-aldoximes were decomposed by ammonium hydroxide to form β-aldoximes. We have found that with aqueous or alcoholic ammonia both nitrile and oxime are obtained except when the reaction is carried out at 0°; at this temperature with concentrated ammonia only oxime has been isolated.

---

[6] It can be seen from Table I that the melting point of the recovered product is somewhat lower than that of the pure acetyl-α-aldoxime.

TABLE I

PERCENTAGE YIELDS OF PRODUCTS FROM ACETYL-α-3,4-METHYLENEDIOXYBENZALDOXIME AND CERTAIN PRIMARY, SECONDARY AND TERTIARY AMINES

Amine		Oxime % yield	Oxime M. p., °C.[a]	Recovered acetyl deriv. % yield	Recovered acetyl deriv. M. p., °C.[a]
Primary					
n-Butylamine		91	108–110		
Aniline		98	108–110		
Secondary					
Piperidine		90	110		
Diethylamine		99	110		
Tertiary					
Pyridine	At 25°			92	105
	At 97–100°[b]			96	104–105
Triethylamine	At 25°			96	104–105
	At 89°[b]			99	95–97

[a] The melting points of these products were raised by recrystallization to those reported in the literature: for the α-aldoxime, 110°; for the acetyl-α-aldoxime, 105°. [b] This solution was heated for one hour.

TABLE II

PERCENTAGE YIELDS OF PRODUCTS FROM ACETYL-β-3,4-METHYLENEDIOXYBENZALDOXIME WITH *n*-BUTYLAMINE AND WITH ANILINE AT VARIOUS TEMPERATURES

Amine	Temp., °C.	Nitrile % yield	Nitrile M. p., °C.[a]	Oxime % yield	Oxime M. p., °C.[a]
n-Butylamine	−10– −5	5	92–93	90	144
	20–30	15	92–93	81	140–141
	25–45[b]	29	93–94	59	142–143
	78 (b. p.)	94	93–94		
Aniline	25–30			92	145–146
	97–100	11[c]	93–94	82	109–110[d]

[a] The melting points of these products were raised by recrystallization to those reported in the literature: for nitrile, 94–95°; for β-aldoxime, 146°. [b] In this case 5 cc. of *n*-butylamine was added all at one time to 1 g. of the acetyl-β-aldoxime; the heat of the reaction caused the temperature of the solution to rise from 25 to 45°. [c] In this case the nitrile might have been produced by a thermal decomposition of the acetyl-β-aldoxime. [d] In this case the β-aldoxime had changed to the α-isomer (m. p. 110°).

TABLE III

PERCENTAGE YIELDS OF PRODUCTS OBTAINED BY ADDING A FEW CUBIC CENTIMETERS OF VARIOUS AMINES IN ONE-CUBIC CENTIMETER PORTIONS TO GRAM SAMPLES OF ACETYL-β-3,4-METHYLENEDIOXYBENZALDOXIME

Amine	Nitrile % yield	Nitrile M. p., °C.[a]	Oxime % yield	Oxime M. p., °C.[a]
Primary				
n-Butylamine[b]	99	91–93		
Aniline			92	145–146
Secondary				
Piperidine[b]	99	92–94		
Diethylamine[b]	92	93–94		
Tertiary				
Pyridine	99	92–94		
Triethylamine	95	94–95		

[a] The melting points of these products were raised by recrystallization to those reported in the literature: for nitrile 94–95°; for β-aldoxime 146°. [b] The reactions with these amines were vigorous, generating considerable heat.

TABLE IV

PERCENTAGE YIELDS OF PRODUCTS FROM ACETYL-β-3,4-METHYLENEDIOXYBENZALDOXIME WITH 1 *M* SOLUTIONS OF CERTAIN AMINES IN WATER, DIOXANE AND AMMONIA

Amine	Solvent	Temp., °C.	Nitrile % yield	Nitrile M. p., °C.[a]	Oxime % yield	Oxime M. p., °C.[a]
n-Butylamine	Water	30	46	90–92	48	105–107[b]
n-Butylamine	Dioxane	30	42	93–95	56	143–144
Piperidine	Water	0	32	89–91	65	138–140
Piperidine	Water	30	63	92–94	28	110[b]
Piperidine	Dioxane	30	73	93–95	17	143–144

Ammonia (14 *M*)	Water	30	28	92–93	65	123–125

[a] The melting points of these products were raised by recrystallization to those reported in the literature: for nitrile, 94–95°; for β-aldoxime, 146°. [b] On standing this oxime had changed to the α-isomer (m. p. 110°).

Experimental

Acetyl-α- and acetyl-β-3,4-methylenedioxybenzaldoximes were prepared according to methods previously described.[2a,b] Samples (1–2 g.) of these compounds were dissolved in 4–6 cc. of amine, the relative yields of oxime and nitrile produced from the β-isomer with certain primary and secondary amines being dependent upon the method of treatment. The solutions of *n*-butylamine, piperidine, diethylamine, pyridine and triethylamine, after standing at least an hour, were shaken with several volumes of crushed ice, and the mixtures filtered through sintered glass crucibles of the Gooch type.[2b] The precipitates were washed with water until free of amines, and then treated with cold 2 *N* sodium hydroxide to dissolve out oxime. The solid remaining in the crucible was identified as nitrile or in certain cases as unchanged acetyl-α-aldoxime. The oxime was precipitated from the alkaline solution with carbon dioxide in the usual manner. In certain cases additional oxime was obtained from the amine filtrates by treatment with carbon dioxide.

The reaction solution obtained from aniline was dissolved in ether and extracted several times with small portions of cold 2 *N* sodium hydroxide. Oxime was precipitated from the alkaline solution by means of carbon dioxide. After drying with "Drierite," the ether solution was saturated with dry hydrogen chloride, the aniline salt filtered off, and the ether evaporated. A small amount of nitrile was obtained in this manner when the reaction had been carried out at 97–100°.

Blanks were run with β-3,4-methylenedioxybenzaldoxime in solutions of *n*-butylamine and pyridine; the oxime was recovered unchanged from these solutions.

The products from the reactions of acetyl-β-aldoxime (1–2 g. samples) with 50 cc. of 1 M solutions of amine in water and in dry dioxane were isolated as follows: after standing several days at 0 or 30°, the solids were filtered off from the aqueous mixtures, and the oxime separated from nitrile by means of alkali; in certain cases additional oxime was obtained from the aqueous amine filtrate. The dioxane solutions were evaporated to dryness in an air-draft, and the residue treated with alkali. In the reactions with aqueous and alcoholic ammonia, oxime and nitrile were isolated in a similar manner.

It has been found also that certain other acetyl-β-aldoximes with aniline give only the corresponding oxime; the yields of this product from acetyl-β-benzaldoxime and acetyl-β-3-nitrobenzaldoxime were 85 and 99%, respectively.

Summary

1. A study has been made of the reactions of acetyl-α- and acetyl-β-3,4-methylenedioxybenzaldoximes with certain primary, secondary and tertiary amines.

2. It has been found that when the acetyl-α-aldoxime is dissolved in the primary or secondary amines it is converted to the corresponding aldoxime; this reaction appears to be quantitative. The acetyl-α-aldoxime, however, is stable in the presence of the tertiary amines under ordinary conditions.

3. The acetyl-β-aldoxime reacts with the tertiary amines to form only nitrile, but, in general, with primary and secondary amines to form both nitrile and β-aldoxime, the yields of these products depending upon the temperature of reaction and apparently upon the basic strength of the amine used.

The Alkaline Decomposition of Cellulose Nitrate. I. Quantitative Studies[1]

By W. O. Kenyon and H. LeB. Gray

Previous workers have shown that the action of alkalies, especially potassium or sodium hydroxides, on aliphatic nitrates is not one of simple saponification regenerating the alcohol and forming sodium nitrate, but is a profound decomposition yielding also sodium nitrite and oxidation products of the aliphatic group. Thus, alkyl nitrates[2–5] give rise to ethers, alcohols, inorganic nitrates and nitrites, aldehydes and resinous bodies when treated with alkalies. Ethylene dinitrate[3,4,6] is stated to yield carbon dioxide, oxalic acid and glycol. The products of the alkaline decomposition of glycerol trinitrate[3,7–13] are stated to include: ammonia, carbon dioxide, formic acid, acetic acid, oxalic acid, mesoxalic acid, alkali cyanides, alkali nitrates, alkali nitrites and intermediate peroxides. The presence of glycerol is affirmed[13] and denied.[7] From nitrated mannose,[3] the formation of nitrates, nitrites, oxalic acid and unidentified organic acids is reported. Glucose,[14–16] levulose and starch trinitrates are said to yield products from which the osazones of oxypyruvic acid or its homologs may be isolated. Partially denitrated carbohydrates were also found.

The products reported by various authors as formed by the alkaline decomposition of cellulose nitrate are naturally greater in number and more complex. These include inorganic nitrates and nitrites,[17,18] ammonia,[18] cyanide,[19] carbon dioxide,[20] oxalic,[17,21,3] malic,[21] glycolic,[21] trioxy-

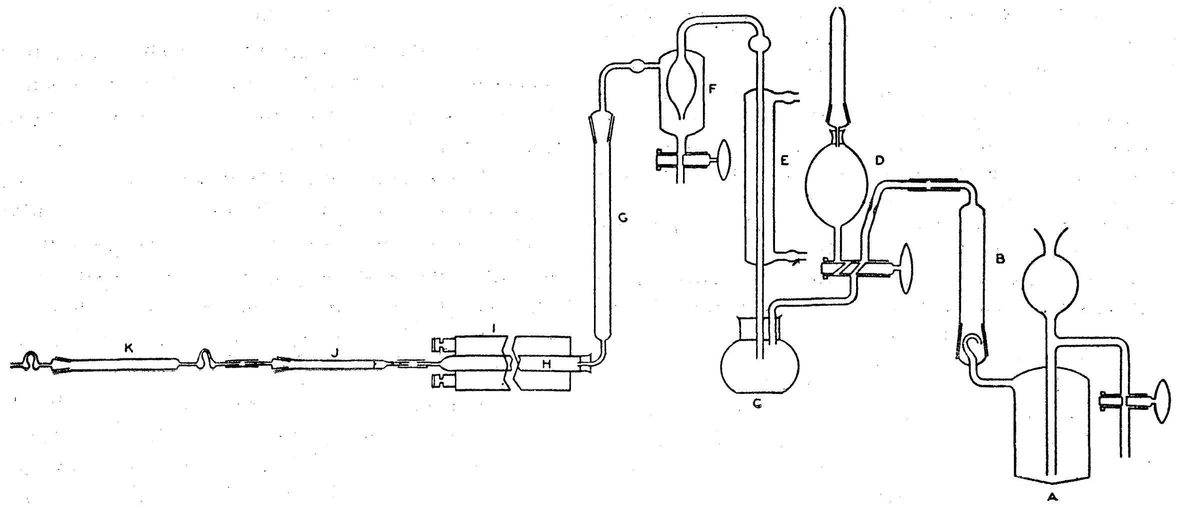

Fig. 1.

glutaric,[21] dioxybutyric,[21] malonic,[21] and tartronic acids,[21] sugars,[18,22] modified celluloses[18] and their nitrates,[23] and partially denitrated cellulose nitrates.[24,22,25] Unidentified complex acids are described.[17,26]

From the products of alkaline decomposition an osazone has been isolated which corresponds to the osazone of oxypyruvic acid.[14,15,16,19,21] Since this osazone may arise from several organic acids, attempts have been made to identify the acid present. One author[27] presents evidence for the presence of oxypyruvic acid (so-called keto form) while others believe the acid to be the semialdehyde of tartronic acid (aldehyde form).[28]

Quantitative studies of this reaction are more or less fragmentary. The formation of nitrites by the action of alkali on alkyl nitrates and the nitrates of ethylene glycol, glycerol, erythritol, mannitol, dulcitol and cellulose has been quantitatively measured.[29–31] Measurements of decomposition of various cellulose nitrates have been made by determination of the alkali consumed.[32,33]

Since no extended studies of the quantitative decomposition of cellulose nitrate could be found, we have studied in a quantitative manner the effect of certain variables: alkali concentration, ratio of alkali to ester, time, temperature and degree of nitration of the cellulose.

Experimental

A. **General Procedures.**—The cellulose nitrate was dried and 10-g. samples weighed to the nearest centigram (±0.1%). These were placed in flasks of suitable size with the amount of water which would yield the desired final concentration of alkali when the calculated amount of standard alkali was added. The water used in all of these experiments was freshly boiled, distilled water containing no amount of carbon dioxide capable of affecting the subsequent analyses.

The standard alkali used in all of these determinations possessed the following analysis: 0.77724 g. of sodium hydroxide per cc. at 25°; 0.007738 g. of sodium carbonate per cc. at 25°. The alkali concentrations given in this paper are expressed as grams of alkali per 100 cc. of water, *i. e.*, 20% = 20 g. per 100 cc. of water.

The aqueous suspensions of the cellulose nitrate were placed in a large water-bath and allowed to come to equilibrium with the temperature of the bath. The alkali was then quickly added with shaking to ensure complete mixing. The flasks were closed with rubber stoppers and placed in the bath until the decomposition was complete as evidenced by the disappearance of the suspended cellulose nitrate. During the reaction, the color of the liquid became reddish-brown. The temperature and total volume of the solutions were measured and the volume calculated to 25°, which was the temperature used for measurements of aliquots for analyses. Portions of the solutions were removed at various intervals, cooled to 25° and aliquots taken for the following measurements: (1) carbon dioxide, (2) optical rotation, (3) nitrites, (4) reducing power. The methods used for making these measurements were as follows.

(1) **Carbon Dioxide.**—Since we have been unable to find volatile organic acids other than carbon dioxide in the products of decomposition, the following method was adopted.

The apparatus used, Fig. 1, is an adaptation of that described by Kemmerer and Hallett.[34] It consists of a

bulb A containing sulfuric acid which acts as a drying chamber for the incoming air as well as a bubble counter. The tube B contains Ascarite to remove carbon dioxide from the air. C is a 100-cc. Pyrex extraction flask in which the sample is placed and D is a dropping funnel to introduce the acid. This is closed by a stopper carrying another Ascarite tube. The evolved gases pass through the condenser E, the bubble counter F containing sulfuric acid and the drying tower G containing Dehydrite. The silica tube H is 35.5 cm. long, the portion within the furnace I being filled with a mixture of lead dioxide and shredded asbestos maintained at 180°. After the gases have passed through this tube, water is absorbed in the phosphorus pentoxide tube J and the dry carbon dioxide absorbed in the tube K, Ascarite being the absorbing medium.

The determination is made by connecting the source of vacuum to the drying tube J by means of the stopcock which serves to regulate the flow of gas through the apparatus. The carefully measured sample is placed in C and enough carbon dioxide-free distilled water added to bring the volume to 10 cc. The flask is replaced and the outfit swept out by passing air through it for one-half hour at a rate of about 100 bubbles per minute. The Ascarite tube K is then placed in the train and the rate of bubbling reduced to about 20–30 per minute. An excess of 5% sulfuric acid solution (boiled to expel carbon dioxide) is added from the dropping funnel (50–100 drops). The contents of the evolution flask are then heated to boiling with a micro burner and boiled for two minutes. The burner is removed and the apparatus swept out at the same rate for one-half hour. The tube K is removed and weighed.

In order to test the accuracy of the method, a series of determinations was made using varying amounts of a standard sodium carbonate solution (4.385 mg. of carbon dioxide per cc. by titration) and a solution containing sodium nitrate and sodium nitrite made up by accurately weighing the pure sodium salts. This latter solution contained 0.075 mole of sodium nitrite per liter and 0.025 mole of sodium nitrate per liter, this composition being approximately that shown by nitrite analyses to be present in the alkaline decomposition mixture. The results are tabulated in Table I.

Table I

Na_2CO_3 soln., cc.	Na_2CO_3, mg.	Nitrate–nitrite soln., cc.	$NaNO_2$, mg.	$NaNO_3$, mg.	Na_2CO_3 found, mg.
1	4.385	..	....	....	4.397
1	4.385	..	....	....	4.391
2	8.770	..	....	....	8.775
4	17.540	..	....	....	17.602
1	4.385	2	10.351	4.250	4.368
1	4.385	4	20.702	8.500	4.396
1	4.385	4	20.702	8.500	4.3875
1	4.385	8	41.404	17.000	4.374
1	4.385	12	62.106	25.500	4.428

It will be seen that good agreement was obtained in all cases. The runs containing 4 cc. of the nitrate–nitrite solutions correspond closely to the greatest nitrate–nitrite concentration encountered in the experiments and even a three-fold excess (12 cc.) had little effect on the determinations.

The carbonate determinations on the decomposition solutions are corrected for the amount of carbonate present in the alkali used.

(2) **Nitrite Determinations.**—The method employed was an adaptation of the procedure of Green and Rideal[35] in which the aniline solution used by them was replaced by a solution of sodium sulfanilate.

(3) **Reducing Power.**—The procedure used in these determinations was the modified method of Bertrand.[36] Using the relationships established experimentally by Bertrand for the reducing power of glucose, we have expressed the total reducing power of the alkaline decomposition solution in terms of glucose. This will be a fairly accurate measure of the moles of reducing substance present assuming one actual or potential aldehyde group for each molecule of reducing substance present.

(4) **Optical Rotation.**—Due to the brown color of the solutions, they were diluted before measuring the rotatory power. The desired amount of the alkaline solution was measured from a buret into a 10-cc. volumetric flask and diluted to 10 cc. The rotation was measured in a Hilger–Lippich half-shade polarimeter using light from a mercury arc lamp which was filtered to give a wave length of 546.1 mμ. A tube length of 0.5 dm. was used in each case. The measurements with this instrument are accurate to ±0.01°.

In each of the various determinations, the results are calculated on the basis of the total amount of solution produced in each experiment. Since the same amount of cellulose nitrate was used in each case, the results are, therefore, expressed on the basis of the same weight of cellulose nitrate.

B. Decomposition at 30°. Constant Ratio of Alkali to Cellulose Nitrate (12.2% *N*). Varying Alkali Concentrations.—The data for the solutions used in this series of experiments are given in Table II. Under the heading "Time of Decomposition" are given the times required for disappearance of the cellulose nitrate. The exact time of disappearance is difficult to judge but the values given represent, at least, the relative order of magnitude.

Table II

No.	Cellulose nitrate, g.	NaOH soln., cc.	NaOH concn., %	Time of dec., hrs.
1	10	100	20	2.58
2	10	200	10	11.13
3	10	400	5	23.33
4	10	800	2.5	170.9
5	10	2000	1.0	245.0

Samples were withdrawn from the solutions at various times and analyzed. Samples from solution 1 are designated as 1A to 1D inclusive, those from solution 2 as 2A to 2D inclusive, etc. The results are tabulated in Table III.

Under the heading "Time of Sampling" are given the intervals elapsed between the addition of the alkali and the withdrawal of samples for analyses.

C. Decomposition at 60°. Constant Ratio of Alkali to Cellulose Nitrate (12.2% *N*). Varying Alkali Concentrations.—This set of experiments was run at 60°, all other conditions as shown in Table IV being the same as in B.

18	9.68	.225	3.15	47.21	2.100	.0489	− .35
19	10.14	.236	3.02	45.28	4.250	.0990	− .14

Attempts were made to investigate quantitatively the alkaline decomposition of cellulose nitrates containing 5.0 and 1.2% of nitrogen. Neither of these decomposed to yield completely water soluble products even when heated for twenty-four hours on the steam-bath in the presence of 20% alkali.

Discussion

Cellulose nitrate, when decomposed by aqueous sodium hydroxide solutions, yields alkali soluble products among which are carbon dioxide and substances capable of reducing alkaline copper solutions. This oxidative decomposition of the cellulose molecule is accompanied by reduction of the nitrate groups to nitrite groups. The time required to decompose a given weight of cellulose nitrate decreases with increasing temperature and alkali concentration but appears independent of the alkali–cellulose nitrate ratio at constant concentration.

The amount of carbon dioxide formed at 30° from cellulose nitrate containing 12.2% *N* (Table III) varied between 0.191 and 0.397 mole per mole of cellulose nitrate, which is equivalent to about 3 to 6% by weight of the cellulose nitrate used. About 60 to 70% of the nitrate groups present were reduced to nitrite. When the solutions were allowed to stand, the amount of carbon dioxide increased and the reducing power decreased.

At 60°, the same cellulose nitrate (Table V) yielded larger amounts of carbon dioxide at the same alkali concentrations, the values increasing with time. The conversion of nitrate to nitrite was about 70 to 72%. The reducing powers of the solutions produced at 60° were decidedly lower than those formed at 30°. The initial reducing powers of the solution were greater when lower concentrations of alkali were used but in each case decreased with increasing reaction time.

The values for carbon dioxide and nitrite conversion, at constant concentration and varying alkali/cellulose nitrate ratio (Table VII), appear to pass through a maximum. The reducing powers of the solutions decreased with increasing alkali ratio.

Experiments at 60° with cellulose nitrate containing 9.34% nitrogen (Table IX) indicated that the amount of carbon dioxide produced increased with decreasing alkali concentration. The conversion of nitrate to nitrite (39–50%) was less than when cellulose nitrate containing 12.2% nitrogen was used. The reducing power of the solutions increased with decreasing concentrations of alkali.

Summary

The decomposition of cellulose nitrates in aqueous sodium hydroxide has been studied in a quantitative manner.

A relatively small amount of carbon dioxide is produced and a relatively large per-

centage of the nitrate groups is reduced to nitrite.

The production of carbon dioxide and of reducing substances appears to be related to time, concentration of alkali, ratio of alkali to cellulose nitrate and the temperature.

The Magenta Series. II. Some Higher Basic Members

BY JOHN T. SCANLAN

In a previous publication[1] the results of an investigation of the "nitrobenzene process" and the "formaldehyde process" for the preparation of Magenta (Fuchsine) were given. In the latter process 4,4′-diaminodiphenylmethane, or one of its homologs, reacts with aniline or its homologs, and it was shown that the reaction involves a scission of the diphenylmethane. This report covers an extension of the same investigation to three of the higher members of the series in which the methyl groups are ortho to the amino groups and not more than two occur in any benzene nucleus. The simplified system of nomenclature explained in the previous publication is used (see Table I).

TABLE I

NOMENCLATURE

Name used in this paper	Scientific name
Magenta IV	3,3′,3″,5-Tetramethyl-4,4′-diaminofuchsonimonium chloride
Magenta V	3,3′,3″5,5′-Pentamethyl-4,4′-diaminofuchsonimonium chloride
Magenta VI	3,3′,3″,5,5′,5″-Hexamethyl-4,4′-diaminofuchsonimonium chloride

The results are even more clean-cut than those obtained with the lower homologs and confirm the conclusions previously stated. As shown by the data in Table II and the corresponding absorption curves in Fig. 1, when 4,4′-diamino-3,3′-dimethyldiphenylmethane reacts with *v-m*-xylidine (Experiments 5Fa and 5Fb) the product is not Magenta IV but Magenta V and when 4,4′-diamino-3,3′,5,5′-tetramethyldiphenylmethane reacts with *o*-toluidine (Experiment 6F) the product is not Magenta V, but Magenta IV. This conclusion is readily arrived at by comparing the products of the above two reactions with that of the reaction between *as-m*-xylidine and *v-m*-xylidine (Experiment 6N, "nitrobenzene process") which must obviously be Magenta V. No attempt was made to prepare Magenta IV and Magenta VI by the "nitrobenzene process" because a necessary intermediate, mesidine, was not readily available and it was thought that further evidence was not required.

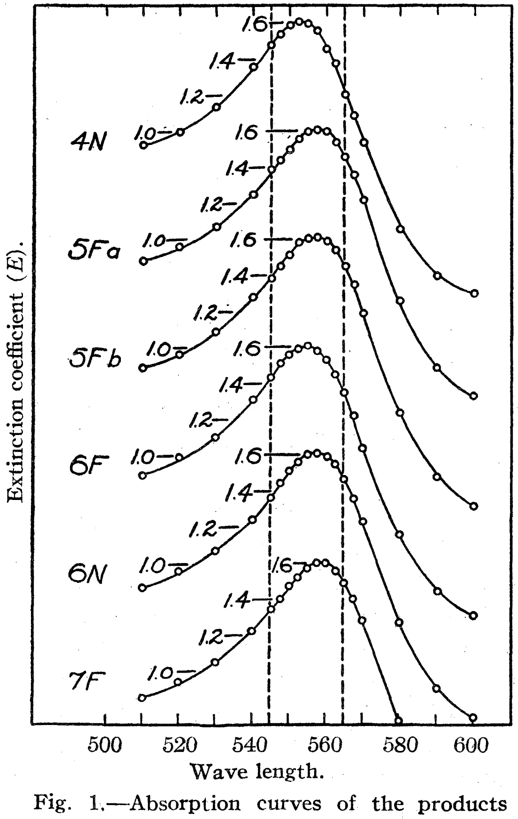

Fig. 1.—Absorption curves of the products obtained in the experiments indicated by the numbers. Solvent, 50% alcohol. The dyes corresponding to the curves are as follows: 4N, magenta III (repeated from previous paper for comparison); 6F, magenta IV; 5Fa, 5Fb and 6N, magenta V; 7F, magenta VI. Further data are given in Table II.

As in the case of the lower homologs, the solubility of these dyes (hydrochlorides) in alcohol decreases with increasing molecular weight. How-

Preparation of Intermediates

4,4′ - Diamino - 3,3′ - dimethyldiphenylmethane.—The method of preparing this compound was described in the previous publication.

Nitro-*m*-xylene.—Prepared by nitration of *m*-xylene[3] and purified by fractional distillation. The fraction boiling at 243–252° was used.

***v*-*m*-Xylidine.**—Technical xylidine[4] from which *as*-*m*-xylidine had been removed was freed from *p*-xylidine[5] and treated according to the method of Winkelhausen[6] to obtain *v*-*m*-xylidine sulfate. Part of this was converted to the chloride by treatment with barium chloride and the balance to the base by treatment with sodium hydroxide. Two kilograms of the technical xylidine yielded 130 g. of *v*-*m*-xylidine base and 189 g. of *v*-*m*-xylidine hydrochloride.

4,4′ - Diamino - 3,3′,5,5′ - tetramethyldiphenylmethane.—Fifty-seven grams of *v*-*m*-xylidine hydrochloride, 2 cc. of concentrated hydrochloric acid and 14 g. of 40% formaldehyde solution were dissolved in 150 cc. of water and heated at 70–75° for four hours. Near the end of the reaction time sufficient warm water was added to dissolve the precipitated hydrochloride. The mixture was then made alkaline with potassium hydroxide and steam distilled. The residual material was redissolved by the addition of hydrochloric acid and fractionally precipitated with ammonium hydroxide as described in the previous paper.[1] The first of the two fractions thus obtained was rejected and the second recrystallized from alcohol; yield 32 g.; m. p. 122.5–123.5°.

Friedländer and Brand[7] give the melting point as 126°.

Preparation of the Dyes

Experiment 5Fa (Magenta V, Formaldehyde Process).—The intermediates used were 40 g. of 4,4′-diamino-3,3′-dimethyldiphenylmethane, 25 g. of *v*-*m*-xylidine hydrochloride, 60 g. of *v*-*m*-xylidine (base), 25 g. of nitro-*m*-xylene and 16 g. of $FeCl_2 \cdot 4H_2O$. The procedure was the same as described for this process in the previous publication. The product was salted out and recrystallized from alcohol. It separates from this solvent in feathery clusters of very fine needles which form a felt-like mass on the filter. When thoroughly dried and ground it has a dull, gray-green color; yield 46 g.; 65% of the theoretical.

The carbinol base was prepared by mixing a hot solution of 4 g. of the dye in 1000 cc. of water with a hot solution of 5 g. of sodium hydroxide in 800 cc. of water. The base precipitated immediately and after boiling the mixture for about an hour, it was allowed to cool, the base was filtered off, washed with dilute ammonium hydroxide and dried over phosphorus pentoxide; yield 2.5 g.; small, ir-

regular prisms, buff-colored and showing only a very slight tendency to become red on standing.

Anal. Calcd. for $C_{24}H_{29}N_3O$: N, 11.20. Found: N, 11.04.

Experiment 5Fb (Magenta V, Formaldehyde Process).—The intermediates used were 26 g. of 4,4′-diamino-3,3′-dimethyldiphenylmethane, 14.5 g. of *v*-*m*-xylidine hydrochloride, 68 g. of *v*-*m*-xylidine (base), 12.6 g. of *o*-nitrotoluene and 9.1 g. of $FeCl_2\cdot 4H_2O$; procedure as above. The product separated from alcohol in feathery clusters of very fine needles. When thoroughly dried and ground it was dull, gray-green in color; yield 13.5 g.; 30% of theoretical.

The carbinol base was prepared as above using 3.5 g. of the dye; yield 1.5 g.; small, irregular prisms, buff-colored and showing only a very slight tendency to become red on standing.

Anal. Calcd. for $C_{24}H_{29}N_3O$: N, 11.20. Found: N, 11.19.

Experiment 6F (Magenta IV, Formaldehyde Process).—The intermediates used were 25 g. of 4,4′-diamino-3,3′,-5,5′-tetramethyldiphenylmethane, 12 g. of *o*-toluidine hydrochloride, 57 g. of *o*-toluidine (base), 12 g. of *o*-nitrotoluene and 8 g. of $FeCl_2\cdot 4H_2O$; procedure as above. The product separated from alcohol as very bright green, rather coarse needles; yield 13.5 g., 36% of theoretical.

Using 3 g. of dye the carbinol base was prepared as above except that in this case it was sufficiently soluble in hot aqueous alkali to permit filtration before it separated; yield 1.3 g.; small, irregular prisms, faintly pink when first precipitated, but acquiring an intense purple coloration on standing.

Anal. Calcd. for $C_{23}H_{27}N_3O$: N, 11.63. Found: N, 11.68.

Experiment 6N (Magenta V, Nitrobenzene Process).—The intermediates used were 36 g. of *as*-*m*-xylidine, 83 g. of *v*-*m*-xylidine hydrochloride, 64 g. of *v*-*m*-xylidine (base), 91 g. of nitro-*m*-xylene and 12 g. of $FeCl_2\cdot 4H_2O$. The procedure was the same as described for the nitrobenzene process in the previous publication. The product was salted out and recrystallized from alcohol. It separated as feathery clusters of very fine needles. When dried and ground it was dull, gray-green in color; yield 32 g., 27% of theoretical.

The carbinol base was prepared from 4 g. of the dye as described under Experiment 5Fa; yield 3.2 g.; small irregular prisms with only a very slight tendency to become red on standing.

Anal. Calcd. for $C_{24}H_{29}N_3O$: N, 11.20. Found: N, 11.08.

Experiment 7F (Magenta VI, Formaldehyde Process).—The intermediates used were 25 g. of 4,4′-diamino-3,3′-5,5′-tetramethyldiphenylmethane, 13 g. of *v*-*m*-xylidine hydrochloride, 65 g. of *v*-*m*-xylidine (base), 12 g. of *o*-nitrotoluene and 8 g. of $FeCl_2\cdot 4H_2O$.

The procedure was the same as that previously described for the formaldehyde process except that, because of the low solubility of this homolog, it could be separated by filtration from the hot solution immediately after the steam distillation. Some large, fused lumps of tarry material were removed manually and the balance was recrystallized from alcohol. A voluminous precipitate of feathery clusters of very fine needles was obtained which, when dried and ground, had a dark gray-blue color; yield 25 g., 60% of theoretical.

The carbinol base was prepared from 4 g. of the dye as described under Experiment 5Fa; yield 3.6 g.; small, irregular prisms, golden-yellow with practically no color change on standing.

Anal. Calcd. for $C_{25}H_{31}N_3O$: N, 10.80. Found: N, 10.89.

Summary

1. Three new homologs of Magenta were prepared, and their identity was established by spectrophotometric examination of the dyes and analysis of their carbinol bases. Absorption curves and absorption ratios suitable for their future identification are given.

2. Examination of these data confirms the conclusion, previously published, that in the "formaldehyde process" for the preparation of Magenta, scission of the diaminodiphenylmethane nucleus occurs.

UNITED STATES DEPARTMENT OF AGRICULTURE]

Some Ketonimine Dyes and Related Compounds

BY J. DAVID REID* AND D. F. J. LYNCH

In a previous investigation for the development of new bactericides the preparation of some symmetrical diamino dyes related to auramine O (the hydrochloride of 4,4′-tetramethyldiaminobenzophenonimine) and their salts was described.[1] This report concerns the preparation of the monoamino ketonimines which correspond to the diamino dyes previously reported, as well as several other new compounds prepared during the course of the investigation.

Experimental

Alkylated Diaminodiphenylmethanes.—The following new propyl and butyl derivatives of 4,4′-diaminodiphenylmethane were prepared with a view to converting them to the corresponding ketones by oxidation with chloranil as was done by Kliegl[2] with the tetramethyl derivative. However, this method of oxidation was not found applicable.

4,4′ - Tetra - *n* - propyldiaminodiphenylmethane.—This compound was prepared according to the method used by Biehringer[3] for the methyl homolog.

35.9 g. of di-*n*-propylaniline was dissolved in 22 g. of 36% hydrochloric acid and diluted with 14 cc. of water. Six grams of 40% formaldehyde was added, and the mixture was held under reflux at 90° for six hours. The mixture was made alkaline with sodium carbonate and extracted with ether. The ether was dried and evaporated. The residual oil was distilled *in vacuo*, and 7 g. of di-*n*-propylaniline was recovered at 105° at 7 mm. pressure. The methane distilled as a heavy oil at 260° at 7 mm.; yield 70%; sp. gr., 0.971^{20}_{20}.

Anal. Calcd. for $C_{25}H_{38}N_2$: N, 7.65. Found: N, 7.50, 7.76.

Dipicrate of 4,4′ - Tetra - *n* - propyldiaminodiphenylmethane.—The dipicrate was prepared as a solid derivative by dissolving 0.6 g. of the methane base and 0.82 g. of picric acid separately in 10-cc. portions of hot alcohol and mixing the two solutions. A gummy mass separated which solidified on cooling. It was crystallized from 40 cc. of alcohol as bright yellow needles; m. p. sinters 165°, decomposes 175°.

Anal. Calcd. for $C_{37}H_{44}N_8O_{14}$: N, 13.59. Found: N, 13.69, 13.74.

4,4′ - Tetra - *n* - butyldiaminodiphenylmethane.—To 10.5 g. of di-*n*-butylaniline in 5.5 cc. of 36% hydrochloric acid plus 4 cc. of water, was added 1.5 g. of 40% formaldehyde. The mixture was treated as described above. The methane distilled as an oily liquid at 270–280° at 6 mm. pressure; yield, about 70%; sp. gr., 0.953^{20}_{20}.

Anal. Calcd. for $C_{29}H_{46}N_2$: N, 6.63. Found: N, 6.26, 6.29.

Dipicrate of 4,4′-Tetra-*n*-butyldiaminodiphenylmethane.—This was prepared as described above for the corresponding propyl compound; m. p. 156°, corr.

Anal. Calcd. for $C_{41}H_{52}O_{14}N_8$: N, 12.72. Found: N, 12.60, 12.41.

***sym* - 4,4′ - Di - *n* - butyldiaminodiphenylmethane.**—To 6 g. of 40% formaldehyde were added 31 g. of *n*-butylaniline in 22 g. of 36% hydrochloric acid and 14 cc. of water. It was treated as above. Four grams of butylaniline was recovered at 100° at 10 mm., and the methane distilled at 260–270° at 8 mm. After standing for one week it crystallized as colorless flat plates; m. p. 45°, corr.; yield, about 80%.

Anal. Calcd. for $C_{21}H_{30}N_2$: N, 9.03. Found: N, 8.76, 8.80.

4-Di-*n*-propylaminobenzoic Acid.—In the attempted preparation of 4,4′-tetrapropyldiaminobenzophenone by the method Michler[4] used to make first 4-dimethylaminobenzoic acid and then his ketone, the corresponding dipropyl acid was synthesized.

Four grams of phosgene was absorbed in 15 g. of di-*n*-propylaniline and allowed to stand overnight. The mass was dissolved in dilute hydrochloric acid, filtered and made alkaline with sodium hydroxide. The dipropylaniline was recovered in ether. The solution was made slightly acidic and allowed to stand overnight. The acid crystallized out. It may be extracted also with ether. It was recrystallized as long tetragonal prisms from 50% alcohol; m. p. 142°, corr.; yield, about 80% based on dipropylaniline used up.

Anal. Calcd. for $C_{13}H_{19}NO_2$: N, 6.33. Found: N, 6.14, 6.22.

4-Di-*n*-propylaminobenzophenone.—The 4-dimethyl and 4-diethylaminobenzophenones used below as well as the new 4-di-*n*-propylaminobenzophenone were prepared by the method of Meister, Lucius and Brüning, as modified by C. D. Hurd and C. N. Webb.[5]

In the preparation of the propyl ketone, 13 g. of phosphorus oxychloride was added to a mixture of 25 g. of di-*n*-propylaniline and 10 g. of benzanilide. The mixture was heated cautiously to 105–125°, at which point the temperature rose very suddenly to about 200°. It was cooled in ice water in time to keep the temperature below 200° and then heated under reflux in a boiling water-bath for four hours. It was then poured into 250 cc. of 10–15% hydro-

chloric acid and warmed until solution took place. The intermediate hydrolyzed overnight to the ketone. The solution was filtered and diluted to 1.5 liters to get the crystalline ketone. It was recrystallized from petroleum ether (b. p. 30–65°) as hexagonal colorless prisms; yield, about 25%; m. p. 100°, corr.

Anal. Calcd. for $C_{19}H_{23}NO$: N, 4.98. Found: N, 5.00, 5.02.

4-Di-*n*-butylaminobenzophenone apparently cannot be prepared by the above method. In several trials only two had the characteristic exothermic reaction. In each case a thick resinous material insoluble in acid was obtained, which was not hydrolyzed by water or alcohol.

Hydrochloride of 4-Aminobenzophenonephenylimide.—The method devised by Madelung[6] to make 4,4′-diaminobenzophenonimine was applied to the preparation of 4-aminobenzophenonimine. The phenylimide intermediate was made by heating 13 g. (0.1 mole) of aniline hydrochloride and 19.7 g. (0.1 mole) of 4-aminobenzophenone in 50 cc. of aniline at 160–180° with occasional stirring for about an hour, or until the mass solidified. After cooling, the aniline was removed by extraction with ether, and the intermediate, 4-aminobenzophenonephenylimide hydrochloride, crystallized from alcohol; yield, about 95%; sinters about 275–280°; no melting point to 400°.

Anal. Calcd. for $C_{19}H_{17}N_2Cl$: N, 9.08. Found: N, 8.97, 8.93.

The phenylimide hydrochloride dyes silk and tannin-mordanted cotton a light yellow but is not fast to light or washing.

The base was liberated from the aqueous solution of the hydrochloride by precipitating with alkali. It was crystallized from benzene after treatment with charcoal; m. p. 154°, corr.

Anal. Calcd. for $C_{19}H_{16}N_2$: N, 10.30. Found: N, 10.22, 9.96.

3,5-Dinitrobenzoate of 4-Aminobenzophenonimine

Method I. From 4-Aminobenzophenonephenylimide Hydrochloride.—Ten grams of the phenylimide hydrochloride was suspended in 100 cc. of alcohol, and ammonia gas was bubbled into the solution until it was saturated and then the liquid was brought to boiling. As done by Madelung, this step was repeated three times to split off the aniline more effectively. The resulting liquor was cooled and the precipitate filtered off and dissolved in about 400 cc. of water, which was just faintly acid with hydrochloric acid. The solution was made alkaline and the imine base extracted with ether. The ether solution was dried over sodium sulfate, and the imine was precipitated as the 3,5-dinitrobenzoic acid salt; yield about 5%; m. p. 198°, corr. A mixed melting point taken with a sample of the same salt prepared by Method II as described below was 198°.

Method II. From 4-Aminobenzophenone.—Ten grams of 4-aminobenzophenone and 10 g. of phosphorus pentachloride, each dissolved in 30 cc. of hot toluene, were cautiously mixed in a steel bomb (100-cc. capacity), and cooled in ice, and liquid ammonia was added cautiously until the weight increased 15 g. The bomb was capped and heated for twelve hours at 100–105°. It was then cooled and opened and the solution evaporated to dryness with an air blast. The mixture of ketone and imine was dissolved in ether and the imine precipitated as a yellow salt by the slow addition of an ether solution of 3,5-dinitrobenzoic acid. The pure base was not obtained, due to the difficulty of separating the imine and the ketone by crystallization. The imine rapidly hydrolyzed to the ketone on treating the salt with alkali. Crystallized from alcohol, the salt had a melting point of 198°, corr. When it was mixed with an equal quantity of 3,5-dinitrobenzoic acid (m. p. 204°) the melting point was depressed to about 110°; yield, about 50%.

Anal. Calcd. for $C_{20}H_{16}N_4O_6$: N, 13.73. Found: N, 13.69, 13.58.

3,5-Dinitrobenzoate of 4-Dimethylaminobenzophenonimine.—Ten grams of 4-dimethylaminobenzophenone[4] was dissolved in 40 cc. of hot toluene, and 10 cc. of phosphorus oxychloride was added. It was cooled and treated with ammonia as in Method II for the preparation of 4-aminobenzophenonimine. Evaporation of the filtered toluene gave an oil from which only the ketone could be crystallized. Distillation of the oily residue *in vacuo* gave a liquid which apparently was about equal parts of ketone and ketonimine. (Calcd.: N, 12.5. Found: N, 9.5.) This material, dissolved in ether and precipitated by 3,5-dinitrobenzoic acid, crystallized from alcohol as yellow needles; yield, about 30%; m. p. 214°, corr.

Anal. Calcd. for $C_{22}H_{20}N_4O_6$: N, 12.84. Found: N, 12.67, 12.68. (Phosphorus pentachloride gave a negligible yield when used in place of the oxychloride. Phosphorus trichloride (b. p. 77°) gave a yield of 5%.)

3,5-Dinitrobenzoate of 4-Diethylaminobenzophenonimine.—This salt was prepared as above, from the 4-diethylaminobenzophenone. However, the precipitate first obtained had to be treated with very dilute alkali, shaken out with ether and reprecipitated in order to free it of ammonium 3,5-dinitrobenzoate. It crystallized from alcohol as yellow needles; yield, about 30%; m. p. 141°, corr.

Anal. Calcd. for $C_{24}H_{24}N_4O_6$: N, 12.07. Found: N, 12.22, 12.11.

An effort was made to prepare 4-di-*n*-propylaminobenzophenonimine from the corresponding ketone by the above method, but no solid product could be isolated. The only action noted was that a yellow color was produced when acid was added to the ether solution of the product.

Benzoyl - 4,4′ - tetraethyldiaminobenzophenonimine. (Benzoyl Ethyl Auramine.)—The benzoyl derivative of 4,4′-tetraethyldiaminobenzophenonimine was made by the method used by Finckh and Schwimmer[7] in preparing the benzoyl derivative of the corresponding methyl compound.

Four grams of 4,4′-tetraethyldiaminobenzophenonimine[1] was refluxed in 20 cc. of benzene with 2.9 g. of benzoic anhydride for five hours. The solution was then diluted to 80 cc. with petroleum ether (b. p. 30–65°). The thick red liquid resulting was separated, and crystallized on standing. It was recrystallized from methyl alcohol as long yellow needles; m. p. 165°, corr.; yield, about 60%.

Solid Salts of Amines.—In working with the alkyl anilines used, it was found convenient to prepare solid derivatives by the use of 3,5-dinitrobenzoic acid. The salt of dimethylaniline has been prepared previously by the same method.[9]

0.002 mole of the dialkylaniline and 0.004 mole of the 3,5-dinitrobenzoic acid (0.002 mole with monobutylaniline) were dissolved in a few cc. of absolute alcohol and allowed to crystallize overnight. The salt was then recrystallized from absolute alcohol with char treatment. All the four salts crystallized as hexagonal prisms (see Table I).

TABLE I

3,5-Dinitrobenzoic acid salt of	M. p., °C., corr.	Nitrogen, % Calcd.	Nitrogen, % Found		Neut. equivalent Calcd.	Neut. equivalent Found
Diethylaniline	120	12.22	12.33	12.41	286.6	280

Summary

In a study of the ketonimine dyes:

1. Di-*n*-butyldiaminodiphenylmethane, tetra-*n*-butyldiaminodiphenylmethane and tetra-*n*-propyldiaminodiphenylmethane have been synthesized. The picrates of the latter two are also given.
2. 4-Di-*n*-propylaminobenzoic acid has been made.
3. 4-Aminobenzophenonephenylimide and its hydrochloride have been prepared.
4. 4-Aminobenzophenonimine, 4-dimethylaminobenzophenonimine and 4-diethylaminobenzophenonimine have been made and characterized as their solid 3,5-dinitrobenzoic acid salts.
5. Benzoyl ethyl auramine was made, and its properties as an indicator are described.
6. The solid derivatives of diethyl-, di-*n*-propyl-, di-*n*-butyl- and *n*-butyl-aniline with 3,5-dinitrobenzoic acid have been prepared and characterized.

Synthesis of Derivatives of Symmetrical Diphenylethane Related to Materials Occurring Naturally. I. Synthesis of the Ring System Proposed for Calciferol

BY SAMUEL NATELSON AND SIDNEY P. GOTTFRIED

A general and flexible method for the synthesis of compounds related to the naturally occurring derivatives of diphenylethane, which include compounds as widely distributed in nature as alkaloids, sterols, bile acids, sex hormones, toad poisons and cardiac aglycones[1] should be of value for the synthesis of degradation products and ultimately for the synthesis of some of the naturally occurring materials themselves.

This report offers a new route to this biologically important series which is capable of wide variation. As an example of its application, a compound having the ring system proposed for calciferol was synthesized in good yield. The formulas proposed by Windaus,[2] Heilbron,[3] Lettré[4] and Müller[5] assume that the phenanthrene ring is open to give a hydrogenated diphenylethane structure to calciferol and tachysterol.

As can be seen from the accompanying flow sheet, the starting materials for this synthesis are the readily available phthalic anhydride and phenylacetic acid.

Phthalic anhydride and phenylacetic acid condense in good yield to form benzal-phthalide (I).[6] The relationship of benzal-phthalide to the naturally occurring materials was recognized and this material and its derivatives were then built up to

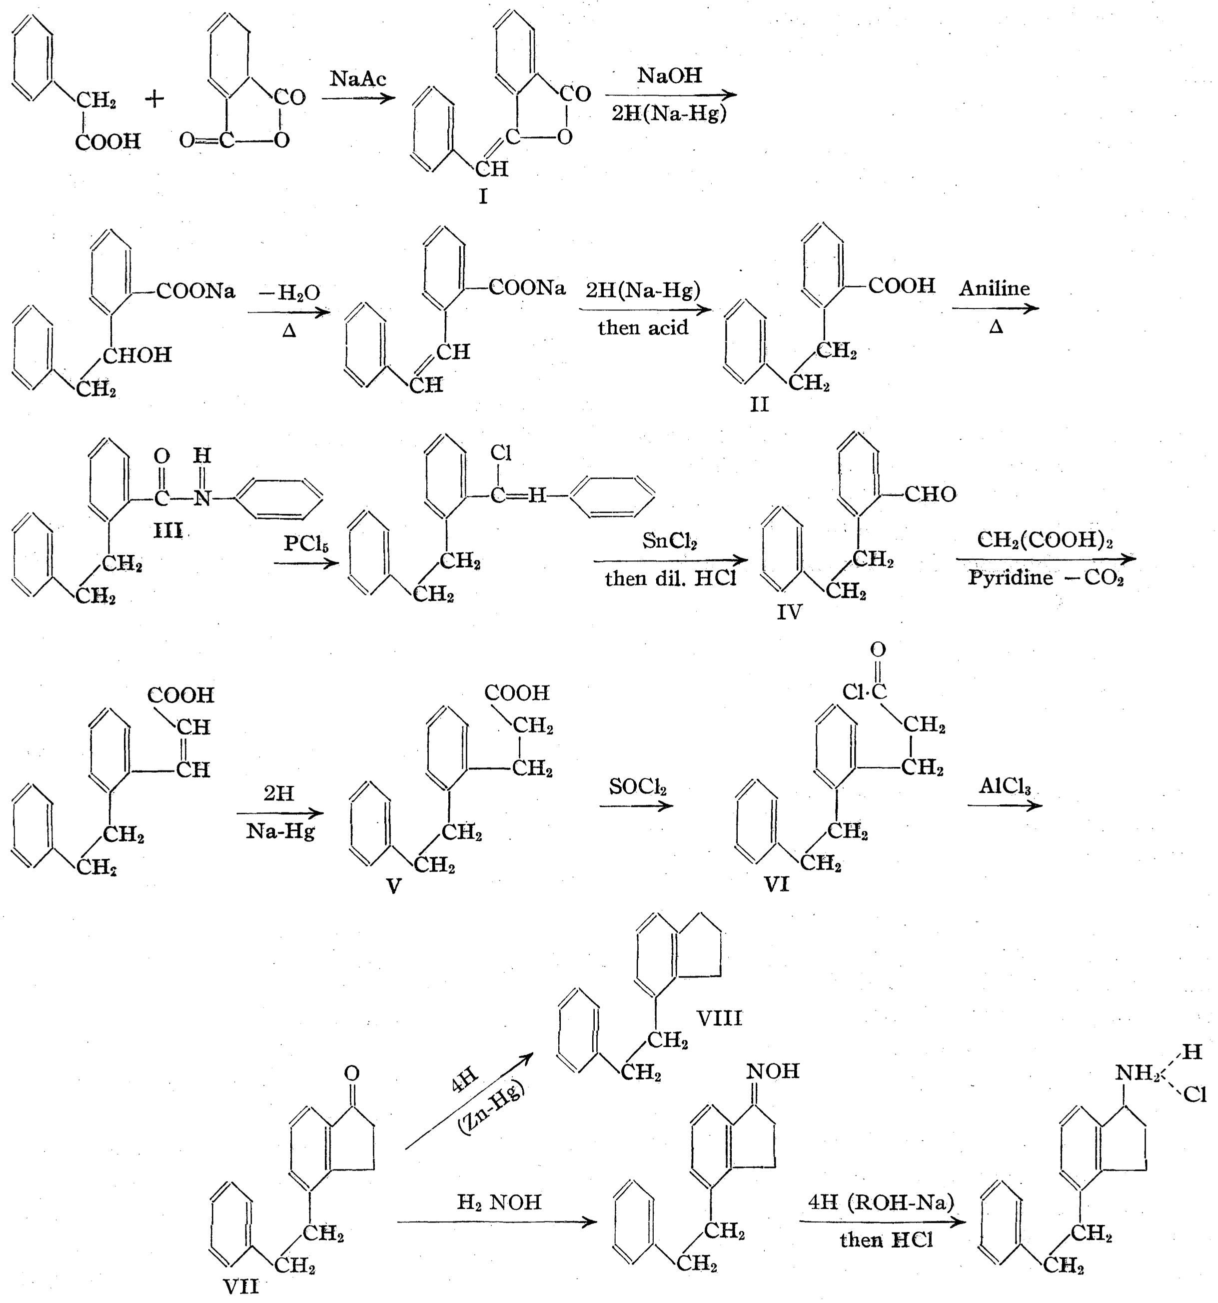
FLOW SHEET



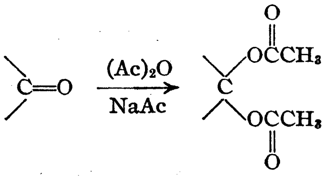
form 4-β-phenethylindane (VIII), the structure proposed for the calciferol nucleus. This was accomplished by converting benzal-phthalide to *o*-β-phenethylbenzoic acid (II) by a reduction, dehydration and further reduction applying and improving the method of Gabriel.[7] The acid was then reduced to the corresponding aldehyde (IV) applying the general procedure of Sonn and Müller. Before this procedure was resorted to, several different methods of reduction had been tried, but all had been abandoned either because of poor yield or inability to be applied to large quantities. The following procedures were found to be inapplicable for preparing the aldehyde from the acid: catalytic reduction of the acid chloride, distillation of the calcium salt of the acid with calcium formate, reduction of the ester with sodium and butyl alcohol followed by chromate oxidation, reduction of the amide electrolytically and with so-

---

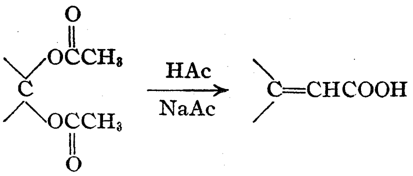
[7] Gabriel and Posner, *Ber.*, **27**, 2506 (1894).

dium amalgam, reduction of the anhydride (mixed) of this acid (II) and acetic acid.

When the Perkin reaction was applied to ortho-β-phenethylbenzaldehyde to form the substituted cinnamic acid, the main product of the reaction was found to be the substituted benzylidine diacetate, although some *o*-β-phenethylcinnamic acid was formed.



o-β-Phenethylbenzylidine diacetate when heated with sodium acetate in the presence of glacial acetic acid yielded the *o*-β-phenethylcinnamic acid. This would seem to be in line with the old Nef theory as to the mechanism of the Perkin reaction.[8]



Because of the poor yields obtained from the Perkin reaction when applied to *o*-β-phenethylbenzaldehyde (IV), this aldehyde was condensed quantitatively with malonic acid in the presence of small amounts of pyridine as a sort of modified Knoevenagel reaction. The reaction between malonic acid and the aldehyde in the presence of traces of pyridine is so satisfactory that it could be used to determine the percentage of aldehyde in a sample, by titrating the water-insoluble acid produced.

The *o*-β-phenethylcinnamic acid was then reduced to *o*-β-phenethylhydrocinnamic acid (V). This acid was then cyclized by treatment of its acid chloride (VI) with aluminum chloride in the presence of petroleum ether. The 4-β-phenethylindanone-1 formed was then reduced by the Clemmensen reduction to 4-β-phenethylindane, the ring system for the proposed structure for calciferol (vitamin D_2) and tachysterol. The formula of (VIII) is written in such a way as to indicate the close relationship to the cholane nucleus.

The over-all yield was good, 230 g. of benzal-phthalide yielding from 34–45 g. of the final product. As can be seen from the experimental part of this paper, the yields can be almost doubled if *o*-β-phenethylbenzoic acid is converted to its anilide (III) from its acid chloride by the action of thionyl chloride. The danger of using this method is that the whole yield can be ruined if traces of mercury, from earlier treatment, are present.

It is noteworthy that the ketone group in 4-β-phenethylindanone-1 is in the same position as the ketone group in androsterone and is in a favorable position for the addition of side chains in the synthesis of compounds related to sterols and bile acids.

It is apparent that by the use of substituted derivatives of phenylacetic acid and phthalic anhydride, various derivatives may be prepared. For example, 6-nitro-3-methoxyphenylacetic acid is being employed in an attempt to bring about a phenanthrene ring closure by the Pschorr method and at the same time prepare a cyclopentenophenanthrene derivative with an hydroxyl group in the same position as for cholesterol or androsterone. The close relationship between the alkaloids and sterols can be emphasized in that benzal-phthalide is closely related to benzylisoquinoline. This observation has suggested an attempt at a new method for the synthesis of benzyl isoquinoline alkaloids.

At the present time a mild reduction of calciferol and its degradation to a product which might be synthesized by this method has been undertaken to test the structure proposed for the antirachitic irradiation product produced from ergosterol.

Experimental

Benzal-phthalide.—Benzal-phthalide was prepared by the method of Weiss[6] using double the quantities specified. The yield of once crystallized material, m. p. 98–99°, is 77–84%. Care should be taken not to allow the temperature to rise above 240° for any length of time, for the yield may be completely destroyed.

Benzyl-phthalide.—Two hundred and thirty grams of benzal-phthalide is dissolved by heating with a solution of 60 g. of potassium hydroxide in 100 cc. of water. Benzal-phthalide is insoluble in hot dilute alkali. The dark red solution is then diluted to 1.5 liters with water and poured onto sodium amalgam, prepared by adding 2100 g. of mercury to 70 g. of molten sodium under mineral oil, with stirring. The solution is vigorously stirred until the color completely disappears, about four to six hours, depending upon the efficiency of the stirrer. The material is then transferred to a large separatory funnel and the mercury is drawn off. Ether is added and the mixture is shaken to remove traces of mineral oil. The lower layer is removed and acidified. The benzyl-phthalide comes down as an oil and then crystallizes in heavy colorless crystals which are

---

[8] Nef, *Ann.*, **298**, 277 (1897).

filtered off, m. p. 61° (recrystallized from dilute alcohol); b. p. 190–200° (5 mm.); yield quantitative.

o-**Carboxystilbene.**—The still moist benzyl-phthalide, from the above preparation, is dissolved in 400 cc. of 95% alcohol with warming; 60 g. of potassium hydroxide is added and the whole is gradually heated in a sand-bath, in a liter flask, until all the alcohol is removed and the light brown residue begins to foam, the temperature is raised to 180° and kept there until the foaming ceases and the whole material solidifies (two to four hours). The solid while still warm is dissolved in 1.5 liters of water. If this acid is desired, the solution is washed with ether, acidified, filtered and dried to give *o*-carboxystilbene. The yield is almost quantitative (210 g.); m. p. 160° (recrystallized from dilute alcohol).

o-*β*-**Phenethylbenzoic Acid.**—The 1.5 liters of solution containing the dissolved sodium salt of *o*-carboxystilbene is added to an amalgam of 70 g. of sodium in 2100 g. of mercury. The mixture is stirred vigorously until a large part of the amalgam reacts. As the reaction proceeds, the solution becomes warm and remains warm until reduction is complete when it goes back to room temperature (four to six hours). The solution is transferred to a separatory funnel, the mercury separated and then washed with ether. All traces of colloidally suspended mercury must be removed if the acid is to be converted to the acid chloride. The solution is therefore filtered through two thicknesses of filter paper with suction, acidified and then either allowed to stand overnight or cooled with crushed ice to complete the crystallization of the acid. The acid is filtered off and dried at 60°; yield 210–211 g.; m. p. 130° (recrystallized from alcohol).

Anal. Calcd. for $C_{15}H_{14}O_2$: C, 79.64; H, 6.19. Found: C, 79.30; H, 6.27.

Acid Chloride of *o*-*β*-**Phenethylbenzoic Acid.**—Two hundred and ten grams of dried, mercury-free *o*-*β*-phenethylbenzoic acid is placed in a flask fitted with a reflux condenser; 400 cc. of thionyl chloride is slowly added through the top of the condenser. This large excess of thionyl chloride is necessary before the reaction will proceed to completion. The excess over the amount consumed is recovered on distillation at the end of the reaction. The acid slowly reacts and dissolves. When addition is complete a calcium chloride tube is placed on top of the condenser and refluxing is continued for one hour on a water-bath. The excess thionyl chloride is recovered under mild vacuum on a water-bath and the residue is distilled, preferably for so large a volume at less than 10 mm. The pale yellow distillate crystallizes when scratched after cooling; yield 190 g.; m. p. 50–55°; b. p. 202° (20 mm.), 180° (5 mm.).

Anal. Calcd. for $C_{15}H_{13}O_2Cl$: Cl, 14.52. Found: Cl, 14.39.

If traces of mercury are present, large amounts of hydrogen chloride are given off and the material turns black and resinifies on attempted distillation. The ability of the smallest traces of mercury to split out large amounts of hydrogen chloride has been pointed out already.[9]

Ethyl Ester of *o*-*β*-**Phenethylbenzoic Acid.**—Two hundred and ten grams of *o*-*β*-phenethylbenzoic acid was added to 500 cc. of absolute alcohol which had been saturated with dry hydrogen chloride. Dry hydrogen chloride was passed through the cooled mixture for one hour when a large part of the acid dissolves. The mixture is then refluxed gently, in the hood, for two hours when a heavy pale yellow oily lower layer is formed. The alcohol is distilled off and the residue is vacuum distilled on a glycerol bath. The yield of pure ester, pale yellow oil, which slowly hydrolyzes in air, is 210–220 g.; b. p. 205° (18 mm.); sp. gr. 1.063 (25°); $n^{29}{}_D$ 1.5528.

Anal. Calcd. for $C_{17}H_{18}O_1$: C, 80.31; H, 7.09. Found: C, 79.99; H, 7.01.

When 64 g. of this ester is reduced with 40 g. of sodium in 400 cc. of anhydrous normal butyl alcohol with 150 cc. of toluene, 30 g. of a pale yellow liquid of b. p. 170–195° (20 mm.) is obtained. On fractional distillation this is separated into two fractions b. p. 177° (20 mm.) and 195° (20 mm.). On careful study neither of these seemed to be the alcohol. It is intended to make a detailed study of this reduction.

Mixed Anhydride of *o*-*β*-**Phenethylbenzoic Acid and Acetic Acid.**—Ten grams of *o*-*β*-phenethylbenzoyl chloride, 3 g. of sodium acetate and 8 g. of acetic anhydride are heated together for six hours at 180°. Water is added and the solution is neutralized with dilute sodium carbonate. The precipitate was filtered off and recrystallized from alcohol in which it is very soluble hot and insoluble cold; heavy colorless prisms which are rather inert but hydrolyze slowly on boiling in water. On hydrolysis by boiling in alkali and then acidification, *o*-*β*-phenethylbenzoic acid and acetic acid are obtained; m. p. 95°.

Anal. Calcd. for $C_{17}H_{16}O_3$: C, 76.12; H, 5.97. Found: C, 76.21; H, 6.03.

o-*β*-**Phenethylbenzanilide. Method 1.**—Two hundred and ten grams of dry *o*-*β*-phenethylbenzoic acid is placed in a liter, three-necked flask, fitted with thermometer, dropping funnel and bent tube leading to a receiver; 96 g. of aniline is added and the material is slowly heated in a sand-bath to 250° when about one-half the aniline distils over with some water. The melt is kept at 250° while 125 g. of aniline is added through the dropping funnel at such a rate that the temperature never drops below 240°. Aniline continues to distil through the bent tube into the receiver carrying the water formed in the reaction with it. After all the aniline has been added (three to four hours) the temperature is kept at 240° until all the aniline distils off. The melt is poured into an aluminum dish and allowed to solidify. The solid is ground to a fine powder in a mortar, washed with dilute hydrochloric acid, transferred back to the original flask and extracted with two hot 400-cc. portions of sodium carbonate solution containing 50 g. of sodium carbonate in each portion. The residue is filtered off, washed with water and recrystallized from hot alcohol, in which it is very soluble hot and difficultly soluble cold. On acidification, the combined sodium carbonate washings yielded 75 g. of the original acid. Hence the percentage yield should be based on 135 g. of the acid; yield 125 g. of the anilide, needle-like crystals slightly colored by this method; m. p. 137°.

Anal. Calcd. for $C_{21}H_{19}ON$: C, 83.72; H, 6.31; N, 4.64. Found: C, 84.22; H, 6.18; N, 4.58.

---

(9) Natelson, *Ind. Eng. Chem.*, **25**, 1391 (1933).

Method 2.—One hundred and ninety grams of the pure crystalline acid chloride is ground in a porcelain dish with 180 g. of aniline. The mixture becomes warm and forms a homogeneous melt. When the reaction has ceased the mixture is heated further on a water-bath for thirty minutes at 90°. On cooling the mass solidifies and is washed with dilute hydrochloric acid and then warm dilute sodium carbonate. On recrystallization from alcohol colorless needles are obtained, m. p. 137°, yield 200 g.

***o*-β-Phenethylbenzaldehyde.**—Three hundred grams of anhydrous stannous chloride, prepared by heating the hydrate over a small flame in a porcelain dish in the hood until all water has been removed and the material solidifies, is dissolved in one liter of anhydrous ether by passing a rapid stream of dry hydrogen chloride through the ether. Two layers form, the heavy oily lower layer contains the dissolved tin. Sonn and Müller in the preparation of this complex for reduction purposes dried their tin salt in a desiccator.[10] This does not dry the tin completely and accounts for inconsistent yields as reported by subsequent investigators. Evidence that their tin was never dry is evinced by the fact that their tin solution was homogeneous. This happens every time moisture gets into the reaction. If dry, the tin solution always separates into two layers before addition of the material to be reduced.

One hundred and twenty grams of recrystallized and dried *o*-β-phenethylbenzanilide is mixed with 110 g. of phosphorus pentachloride in a 500-cc. Claisen flask. The mixture is warmed in a water-bath until the mixture begins to liquefy. The flask is removed from the water-bath and shaken as the reaction proceeds slowly, until the mixture is all liquid except for the lumps of excess phosphorus pentachloride. The phosphorus oxychloride is removed under vacuum over a water-bath and the residue is dissolved from the excess phosphorus pentachloride by two 200-cc. portions of anhydrous ether. The ether washings are added to the stannous chloride solution and allowed to stand overnight. A vigorous reaction immediately ensues and the lower layer turns red, the tin complex of the aldehyde anil crystallizing out in yellow plates. The complex is filtered off from the heavy oily mixture and washed with ether, until the red color has been washed out; yield 138 g., yellow crystals, dec. 213°.

Anal. Calcd. for $C_{21}H_{20}NCl_3Sn$: N, 2.77. Found: N, 3.00.

To the crystals of the tin complex is added 50 cc. of 10% hydrochloric acid and steam is passed through the mixture in a steam distillation outfit. A pale yellow oil separates at the top of the solution and a small amount of the material steam distils over. The distillate and residue are combined and extracted with ether. The ether is dried over anhydrous sodium sulfate, filtered and the ether is evaporated off; yield 60 g. of a pale yellow oil; sp. gr. 1.089; n^{29}_D 1.5827.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.71; H, 6.67. Found: C, 86.00; H, 6.51.

Phenylhydrazone of *o*-β-phenethylbenzaldehyde was prepared by heating 1 g. of the aldehyde with a few drops of phenylhydrazine in 5 cc. of alcohol, adding water and recrystallizing from 80% alcohol; colorless feathery needles which turn brown on standing, m. p. 95°.

Anal. Calcd. for $C_{21}H_{20}N_2$: N, 9.33. Found: N, 9.02.

This aldehyde forms a sodium bisulfite derivative on long shaking with a saturated solution of sodium bisulfite.

***o*-β-Phenethylcinnamic Acid.**—Sixty grams of *o*-β-phenethylbenzaldehyde is added to 35 g. of malonic acid in a 600-cc. flask fitted with a calcium chloride tube; 6 g. of pyridine is added and the mixture is warmed on a water-bath at 90° for two hours. The material separates into two layers and the lower layer slowly dissolves as carbon dioxide slowly is given off. At the end of two hours the material crystallizes on shaking or cooling. The material is dissolved in 40 g. of sodium carbonate dissolved in 500 cc. of warm water. If *o*-β-phenethylhydrocinnamic acid is desired the solution is reduced directly. If *o*-β-phenethylcinnamic acid is desired the solution is extracted with ether, to remove pyridine and impurities, acidified, filtered and dried. Drying has to be finished in a desiccator for this acid holds the last traces of water tenaciously; yield 71–72 g.; m. p. 149–150° (from dilute alcohol).

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 80.95; H, 6.34. Found: C, 80.31; H, 6.47.

***o*-β-Phenethylhydrocinnamic Acid.**—The solution in sodium carbonate of *o*-β-phenethylcinnamic acid is poured directly onto sodium amalgam, prepared by dissolving 24 g. of sodium in 620 g. of mercury, and vigorously stirred until the solution has come back to room temperature and most of the amalgam has been decomposed (four to six hours). The mixture is transferred to a separatory funnel, the mercury separated, and the solution washed with ether. The aqueous layer is separated and filtered through a double suction filter. Since the next step is the conversion to the acid chloride, every trace of suspended mercury must be scrupulously removed even if it is necessary to filter several times. The solution is acidified, allowed to stand for several hours, filtered, washed with water and dried; yield 72 g.; colorless thick crystals; m. p. 110–111° (recrystallized from dilute alcohol).

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.30; H, 7.08. Found: C, 80.11; H, 7.20.

Perkin Reaction on *o*-β-Phenethylbenzaldehyde

1. With Sodium Acetate.—Ten grams of the aldehyde, 2.5 g. of sodium acetate and 8 g. of acetic anhydride heated together for sixteen hours at 180–200° yields on extraction with sodium carbonate solution and acidification, 0.5 g. of *o*-β-phenethylcinnamic acid, m. p. 149–150° (from dilute alcohol), 1.0 g. of *o*-β-phenethylbenzylidine diacetate and 8 g. of unchanged aldehyde (average of several experiments).

2. With Potassium Acetate.—Ten grams of the aldehyde, 3 g. of potassium acetate and 8 g. of acetic anhydride heated together for six hours yield 1 g. of *o*-β-phenethylcinnamic acid, m. p. 149–150°, 8.6 g. of *o*-β-phenethylbenzylidine diacetate and practically no aldehyde. *o*-β-Phenethylbenzylidine diacetate melts at 85°.

Anal. Calcd. for $C_{19}H_{20}O_4$: C, 73.08; H, 6.41. Found: C, 73.51; H, 6.24.

3. Conversion of the Diacetate to *o*-β-Phenethylcinnamic Acid.—Eighteen grams of *o*-β-phenethylbenzylidine diacetate, 33 g. of acetic acid and 28 g. of sodium acetate heated at 200° for ten hours yields 10 g. of *o*-β-phenethyl-

---

[10] Sonn and Müller, *Ber.*, **52**, 1927 (1919).

cinnamic acid, m. p. 149–150° (from dilute alcohol). The acids obtained from the Perkin reaction all reduced quantitatively to *o*-β-phenethylhydrocinnamic acid, m. p. 110–111°.

***o*-β-Phenethylhydrocinnamoyl Chloride.**—To 70 g. of *o*-β-phenethylhydrocinnamic acid is added 140 cc. of thionyl chloride. The mixture is refluxed for one hour and the excess thionyl chloride is removed on a water-bath. Vacuum is applied and everything that can be removed up to 100° at 10 mm. is removed. The material is transferred quantitatively with the aid of a small amount of ether to a 300-cc. distilling flask, which is sealed off at the top and connected by means of a wide side-arm to an inner seal in a 125-cc. receiving flask. The ether is evaporated off from the outfit under vacuum on a water-bath and the receiver is connected to a high vacuum produced by a mercury vapor pump backed by an oil pump. The traps are cooled with alcohol–solid carbon dioxide mixture while the receiver is cooled by an ordinary ice and salt-bath. The pressure is measured on a McLeod gage. The distilling flask is heated in a dibutyl phthalate bath. The temperature was determined by placing a thermometer in the bath. The acid chloride comes over as an almost colorless, pale yellow, mobile liquid at a bath temperature of 155–165° (slow heating) at a pressure of 0.002–0.004 mm.; yield 57 g. On heating with sodium hydroxide solution the acid chloride dissolves and on precipitation regenerates *o*-β-phenethylhydrocinnamic acid; m. p. 110°; b. p. 155–165° (0.002–4 mm.); sp. gr. 1.015; n^{29}D 1.5664.

Anal. Calcd. for $C_{17}H_{17}OCl$: Cl, 13.27. Found: Cl, 13.20.

4-β-Phenethylindanone-1.—Fifty-seven grams of *o*-β-phenethylhydrocinnamoyl chloride is dissolved in 200 cc. of redistilled, over sulfuric acid, anhydrous petroleum ether, b. p. 45–65°, 57 g. of fresh anhydrous aluminum chloride is covered with 50 cc. of petroleum ether and the petroleum ether solution of the acid chloride is added, refluxing the solution on the water-bath. Refluxing is continued for one-half hour after the final addition. Almost all the color goes from the petroleum ether layer to the aluminum chloride which now becomes a deep brown. The mixture is cooled, decomposed with crushed ice and dilute hydrochloric acid and extracted with two 250-cc. portions of ether. The combined extracts are dried with anhydrous sodium sulfate, and the mixture of petroleum ether and diethyl ether is evaporated off. The residue is extracted with hot sodium carbonate solution to recover unchanged acid, dissolved in ether, washed with water, dried with anhydrous sodium sulfate and evaporated. The residue is then distilled under high vacuum as for the acid chloride. A pale yellow viscous oil comes over up to 160° at 0.0003 mm. A better vacuum could be maintained in the absence of the acid fumes; yield 42 g. of a viscous oil which gelled at room temperature but would not crystallize. It softens to a mobile liquid just below 38° and its melting point is probably in that vicinity. On standing for several months, during which time this compound was prepared numerous times in order to attempt to obtain it crystalline, the material partly resinified. The material as first obtained is of a high degree of purity as shown by analysis and in that it gave an 88% yield of oxime and a 92% yield of hydrocarbon on reduction.

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.40; H, 6.80. Found: C, 86.08; H, 6.98.

4-β-Phenethylindanoxime-1.—Four grams of 4-β-phenethylindanone-1 is dissolved in 50 cc. of alcohol. To this mixture is added 1.6 g. of hydroxylamine sulfate dissolved in 6 cc. of water. Two drops of phenolphthalein solution are added and 10% potassium hydroxide solution is added drop by drop from a pipet until the solution is just alkaline. The mixture is refluxed and drops of alkali are added from time to time to keep the solution just alkaline. At the end of one hour the barely alkaline solution is allowed to cool, when flat glistening plates of the oxime crystallize out. If rapidly cooled the oxime comes out as needles, m. p. 135° (from alcohol in which it is very soluble hot and insoluble cold).

Anal. Calcd. for $C_{17}H_{17}ON$: N, 5.56; C, 81.31; H, 6.77. Found: N, 5.49; C, 81.40; H, 6.44.

4-β-Phenethylindanamine-1.—Three grams of 4-β-phenethylindanoxime-1 is dissolved in 100 cc. of absolute alcohol, 3 g. of sodium is added in small bits and the solution is refluxed under a condenser with a calcium chloride tube for one hour, the sodium dissolving. The solution is cooled and neutralized with concd. hydrochloric acid, 50 cc. of water is added and the alcohol is evaporated off. Some of the hydrochloride of the amine crystallizes from the aqueous solution at this point. The whole mixture is made alkaline with 10% sodium hydroxide and the amine is extracted with 50 cc. of benzene in two portions. The benzene solution is dried with anhydrous sodium sulfate and filtered. The dry benzene solution is saturated with dry hydrogen chloride and then evaporated to 10 cc. on a steam-bath; 75 cc. of anhydrous petroleum ether is added and the hydrochloride of the amine comes out in fine crystals. The crystals are filtered and washed with a 3 to 1 mixture of petroleum ether and benzene; yield 2.8 g.; m. p. 192°.

Anal. Calcd. for $C_{17}H_{21}NCl$: N, 5.12; Cl, 12.98. Found: N, 5.16; Cl, 12.96.

4-β-Phenethylindane.—Into a two-liter flask fitted with a reflux condenser, 300 g. of zinc dust is added and 4 g. of mercuric chloride dissolved in 25 cc. of hot water. The solution is slowly added to the zinc dust and thoroughly shaken and warmed.

Forty grams of 4-β-phenethylindanone-1 is dissolved in 500 cc. of alcohol which is added to the zinc dust from the top of the condenser; 400 cc. of concd. hydrochloric acid is added from the top of the condenser drop by drop refluxing the alcohol until all the hydrochloric acid has been added and a large amount of the zinc has dissolved (four hours). The condenser is turned down and the alcohol is distilled off. Care must be taken not to go too far, for the hydrocarbon which comes out as a colorless oil has a tendency to steam distil to some extent. The oil which separates at the surface of the residue is taken up in ether, dried with anhydrous sodium sulfate, filtered and the ether is evaporated off. The oil which remains is distilled under high vacuum to a colorless mobile liquid, b. p. 115–120° (0.0001 mm.); sp. gr. 1.020 (25°); n^{29}D 1.5640; yield 34 g.

Anal. Calcd. for $C_{17}H_{18}$: C, 91.89; H, 8.11. Found: C, 91.31; H, 8.10.

The authors are indebted to Dr. B. Kramer and Albert E. Sobel for their advice and encouragement during the course of this investigation.

Summary

1. A new route to derivatives of diphenylethane related to materials occurring naturally is demonstrated.

2. 4-β-Phenethylindane is synthesized as representing the ring system for the proposed structure for calciferol and tachysterol.

A Modification of the Clemmensen Method of Reduction[1]

BY ELMORE L. MARTIN

While a great many compounds containing the carbonyl group can be reduced by the method of Clemmensen,[2] the results sometimes leave much to be desired. Substances which neither dissolve appreciably in the acid mixture nor melt at the boiling temperature usually present difficulties and a number of readily available β-aroylpropionic acids which are of use in the synthesis of polynuclear hydrocarbons are of this type. Thus Fieser and Peters[3] observed that β-3-acenaphthoylpropionic acid is but little affected by prolonged boiling with hydrochloric acid and amalgamated zinc, Haworth and Mavin[4] found β-1-methyl-4-naphthoylpropionic acid to be unusually resistant to reduction, and Cook and Hewett[5] were unable to reduce β-1-pyrenoylpropionic acid by any of the usual modifications in the original procedure of Clemmensen. Although the addition of a miscible solvent such as alcohol, acetic acid, or dioxane facilitates the reduction of certain ketonic compounds (ketocholanic acids, hydrindones), this leads in the above cases only to resinification. The keto acid appears to undergo polymolecular reduction or condensation at the surface of the metal with the formation of a gummy, insoluble coating which obstructs the normal functioning of the zinc.

It was found by Fieser and Peters[3] and by Haworth and Mavin[4] that the reduction of the above two keto acids can be accomplished by the use of the lower-melting esters, but the yield in the first case was only 40% and the process was tedious. After repeating Fieser and Peters' experiments with the same results it was found that when toluene was added in quantity sufficient to retain the ester in a clear surface layer the yield of the pure reduction product rose to 60% and the process was greatly simplified. The surface of the metal remained clean and bright throughout the reaction and the product was easily isolated from the toluene layer. Attempts to reduce free β-3-acenaphthoylpropionic acid in the presence of toluene were successful only when a small amount of acetic acid was used to provide the required, slight concentration of the keto acid in the aqueous layer. The toluene probably is beneficial partly because it keeps the otherwise undissolved material out of contact with the metal and partly because in the two-phase system the reduction occurs at such a high dilution that polymolecular reactions are largely inhibited.[6]

Various fellow workers engaged in synthetic experiments in this Laboratory kindly coöperated in testing the toluene method, and the yields of purified products, usually checked in two or more experiments, are summarized in Table I. The author is indebted to Mr. C. K. Bradsher, Mr. J. T. Dunn, Mrs. L. F. Fieser, Dr. E. B. Hershberg, Mr. H. L. Holmes, Mr. W. C. Lothrop, Dr. M. S. Newman and Mr. C. C. Price for permission to report their results. The β-aroylpropionic acids investigated were invariably reduced more satisfactorily in the presence of toluene than without it, and two acids could be reduced in this way but not by the usual procedure. With β-1-pyrenoylpropionic acid, however, the results were negative both with and without toluene. The modification seems definitely advantageous with compounds containing methoxyl groups, for the difficulties frequently experienced are at least mini-

[a] Following the procedure of "Organic Syntheses," Vol. XV, 1935, p. 64. [b] Acetic acid was added to the reaction mixture. [c] Isolated as the ester; b. p. 185–187° at 6 mm. [d] Four 100-g. portions were reduced and the products combined for purification. The heating was continued in this case for forty-one hours; in earlier reductions continued for only twenty to twenty-two hours the yield was poorer by 10–15%. [e] To complete the reduction it was necessary to submit the crude product to further reaction with no added toluene. [f] B. p. 122–125° at 14 mm.

mized. With neutral ketones of very slight water-solubility it is sometimes difficult to effect complete reduction using toluene, and in the case of hydrindones it probably is better to use a water-miscible solvent.

γ-*m*-Methoxyphenylbutyric acid, a useful intermediate in synthesis, has been prepared from *m*-methoxybenzoyl chloride in about 2% yield in a two-step process involving a Clemmensen reduction[7] and from *m*-methoxybenzaldehyde in eight steps in about 35% yield.[11] A third method was tried in the present work but found unsatisfactory. β-*m*-Methoxybenzoylpropionic acid was obtained fairly satisfactorily from β-benzoylpropionic acid through the *m*-nitro compound, but, although on a small scale the Clemmensen reduction in the presence of toluene seemed promising (60% yield) in comparison with Thompson's results,[7] on a larger scale a resinous oil separated from the toluene layer, the product was difficult to purify, and the yield was poor.[11a] In contrast to this experience β-3-methoxy-4-methylbenzoylpropionic acid was prepared easily from β-*p*-toluylpropionic acid through the nitro compound and there was no difficulty in effecting the reduction on either a small or large scale, γ-3-methoxy-4-methylphenylbutyric acid being obtained in an over-all yield of 35%. The 3,4-dimethoxy compound (Table I) is also reduced smoothly, and it appears that the abnormal side reaction noted in one case is inhibited by a substituent in the position ortho to the methoxyl and para to the group undergoing reduction.

Turning to another type of reaction, it was found that anthracene and β-methylanthracene can be obtained in excellent yield and high purity by the reduction of the anthrones with zinc dust

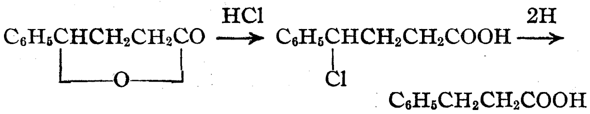
(11) Robinson and Schlittler, *ibid.*, 1288 (1935).

(11a) In a paper which has come to our hands as the present communication is going to press, Chuang and Huang, *Ber.*, **69**, 1505 (1936), have described the same process for the preparation of γ-*m*-methoxyphenylbutyric acid. The procedures for carrying out the various steps differ in some details but the results are much the same up to the Clemmensen reduction. Regarding the final step we feel that Chuang and Huang have not adequately demonstrated that the reaction proceeds as well as their statements imply, for they report a yield (67%) only for the crude, alkali-soluble fraction remaining after evaporation of the ether (14-g. run). Martin's yield (60%) for 3–5 g. runs refers to material that had been re-methylated, distilled and obtained as a solid, m. p. 45–47°. It is the general experience in this Laboratory that methoxy compounds invariably are demethylated to some extent even when using toluene, and we found that the resinous material which appeared when operating with moderately large amounts is alkali-soluble and cannot be removed effectively except by distillation. In view of the irregular and generally unsatisfactory results obtained repeatedly by both Martin and Hershberg, we do not share the favorable opinion of the method expressed by the Chinese investigators.—L. F. FIESER.

and sodium hydroxide in the presence of toluene. The process is simpler and more convenient than the usual one.

An incidental observation having some bearing on the mechanism of the Clemmensen reaction is that γ-phenylbutyrolactone gives about as good a yield of γ-phenylbutyric acid as does β-benzoylpropionic acid. Clearly it is not the lactone itself which combines with hydrogen, for the carboxyl group could not then appear in unmodified form, and it may be inferred that the lactone ring first opens with the formation of either the γ-hydroxy acid or the γ-chloro acid and that it is one or the other of these substances which suffers reduction. The chloro compound probably is formed in preponderant amount:



$$C_6H_5\underset{\lfloor\_\_\_O\_\_\_\rfloor}{CHCH_2CH_2CO} \xrightarrow{HCl} C_6H_5\underset{Cl}{CH}CH_2CH_2COOH \xrightarrow{2H} C_6H_5CH_2CH_2COOH$$

Possibly the reduction of a carbonyl compound with zinc and hydrochloric acid normally proceeds through the alcohol and the chloride. The idea is supported to some extent by the observation that both benzyl alcohol and benzyl chloride, like benzaldehyde,[2a,12] yield a certain amount of toluene on reduction with zinc and hydrochloric acid. Benzhydrol,[12] triphenylcarbinol[13] and triphenylbromomethane[13] have been similarly reduced to the hydrocarbons, but these perhaps are special cases. On the other hand, there have been some reports of the failure to reduce primary[2b] and secondary alcohols, the most striking example being in the bile acid series. For the conversion of a hydroxycholanic acid into a cholanic acid the standard method is to oxidize the substance to a ketone and then apply the Clemmensen reaction, for the hydroxy acid usually is converted only into resinous products when treated directly with zinc and acid.[14] Although this would seem to indicate that the alcoholic compound is not an intermediate in the reduction of the ketone, the direct replacement of a hydroxyl group by hydrogen, however rare, has been observed in at least one case (3-hydroxy-12-ketocholanic acid).[14] Possibly the poor result obtained with a hydroxycholanic acid is due not to the failure of the substance to undergo reduction but to the occurrence of side reactions, such as dehydration, when the alcoholic compound is present from the start in high concentration. That the carbonyl compound gives a better result may be because the alcohol is never present in large amounts but is rapidly removed from the destructive influence of the acid by reduction, either as such or through the chloride. Possibly it is merely because the di- and tri-aryl carbinols are not subject to dehydration that the direct reduction presents no difficulties.

Experimental Part

Modified Clemmensen Method

General Procedure.—It was found that the time allowed for amalgamating the zinc can be shortened and equally active material obtained by shaking for five minutes a mixture of 100 g. of mossy zinc, 10 g. of mercuric chloride, 5 cc. of concentrated hydrochloric acid and 150 cc. of water. The solution was decanted and the other reagents were added in order as follows: 75 cc. of water, 175 cc. of concentrated hydrochloric acid, 100 cc. of toluene and 50 g. of the carbonyl compound to be reduced. In the case of substances very sparingly soluble in water a small amount (3–5 cc.) of glacial acetic acid was added. The mixture was refluxed briskly for twenty-four hours, three 50-cc. portions of concentrated hydrochloric acid being added at intervals of about six hours. Although this treatment usually is sufficient to complete the reduction, further heating of the reaction mixture with the addition of fresh acid does no harm and in some of the experiments there were indications that the yield is increased slightly by extending the refluxing period.

In the preparation of γ-phenylbutyric acid, its homologs, and other low-melting substances readily soluble in toluene the reaction mixture was cooled to room temperature, the toluene layer was separated and the aqueous layer was diluted and extracted with ether. After removing the solvent from the combined extracts the product was distilled in vacuum, giving material which ordinarily required no further purification. In working up the reaction mixtures from methoxylated keto acids the procedure was modified as follows to provide for the recovery of demethylated material. The combined solution in toluene and ether was mixed with an excess of dilute alkali, the solvent was removed by steam distillation, and after cooling the alkaline solution to about 80° an excess of dimethyl sulfate (20–25 cc.) was added, keeping the solution alkaline. In case the solution tended to darken, sodium hydrosulfite was added. Any ester which may be formed is saponified in the hot alkaline medium. The solution was clarified if necessary, after neutralizing the excess alkali, cooled and acidified. The product usually was dried in ether and purified by vacuum distillation. In preparing higher-melting, less soluble compounds such as the γ-naphthylbutyric acids the toluene layer was separated after allowing the solution to cool to 50–60°, benzene being used if necessary to keep the material in solution and for extraction of the water layer. In case the combined extracts contained coloring matter arising from the presence of impurities in the starting material, it was found most effective to clarify the solution with active carbon while still wet. A part of the solvent was removed by distillation along with any residual water, and on cooling the product

[12] Steinkopf and Wolfram, *Ann.*, **430**, 113 (1923).

[13] Acree, *Ber.*, **31**, 616 (1898).

[14] Borsche and Hallwass, *ibid.*, **55**, 3325 (1922).

crystallized, usually in a very pure condition. To recover the material retained in the mother liquor it was sometimes convenient to steam distil the solvent from a mixture with soda solution, clarify the cooled aqueous solution, and precipitate the product.

In several cases the quantity of the carbonyl compound was increased to 100–150 g. without any essential change in the procedure or in the yield.

Special Cases.—In the reduction of γ-phenylbutyrolactone (Table I), 5 g. of material was used and the mixture was refluxed for thirteen hours. In attempting to reduce β-pyrenoylpropionic acid it was found that both the acid and the ester remained unchanged after long boiling and that the addition of acetic acid led only to the resinification of the product. *o*-Benzoylbenzoic acid was reduced successfully by the modified procedure but the process was less convenient than reduction with zinc dust and alkali and the yield was not as good. Benzyl alcohol was reduced by heating for nine hours a mixture of 25 g. of the material, 50 g. of amalgamated zinc, 90 cc. of concentrated hydrochloric acid and 40 cc. of water, adding 50 cc. more acid from time to time. Fractionation of the mixture yielded 4 g. (19%) of toluene, b. p. 110–113°, and there was considerable high-boiling material. Reduced in the same manner 25 g. of benzyl chloride gave 5 g. (27%) of toluene.

Reduction with Zinc Dust and Alkali

Anthracene from Anthrone.—Twenty-five grams of zinc dust was allowed to stand for a few minutes with an aqueous solution of 0.1 g. of copper sulfate crystals, the solution was poured off and to the activated metal were added 400 cc. of 2 *N* sodium hydroxide, 100 cc. of toluene, and lastly 10 g. of anthrone. The mixture was heated under reflux in an oil-bath and kept boiling gently for twelve hours. The aqueous layer at first assumed a bright red color, after about three hours it turned to a light yellow, and finally both layers became colorless. The mixture was allowed to cool slightly, 100 cc. of benzene was added, and the liquid mixture was transferred to a separatory funnel, using 100 cc. more benzene to wash the zinc residue. The hydrocarbon solution was treated with active carbon while still wet, concentrated to a volume of 50–60 cc., and allowed to cool. The anthracene separated in the form of thin, colorless, highly fluorescent plates, m. p. 216–216.5°, corr.; yield 8.6 g. (93%).

Anthracene from Anthraquinone.—Following the same procedure as above but starting with the quinone it was necessary to continue the refluxing for forty-eight hours and the anthracene, obtained in 80% yield, did not exhibit the beautiful fluorescence of the product from anthrone and melted about one degree lower.

β-**Methylanthracene** was prepared as above from 2-methylanthrone-9, the yield of once recrystallized material being 86%; m. p. 209–209.5° corr. The yield from β-methylanthraquinone was 80% and the reduction was complete only after four days.

γ-*m*-Methoxyphenylbutyric Acid

β-*m*-**Nitrobenzoylpropionic Acid.**—To a mechanically stirred mixture of 60 cc. of nitric acid (sp. gr. 1.5) and 6 cc. of concentrated sulfuric acid 30 g. of β-benzoylpropionic acid was added in portions while keeping the mixture at −10 to 0° by efficient cooling. This required twenty to twenty-five minutes. The temperature was then allowed to rise to 15° in the course of thirty minutes and the solution was slowly stirred into ice and water. The precipitated material was washed free of acid and crystallized from methyl alcohol, giving nearly colorless needles, m. p. 162–164°, corr., of the meta isomer; yield, 21–23 g. (57–62%). The substance crystallizes from water as long, faintly yellow needles.

Anal. Calcd. for $C_{10}H_9O_5N$: C, 53.79; H, 4.07. Found: C, 53.90; H, 4.05.

The methyl ester crystallized from ether–petroleum ether as colorless needles, m. p. 68–69°, corr.

Anal. Calcd. for $C_{11}H_{11}O_5N$: C, 55.67; H, 4.68. Found: C, 55.84; H, 4.63.

β-*m*-**Aminobenzoylpropionic Acid.**—A solution of 44.6 g. of the nitro compound in 125 cc. of ammonium hydroxide (sp. gr. 0.90) and 75 cc. of water was saturated with hydrogen sulfide, keeping the temperature from rising above 50° by good cooling. The ammonium salt of the starting material at first separated but later redissolved as the exothermic reaction proceeded. The resulting solution was allowed to stand at room temperature for one hour and boiled gently to expel excess gases, the color changing from dark orange-red to yellow-green. The addition of 1–2 g. of sodium hydrosulfite produced a pale yellow solution, and after removing the precipitated sulfur by filtration the solution was boiled with 50 cc. of concentrated hydrochloric acid to coagulate traces of sulfur, it was clarified with active carbon, treated with 50 cc. more of the concentrated acid, and evaporated under vacuum until crystals of the amine hydrochloride began to separate. After thorough cooling the slightly yellow hydrochloride which crystallized was collected and washed with a small amount of cold concentrated hydrochloric acid; yield, 35–40 g. (77–87%). The salt is readily soluble in water and is only partially precipitated by the addition of concentrated hydrochloric acid, giving colorless needles, m. p. above 250° with decomposition.

Anal. Calcd. for $C_{10}H_{12}O_3NCl$: C, 52.27; H, 5.27. Found: C, 52.52; H, 5.30.

The free amine was obtained by adding slightly less than one equivalent of alkali to a solution of the hydrochloride. Thin, colorless plates, m. p. 131–132°, corr., were obtained by crystallization from water (80% conversion).

Anal. Calcd. for $C_{10}H_{11}O_3N$: C, 62.14; H, 5.74. Found: C, 61.95; H, 5.68.

Reduction of the nitro compound with sodium hydrosulfite or stannous chloride was less satisfactory. Dr. E. B. Hershberg employed the method of catalytic hydrogenation with success and obtained about the same yield as above.

β-*m*-**Hydroxybenzoylpropionic Acid.**—A solution of 7.7 g. of the amine in 35 cc. of water containing 5.5 cc. of concentrated sulfuric acid was cooled to 0° and the paste of the sulfate was treated with a solution of 2.7 g. of sodium nitrite in 10 cc. of water. To the clear solution of the diazonium salt was added 5 cc. of concentrated sulfuric acid and 3.7 g. of boric acid and the mixture was slowly heated to gentle boiling. The evolution of nitrogen was complete soon after the mixture had reached the boiling point. Enough water was added to dissolve the hydroxy com-

pound and the solution was clarified with charcoal and the slightly yellow filtrate cooled in salt–ice. The product separated as nearly colorless crystals, m. p. 137–140°, yield 7 g. (90%). Crystallization from water (charcoal) gave colorless plates, m. p. 144–145°, corr.; yield 6.2 g. (80%).

Anal. Calcd. for $C_{10}H_{10}O_4$: C, 61.82; H, 5.19. Found: C, 61.63; H, 5.33.

The semicarbazone crystallized from alcohol as colorless needles, m. p. 198–200°, corr.

Anal. Calcd. for $C_{11}H_{13}O_4N_3$: C, 52.57; H, 5.32. Found: C, 52.55; H, 5.46.

β-*m*-Methoxybenzoylpropionic Acid.—A solution of 6.2 g. of the hydroxy compound in 40 cc. of a 10% solution of sodium hydroxide was treated with 6 cc. of dimethyl sulfate at 40–50° and the ester produced was saponified by boiling in alkaline solution. Excess alkali was neutralized and the solution was treated with charcoal. The nearly colorless filtrate was cooled to 40° and acidified, and after thorough cooling the colorless, crystalline product was collected and washed; m. p. 102–104°, yield 6.1 g. (92%). Crystallization from methyl alcohol gave fine, colorless needles, m. p. 107–108°, corr.; yield 5.7 g. (86%). Thompson[7] reports the melting point of the acid as 110–111°.

Anal. Calcd. for $C_{11}H_{12}O_4$: C, 63.43; H, 5.81. Found: C, 63.20; H, 5.76.

The semicarbazone melted at 177–178°, corr., in agreement with the value given by Thompson.

When small amounts (3–5 g.) of the keto acid were reduced by the modified Clemmensen method the toluene layer remained clear and γ-*m*-methoxyphenylbutyric acid of apparently good quality was obtained in the final distillation in 60% yield. With larger amounts (15–25 g.) oily resinous matter separated from the toluene as stated above whether the mixture was boiled from the start or allowed to stand for several hours at room temperature, and also when the keto acid was added in small portions to the boiling mixture.

γ-3-Methoxy-4-methylphenylbutyric Acid

This acid was prepared from β-*p*-toluylpropionic acid in a series of processes entirely similar to those described above. The yields in the various reactions, given for purified products, and the physical constants and analyses of the compounds are given in Table II.

Summary

1. It is shown that in the reduction of carbonyl compounds by the Clemmensen method improved results are often obtained by adding a layer of toluene to the reaction mixture. The modification is particularly useful in the preparation of γ-arylbutyric acids and in the reduction of compounds containing the methoxyl group. The immiscible solvent also can be used to advantage in the reduction of anthrones to anthracenes with zinc dust and alkali.

2. It is suggested that the Clemmensen reduction of a carbonyl compound proceeds through the alcohol and the chloride, and one or two observations offering some support for this view are recorded.

3. A new route to γ-*m*-methoxyphenylbutyric acid has been investigated and found unsatisfactory in the final step, although by the same process the *m*-methoxy-*p*-methyl derivative can be prepared in good yield.

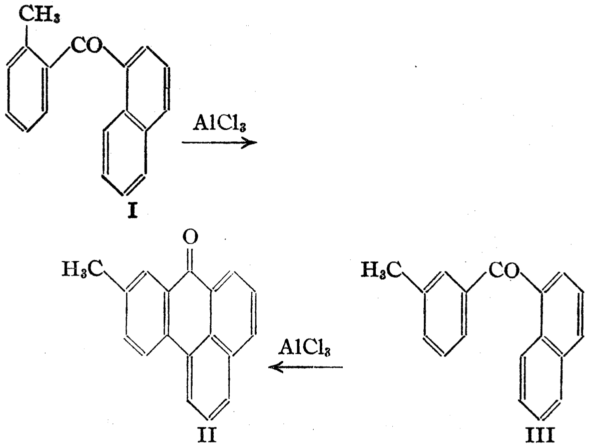
The Conversion of Tolyl Naphthyl Ketones into Methylbenzanthrones

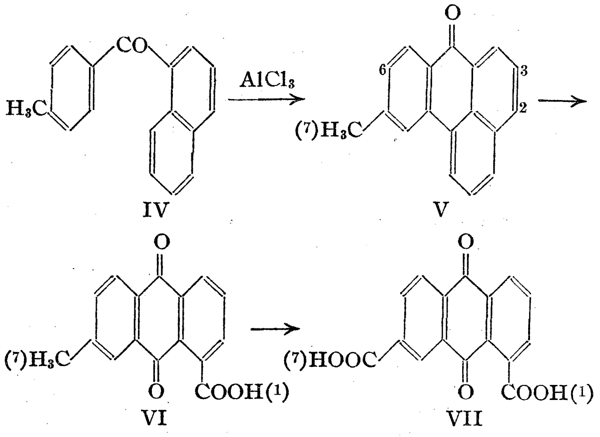
BY L. F. FIESER AND E. L. MARTIN

Among other instances of the migration of methyl groups in the course of the Scholl reaction reported by Mayer, Fleckenstein and Günther,[1] it was stated that both *o*-tolyl α-naphthyl ketone (I) and *m*-tolyl α-naphthyl ketone (III) yield the same (6)-methylbenzanthrone (II) on being heated with aluminum chloride. Scholl and Seer[2] had reported the reactions and established structure of the product from III by an independent synthesis of II, but had not recognized the identity of the substance obtained from the isomeric ketone, m. p. 64°, which they prepared from *o*-toluyl chloride and naphthalene and for which they assumed the structure I. In preparing a quantity of *o*-tolyl α-naphthyl ketone for a proposed study of the Elbs reaction we employed α-naphthylmagnesium bromide and *o*-tolunitrile and obtained a ketone, m. p. 52–53°, apparently different from that of Scholl and Seer, and since the observation cast some doubt on the reported rearrangement the matter was investigated further. Since a ketone having the melting point of the Scholl and Seer compound was obtained from *o*-tolylmagnesium bromide and β-naphthonitrile, it is probable that the purified product isolated by these investigators was *o*-tolyl β-naphthyl ketone. From the β-isomer we were unable to obtain a benzanthrone, while the pure α-isomer (I) was found to yield 6-methylbenzanthrone, II, which we also prepared from *m*-tolyl α-naphthyl ketone (III), synthesized by a method which establishes its structure. Although the original evidence was unsound, the conclusion of Mayer and co-workers is thus shown to be valid. It is probable that both earlier investigators employed the crude ketone mixture from the Friedel and Crafts reaction and that this contains a considerable proportion of the α-isomer (I) along with the substance actually isolated.



Samples of pure *m*-tolyl- and *p*-tolyl α-naphthyl ketone prepared by Grignard reactions corresponded in melting point and in their behavior with aluminum chloride to the descriptions of Scholl and Seer and of Mayer and co-workers. The corresponding β-isomers differ little in melting point but do not yield benzanthrones in the Scholl reaction.

The methylbenzanthrone obtained from pure *p*-tolyl α-naphthyl ketone (IV) corresponded to the earlier descriptions.[1,2] To test the assumption[1,2] that this is the 7-methyl derivative (V) and that no migration occurs in its formation, the substance was oxidized to a methylanthraquinone carboxylic acid and then to an anthraquinone dicarboxylic acid. The former substance yielded β-methylanthraquinone on decarboxylation, whence the original methyl group must be at the 2-, 3-, 6- or 7-position. Since 2- and 6-methylbenzanthrone are both known substances different from the compound in question, these positions are eliminated. The dicarboxylic acid could only be the 1,3- or the 1,7-derivative and on preparing the former substance[3] for comparison it was found to be different.



---

[1] Mayer, Fleckenstein and Günther, *Ber.*, **63**, 1464 (1930).

[2] Scholl and Seer, *Ann.*, **394**, 111 (1912).

[3] Elbs and Günther, *Ber.*, **20**, 1364 (1887).

Therefore the oxidation products are the 1,7-derivatives VI and VII and the product of the Scholl reaction is 7-methylbenzanthrone (V). 6-Methylanthraquinone-1-carboxylic acid and anthraquinone-1,6-dicarboxylic acid were prepared for comparison from II.

Experimental Part

Preparation of the Ketones.—The components employed are indicated in Table I. The Grignard reagent was prepared under nitrogen from 3 g. of magnesium, 0.1 mole of the bromo compound and 120 cc. of dry ether, and to this was added a solution of 0.1 mole of the nitrile in 125 cc. of dry, thiophene-free benzene. A crystalline solid usually separated but when the ether was removed by slow evaporation in the nitrogen stream this dissolved. The reddish-brown benzene solution was refluxed for twenty-four hours and poured onto a mixture of water (100 cc.), ice (100 g.) and concentrated hydrochloric acid (30 cc.). The mixture was submitted to steam distillation for one hour both to remove the solvent and unreacted nitrile and to effect hydrolysis of the ketimine. The residual oil was taken up in ether, washed with sodium carbonate solution, and on vacuum distillation the ketone was obtained as a pale yellow oil which afforded a colorless, crystalline product when a fairly dilute solution in methyl alcohol was allowed to stand for some time. Further crystallization did not alter the melting points of the first crystallizates and the yields are reported for these products.

TABLE I

TOLYL NAPHTHYL KETONES

Ketone	Prepared from	Yield (pure) %	M. p., °C. Found	M. p., °C. Lit.

[a,b,c] *Anal.* Calcd. for $C_{18}H_{14}O$: C, 87.77; H, 5.73. Found: (a) C, 87.97; H, 5.85; (b) C, 87.66; H, 5.56; (c) C, 87.66; H, 5.75.

The mother liquor often yielded 10–15% more material melting 2–3° low. The procedure was varied in some experiments by shaking the benzene solution with acetic acid (10 cc.), water (100 cc.) and ice (100 g.), discarding the water layer, and precipitating the ketimine hydrochloride as an oil by the addition of 100 cc. of concentrated hydrochloric acid. After decanting the liquor the oil was boiled with 200 cc. of water for one hour to effect hydrolysis, and the ketone was purified as above. The product was obtained in no better yield or purity than before and it seemed that the simpler procedure is preferable. In the experiment using β-naphthoyl chloride the Grignard reagent was added inversely to a solution of the chloride (0.1 mole) in 200 cc. of ether. The ketones were all obtained completely colorless, usually as needles, from methyl alcohol.

6-Methylbenzanthrone (II).—No difference was noted in the yield or quality of the material obtained from either *o*-tolyl α-naphthyl ketone or *m*-tolyl α-naphthyl ketone. When either ketone (3 g.) was heated with aluminum chloride (15 g.) at 150° the yield of pure product isolated was 0.5 g. (17%), but the yields were much improved by employing sodium aluminum chloride. To a melt prepared from 20 g. of aluminum chloride and 4 g. of sodium chloride 2.46 g. of either ketone was added and the temperature was raised from 90 to 150° in one and one-half hours and maintained at 150° for two hours. The red melt was stirred into ice and hydrochloric acid and the tarry product was extracted with acetic acid and precipitated with water and then crystallized to a constant melting point from alcohol; yield 1.4 g. (58%). The compound formed fine, bright yellow needles, m. p. 167–168°, in agreement with the literature.[1,2]

7-Methylbenzanthrone (V) was obtained from *p*-tolyl α-naphthyl ketone in 16–20% yield (pure) using aluminum chloride and in 50% yield with sodium aluminum chloride; fine, bright yellow needles, m. p. 158–159°.

6-Methyl- and 7-Methylanthraquinone-1-carboxylic Acid.—A solution of 1 g. of 6-methylbenzanthrone in 20 cc. of glacial acetic acid was prepared at 70° and treated slowly with 4 g. of chromic anhydride in 2 cc. of water diluted with 20 cc. of acetic acid, keeping the temperature at 60–70° by occasional cooling. Soon after the addition was complete the product was precipitated by adding water. The crude acid was dissolved in dilute ammonia solution, and after clarification with Norite the light yellow filtrate was acidified at the boiling point. On crystallization from dilute alcohol 6-methylanthraquinone-1-carboxylic acid (a) separated slowly as light yellow needles, m. p. 264–266°; yield 0.7 g. (64%). 7-Methylanthraquinone-1-carboxylic acid (b), obtained similarly from V in 55% yield, formed stout yellow needles, m. p. 310–312° from acetic acid. Mayer, *et al.*,[1] report 312–314°. The alkaline solutions of the acids are pale yellow, the vats are deep red.

Anal. Calcd. for $C_{16}H_{10}O_4$: C, 72.15; H, 3.79. Found: (a) C, 72.20; H, 3.75; (b) C, 72.01; H, 3.82.

Each acid was decarboxylated in quinoline solution at 170° in the presence of Naturkupfer C, and the product was obtained by pouring the mixture onto water and adding hydrochloric acid. Crystallized from alcohol, the product in each case melted at 173–174° alone or when mixed with authentic β-methylanthraquinone; yield 90%.

Anthraquinone-1,6- and 1,7-Dicarboxylic Acids.—After heating 0.2 g. of 6-methylanthraquinone-1-carboxylic acid with 3 cc. of nitric acid, sp. gr. 1.1, in a sealed tube at 200–210° for five hours, there was obtained on cooling 0.21 g. of bright yellow needles of the 1,6-acid (a). This was purified by precipitation from a clarified ammonium hydroxide solution, by refluxing with a concentrated nitric acid (6 cc.)-water (1 cc.) mixture, which left the substance undissolved but less highly colored, and finally by crystallization from a large volume of alcohol; faintly yellow needles, m. p. 336–338°. Anthraquinone-1,7-dicarboxylic acid (b), similarly prepared and purified, formed light yellow, microscopic crystals, m. p. 346–348°. The alkaline solutions of the acids are nearly colorless, the vats are red.

Anal. Calcd. for $C_{16}H_8O_6$: C, 64.84; H, 2.72. Found: (a) C, 64.90; H, 2.90; (b) C, 64.64; H, 2.73.

Anthraquinone-1,3-dicarboxylic Acid.—Phthalic anhyhydride (7.4 g.) was condensed with *m*-xylene (25 cc.) by the addition of aluminum chloride (15 g.), heating the mixture on the steam-bath for one-half hour to complete the reaction. The keto acid precipitated from soda solution, yield 11.5 g. (91%), m. p. 130–133°, was heated with 55 cc. of concentrated sulfuric acid for one hour on the steam-bath, giving after one crystallization from alcohol 6.9 g. (63%) of 1,3-dimethylanthraquinone, m. p. 159–160°. For the oxidation 0.2 g. of material was heated with 3 cc. of nitric acid, sp. gr. 1.1, for six hours at 180–190°. The product formed pale yellow needles from dilute alcohol (0.15 g.). The substance decomposes at 320–325°.

Anal. Calcd. for $C_{16}H_8O_6$: C, 64.84; H, 2.72. Found: C, 64.60; H, 2.89.

Summary

On preparing the six possible tolyl naphthyl ketones by methods leaving no doubt as to their structures it was found that two of the isomers had been confused in the literature but that the previous conclusions regarding the formation of methylbenzanthrones by the action of aluminum chloride on the tolyl α-naphthyl ketones are substantiated by the results of experiments with the pure ketones and by more rigid evidence of the structure of one of the reaction products.

The Activation of Specific Bonds in Complex Molecules at Catalytic Surfaces. I. The Carbon–Hydrogen Bond in Methane and Methane-d_4

BY KIYOSHI MORIKAWA,[1] W. S. BENEDICT AND HUGH S. TAYLOR

In a preliminary communication[2] to THIS JOURNAL we have recorded the ready interaction of methane and deuterium at reduced nickel catalyst surfaces at temperatures of 184° and upward. At that time we suggested that the reaction must be determined in rate by the activated adsorption of methane and called attention to the fact that, if this were so, we have in the exchange reaction a more sensitive index of activated adsorption than is available in adsorption measurements of gases on catalytic surfaces. The evidence that we present in the following pages confirms these views and lays the foundations for a comprehensive program of research upon the activation of specific bonds in complex molecules, a central problem in the field of contact catalysis, that of specific activity.

We have studied the interaction of methane and deuterium, of methane-d_4 and hydrogen, of methane and methane-d_4 and of methane and deuterium oxide at surfaces of catalytic nickel through a range of temperatures. From the measurements of reaction velocity and the derived energy of activation of the processes we are able to show that the rate-determining step is to be ascribed to the activation of the C–H bond of the methane molecule. These studies represent an extension to saturated hydrocarbon molecules of the phenomenon of isotope exchange already demonstrated to occur with unsaturated hydrocarbon molecules by the researches of Farkas, Farkas and Rideal[3] and by Polanyi and his collaborators.[4] We shall show that our results with the saturated hydrocarbons are of material importance in view of the theories of the exchange reaction developed by the latter group of authors.[4b]

Experimental Details

Materials.—The deuterium gas employed was obtained by electrolysis of our purest heavy water d^{25}_{25} 1.1079 containing 0.5 *M* NaOD as electrolyte. It was freed from oxygen by passage over a glowing platinum wire and dried by passage through a dry-ice trap.

Methane was prepared catalytically from carbon monoxide and excess hydrogen over a nickel catalyst at 255°, the excess hydrogen being removed by passage repeatedly over granular copper oxide at 300° after which carbon dioxide and water vapor were removed by soda lime and a solid carbon dioxide trap. The product used was further purified by fractional condensation and evaporation.

Methane-d_4 was prepared in a similar manner from carbon monoxide and pure deuterium, care being exercised to remove all hydrogen from the reaction system by exhaustion and repeated flushing with deuterium gas. The product was a very pure methane of which 98% of the bonds were found by analysis to be C–D bonds.

[4] (a) Horiuti, Ogden and Polanyi, *Trans. Faraday Soc.*, **30**, 663 (1934); (b) Horiuti and Polanyi, *ibid.*, **30**, 1164 (1934).

The deuterium oxide vapor employed came from our heavy water supply, d^{25}_{25} 1.1079.

The nickel catalyst was a very active nickel–kieselguhr preparation made by precipitation of the carbonate on kieselguhr, ignition and reduction in hydrogen (or deuterium) at progressively increasing temperatures to 450°. It contained 15% nickel and 2 g. was employed. At all times care was exercised to ensure absence of hydrogen when deuterium was being studied and *vice versa*. In experiments with the methanes alone residual adsorbed hydrogen or deuterium gas was removed by frequent evacuations and flushings with methane.

Analytical Procedure.—The progress of reaction was in every case followed by measurements of absorption in the infra-red region using a rock salt spectrometer system. The apparatus was calibrated by measurements of the absorption coefficients of the several deuteromethanes and of various mixtures of these gases as well as upon equilibrium mixtures of known H- and D-contents. Details of these measurements form the subject of a separate communication by Benedict, Morikawa and Barnes.[5] The absorption coefficients were measured on controlled pressures of gas (~200 mm.) in cylindrical Pyrex vessels with rock salt windows. The mixtures were analyzed in presence of the hydrogen and deuterium used in the experiments, since special test showed these to be without influence on the absorption measurements.

The absorption coefficients (ϵ) were normally measured at 3020 cm.$^{-1}$ (ϵ_H) and 2250 cm.$^{-1}$ (ϵ_D) to give check measurements on the percentages of C–H and C–D bonds, respectively. In general these measurements were concordant, though some deviations amounting to a 5% uncertainty in D-content have been observed. In the experiments with methane and methane-d_4 as reactants, additional measurements of absorption were made at 1160 and 1180 cm.$^{-1}$ and the measurements combined in a coefficient (ϵ_3) which measures the concentration of CH_3D, at 1090 cm.$^{-1}$ (ϵ_4) which measures CH_2D_2, and at 1035 cm.$^{-1}$ (ϵ_5) which includes both CHD_3 and CH_2D_2. The analytical results on these samples due to the more complete analysis are more accurate and the errors should not exceed 2% on the D-content. The values of ϵ given in the several tables are derived from the formula

$$\epsilon = \frac{-\log I/I_0}{lP} \times 10^7$$

where I and I_0 are the transmitted and incident intensities, l is the length of absorption path in cm. and P is the gas pressure expressed in mm. at 25°.

Experimental Procedure.—Known amounts of the reacting gases were introduced into a cylindrical Pyrex vessel of 100 cc. volume at the bottom end of which the nickel catalyst was placed. The gases were introduced through a trap of small volume cooled continuously to −78° which itself formed 30 cc. of the reaction volume. This trap served to remove the quantity of mercury vapor introduced with the gases and also, acting as a thermo-siphon, promoted a circulation of gases over the catalyst heated to controlled temperatures. Tubes of large diameter (15 mm.) were used for the connections between the vessel and trap to minimize resistance to this gas circulation. The total volume was ~150 cc. From time to time the gases were momentarily withdrawn from the reaction space and re-introduced in order to minimize stratification of the reactants. After completion of a run the gases were withdrawn by a Töpler pump and transferred to the analytical vessel.

Experimental Results

Methane–Deuterium Reaction.—The data of Table I indicate that no appreciable reaction occurs on our nickel preparation at 110°, but that from 184° upward an increasingly rapid exchange reaction can be measured. At the longer times of contact at each temperature, since the percentage of C–D bond approximates to 35% for equimolecular mixtures of CH_4 and D_2 it is apparent that the equilibrium state has been reached and that the equilibrium constant must be slightly greater than 1.

TABLE I

EXCHANGE REACTION BETWEEN METHANE AND DEUTERIUM ON NICKEL CATALYST

5	39.7	40.0	218	20	1190	950	35

The equilibrium state can be established from the methane-d_4–hydrogen side as well as from the methane–deuterium side as the data of Table II indicate.

TABLE II

EQUILIBRIUM FROM CH_4–D_2 AND CD_4–H_2

Catalyst no.	Cc.		Cc.		Temp., °C.	Time, hrs.	ϵ_H	ϵ_D	% C–D	K
	CH_4	CD_4	D_2	H_2						
2	38.4		78.3		218	75.5	790	1320	61	2.3
4		49.2		99.3	218	213	849	1130	56	1.8
2	42.0		83.9		255	50	830	1190	57	1.8
4		49.2		99.3	255	95			53	1.4
4		49.2		99.3	302	101	972	1125	50	1.1

No great accuracy can be assigned to these determinations since only the absorption coefficients ϵ_H and ϵ_D were determined. It is to be noted however that the mean values for the equilibrium constant $K = [C—D][H]/[C—H][D]$, at successive temperatures are: $K_{(200)} = 2.3$; $K_{(250)} = 1.6$;

[a] The absorption coefficient ϵ_3 refers to measurements at 1160 and 1180 cm.$^{-1}$. [b] The conversions in the final column have the following meanings. In the first and last four experiments of the table, the data given indicate the percentage of C–H bonds changed to C–D bonds. The remaining data give the percentage conversion from the original CH_4–CD_4 mixture to the equilibrium mixture of the five methanes.

$K_{(300)} = 1.2$. The values calculated from theoretical grounds[5] are 1.6, 1.5 and 1.4 at these temperatures. The agreement is within the rather large limits of experimental error in these analyses.

The Reaction between Methane and Methane-d_4.—A comparison of the velocities of reaction of $CH_4 + D_2$ and $CH_4 + CD_4$ can be obtained from the data of Table III. All of the experiments were conducted on the same catalyst, No. 6, 2 g. weight. It was reduced in deuterium for several hours at 450°, about 100 cc. of gas being consumed. The catalyst was evacuated for three and a half hours with a mercury vapor pump system but through 90 cm. of 3-mm. capillary tube and three stopcocks. The first experiment, with 39.2 cc. of methane alone, reacting at 218°, indicates that 3.6 cc. of D_2 (or D_2O) was still retained on the catalyst after evacuation and prior to the first experiment. Accordingly, before the next experiment, the catalyst was washed three times each with 14 cc. of methane, each washing being followed by evacuation at 218°. No deterioration of the catalyst occurred.

When the conversions recorded in the final column of Table III are recalculated to give initial rates of reaction at the several temperatures the data of Table IV are obtained. From these values, which must, however, be regarded as of only an approximate nature, it can be seen that the rate of reaction of $CH_4 + CD_4$ is several times faster at the lowest temperature, 138°, than that of methane–deuterium on the same surface at the same temperature. From a log rate *vs.* $1/T$ plot, straight lines result in each case giving activation energies, $E_{CH_4 + CD_4} \sim 19$ kcal. and $E_{CH_4 + D_2} \sim 28$ kcal.

TABLE IV

RATES OF REACTION OF METHANE WITH METHANE-d_4 AND WITH DEUTERIUM

Temp., °C.	$CH_4 + CD_4$ % conversion per hr.	$CH_4 + D_2$ % conversion per hr.
138	1.1	0.07
184	11.2	3.2
218	~60	15.5
255	~240	. . .

The higher activation energy of the reaction involving deuterium may be attributed to the influence of temperature in removing the more strongly adsorbed deuterium from the surface, giving greater accessibility to the methane. We shall later confirm this interpretation by a report of experiments on the interaction of ethane and hydrogen on such nickel catalysts. The activation energy of the $CH_4 + CD_4$ reaction, $E = 19$ kcal., is to be associated with the activation energy of desorption of the methane molecule, since, in these experiments, the processes occurring consist only in the activated adsorption and desorption of one or other of the methanes.

The Reaction between Methane and Deuterium Oxide.—In these experiments the reaction was conducted in a sealed vessel, 140 cc. in volume, to avoid difficulties due to stopcocks. The resultant gases were withdrawn for analysis through a connecting tube fitted with an internal capillary seal broken by a magnetically operated breaker on completion of an experiment. A slower reaction of methane occurs on the nickel catalyst with deuterium oxide than with deuterium as shown by the results in Table V.

Table V

Exchange Reaction between Methane and Deuterium Oxide

CH_4, cc.	D_2O vap., cc.	Temp., °C.	Time, hrs.	ϵ_H	ϵ_D	ϵ_3	ϵ_4	ϵ_5	% C–D
35	40	255	20	928	686	920/600	840	800	27.5
40.3	40	184	11	480	205	200/180	140	190	9
40.1	40	184	11	450	158	174/140	135	245	9

Analysis of the residual gas in the first two experiments indicated a slight reaction of methane and water to yield hydrogen and carbon dioxide. At 255° the gas contained 5% carbon dioxide and 8% $H_2(D_2)$; at 184° 1.5% of each gas was found. During this analytical work it was established that the exchange reaction did not occur on the copper–copper oxide mass which was used to burn hydrogen in the presence of methane at a temperature of 302°. On a 15-g. sample of oxide approximately 10% reduced to metal no exchange was found between 39.8 cc. of CH_4 and 40.3 cc. of D_2. The reaction time varied from one-half to one hour, during which the deuterium is rapidly burnt, but the water vapor formed remains in contact with the surface until condensed in the adjacent carbon dioxide traps. We also established the inertness of copper–copper oxide at this temperature with ethane–deuterium mixtures.

The slow reaction of methane and deuterium oxide is probably to be ascribed to the strong adsorption of water vapor on the nickel leaving little free surface for the activated adsorption of the methane. In the actual experiments it was observed that the whole charge of water vapor, $\sim$40 cc., was adsorbed at room temperature. The strong adsorption of water vapor would also account for the distribution of methanes obtained in the two last experiments which were as follows: CH_4, 83 and 80%; CH_3D, 8 and 12%; CH_2D_2, 4 and 5%; CHD_3, 3 and 2%; CD_4, 2 and 1%. The normal equilibrium distribution for a 9% C–D methane would be CH_4, 69; CH_3D, 27; CH_2D_2, 4; CHD_3, 0.5; CD_4, 0%. Such a distribution, however, is for the mixture in the gaseous phase and is evidently upset by the abnormal ratio of the two reactants on the surface. It would seem that an adsorbed methane molecule might suffer several substitutions with D atoms before escaping to the gas phase. The 27.5% C–D product, which we regard as close to the equilibrium point, was in fact a normal equilibrium distribution of the several methanes.

General Discussion

These exchange reactions between methane and deuterium and its compounds indicate that the same possibilities of replacement of hydrogen by deuterium exist in the case of saturated hydrocarbons as have hitherto been studied with unsaturated aliphatic hydrocarbons and benzene. The differences are of a quantitative nature but not of principle. The exchanges are slower than those of the unsaturated hydrocarbons and, for this reason, Farkas, Farkas and Rideal observed that the atomic exchange between deuterium and ethane does not occur under the conditions where the exchange reaction between ethylene and deuterium takes place rapidly. Indeed, such a conclusion was indicated in the results of Turkevich and Taylor[6] on the activated adsorption of hydrocarbons. The results now obtained indicate that the presence of a double bond in the reactant hydrocarbon is not an indispensable essential in such exchange processes, and that theories of mechanism, such as those of Horiuti and Polanyi,[4b] based upon the double bond characteristics can only be restricted considerations of the complete problem.

Unless one wishes to postulate the existence on the surface of associative complexes of the type CH_4D as intermediates in the exchange process, which we regard as very improbable, the conclusion is reached that the activated adsorption of the hydrocarbon is essentially a *dissociative* adsorption. The interaction of the two methanes CH_4 and CD_4 enforces this conclusion. The first stage of the dissociative process with methane would be the formation of CH_3 and H, entirely analogous to the now generally accepted postulate of the dissociation of hydrogen into two atoms on hydrogenation surfaces. The extent to which such dissociative processes of adsorption occur will obviously depend on the temperature, pressure and surface characteristics of the catalyst. In the limit, the dissociative process will proceed to the state in which all carbon and hydrogen bonds are severed, a condition which must obtain when the catalytic reaction $CH_4 = C + H_2$ occurs. All these dissociative processes

[6] Turkevich and Taylor, This Journal, **56**, 2254 (1934).

on the surface establish there an equilibrium condition with the reverse processes, the association of adsorbed methyl radicals, or even more dissociated fragments with adsorbed hydrogen or deuterium atoms, yielding finally an equilibrium mixture of CH_xD_y, where $x + y = 4$. We see no reason why such dissociative processes of adsorption should not also occur with the more readily adsorbed ethylenic hydrocarbons, and contribute thereby to the exchange process. Such processes would supplement the associative type of mechanism

$$C_2H_4 + D \longrightarrow C_2H_4D \longrightarrow C_2H_3D + H$$

discussed in detail by Horiuti and Polanyi. These authors excluded the dissociative mechanism from consideration because of their observation, which agrees with our results with methane, that the exchange reaction rate is so greatly reduced when heavy water is used in place of deuterium. In our case, where a dissociative adsorption of the methane seems unavoidable, we ascribe this slower rate in presence of heavy water to the lower accessibility of the methane to the surface owing to the known stronger adsorption of the water relative to hydrogen.

Summary

1. The saturated hydrocarbon, methane, undergoes exchange with deuterium, methane-d_4 and deuterium oxide on active nickel catalysts at temperatures of 138° and higher.

2. At 184° the rate of reaction of methane with methane-d_4, deuterium and deuterium oxide decreases in the order given.

3. The activation energies of reaction with methane-d_4 and deuterium are $\sim$19 and $\sim$28 kcal., respectively.

4. The mechanism of reaction is associated with an activated, dissociative adsorption of methane on areas of surface unoccupied by hydrogen–deuterium or deuterium oxide.

Wetting Characteristics of Solids of Low Surface Tension such as Talc, Waxes and Resins

BY F. E. BARTELL AND H. H. ZUIDEMA

The degree of wetting can most readily be determined by measuring the angle of contact formed with the liquid and solid in question. Degree of wetting is designated as the change in free surface energy, ΔF_s, which occurs when a liquid is brought into contact with a solid (*i. e.*, $\Delta F_s = S_1 - S_{1n}$).[1] Since the free surface energy of a system is numerically equal to the surface tension, the energy change expressed in ergs per sq. cm. is numerically equal to the adhesion tension, A_{1n}, expressed in dynes per cm.

$$S_1 - S_{1n} = A_{1n} \qquad \text{(I)}$$

The adhesion tension can be evaluated in terms of the surface tension of the liquid, S_n, and the contact angle, θ_{1n}, which the liquid forms with the solid, for, from the Young equation[2]

$$S_1 - S_{1n} = S_n \cos \theta_{1n} \qquad \text{(II)}$$

or, for water

$$S_1 - S_{13} = S_3 \cos \theta_{13} \qquad \text{(III)}$$

and hence

$$A_{1n} = S_n \cos \theta_{1n} \qquad \text{(IV)}$$

or

$$A_{13} = S_3 \cos \theta_{13} \qquad \text{(V)}$$

The adhesion tension and degree of wetting of a liquid against a solid cannot be measured directly if the contact angle is zero, but in such instances it can be determined by application of the Bartell–Osterhof[3] equation

$$A_{13} - A_{1n} = S_{n3} \cos \theta_{1n3} \qquad \text{(VI)}$$

if the interfacial contact angle, θ_{1n3}, is finite and measurable (as it usually is), and if the solid–water–air contact angle, θ_{13}, is finite, so that the adhesion tension, A_{13}, can be calculated from equation (V). For solids on which water gives a zero angle, some organic liquid can usually be found which gives a finite contact angle, and equation (VI) can be used to calculate A_{13}.

---

(1) The symbols used in this paper are essentially the same as have been used in recent publications from this Laboratory. S_1 = surface tension or free surface energy of a solid in air, S_n = surface tension or free surface energy of an organic liquid and S_3, the surface tension or free surface energy of water. The subscripts 1, n and 3 refer to solid, organic liquid and water phases, respectively. In this paper an interfacial contact angle between solid, organic liquid and water will be represented by θ_{1n3}.

(2) Young, *Trans. Roy. Soc.* (London), **A95**, 65 (1805).

(3) Bartell and Osterhof, "Colloid Symposium Monograph," **5**, 113 (1927).

The Bartell–Osterhof equation (VI) can be derived mathematically by subtracting equation (II) from equation (III) and substituting in the Young[2] equation

$$S_{1n} - S_{13} = S_{n3} \cos \Theta_{1n3} \qquad \text{(VII)}$$

We thus obtain the equation

$$S_3 \cos \Theta_{13} - S_n \cos \Theta_{1n} = S_{n3} \cos \Theta_{1n3} \qquad \text{(VIII)}$$

and hence from equations (IV) and (V)

$$A_{13} - A_{1n} = S_{n3} \cos \Theta_{1n3} \qquad \text{(VI)}$$

It has been impossible, heretofore, to test the Bartell–Osterhof equation experimentally since for no solid examined could the value of each term be determined experimentally. In the present investigation, however, solids were studied which showed markedly different properties from those of solids previously studied and reported upon in papers from this Laboratory, and one of these solids, talc, has made possible the experimental testing of this equation.

The extent to which a liquid will spread over the surface of a solid is dependent upon the relative magnitudes of the three tensions involved, namely, S_1, the surface tension of the solid, S_{1n} or S_{13}, the interfacial tension solid–liquid and S_n or S_3, the surface tension of the liquid. If S_1 is greater than the sum of the other two tensions, the liquid will spread over the surface of the solid forming a continuous film. If S_1 is less than the sum of the other two tensions, spreading will be limited, a drop of the liquid will be formed which will give a definite angle of contact with the surface of the solid.

An indication of the relative surface tension values of solids is given by their relative hardness. In hard solids the atoms or ions are close together.[4-8] The force of attraction between the elementary units comprising the solids is therefore large, and the work of cohesion, and hence the surface tension, is high. In soft solids the elementary units are farther apart, and the force of attraction is much less. The work of cohesion and surface tension of soft solids is therefore small in comparison with the values for harder solids. Waxes, some resins and certain solids such as talc, pyrophyllite, graphite, etc., are very soft. Their force of cohesion, work of cohesion and hence surface tension are very low. Tests made upon some of these low surface tension solids showed that water or any organic liquid of fairly high surface tension value formed a drop, and hence a measurable contact angle upon the solid.

Experimental

The wetting characteristics of the solids studied were determined by contact angle measurements using the sessile drop method. Mack[9] has recently shown that the effect of gravity in deforming the spherical outline of sessile drops is negligible for drops of 0.5 mm. or less in diameter, except for contact angles very near 180°, and that for angles under 90° the effect is negligible even for somewhat larger drops (Figs. 1a, b and c). For a drop whose outline is the segment of a sphere, the contact angle may be calculated from the equation

$$\tan \Theta/2 = 2h/d \qquad \text{(IX)}$$

where h is the height, and d the diameter of the drop. This equation holds for acute and obtuse angles alike, and is of simple geometric derivation. Since all the drops used in this investigation were 0.5 mm. or less in diameter, equation (IX) could be used for calculating their angles of contact. Avoiding the effect of gravity by the use of small drops had the advantage that the dimensions of the drop in standard units were not required. It was necessary only to determine the ratio of h to $d/2$.

All contact angle measurements were made on freshly cleaved or freshly solidified surfaces, depending upon whether the solid was crystalline or amorphous. The liquids used were all very carefully purified and their surface tension values were in good agreement with the generally accepted values in the literature. Satisfactory results were obtained by the method if sufficient care was taken in the preparation of the surface and in placing the drop on the surface. All interfacial contact angles were measured through the water phase.

In carrying out a determination, a freshly cleaved crystal or freshly solidified surface of the solid was placed in a cell about 3 × 3 × 3 cm. with plane plate-glass sides. The solid was mounted in air or in a liquid, depending upon whether measurement was to be made of a solid–liquid–air contact angle or an interfacial contact angle. A cover, ground to fit, and having a very small hole in the center for the introduction of a

capillary pipet, was fitted over the top of the cell. The capillary pipet containing the liquid was next lowered by means of a ratchet and pinion device until it almost touched the surface of the solid. By applying air pressure at the top of the pipet, a drop of liquid was forced out on the solid, and was allowed to advance until it had a diameter of about 0.5 mm., when the pipet was removed by carefully raising it. A light source was placed behind the cell and the drop was observed with a microscope mounted in a horizontal position. The height and diameter of the drop were measured by means of a graduated ocular. On occasion, photographs were made of drops by means of a camera attached to the microscope.

Since individual drops show slight variations, a minimum of six individual determinations was made for each system investigated. If the angles of the individual drops varied by more than three or four degrees, eight or ten determinations were made.

Talc

The data obtained for talc are given in Table I. The data for contact angle in air, column 4, show that talc is neither strongly hydrophilic nor strongly organophilic since finite contact angles were measured on talc both with water and with a number of organic liquids. The data in column 6 show that talc must be considered to be organophilic in nature, however, since all the interfacial contact angles measured upon it (*i. e.*, measured through the water phase) were greater than 90°

[a] Organic liquid "advancing." [b] Determined by the capillary rise method. All the other surface tension values given are from the literature. [c] The interfacial tension of benzyl alcohol against water was determined by means of the double cylinder method.[10] All the other interfacial tension values given are taken from the literature.

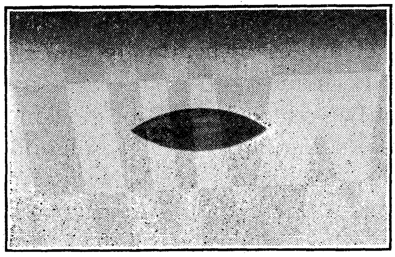

Fig. 1a.

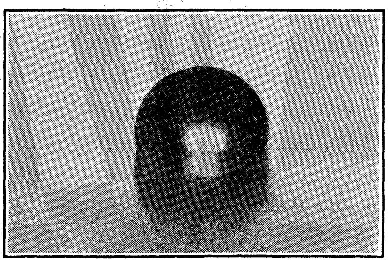

Fig. 1b.

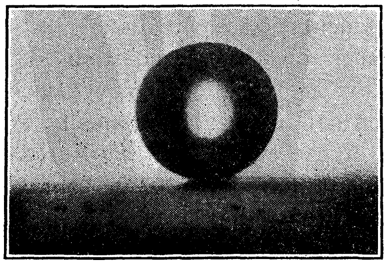

Fig. 1c.

The data in column 6 give the observed contact angles and the data in column 5 give the contact angles calculated from the Bartell–Osterhof equation (equation VIII). The observed interfacial angle values given in column 6 are all for organic liquid advancing angles. This does not mean that measurements were made on a dynamic advancing angle. The measurement was made on a static angle, but in each case the talc was first covered with water, the organic liquid was then introduced in the form of a drop which advanced over a surface previously wet by water. This method of procedure was considered best because

---

[10] Bartell and Miller, THIS JOURNAL, **50**, 1961 (1928).

talc has a lower adhesion tension against water than against organic liquids, hence water will be more easily displaced from it by the organic liquid than will the organic liquid be displaced by water.

The agreement between the observed and calculated interfacial angles is remarkably close for all of the systems for which the calculation was possible with the single exception of the benzyl alcohol system. (Some of the organic liquids form zero contact angles with talc and the calculation could not be made.) The lack of agreement in the case of benzyl alcohol can be explained on the basis of the comparatively high solubility of the alcohol in water and its very low interfacial tension against water. In the development of the Bartell–Osterhof equation, the S_{1n} and S_{13} of equation VII are for organic liquid and water mutually saturated, for the two liquids are in contact with each other. The S_{1n} of equation II is for pure organic liquid, however, and the S_{12} of equation III is for pure water. The error thus introduced is apparently negligible for organic liquids of high interfacial tension against water and low solubility in water, but may become great when the interfacial tension is low and the mutual solubility appreciable. Benzyl alcohol has an interfacial tension value against water of only 4.2 dynes, as compared with values ranging from 34 to 48 dynes for the other five liquids for which the calculation was made.

As a check on this explanation for the discrepancy in the case of benzyl alcohol–water system, contact angle measurements were made with each of the two liquids saturated with the other. The data are included in Table I. It will be observed that the agreement between the observed and calculated interfacial angles is very much better than before, although not so close as was found for the other systems. Experimental error in the determination of any one of the four quantities, Θ_{1n}, Θ_{13}, S_n or S_3 introduces a large percentage error in the calculated Θ_{1n3}, for the calculation involves the small difference between $S_3 \cos \Theta_{13}$ and $S_n \cos \Theta_{1n}$.

It seems justifiable to conclude that the Bartell–Osterhof equation is applicable to systems of insoluble solids when used in conjunction with liquids of low mutual solubility and high interfacial tension. It is probably applicable also to systems involving liquids of low interfacial tension, provided the mutual solubility effects of the liquids are taken into account.

As has been pointed out above, talc shows a marked difference in behavior from the harder solids previously examined in that it forms contact angles with water and with organic liquids of high surface tension. Talc also shows another marked difference from the harder solids previously examined. The data in column 6, Table I, show that the interfacial angles formed on talc by different organic liquids against water are different. The empirical equations of Bartell and Bartell[10] do not therefore apply to talc. Talc has been shown to be organophilic in nature, but its relative degree of organophilic nature cannot be measured on the convenient K_{n3} scale of Bartell and Bartell.[11]

Waxes and Resins

Many amorphous substances such as waxes and resins are soft and have low surface tension values. Their wetting characteristics would therefore be expected to be similar to those of the soft crystalline solid, talc.

A large number of substances, including paraffin, Japan wax, beeswax, spermaceti, a number of synthetic waxes including halogenated naphthalenes and biphenyls, and many natural and synthetic resins were investigated. Practically all of them were found to give large angles with water, and most of them gave fairly large angles with the organic liquids of high surface tension. Many of them were somewhat soluble in the organic liquids, however. Five substances in which the solubility effects were fairly low were chosen for detailed study, namely, Glyptal resin,[12] de Khotinsky cement (hard), carnauba wax, shellac and Opal wax 20.[13]

Fresh surfaces of these substances were obtained by melting them and allowing them to solidify on clean glass plates. The data obtained for contact angles in air and for interfacial contact angles are given in Table II. The solid–liquid–air angles are easily reproducible, since for any solid with a low surface tension value (*i. e.*, low free surface energy) there is very little tendency for the solid to be carried to a lower energy level by the adsorption of water vapor, atmospheric gases, etc. This fact is probably responsible for the good agreement found in the literature for the contact angle of water on paraffin as reported by different investigators. The interfacial angles were measured with organic liquid "advancing."

The data obtained on waxes and resins cannot be considered as accurate data because of errors introduced by solubility effects. Measurements with the du Noüy Tensiometer showed that the surface tension of alpha-bromonaphthalene saturated with carnauba wax was practically the same as that of the pure liquid. The surface tension of water saturated with the wax was slightly lower than that of pure water, however, and the interfacial tension of alpha-bromonaphthalene against water was also lowered to some extent by the presence of carnauba wax.

Another factor to be considered is that the solids, being appreciably soluble in the organic liquids, are pitted when a drop of organic liquid is placed upon them. The surface under the drop is no longer plane. The measured angle is therefore not the true angle, for it is measured between the arc of the drop and the plane of the surface of the solid. Angles thus measured are reproducible and give an indication of the wetting properties of the solid, but they cannot be used for checking the Bartell–Osterhof equation. Since the interfacial angles measured on a given surface by water against different organic liquids were different, the indication is that the empirical equations of Bartell and Bartell[11] do not apply in these soft solids.

As has been pointed out, the behavior of soft solids can be explained on the basis of their low surface tension values. Waxes have very low surface tension values, the value for paraffin being given in the literature as 40 dynes. Measurements of the surface tension of molten waxes were made with the du Noüy Tensiometer. Temperature–surface tension curves were drawn and extrapolated to room temperature. They are shown in Fig. 2. The extrapolated values, which lie between 33 and 38 dynes (at 25°), should give a fairly accurate indication of the surface tension of the solid, for the curves are straight lines down to the point of solidification.

Since the waxes have surface tension values which are, presumably, lower than that of talc, they should give angles with liquids of fairly low surface tension which form zero angles on talc.

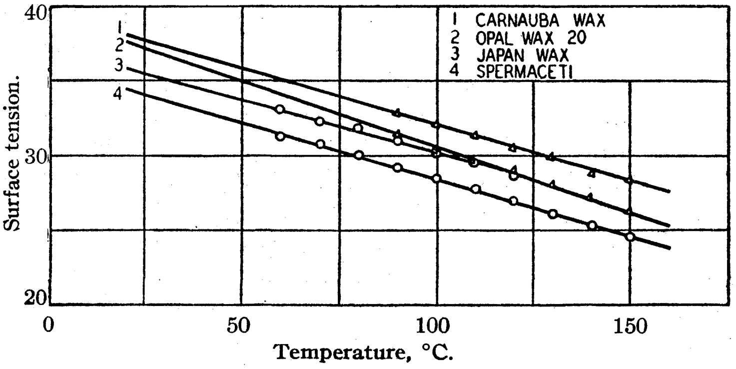

Fig. 2.

This has been shown to be the case. Talc gave a small angle with bromobenzene (S_n = 35.9) and larger angles with liquids with higher surface tension values, but gave zero angles with liquids of lower surface tension. The waxes and resins gave measurable angles with butyl acetate (S_n = 24.1), and some of them gave measurable angles even with amyl alcohol (S_n = 23.4).

Summary and Conclusions

1. The wetting characteristics of talc and of a number of waxes and resins have been studied by measurements of the contact angles formed by small drops of liquid on these solids.

2. Both water and organic liquids (of high surface tension) form contact angles on these solids, thus indicating that the surface tension of these solids is low.

3. Soft solids of low surface tension are wetted less readily by liquids than are hard solids which possess a higher surface tension.

4. On talc, accurate measurements could be made of interfacial contact angles as well as of contact angles in air both with water and with organic liquids. This made possible the experimental testing of the Bartell–Osterhof equation relating adhesion tension and interfacial contact angles. This equation was found to hold.

The Absorption Spectrum of Ethyl Methyl Ketone

BY A. B. F. DUNCAN, VICTOR R. ELLS AND W. ALBERT NOYES, JR.

The spectroscopy and photochemistry of acetone have been the subjects of numerous investigations. The spectrum consists of a broad absorption region extending from about 2200 to about 3200 Å. with a definite fine structure on the long wave end, a series of discrete bands extending from 1995 to about 1820 Å., and at shorter wave lengths other bands, some of which fitted a Rydberg formula predicting an ionization potential of 10.2 volts.[1] At still shorter wave lengths there is continuous absorption extending down to the limit of the observations made, about 800 Å. In the near ultraviolet fluorescence is observed, although attempts to find this phenomenon in the neighborhood of 1900 Å. failed.[2]

The next higher ketone is ethyl methyl ketone. The electronic structure of the carbonyl group must be very similar to that in acetone. However, the symmetry operations which may be performed on the two molecules differ considerably. If the methyl group forming part of the ethyl group is considered to execute a perfectly symmetrical rotation around the adjacent carbon–carbon bond, there will be only one symmetry operation aside from the identity, namely, reflection in the plane containing the carbonyl group and the two adjacent carbon atoms. However, due to various types of interaction between the different parts of the molecule, this particular rotation might not be expected to be completely symmetrical so that ethyl methyl ketone must be considered to possess a very low order of symmetry.

Experimental Procedure and Discussion of Results

The methyl ethyl ketone used in these experiments was prepared by the acetoacetic ester synthesis, using acetoacetic ethyl ester and methyl iodide. It was purified by formation of the sodium bisulfite compound, dried with potassium carbonate and fractionally distilled.[3]

For investigation of the near ultraviolet absorption a Hilger E_3 spectrograph was used together with Eastman III-O and 33 plates.

The absorption spectrum of the liquid in this region has been investigated, but that of the vapor has not been reported. Two absorbing columns of 1 and 10 meters with pressures of 3 to 86 mm. (the vapor pressure at 25°) were used. At the highest pressure the absorption extended from approximately 3200 to 2400 Å. No trace of vibrational fine structure was observed under any conditions.

Ethyl methyl ketone shows strong fluorescence when illuminated with approximately monochromatic 3130 Å. radiation. The fluorescence viewed with a hand spectrograph appeared to consist of a continuous band in the green. We were unable to obtain photographs of the fluorescence with the E_3 spectrograph, but the matter is being pursued further.

In view of this fluorescence, particular care was used in making the absorption measurements to vary the pressures over a wide range, and at each

(3) The authors wish to express their appreciation to Professor C. B. Wooster for suggesting the method of synthesis and supervising its execution.

pressure to make a number of exposures for different lengths of time, in order to provide suitable contrast. It is possible that the lowest pressure was still too high to permit the observation of structure and a still longer column may be necessary.

The near ultraviolet spectrum is followed by a region of almost complete transmission extending down to 1975 Å. At this point a spectrum consisting of discrete bands begins, which continues, broken by short regions of high transmission, down to about 1550 Å. At still shorter wave lengths there is strong continuous absorption extending down to about 780 Å., the limit of the observations. No structure could be found in this continuum even at low pressures where the continuous absorption was weak. Any discrete bands must be weaker than the continuous absorption below 1567 Å.

A one-meter, normal incidence vacuum spectrograph with a 120,000 line glass grating was used to photograph this region. The modified Lyman continuum served as the source.[1e,1f] Eastman III-O plates sensitized with Nujol were used. The plates were measured and reduced in the usual way and emission lines in the source, chiefly due to carbon, were used as standards. The dispersion was approximately 8.5 Å./mm.

The frequencies of the bands are given in Table I with visually estimated intensities. The intensity of the weakest band is arbitrarily placed as 1, which means that some rather high values must be given without implying, however, any greater accuracy in estimating intensities than was obtained with acetone. The red edges of the bands are given.

TABLE I

FAR ULTRAVIOLET BANDS OF ETHYL METHYL KETONE

Frequency, cm.^{-1}	Intensity	Frequency, cm.^{-1}	Intensity
50634	8	53119	2
50675	8	58110	12
50728	8	58662	20
50857	6	59102	1
50891	6	59360	1
50948	6	62283	16
51209	4	63523	200
51915	3	63817	250
52426	3		

The edges of the first six bands are quite sharp and the accuracy should be five to ten wave numbers. For most of the other bands the edges were quite diffuse, but it is felt that in no case does the error exceed fifty wave numbers.

The first ten bands, 50,634 to 53,119 cm.$^{-1}$, evidently involve one upper electronic state. The spectrum here is similar to that in acetone in the region 51,000 to 55,000 cm.$^{-1}$. There are three main bands forming an upper state progression involving a frequency of 1281 cm.$^{-1}$. Two other upper state frequencies appear, one about 220 and the other 575. The origin of the system is the triple band (50,634, 50,675, 50,728), which corresponds to the (51,171, 51,226, 51,285) band in acetone which is also triple headed. Table II shows the arrangement of the bands.

TABLE II

ARRANGEMENT OF ETHYL METHYL KETONE BANDS (50,634 to 53,119)

(All transitions are considered to occur from the lowest level of the ground state)

v_1', v_2', etc. $= 0$	50634	50675	50728
	223	216	220
$v_1' = 1$	50857	50891	50948
	1281		
$v_2' = 1$	51915		
	1204		
$v_2' = 2$	53119		
	575		
$v_3' = 1$	51209		
	514		
$v_2' = 1$, $v_3' = 1$	52426		

The second electronic state involving a transition below 1975 is evidenced by four bands, the two of shortest wave length being of extremely low intensity. Acetone has an analogous state giving transitions between 60,086 and 62,529 cm.$^{-1}$. The two strongest bands are separated by 552 cm.$^{-1}$. It appears probable that this is an upper state difference and that the origin of this state lies at 58,110 cm.$^{-1}$. One of the weak bands, 59,360, is separated from this by 1250 cm.$^{-1}$.

The differences between the remaining three bands are as follows: 63,523 to 62,283 = 1240; 63,817 to 63,523 = 294. The two bands of highest frequency evidently belong to the same electronic transition; the first of the three may also belong to the same transition. If the three bands belong together, the intensity relationships are such that 62,283 cannot be the origin of the system, in which case 1240 would have to be a ground state difference. This is unlikely due to the small Boltzmann factor (0.0015) for such a large frequency. It seems better, then, to put 62,283 in a separate electronic transition. Whether the 294 difference for the remaining two bands is an upper or ground state difference cannot be determined.

The significance of the various frequency differences may be discussed briefly. v_2 is most probably a carbon–oxygen frequency which is 1734 cm.$^{-1}$ in the normal state. The corresponding frequency in acetone for this state is about 1200 cm.$^{-1}$ (1712 in the normal state). v_1 is probably analogous to 321 found in acetone in this region. It is probably associated with a simultaneous bending of the methyl and ethyl groups with respect to the carbon–oxygen axis. v_3 may possibly represent a motion in which the ethyl and methyl groups are stretched as units in reference to the carbonyl group.

The Electronic States of Ethyl Methyl Ketone

It is apparent from the above discussion that four, or more probably five, well separated excited electronic states of ethyl methyl ketone have been found here. The first excited state probably has unresolved fine structure, since fluorescence is caused by absorption in this region. The other states possess discrete vibrational levels as indicated. In addition there are other states, perhaps repulsive, which are necessary to account for the continuum overlying the discrete structure, particularly at short wave lengths.

Obviously no two of the origins of these states fit a Rydberg formula which would converge to a reasonable limit.[4] The band in ethyl methyl ketone most similar to a member of the acetone Rydberg series[1f] is either 63,525 or 63,817 (depending on which is considered to be the origin of this particular electron transition). One of these bands is believed to be the first member of a Rydberg series whose other members are masked by continuous absorption. Accordingly the ionization potential of the molecule could not be determined by spectroscopic means.

The ionization potential was then determined by the method of electron bombardment.[5] The value obtained was 10.5 ± 0.5 volts, as compared to 10.1 volts (by electron impact) for acetone.

According to Mulliken[4] a (2 p_yb_2) electron in formaldehyde should have a lower ionization potential than any other and the agreement between the theoretically predicted value and that obtained by convergence of a Rydberg series lends support to this statement.[6] In acetone a similar electron must be involved in the Rydberg series and this must be true for the hypothetical Rydberg series in ethyl methyl ketone. This electron is described as one occupying a non-bonding oxygen orbital and transitions involving it should change the fundamental frequency of the carbonyl group only slightly.

Since most of the discrete bands and the near ultraviolet continuum do not fit a Rydberg series, it is probable that other electrons of the bonding or anti-bonding types are involved in these transitions. Little of a definite nature can be said concerning these electron states, although others have attempted to correlate frequencies of the various states of carbon monoxide with the frequencies of the carbonyl group.

Summary

1. The absorption spectrum of ethyl methyl ketone has been investigated at room temperature from the visible down to about 780 Å.

2. Four (possibly five) different excited electron states in addition to any which may be involved in the short wave continuum must be used to explain the different absorption regions.

3. The bands in the region from 1975 to 1883 Å. may be classified as belonging to a single electron transition, using three vibration frequencies in the upper state.

4. A brief discussion, including a general comparison with the acetone bands, has been given.

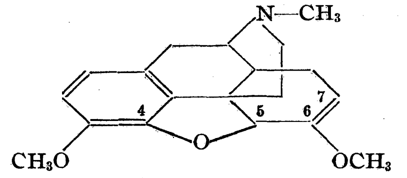
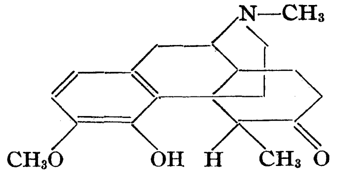
The Addition of Organomagnesium Halides to Pseudocodeine Types. II. Preparation of Nuclear Alkylated Morphine Derivatives[1]

BY LYNDON SMALL, HOWARD M. FITCH[2] AND WILLIAM E. SMITH

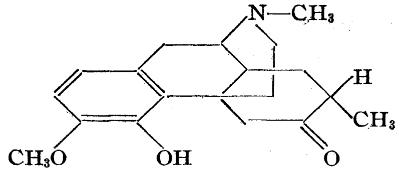
Derivatives of the morphine alkaloids having an alicyclic unsaturated linkage in the β,γ-position to the 4,5-ether linked oxygen atom (*i. e.*, allyl ether types) show a general tendency to undergo reduction or addition reactions in which both the ether oxygen and the double bond are involved.[3] In previous papers we have demonstrated that organomagnesium halides react with pseudocodeinone and desoxycodeine-C to yield phenolic bases containing the organic radical of the Grignard compound used,[4] probably at the 5- or 7-position in the nucleus. The present communication deals with the application of this reaction to dihydrothebaine and with the transformation of the product into a series of nuclear alkylated dihydromorphine derivatives.



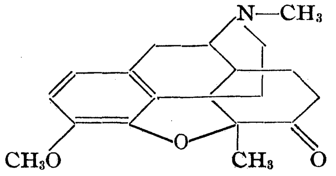
I. Dihydrothebaine



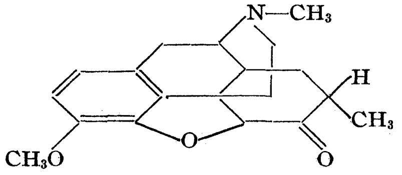
II. 5-Methyldihydrothebainone



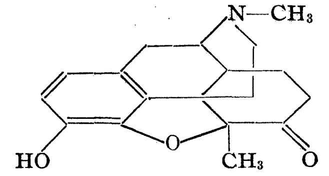
III. 7-Methyldihydrothebainone



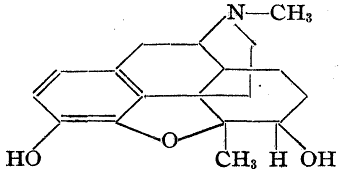
IV. 5-Methyldihydrocodeinone



V. 7-Methyldihydrocodeinone



VI. Methyldihydromorphinone (?)



VII. Methyldihydromorphine (?)

The structure of dihydrothebaine (I), at least as far as the position of the alicyclic unsaturation is concerned, is amply demonstrated by the facile hydrolysis to dihydrocodeinone,[5] and by the behavior toward ozone.[6] The double bond is located as in pseudocodeine and desoxycodeine-C; nevertheless, under the ordinary conditions imposed for reaction with Grignard's reagent, dihydrothebaine is not appreciably affected, a fact which may be attributed in part to its low solubility in ether, and perhaps in part to the presence of the enol ether group. When dihydrothebaine is extracted from a Soxhlet apparatus into boiling ethereal methylmagnesium iodide an addition compound slowly separates, and at the end of five days no more dihydrothebaine can be detected. The product consists principally of a phenolic ketone, methyldihydrothebainone (tentative formula II or III) and in small amount (10% yield), of an isomeric substance, isomethyldihydrothebainone. The enol ether group present in the starting material has been hydrolyzed, either during the reaction or more probably during the isolation of the reaction products, which is necessarily accomplished with the use of acidic reagents. In this respect the dihydrothebaine reaction presents a striking contrast to that of thebaine, where the products (phenyldihydrothebaine or the methyldihydrothebaines) are extremely resistant to hydrolysis. An enol ether of instability com-

parable to that of the hypothetical intermediate methyldihydrothebainone methyl enolate has, however, been isolated in this Laboratory during the reduction of thebaine by the Wieland and Kotake procedure.[7]

The presence of the ketone group at C–6 in methyldihydrothebainone implies an active methylene group at C–5 (III) or at C–7 (II), depending upon whether methylmagnesium iodide has added to dihydrothebaine in the 1,4- or 1,2-manner. Schöpf has demonstrated for dihydrothebainone and for dihydrometathebainone the feasibility of reforming the 4,5-oxide bridge characteristic of the naturally-occurring bases of the morphine series.[8] The compound of formula III (and possibly II) should undergo ether ring closure under similar conditions. Methyldihydrothebainone reacts with two moles of bromine to form a dibromo derivative (not isolated), which on treatment with cold dilute sodium hydroxide is converted to the non-phenolic 1(?)-bromomethyldihydrocodeinone. Elimination of bromine (catalytic hydrogen) yields IV or V, methyldihydrocodeinone. By this series of reactions we arrive at the first known nuclear alkylated derivative of the morphine group.

It has been found by repeated experiments in this Laboratory[9] that dihydrocodeinone can be reduced at the carbonyl group by the catalytic method to give dihydrocodeine, with no detectable amount of the epimer, dihydroisocodeine. Methyldihydrocodeinone, under the same conditions, takes up one mole of hydrogen with formation of methyldihydrocodeine, in which the codeine configuration for the alcoholic hydroxyl group is assumed on the basis of the above cited evidence.

Like most saturated derivatives of the morphine series, the compounds of the group described in this communication are relatively stable toward rearrangement or decomposition in the presence of concentrated halogen acids, and methyldihydrocodeinone can be demethylated smoothly with 48% hydrobromic acid. The product is methyldihydromorphinone (VI), a homolog of the well known drug dihydromorphinone ("Dilaudid"). Methyldihydromorphinone can be reduced at the ketone group, with formation of methyldihydromorphine (VII).[10] The relationship of the latter to the above-mentioned methyldihydrocodeine was established by methylation with diazomethane.

Isomethyldihydrothebainone can be separated from the main reaction product through differences in solubility of the respective hydrochlorides and ultimately through its properties as a cryptophenol. The presence of the phenolic hydroxyl is shown by the formation of an acetyl derivative and by the solubility in alkali, from which, however, in contrast to methyldihydrothebainone, the base can be extracted with ether. On treatment with two moles of bromine, and subsequently with dilute alkali, isomethyldihydrothebainone yields a non-phenolic product, bromoisomethyldihydrocodeinone (not crystalline), which can be debrominated to isomethyldihydrocodeinone (Formula IV or V ?). The demethylation and reduction reactions which will lead to the isomethyldihydromorphinone and isomethyldihydromorphine types have been postponed until more material is available.

Determination of the position of the new methyl group in methyldihydrocodeinone presents serious difficulty, and definite proof will probably be obtained only by degradation. This is at present not practicable because of lack of material. It is certain that in the bromination of methyldihydrothebainone and its isomer one bromine atom enters at C–5, else the ether ring closure would not be possible. This fact may indicate that the methyl group occupies C–7, for it has been shown that in the bromination of 1-methylcyclohexanone, bromine substitutes at the methylene group adjacent to the carbonyl in preference to the methenyl group.[11] Furthermore, the presence of a methyl group on C–5 might well be expected to offer some hindrance to closure of the ether ring. If this reasoning were valid, then isomethyldihydrothebainone would be easily accounted for as a diastereomer, the methyl group having added at C–7 in both possible configurations. The last hypothesis is susceptible of direct proof. If methyldihydrocodeinone and isomethyldihydrocodeinone differ only in the configuration at C–7, their enol acetates must be identical[12] (V, V-a ⟶ VIII).

Both methyldihydrocodeinone and isomethyldihydrocodeinone can be acetylated under the conditions which are imposed to transform dihydrocodeinone to its enol acetate ("Acedicon").

[9] David E. Morris, unpublished results.

[10] Formulas VI and VII are offered with reservation concerning the position of the methyl group.

[11] Kötz and Steinhorst, *Ann.*, **379**, 10, 15 (1911).

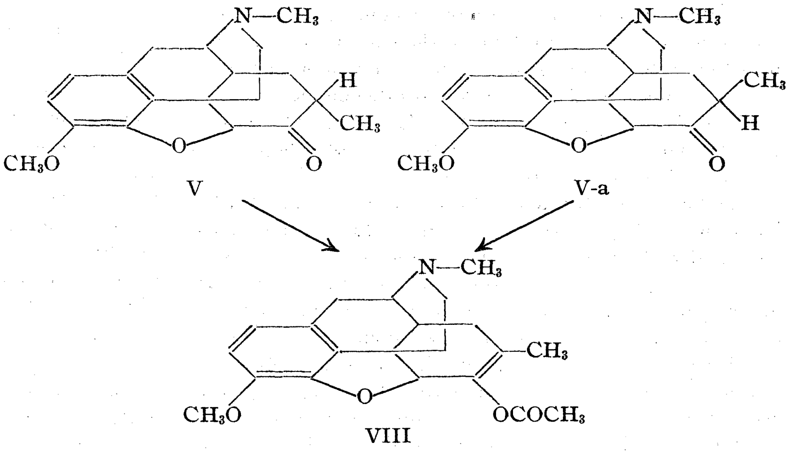
[12] This reasoning does not take into account the possibility of an enolization in which the hydrogen atom located on C-5 might participate.

The "methylacedicons" which are obtained from the isomeric ketones can scarcely be other than enol acetates, as is indicated by the ease with which they can be hydrolyzed back to the starting ketones, but they are not identical, a fact which we regard as weighing in favor of the 5-position for the new methyl group.

We have not neglected the possibility that methyldihydrothebainone and isomethyldihydrothebainone might have been formed by competing 1,2- and 1,4-additions of methylmagnesium iodide to the ether oxygen, double bond system of dihydrothebaine. The products in this case would owe their isomerism to the position of the methyl group at C-5 and C-7 (Formulas II and III), and, of the isomeric methyldihydrocodeinones, the 5-methyldihydrocodeinone (IV) should contain an active methylene group, in contrast to 7-methyldihydrocodeinone (V). An answer to this question was sought in the condensation reaction with ethyl oxalate according to Claisen,[13] a reaction which proceeds with methylene, but not with methenyl, groups adjacent to a carbonyl. Both of the methyldihydrocodeinones reacted with ethyl oxalate in the presence of absolute alcoholic sodium ethylate (although they were not affected by sodium ethylate alone), which again points to a location of the methyl group in two configurations at C-5. Against any final conclusion to be drawn from the evidence here presented we wish to cite the rather convincing stereochemical speculations of Schöpf,[14] which make it seem doubtful whether a 4,5-ring closure in more than one configuration would be possible.

The fact that one of the methyldihydrothebainones behaves as a cryptophenol while the other is normal in its phenolic nature suggests to us a greater structural difference than diastereoisomerism at C-5. Furthermore, when methyldihydrocodeinone is converted to its enol acetate, the specific rotation is changed only from −147 to −143°, while in the case of isomethyldihydrocodeinone the change is from −179 to −250°, indicating that in the latter an asymmetric center (C-7) may have been disturbed.

Incidentally, if it can be proved that the methyl group in one of our methyldihydrothebainones is located at C-5, the Knorr-Wieland formula for morphine (which we do not regard as yet disproved) will be put out of all question, for a linkage of the ethanamine chain at C-5 would exclude bromination and subsequent ring closure at this point.



The pharmacological action of the dihydromorphine and dihydrocodeine homologs described in this communication will be reported from the University of Michigan by N. B. Eddy and coworkers. The chemical studies in the series will be extended to embrace further conversion products of these bases (especially the desoxylated derivatives) and to include the introduction of groups other than methyl.

It is a pleasure to acknowledge our indebtedness to Merck and Co., Rahway, N. J., for the gift of the large amount of thebaine used in this research, and to E. R. Squibb and Sons for the fellowship grant under which most of the work was carried out.

Experimental Part

Dihydrothebaine.—The conditions influencing the hydrogenation of thebaine in acid solution have been so thoroughly studied by Schöpf and Winterhalder[3a] that we shall confine our description of the reduction to the convenient large scale preparation of dihydrothebaine without regard to the by-products formed. To a solution of 75 g. of thebaine (Merck and Co., Rahway, N. J.) in 150 cc. of 3 *N* acetic acid was added 4 cc. of concd. hydrochloric acid, 4 cc. of 1% palladous chloride solution and 0.1 g. of gum arabic. The solution was hydrogenated on the Adams machine at an initial pressure of 46 lb. (3.1 atm.); the pressure dropped 32 lb. (2.1 atm.) in twelve to twenty-four hours, corresponding to absorption of about 1.7 moles of hydrogen. Reduction was found to proceed much faster and more smoothly if the process was made continuous, the next 75 g. batch being put immediately

into the pressure bottle without removal of the residue of used catalyst.

Most of the colloidal palladium was removed by filtration through Norit, and the solution was treated slowly with an excess of dilute sodium hydroxide in the presence of a few cc. of ether. Dihydrothebaine separated crystalline, yield 30 to 40 g. (40–54%). It was recrystallized from alcohol, filtering to remove traces of palladium; 25 g. (33%) of pure white dihydrothebaine, m. p. 161–163°, was obtained, and from the mother liquors, 3 g. more of the same purity. Three kilos of thebaine yielded 1099 g. (36.4%) of dihydrothebaine. The alkaline mother liquors of a 75-g. run gave 15–20 g. of dihydrothebainone on treatment with ammonium chloride. The accumulated oily residues will be examined for the presence of Schöpf's epi-dihydrothebainone or other isomers.

The Grignard Reaction.—Forty grams of dihydrothebaine in a Soxhlet extractor, on a three-necked flask equipped with a mercury-sealed stirrer, was extracted into 600 cc. (500% of the calculated amount) of molar methylmagnesium iodide in thirty-six hours. Heating and stirring was continued for seventy-two hours longer, during which time the white precipitate increased notably. Attempts to shorten the reaction time by using isopropyl ether were unsatisfactory. The amorphous magnesium complex was decomposed with and dissolved in 800 cc. of 3 *N* hydrochloric acid, and the solution was extracted with 1.5 liters of ether, which removed a little oily material. The aqueous layer, made alkaline with ammonia, was extracted with eight liters of ether, with occasional addition of a little sodium hydrosulfite to prevent oxidation (evidenced by red coloration). Although further extraction with ether or chloroform removed no appreciable amount of material at this point, the aqueous layer gave a strong test with Mayer's reagent, and addition of picric acid precipitated 26 g. (37%) of an amorphous picrate. From this picrate only 1.6 g. of methyldihydrothebainone could be recovered, and the nature of the remaining (resinous) substance could not be ascertained. The ether extracts yielded 18 to 23 g. (45–58%) of oily crystals, which were recrystallized twice from absolute alcohol; yield of pure methyldihydrothebainone, 6 to 7 g. (15–17.5%). The alcohol mother liquors were concentrated and treated with alcoholic hydrogen chloride, giving 6 to 7 g. of hydrochloride, from which 4 to 6 g. of less pure methyldihydrothebainone could be recovered.

The alcohol filtrate from precipitation of the hydrochloride was freed of alcohol, dissolved in water, and treated with excess of sodium hydroxide. The clear alkaline solution was extracted with ether, from which 3.5 to 4.5 g. (9–11%) of crude isomethyldihydrothebainone was obtained. This was purified from acetone; yield 2 to 2.5 g.

Methyldihydrothebainone.—The base is very soluble in organic solvents, soluble in sodium hydroxide and precipitated from the alkaline solution by carbon dioxide. It can be purified from acetone or alcohol. It crystallizes in short rods from absolute alcohol, in plates from 95% alcohol, and the two forms are interconvertible. It sublimes in an oil-pump vacuum at 130°. In alcohol, $[\alpha]^{25}\text{D}$ −20.5° (c = 1.026) was found; the m. p. is 192–193°.

Anal. Calcd. for $C_{19}H_{25}O_3N$: C, 72.33; H, 7.99; OCH_3, 9.83. Found: C, 72.11; H, 7.96; OCH_3, 10.13.

The hydrochloride was prepared in absolute alcohol and purified from this medium. It also crystallizes well from water, m. p. 283–285° (evac. tube) with decomp.; $[\alpha]^{25}\text{D}$ −6.8° (water, c = 1.025).

Anal. Calcd. for $C_{19}H_{26}O_3NCl$: Cl, 10.08. Found: Cl, 10.18.

The methiodide was prepared by warming the base in methyl iodide, and was purified from acetone; m. p. 212–216° (evac. tube); $[\alpha]^{26}\text{D}$ +3.9° (water, c = 1.030).

Anal. Calcd. for $C_{20}H_{28}O_3NI$: I, 27.88. Found: I, 27.63.

The oxime hydrochloride separates crystalline when an aqueous suspension of methyldihydrothebainone is warmed with the calculated amount of hydroxylamine hydrochloride. After two crystallizations from water the hydrochloride had the m. p. 244° (evac. tube, gas evolution) and $[\alpha]^{24}\text{D}$ +38.9° (water, c = 0.514). Addition of sodium carbonate to an aqueous solution of the oxime hydrochloride caused precipitation of the oxime, which crystallized from dilute alcohol in rosets of white needles; m. p. 244° (evac. tube, gas evolution), and $[\alpha]^{24}\text{D}$ +69.4° (alcohol, c = 0.504).

Anal. Calcd. for $C_{19}H_{26}O_3N_2$: N, 8.48. Found: N, 8.51.

Acetylmethyldihydrothebainone.—One gram of methyldihydrothebainone in 15 cc. of acetic anhydride with 1.0 g. of dry sodium acetate was heated under reflux for one hour. After removal of excess acetic anhydride under diminished pressure at 60°, the oily residue was treated with ice and dilute ammonia, and extracted with ether. The product was recrystallized twice from ethyl acetate and sublimed at 0.01 mm., yield 0.4 g., of m. p. 179–179.5°. Prolonged heating with acetic anhydride yielded no diacetyl derivative. The monoacetyl compound has $[\alpha]^{26}\text{D}$ +13.1° (alcohol, c = 0.992).

Anal. Calcd. for $C_{21}H_{27}O_4N$: C, 70.55; H, 7.62. Found: C, 70.87; H, 7.81.

Bromomethyldihydrocodeinone.—A solution of 20 g. of methyldihydrothebainone in 200 cc. of glacial acetic acid, mechanically stirred, was treated dropwise with 193 cc. (2 moles) of a solution of bromine in glacial acetic acid (32 g. of bromine in 300 cc. of solution). The addition took about three hours, the bromine color being destroyed rapidly and hydrogen bromide evolved. The clear yellow solution was concentrated to a viscous mass at 70° under a water-pump vacuum, the oil was dissolved in water, treated with excess of 10 *N* sodium hydroxide, and the precipitated base extracted into ether. The ether was washed with four 100-cc. portions of normal sodium hydroxide and yielded 18.2 g. (73%) of slightly oily crystals of bromomethyldihydrocodeinone. The base is very soluble in organic media, but could be purified from ethyl acetate; white crystals of m. p. 143.5–145°; $[\alpha]^{24}\text{D}$ −109.4° (alcohol, c = 1.024). It sublimed in a high vacuum with slight decomposition.

Anal. Calcd. for $C_{19}H_{22}O_3NBr$: Br, 20.33. Found: Br, 20.08.

Bromomethyldihydrothebainone.—The alkaline mother liquor and washings from the preparation of bromomethyldihydrocodeinone were treated with an excess of ammonium chloride and extracted with ether until the Mayer's test was negative. The product was 4.1 g. of yellow powder which was obtained white by crystallization from acetone or ethyl acetate; it sublimes with slight decomposition in a high vacuum. The m. p. is 207–208° (evac. tube) with dec., $[\alpha]^{24}\text{D}$ −33.2° (alcohol, $c = 0.995$). Its nature as bromomethyldihydrothebainone was shown not only by analysis, but by catalytic debromination to methyldihydrothebainone. It appears to result from incomplete bromination of methyldihydrothebainone, but the use of correspondingly larger quantities of bromine did not increase the yield of the desired bromomethyldihydrocodeinone.

Anal. Calcd. for $C_{19}H_{24}O_3NBr$: Br, 20.23. Found: Br, 20.14.

Methyldihydrocodeinone.—A solution of 18.2 g. of crude bromodihydrocodeinone in 200 cc. of 2 *N* acetic acid with 5 g. of potassium acetate, a little gum arabic and 10 cc. of 1% palladous chloride solution took up 1142 cc. (corr.) of hydrogen (calcd. for one mole, 1062 cc.). The solution was made alkaline with sodium hydroxide after removal of the catalyst, and extracted with 2 liters of ether. The ether, after thorough washing with dilute alkali, yielded 12.0 g. (83%) of white crystalline methyldihydrocodeinone of m. p. 138–140°. The alkaline extracts gave 1.5 g. of a wax-like unidentified solid. Methyldihydrocodeinone is very soluble in organic media, but can be purified from ethyl acetate, acetone, or ether; long needles of m. p. 144–144.5°, $[\alpha]^{23}\text{D}$ −146.9° (alcohol, $c = 0.994$). It sublimes at 130° in a high vacuum.

Anal. Calcd. for $C_{19}H_{23}O_3N$: C, 72.80; H, 7.40. Found: C, 72.71; H, 7.41.

The methiodide was prepared by warming the base with methyl iodide, and crystallizing from alcohol. It melts at 246–248° (evac. tube) and has $[\alpha]^{24}\text{D}$ −74.2° (water, $c = 1.024$).

Anal. Calcd. for $C_{20}H_{26}O_3NI$: I, 27.88. Found: I, 27.67.

The oxalate, sulfate and hydrochloride are also crystalline.

Ethyl Oxalate Condensation.—Before attempting to demonstrate the presence of an active methylene group in methyldihydrocodeinone through Claisen's ethyl oxalate condensation, it was necessary to show that this condensation reaction proceeds with morphine bases which are known to contain an active methylene group, and does not take place with a typical base lacking such a group.[15] Two grams of dihydrocodeinone and 1.5 g. of ethyl oxalate were dissolved in 10 cc. of absolute alcohol containing 0.31 g. of sodium. After two days the solution was fluorescent red; removal of the alcohol left an amorphous mass, 90% of which was soluble in water and could not be extracted into ether. It probably consisted of dihydrocodeinone-7-glyoxalic acid, or its internal salt. Treatment of 2.0 g. of dihydrocodeine with ethyl oxalate in exactly the same manner resulted in recovery of 1.9 g. of unchanged dihydrocodeine.

Two grams of methyldihydrocodeinone, treated with ethyl oxalate as described above, gave a red fluorescent solution in two days. Alcohol was removed under diminished pressure, and the residue extracted with 500 cc. of ether, and 200 cc. of benzene; total extracted oily material, 0.3 g. The undissolved product was taken up in a little water (readily soluble), and extracted with ether (0.2 g. of unreacted methyldihydrocodeinone), then with much benzene and chloroform, which removed a little red oil. The aqueous layer, made just acid, was treated with excess of picric acid; yield 0.7 g. of picrate. The picrate was suspended in dilute hydrochloric acid, and extracted with isoamyl alcohol until all picric acid was removed. Evaporation of the aqueous layer gave the crystalline hydrochloride of methyldihydrocodeinone glyoxalic acid, which could be purified by recrystallizing from 3 *N* hydrochloric acid.

Anal. Calcd. for $C_{21}H_{24}O_6NCl$: C, 59.76; H, 5.73; Cl, 8.41. Found: C, 59.58; H, 5.81; Cl, 8.75.

Methyldihydrocodeinone in sodium ethylate solution without the ethyl oxalate was recovered unchanged.

Methyldihydrocodeinone Enol Acetate (Methyl Acedicon).—A solution of 1 g. of methyldihydrocodeinone in 15 cc. of acetic anhydride with 1 g. of anhydrous sodium acetate was heated under reflux for six hours. Acetic anhydride was removed under diminished pressure, and the oily residue was treated with ice and ammonia and extracted with ether. The crystals obtained from the ether (0.5 g.) were purified from ethyl acetate and sublimed in a high vacuum at 150°. The pure product melted at 191.5–194.5° and had in alcohol $[\alpha]^{23}\text{D}$ −142.9° ($c = 0.980$).

Anal. Calcd. for $C_{21}H_{25}O_4N$: C, 70.95; H, 7.10. Found: C, 70.87; H, 7.17.

On boiling the enol acetate for three minutes with 3 *N* hydrochloric acid, methyldihydrocodeinone was obtained.

Methyldihydrocodeine.—A solution of 1.9 g. of methyldihydrocodeinone in 30 cc. of alcohol with 0.1 g. of platinum oxide absorbed 183 cc. of hydrogen slowly (0.1 g. catalyst added during the reduction); calculated for one mole, 180 cc. The oil resulting from concentration of the solution crystallized when rubbed with ethyl acetate, yield 1.1 g. Methyldihydrocodeine crystallizes as the monohydrate in 8-sided crystals from acetone, ethyl acetate, ether or 50% alcohol; m. p. 98–102°, $[\alpha]^{24}\text{D}$ −84.8° (alcohol, $c = 0.990$).

Anal. Calcd. for $C_{19}H_{25}O_3N + H_2O$: C, 68.42; H, 8.17; H_2O, 5.41. Found: C, 68.39; H, 8.05; H_2O, 5.64.

By sublimation in a high vacuum, a crystalline anhydrous form of m. p. 85–88° is obtained.

The hydrochloride, which may be used advantageously to purify methyldihydrocodeine, was prepared in and purified from absolute alcohol. It melts at 286–287° (evac. tube) and has $[\alpha]^{23}\text{D}$ −64.5° (water, $c = 0.992$).

Anal. Calcd. for $C_{19}H_{26}O_3NCl$: Cl, 10.08. Found: Cl, 10.28.

The methiodide, prepared in the usual way, was purified from alcohol. It melts at 269–271° (evac. tube) and has $[\alpha]^{24}\text{D}$ −47.9° (water, $c = 1.024$).

Anal. Calcd. for $C_{20}H_{28}O_3NI$: I, 27.76. Found: I, 27.76.

---

(15) An erroneous structural concept of pseudocodeinone was for many years based on the ability of this compound to condense with benzaldehyde [Knorr and Hörlein, *Ber.*, **40**, 3341 (1907)]; it has only recently been shown that a benzaldehyde condensation takes place with dihydrocodeine, and therefore is inacceptable as evidence for the $COCH_2$ group in the morphine series (ref. 4a).

Methyldihydromorphinone.—A solution of 2 g. of methyldihydrocodeinone in 10 cc. of 48% hydrobromic acid was boiled for twenty-five minutes (complete alkali solubility). The solution was diluted, made strongly alkaline, and extracted with ether (0.1 g. of unchanged material). Addition of ammonium chloride caused precipitation of the phenolic product, 1.7 g. of brown powder; yield after sublimation in a high vacuum at 180°, 1.4 g. of white crystals. Methyldihydromorphinone is only sparingly soluble in organic media. It crystallizes from alcohol in long needles of m. p. 243–245° (evac. tube, sintering at 235°); $[\alpha]^{24}\text{D}$ −140.7° (alcohol, c = 1.009).

Anal. Calcd. for $C_{18}H_{21}O_3N$: C, 72.18; H, 7.05. Found: C, 72.46; H, 7.10.

The hydrochloride was prepared in absolute alcohol and was recrystallized from alcohol. It melts with decomp. at 315–318° (evac. tube) and has $[\alpha]^{24}\text{D}$ −104.8° (water, c = 1.002).

Anal. Calcd. for $C_{18}H_{22}O_3NCl$: Cl, 10.57. Found: Cl, 10.67.

Methyldihydromorphine.—Preparation of methyldihydromorphine by demethylation of methyldihydrocodeine was unsuccessful because of extensive decomposition. A suspension of 1.4 g. of methyldihydromorphinone in 30 cc. of alcohol with 0.1 g. of platinum oxide absorbed one mole of hydrogen slowly (0.1 g. of catalyst added during the reduction). The product was isolated as in the case of methyldihydrocodeine, and was purified by crystallization from ethyl acetate and sublimation in a high vacuum at 180°; yield 1.2 g. The compound melts at 206–207° and has $[\alpha]^{24}\text{D}$ −92.9° (alcohol, c = 1.017).

Anal. Calcd. for $C_{18}H_{23}O_3N$: C, 71.71; H, 7.70. Found: C, 71.74; H, 7.72.

By methylation of methyldihydromorphine with diazomethane, the above-described methyldihydrocodeine was obtained.

Methyldihydromorphine hydrochloride was prepared in absolute alcohol and purified from alcohol. It melts at 316–317° with dec. (evac. tube) and has $[\alpha]^{23}\text{D}$ −65.7° (water, c = 1.004).

Anal. Calcd. for $C_{18}H_{24}O_3NCl$: Cl, 10.50. Found: Cl, 10.40.

The hydriodide was prepared in the usual way and purified from absolute alcohol. It melts at 289–291° (evac. tube) and has $[\alpha]^{23}\text{D}$ −50.5° (water, c = 0.991).

Anal. Calcd. for $C_{18}H_{24}O_3NI$: I, 29.58. Found: I, 29.42.

Isomethyldihydrothebainone.—This compound, isolated as described above, crystallizes from acetone in white needles of m. p. 168–168.5°. It is soluble in dilute sodium hydroxide, and is precipitated from the alkaline solution by carbon dioxide. It can be sublimed in an oil-pump vacuum at 140°. In alcohol, $[\alpha]^{24}\text{D}$ −57.0° (c = 1.023).

Anal. Calcd. for $C_{19}H_{25}O_3N$: C, 72.33; H, 7.99; OCH_3, 9.83. Found: C, 72.66; H, 8.03; OCH_3, 9.85.

The oxime was prepared by boiling an aqueous suspension of the base for several minutes with 2 moles of hydroxylamine hydrochloride. The oxime hydrochloride did not crystallize in this case, and the oxime was precipitated with sodium carbonate and recrystallized from alcohol, long silky needles of m. p. 191–192° (evac. tube, gas evolution at 210°); in alcohol, $[\alpha]^{24}\text{D}$ −82.4° (c = 0.498).

Anal. Calcd. for $C_{19}H_{26}O_3N_2$: N, 8.48. Found: N, 8.37.

Acetylisomethyldihydrothebainone.—The acetyl derivative was prepared exactly as described under methyldihydrothebainone, and was purified by crystallization from acetone and sublimation at 135° (0.01 mm.). It forms white crystals of m. p. 157–158°, $[\alpha]^{24}\text{D}$ −9.9° (alcohol, c = 0.452).

Anal. Calcd. for $C_{21}H_{27}O_4N$: C, 70.55; H, 7.62. Found: C, 70.43; H, 7.63.

Isomethyldihydrocodeinone.—A solution of 10.2 g. of isomethyldihydrothebainone in 100 cc. of glacial acetic acid was treated with 2 moles of bromine as described for methyldihydrothebainone. Acetic acid was removed at 60°, the oily product dissolved in water, treated with excess sodium hydroxide, and extracted with 3 liters of ether. The oil obtained from the ether was dissolved in hydrochloric acid, and precipitated as an amorphous powder with sodium hydroxide; yield of crude bromoisomethyldihydrocodeinone, 9.5 g. (75%). It could not be induced to crystallize. The crude product was hydrogenated as described under methyldihydrocodeinone (absorption, 1 mole) and yielded from ether 6.9 g. of crude isomethyldihydrocodeinone. It was dissolved in hydrochloric acid, and precipitated crystalline with excess of sodium hydroxide (yield 5.0 g.). Pure white crystals were obtained after two crystallizations from ethyl acetate. The compound sublimes in a high vacuum at 130°; the melting point is 144–145°. A depression of 25° is observed in the mixed melting point with methyldihydrocodeinone. In alcohol, isomethyldihydrocodeinone has $[\alpha]^{24}\text{D}$ −179.4° (c = 0.995).

Anal. Calcd. for $C_{19}H_{23}O_3N$: C, 72.80; H, 7.40. Found: C, 72.57; H, 7.32.

Condensation of isomethyldihydrocodeinone with ethyl oxalate under the conditions described above gave a water-insoluble oil from which no crystalline derivatives could be obtained. None of the ketone could be recovered unchanged from the reaction. While no analytical product could be isolated, it appears as though condensation with the ethyl oxalate must have taken place, for isomethyldihydrocodeinone was found to be largely unaffected by sodium ethylate in the absence of ethyl oxalate.

Isomethyldihydrocodeinone Enol Acetate.—Acetylation of 1 g. of isomethyldihydrocodeinone under the conditions described for methyldihydrocodeinone gave 1.1 g. of oily crystals which were purified from ethyl acetate and 50% alcohol, 0.6 g., m. p. 123–124°. It sublimes in a high vacuum at 110°; $[\alpha]^{24}\text{D}$ −250.3° (alcohol, c = 1.00).

Anal. Calcd. for $C_{21}H_{25}O_4N$: C, 70.95; H, 7.10. Found: C, 70.90; H, 7.30.

Hydrolysis of the enol acetate with 3 *N* hydrochloric acid gave isomethyldihydrocodeinone in poor yield.

Summary

1. Dihydrothebaine reacts with methylmagnesium iodide to yield two isomeric phenolic ketones, methyldihydrothebainone and isomethyldi-

hydrothebainone. In these the ether ring present in dihydrothebaine has been opened, the enol ether group at position-6 has been hydrolyzed, and a methyl group has been added to the nucleus.

2. Nuclear methylated analogs of dihydrocodeinone, namely, methyldihydrocodeinone and isomethyldihydrocodeinone, can be prepared by closure of the 4,5-ether bridge.

3. By demethylation and reduction, methyldihydrocodeinone can be converted to nuclear methylated analogs of dihydromorphinone, dihydromorphine and dihydrocodeine.

4. The nuclear position of the new methyl group is not certain, but the fact that the isomeric methyldihydrocodeinones yield isomeric enol acetates suggests that in one isomer the methyl group may be at C–5, and in the other at C–7.

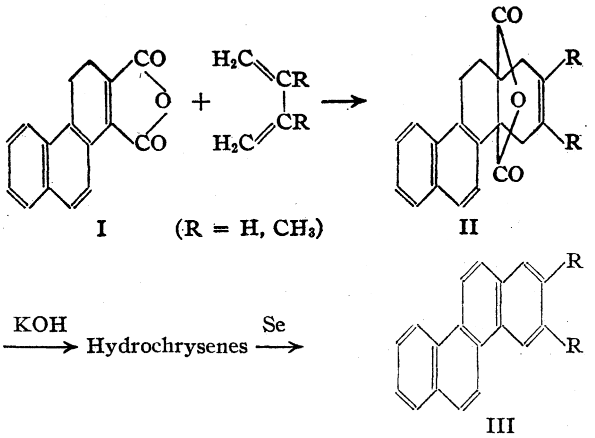
The Synthesis of Phenanthrene and Hydrophenanthrene Derivatives. III. Hydrocarbons of the Chrysene, Acechrysene, and 3,4-Benzphenanthrene Series; 1,2-Benzpyrene Derivatives

BY L. F. FIESER, M. FIESER AND E. B. HERSHBERG

On investigating further applications of the hydrocarbon synthesis of Fieser and Hershberg[1] it has been found that chrysene and 2,3-dimethylchrysene can be obtained conveniently from 3,4-dihydrophenanthrene-1,2-dicarboxylic anhydride[2] (I) by the reactions indicated. The yields were very satisfactory throughout and the two aromatic hydrocarbons were easily obtained in a highly pure condition. The synthetic chrysene agreed well in melting point (254.5–255°, corr.) with other synthetic preparations[3] and it was indistinguishable from the purified material from coal tar employed in Baxter and Hale's[4] atomic weight work. Incidentally the synthetic phenanthrene previously described[1] was found to be incompletely dehydrogenated, and after suitable treatment the material melted at 100.7–101°, corr., a temperature appreciably higher than most values reported for highly purified samples from coal tar.[5]



The distillates obtained after fusing the diene addition products of the type II with alkali solidified easily but, as in the cases previously studied, they appeared to consist of mixtures of hydrocarbons in different stages of hydrogenation. The material from the butadiene product (R = H) seems to undergo disproportionation in solution, for after repeated crystallization some chrysene was obtained. The crude distillate gave with picric acid a stable compound having the composition of a dihydrochrysene picrate, and the regenerated hydrocarbon exhibited the same mutation in solution as the crude material.

In further extensions of the synthetic method little difficulty was experienced in obtaining the unsaturated anhydrides[2] required for the Diels–Alder reaction or in effecting the diene addition with these substances. 3,4-Dihydronaphthalene-1,2-dicarboxylic anhydride adds cyclopentadiene and cyclohexadiene about as readily as it does the open-chain dienes. The alkali fusion and the final step of dehydrogenation, however, are not always satisfactory. Although compounds of the type IV were obtained in good yield (80%) from 1,2-dihydrophenanthrene-3,4-dicarboxylic anhydride[2] and butadiene or 2,3-dimethylbutadiene, difficulties were encountered in attempting to con-

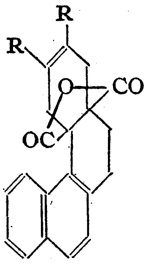
(2) Fieser and Hershberg, *ibid.*, **57**, 1851 (1935).

(3) Ruzicka and Hösli [*Helv. Chim. Acta*, **17**, 470 (1934)] record the value 255°, corr.

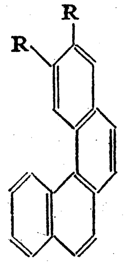
(4) Baxter and Hale, THIS JOURNAL, **58**, 510 (1936).

(5) Unfortunately a typographical error was made in reporting Dr. R. D. Haworth's melting point for 2,3-dimethylphenanthrene styphnate; this should read 147–148°.

vert the substances into 3,4-benzphenanthrenes, V. 6,7-Dimethyl-3,4-benzphenanthrene was obtained in this way in a satisfactory condition of purity, but both the potassium hydroxide fusion and the dehydrogenation proceeded poorly and the yield was quite low. Attempts to prepare the parent hydrocarbon by the same method were unsuccessful. An oil resulted in small amount from the fusion of IV (R = H) with alkali, but the material recovered after this had been heated with selenium or sulfur showed no difference in the boiling range or composition from the starting material. Hydrogenation of IV prior to the fusion did not improve the results and only resulted in an increase in the temperature at which reaction occurred.

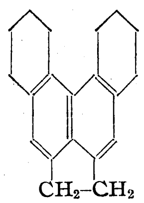


IV (R = H, CH$_3$)



V (R = CH$_3$)

A similar difficulty was experienced in attempting to aromatize another hydrogenated 3,4-benzphenanthrene derivative (VI) investigated in conjunction with Mr. E. L. Martin. A quantity of the octahydro compound VI was prepared from a ketone previously synthesized[6] in this Laboratory from tetrahydroacephenanthrene, but attempted dehydrogenations with selenium, sulfur or platinum black resulted only in the complete destruction of the material.



VI

3,4-Benzphenanthrene derivatives are of interest because of the discovery that the parent hydrocarbon[7] has cancer-producing properties.[8] The aromatic compound corresponding to VI would have an additional structural feature of interest in the dimethylene bridge extending across peri-positions. While 1,2-benzanthracene has little if any carcinogenic properties,[8] the addition of such a bridge in the 5,10-position leads to the potently tumor-inducing hydrocarbon cholanthrene (VII).[9,10] The isomeric 8,9-dimethylene derivative VIII (8,9-ace-1,2-benzanthracene) is less potent[10] than cholanthrene, but nevertheless active. It is of interest to learn if similar dimethylene derivatives of other hydrocarbons exhibit an enhanced activity, and as one step in this direction the synthesis of 6,7-acechrysenes of the type X was investigated. The required anhydrides (IX) were obtained without difficulty by condensing the ethyl ester of γ-(3-acenaphthyl)-butyric acid[6] with oxalic ester, cyclizing the product with 80% sulfuric acid to the unsaturated anhydride (a mixture of acetic and sulfuric acids gave the di-ester), and adding the appropriate diene. The remaining two steps presented the same difficulties as in the 3,4-benzphenanthrene series and again it was only in the case of the dimethyl derivative that the synthesis could be brought to a successful conclusion. 2,3-Dimethyl-6,7-acechrysene (X) was obtained in quantity sufficient for biological tests, if in poor yield, but the unsubstituted hydrocarbon could not be prepared. From the potassium hydroxide fusion of the anhydride IX (R = H) there was isolated an apparently pure hydrocarbon having the composition of a dihydro derivative, $C_{20}H_{16}$, but this was converted by sulfur or selenium treatment only into another substance of the same empirical formula.

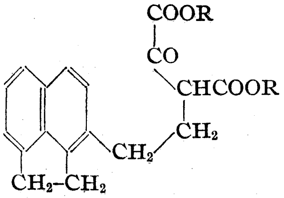
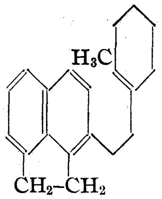
The cyclization of the condensation product XI from the methyl ester of γ-(1-acenaphthyl)-butyric acid[6] and oxalic ester was much less satisfactory than in other cases investigated. In view of the low yield (27.5%) and the inaccessibility of the starting material the synthetic uses of the resulting unsaturated anhydride were not investigated. The unfavorable behavior of the 1-substituted acenaphthene derivative in contrast to the 3-isomer recalls the observation of Cook, Haslewood and Robinson[11] that difficulty was experienced in effecting a normal cyclization of the similarly constituted hydrocarbon XII. The fact that both reactions involve ring closure at a β-position of the naphthalene nucleus may be partly responsible for the poor results.



XI



XII

It was found that 1,2-benzpyrene derivatives can be obtained readily by application of the Bougault reaction, for no difficulty was experienced in preparing and cyclizing the diethyl ester of α-oxalyl-γ-(1-pyrenyl)-butyric acid, XIII. The resulting unsaturated anhydride was dehydrogenated with sulfur to the aromatic anhydride XIV, which has been examined by Dr. M. J. Shear for possible carcinogenic activity. The anhydride itself produced no tumors after seven months and the disodium and dipotassium salts of the corresponding acid proved to be toxic to mice and produced hemorrhages.

XIV

Experimental Part[12]

Preparation of the Anhydrides

3,4-Dihydro-8,9-acephenanthrene-1,2-dicarboxylic Anhydride.—Ethyl γ-(3-acenaphthyl)-butyrate, b. p. 188–191° at 0.5 mm., was condensed with ethyl oxalate in the presence of potassium ethylate following the procedure outlined for the similar reaction of ethyl γ-phenylbutyrate.[2] The greater part of the reaction product separated in the form of the potassium salt, but a further small quantity was recovered by extraction of the acidified mother liquor. For cyclization the combined crude material was heated with 80% sulfuric acid for one-half hour at 70–80°, and the unsaturated anhydride was obtained in a good condition in 60% yield. The substance dissolves slowly in benzene and separates, after the solution has been concentrated, in the form of lustrous, deep orange needles. The melting point is dependent upon the material from which the capillary tube is constructed and upon the temperature at which the sample is introduced to the heating bath. When heated from 25° in a soft glass tube the melting occurs over the range 220–240°; in Pyrex the sample softens at 220° and melts at 230–232°. Introduced to a bath preheated to 222°, the sample melts completely at this temperature. In quartz the melting point is 229–232° with previous softening.

Anal. Calcd. for $C_{18}H_{12}O_3$: C, 78.24; H, 4.38. Found: C, 78.24; H, 4.63.

α-Oxalyl-γ-(3-acenaphthyl)-butyric acid diethyl ester was isolated as a solid in one experiment when the oily condensation product was allowed to stand until crystallization occurred. The substance formed fine, colorless needles, m. p. 83–85°, from ether–petroleum ether.

Anal. Calcd. for $C_{22}H_{24}O_5$: C, 71.70; H, 6.57. Found: C, 71.59; H, 6.42.

Diethyl 3,4-dihydro-8,9-acephenanthrene-1,2-dicarboxylate was obtained, along with some of the above anhydride, in an attempt to improve the yield in the Bougault ring closure by employing a mixture of equal parts of glacial acetic acid and 82% sulfuric acid (70–80°) in place of 80% sulfuric acid. The diester is much more soluble than the anhydride and it was obtained as yellow plates, m. p. 140.2–140.6°, by crystallization from benzene–ligroin.

Anal. Calcd. for $C_{22}H_{22}O_4$: C, 75.40; H, 6.33. Found: C, 75.49; H, 6.45.

For conversion to the anhydride the diester was hydrolyzed with alcoholic alkali and the free acid (2 g.) refluxed for a short time with a mixture of concentrated hydrochloric acid (20 cc.) and glacial acetic acid (125 cc.). The total yield of anhydride by this method was 50%.

3,4-Dihydro-5,10-aceanthrene-1,2-dicarboxylic anhydride was obtained in 27.5% yield by the standard procedure from methyl γ-(1-acenaphthyl)-butyrate, b. p. 223–226° at 8 mm. The Bougault reaction proceeded as above and the loss appeared to occur in the cyclization. The anhydride formed fine, orange-red needles from benzene, m. p. 276–277°.

Anal. Calcd. for $C_{18}H_{12}O_3$: C, 78.24; H, 4.38. Found: C, 77.75; H, 4.18.

1′,2′-Dihydro-1,2-benzpyrene-3′,4′-dicarboxylic Anhydride.—The required starting material was obtained by suspending γ-(1-pyrenyl)-butyric acid,[13] prepared in the manner previously reported[14] and with the same yields, in ethyl alcohol and passing in hydrogen chloride nearly to

saturation. The acid soon gave way to the oily ester, and after distilling off most of the solvent this was dried in ether first with calcium chloride solution and then with sodium sulfate and distilled, b. p. 245–247°, uncorr., at 1 mm.; yield 91%. The distillate solidified and was obtained from ligroin as straw-colored prisms, m. p. 48.5–49°. The methyl ester was obtained as cottony clusters of colorless needles from hexane, m. p. 51.5–52°. Both preparations gave, on hydrolysis with alcoholic potassium hydroxide, followed by crystallization of the product from glacial acetic acid, completely colorless plates of γ-(1-pyrenyl)-butyric acid, m. p. 190–190.5°, whereas the acid as originally prepared and crystallized from xylene was invariably obtained as slightly brown or pink crystals.

The ester condensation of ethyl γ-(1-pyrenyl)-butyrate (10 g.) was carried out in the usual way,[2] the potassium salt of the product separating completely from the carmine-colored solution as a dark brown oil which slowly solidified. After decanting the mother liquor the salt was washed with dry ether and decomposed with an ice-cold mixture of 5 cc. of concentrated sulfuric acid and 100 cc. of water, when a solid oxalyl ester was obtained. This was taken up in benzene and the solution was washed with water and dried, and on adding ligroin a part of the oxalyl ester crystallized and a sample was purified as described below. The remainder of the material was recovered by evaporation under vacuum and treated with 80% sulfuric acid at 80–90° for one hour to effect cyclization. The orange anhydride soon separated and it was filtered off from the still warm solution and washed with 80% acid and then with alcohol; yield 7.5 g. The substance is very sparingly soluble in glacial acetic acid, acetic anhydride or toluene and moderately soluble in pyridine. After two crystallizations from tetrachloroethane (60 cc. per g.) it formed small rosets of feathery orange needles, m. p. 338–340°, dec. Further crystallizations from pyridine gave short, dark orange needles of the same melting point.

Anal. Calcd. for $C_{22}H_{12}O_3$: C, 81.46; H, 3.74. Found: C, 81.79; H, 4.13.

α-Oxalyl-γ-(1-pyrenyl)-butyric Acid Diethyl Ester (XIII).—The crude material on recrystallization from benzene–ligroin formed cream-colored needles, m. p. 106–107°.

Anal. Calcd. for $C_{26}H_{24}O_5$: C, 74.96; H, 5.81. Found: C, 74.62; H, 5.99.

1,2-Benzpyrene-3′,4′-dicarboxylic Anhydride (XIV).—For the dehydrogenation 2.75 g. of the dihydro compound was dissolved in 20 cc. of quinoline, 0.287 g. of sulfur was added and the solution was refluxed for two hours, when the evolution of hydrogen sulfide had practically ceased. On allowing the solution to cool the product separated as permanganate-colored prisms, and after sublimation in vacuum 2.4 g. of bright orange-red material, m. p. 378–380°, was obtained. The substance is practically insoluble in glacial acetic acid or dioxane. It is very soluble in quinoline and moderately so in pyridine, the latter solvent giving orange-brown prisms. After recrystallization from quinoline and from pyridine, followed by vacuum sublimation, the compound melted at 380–382°.

Anal. Calcd. for $C_{22}H_{10}O_3$: C, 81.96; H, 3.14. Found: C, 82.11; H, 3.66.

For conversion to the metal salts the anhydride was dissolved in pyridine, strong potassium or sodium hydroxide solution was added and most of the pyridine was removed by distillation. Methyl alcohol was added and the yellow salt was collected and washed. Both salts are readily soluble in water and the aqueous solutions show a strong blue fluorescence. In high dilution the potassium salt is hydrolyzed giving a colloidal solution of the acid.

The Diels–Alder Reaction

The previously reported preparation[1] of the addition products of the types II and IV by heating the components in dioxane solution was improved by raising the temperature. A shorter time was required in this case and usually heating for twenty-four hours at 160–180° was sufficient. The dioxane solution was then transferred to an all-glass distilling apparatus and after removing the solvent the residual oil was distilled in high-vacuum (3 microns). The reaction product was in this way obtained as a clean solid distillate free from polymerized diene, which otherwise hinders the process of crystallization. In the course of the subsequent crystallizations the addition product sometimes was found to be contaminated with a small amount of the completely aromatic anhydride evidently arising from a partial dehydrogenation of the starting material. This by-product can be removed easily by virtue of its sparing solubility in benzene, which easily dissolves the addition products. After filtration, partial evaporation, and dilution with ligroin the addition products separated as colorless crystals. By this modified procedure 5,6-benz-1,4,9,10,11,12-hexahydrophenanthrene-11,12-dicarboxylic anhydride[1] and its 2,3-dimethyl derivative[1] were obtained in 87 and 81% yield, respectively.

1,4,11,12,13,14 - Hexahydrochrysene - 13,14 - dicarboxylic anhydride, II (R = H) was obtained as colorless microcrystals, m. p. 143.5–144° from benzene–ligroin, in 67% yield.

Anal. Calcd. for $C_{20}H_{16}O_3$: C, 78.92; H, 5.30. Found: C, 79.08; H, 5.62.

The yield of the 2,3-dimethyl derivative[1] was 94%.

1,4,11,12,13,14 - Hexahydro - 6,7 - acechrysene - 13,14-dicarboxylic anhydride, IX (R = H) formed small colorless needles, m. p. 189–189.3°, from benzene–ligroin; yield 81%.

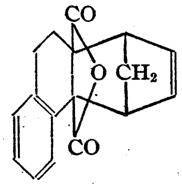
The 2,3-dimethyl derivative, IX (R = CH_3) forms prisms, m. p. 187.5–188°; yield 67–73%.

Anal. Calcd. for $C_{24}H_{22}O_3$: C, 80.41; H, 6.19. Found: C, 80.41; H, 6.28.

1,4 - *Endo*methylene - 1,4,9,10,11,12 - hexahydrophenanthrene-11,12-dicarboxylic anhydride was prepared



by heating 5 g. of 1,2-dihydronaphthalene-3,4-dicarboxylic anhydride with 10 g. of cyclopentadiene for twenty-four hours at 100° in a sealed tube. The excess diene and its dimer were removed by distillation in vacuum and the solid residue was crystallized from benzene–ligroin. The pure addition product collected amounted to 3.2 g. and the material from the mother liquor was contaminated with unchanged starting compound. The *endo*methylene compound melts at 158–159° with vigorous evolution of gas; this was found to be due to decomposition into the components by reversal of the Diels–Alder reaction.

Anal. Calcd. for $C_{17}H_{14}O_3$: C, 76.66; H, 5.30. Found: C, 76.55; H, 5.30.

The 2,3-dihydro derivative of the above compound, obtained by hydrogenation in glacial acetic acid solution with Adams catalyst, formed colorless prisms from benzene–ligroin, m. p. 156–156.5° (no decomposition).

Anal. Calcd. for $C_{17}H_{16}O_3$: C, 76.09; H, 6.02. Found: C, 76.32; H, 6.20.

1,4 - *Endo*dimethylene - 1,4,9,10,11,12 - hexahydrophenanthrene-11,12-dicarboxylic anhydride was obtained in 70% yield by heating 2 g. of the unsaturated anhydride with 4 g. of cyclohexadiene for eight days at 100°. The excess liquid hydrocarbon was eliminated by distillation in vacuum and the residual solid crystallized from benzene–ligroin; colorless prisms, m. p. 137–138°.

5,6 - Benz - 1,2,3,4,9,10,11, 12 - octahydrophenanthrene-11,12-dicarboxylic anhydride, obtained by the hydrogenation of the previously described addition product in glacial acetic acid, formed colorless needles, m. p. 182.8–183.2°.

Anal. Calcd. for $C_{20}H_{18}O_3$: C, 78.40; H, 5.92. Found: C, 78.26; H, 5.90.

Conversion to Hydrocarbons

Chrysene.—For the elimination of the anhydride group of the butadiene addition product II (R = H) 5 g. of the material was cautiously heated with 8 g. of potassium hydroxide and 8 cc. of water at about 150° in a distilling flask with sealed-on receiver until conversion to the solid potassium salt was complete and then until the water had been largely evaporated. The temperature of the bath was then increased and the flask was connected to a water pump through a trap to catch sublimed material. Decomposition began at about 320–330° and a light yellow oil distilled and soon solidified. The temperature was gradually increased to 380–400°, when no more oil distilled and the residue in the flask carbonized. The yield of product melting over the range 198–204° was 2.6 g. (69%) and similar results were obtained in several other experiments. The crude solid is very readily soluble in benzene and sparingly soluble in alcohol. After six crystallizations from alcohol and one from glacial acetic acid there was obtained 0.2 g. of a constant melting fraction identified as chrysene. No other fractions of constant melting point were observed, and the mother liquor on further working yielded additional small amounts of chrysene apparently arising in the process of crystallization. The picrate of the chief primary constituent was more stable. An alcoholic solution of 1.9 g. of the crude distillate from the alkali fusion on treatment with 2.5 g. of picric acid deposited 2.7 g. of orange needles melting at 142–144°, and the melting point was not altered by further recrystallization. The substance forms lustrous orange needles which become opaque on drying even at room temperature, and it has the composition of a **dihydrochrysene picrate.**

Anal. Calcd. for $C_{18}H_{14} \cdot C_6H_3O_7N_3$: C, 62.73; H, 3.73; N, 9.15. Found: C, 62.42; H, 3.45; N, 9.06.

The hydrocarbon recovered from the purified picrate melted initially at 223–226°, but on repeated crystallization from glacial acetic acid the melting point steadily rose and eventually pure chrysene was again obtained. Chrysene itself was not observed to form a picrate in alcoholic solution, although in benzene clusters of small orange-red needles, m. p. 174–175°, were obtained.

For the production of chrysene 11.3 g. of the crude hydrocarbon from the alkali fusion was heated with 6 g. of selenium at 300–310° for fourteen hours and then, since the material isolated turned slightly purple and evidently was not completely dehydrogenated, 5 g. of selenium was added and the heating continued for forty-eight hours longer. The reaction product was extracted with benzene and the solution refluxed over fresh portions of sodium wire to remove traces of selenium. The process was repeated with more effectiveness when the benzene was replaced by toluene so that the sodium melted. The clarified solution on cooling deposited 7.6 g. of colorless crystals and 1 g. more was obtained from the mother liquor. The first crop was distilled at 2 mm. pressure and reserved for use in the atomic weight work of Professor G. P. Baxter. A sample crystallized from toluene formed colorless plates with a blue fluorescence, m. p. 254.5–255°.

2,3-Dimethylchrysene, III (R = CH_3).—The fusion of the addition product (5.5 g.) was conducted as above and the crude distillate (3.2 g.) was heated with a large excess of selenium for forty hours. The crystallized product (1.8 g.) was purified with sodium, distilled, and further crystallized from benzene, giving colorless plates, m. p. 215–215.3°.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.70; H, 6.30. Found: C, 93.47; H, 6.33.

Oxidation of the hydrocarbon with chromic anhydride in acetic acid solution gave after crystallization a bright red product which appeared from microscopic examination and from the melting range (222–232°) to be a mixture of two ortho quinones.

6,7-Dimethyl-3,4-benzphenanthrene, V (R = CH_3).—On fusing 5 g. of the addition product IV with potassium hydroxide a reaction occurred at a bath temperature of 330–340° but in a few minutes the residue turned black and the distillation of light yellow oil promptly stopped. In several experiments the oily product amounted to 0.5–0.8 g. The combined material from three runs was dehydrogenated as above and since the purified oil obtained did not solidify it was treated with picric acid in alcoholic solution. After removing a small amount of high-melting material which first separated there was obtained 2 g. of fine orange needles of the **picrate.** After further crystallizations this melted at 143–144°.

Anal. Calcd. for $C_{20}H_{16} \cdot C_6H_3O_7N_3$: N, 8.66. Found: N, 8.45.

The hydrocarbon recovered by decomposition of the purified picrate with ammonia solution retained a slight yellow color after crystallization from benzene–petroleum ether. On passing a benzene–ligroin solution through a tower of activated alumina the first fraction was colorless and on partial evaporation deposited colorless plates having a strong blue fluorescence, m. p. 94.5–95°.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.30. Found: C, 93.89; H, 5.94.

2,3-Dimethyl-6,7-acechrysene, X.—The fusion of 4 g. of the anhydride IX (R = CH_3) with potassium hydroxide at 360–380° gave 0.65 g. of solid distillate from which after several crystallizations from glacial acetic acid there was obtained 0.25 g. of colorless plates, m. p. 193.5–194.5°. This appears to be a **dihydro derivative.**

Anal. Calcd. for $C_{22}H_{20}$: C, 92.91; H, 7.09. Found: C, 92.88; H, 7.42.

The crude distillate served as well for the dehydrogenation as the purified dihydro derivative. From 0.5 g. of the distillate there was obtained after purification as above and final crystallization from benzene–ligroin 0.07 g. of colorless needles of the aromatic hydrocarbon, m. p. 222.6–223.1°.

Anal. Calcd. for $C_{22}H_{18}$: C, 93.57; H, 6.43. Found: C, 93.26; H, 6.52.

Attempts to Prepare 6,7-Acechrysene.—Two grams of the starting material (IX, R = H) gave 0.2 g. of solid distillate about half of which was obtained on crystallization from benzene–ligroin as fine, colorless needles, m. p. 153.2–153.5°. The analysis corresponds most closely to a **dihydroacechrysene.**

Anal. Calcd. for $C_{20}H_{16}$: C, 93.70; H, 6.30. Found: C, 93.32; H, 6.52.

The crude hydrocarbon distillate (0.5 g.) on treatment with selenium at 300–310° for twenty-six hours gave after purification a substance separating from benzene–ligroin as faintly yellow needles, m. p. 181–182°, and having nearly the same composition as the starting material. The same hydrocarbon was obtained in smaller amount when sulfur was used in place of selenium.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.70; H, 6.30. Found: C, 93.99; H, 6.18.

5,6 - Tetramethylene - 1,2,3,4 - tetrahydro - 8,9-acephenanthrene, VI,[15] was prepared in 77% yield (pure) by the high pressure (3000 lb.) hydrogenation of 5,6-tetramethylene-1-keto-1,2,3,4-tetrahydro-8,9-acephenanthrene[6] with Adkins catalyst No. 37 KAF in alcohol at 200°. The same method gave 72–83% yields in the preparation of one of the intermediates, 1,2,3,4-tetrahydro-8,9-acephenanthrene. The hydrocarbon VI was crystallized from alcohol in which it is sparingly soluble, forming long, stout, colorless needles, m. p. 148.6–149.0°.

Anal. Calcd. for $C_{20}H_{22}$: C, 91.53; H, 8.46. Found: C, 91.48; H, 8.31.

A number of attempts were made to effect the dehydrogenation of the hydrocarbon with selenium, sulfur, and platinum black under a variety of conditions, but the only action noticed was that of complete decomposition.

Summary

γ-Arylbutyric esters derived from naphthalene, acenaphthene, and pyrene can be converted by condensation with oxalic ester and cyclization into unsaturated dicarboxylic anhydrides of the phenanthrene, acephenanthrene, aceanthrene and 1,2-benzpyrene series. The yields usually are good and the products can be aromatized without difficulty, or they can be converted in excellent yield into diene addition products. The conversion of the diene addition compounds into aromatic hydrocarbons is the least satisfactory part of the synthesis, for the results are variable. While chrysene and 2,3-dimethylchrysene were obtained easily by this method, attempts to prepare hydrocarbons of the 3,4-benzphenanthrene and 6,7-acechrysene series were only in part successful and then the yields were poor.

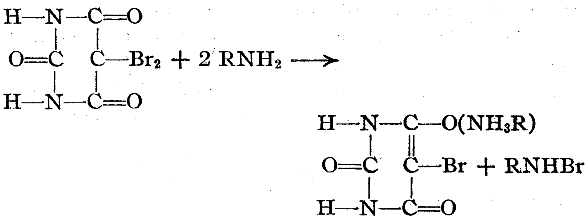
Phenyl Nitrogen Substitution and Reactivity in the Barbituric Acid Series[1]

BY DOROTHY NIGHTINGALE AND LLOYD C. MORRIS

Dibromobarbituric acid reacts rapidly with primary and secondary amines to form the corresponding amine salt of monobromobarbituric acid.[2] As interpreted by Cope, the reaction may proceed as follows



It reacts with aniline or dimethylaniline to form monobromobarbituric acid and *p*-bromoaniline or *p*-bromodimethylaniline, respectively.[3] With thiourea it forms thiopseudouric acid.[4]

When the halogen derivatives of phenyl nitrogen substituted barbituric acids were used, it was found that the substitution of phenyl groups for hydrogen had a definite effect in the above types of reactions. On the other hand, these nitrogen substituted dibromobarbituric acids both reacted equally well with substituted hydrazines to form hydrazones of the corresponding alloxan, and Macbeth, Nunan and Traill[5] report no difference in the rates of their rapid reaction with hydrazine hydrate.

In the condensation reactions of the methylene group of the barbituric acids with aromatic aldehydes such as cinnamaldehyde and with diphenylformamidine, nitrogen substitution seems to have little if any effect on the rate of the reaction.

Experimental

The 1-phenyl and 1,3-diphenylbarbituric acids and their halogen derivatives were prepared according to the directions of Whiteley[6] and of Macbeth, Nunan and Traill,[5] with some necessary refinements in their procedures. The phosphorus oxychloride and malonyl chloride methods were both used. Even in the malonyl chloride method, by-products soluble in sodium carbonate solution are formed, which are not always completely removed from the barbituric acid by many recrystallizations. This is especially true with 1,3-diphenetylbarbituric acid.

In the preparation of the monohalogen derivatives of these barbituric acids, the acid is suspended in dry chloroform, and the 10% solution of bromine in chloroform must be added very slowly and with stirring. The same precautions must be observed in the preparation of the dihalogen barbituric acids, using glacial acetic acid as the solvent. In either preparation, a gummy product results if the bromine is added too rapidly.

Halogen Barbituric Acids and Aliphatic Amines.—Dibromobarbituric acid reacts rapidly in warm alcohol solution with butylamine to give a 73% yield of the relatively stable butylamine 5-bromobarbiturate. When 1-phenyl-5,5-dibromobarbituric acid was used in warm or cold absolute alcohol solution, a tar was obtained which would not yield crystals. Benzene was found to be a satisfactory solvent for the reaction. The 1-phenyl-5,5-dibromobarbituric acid (3.6 g.) was dissolved in dry benzene and the solution cooled to +10°. The butylamine (1.5 g.) in a little dry benzene was slowly added with stirring. Some tar formed and adhered to the beaker, but when the benzene was poured off and allowed to stand in the cold for several hours, about 1.2 g. of a mixture of butylamine hydrobromide and the amine barbiturate separated. Attempts to purify this mixture resulted in a tar. Decomposition with the formation of a tar took place when the product was heated above 100° or if it was allowed to come in contact with moist air. Kjeldahl analysis indicated a nitrogen content of 10.97%. Butylamine hydrobromide and butylamine 1-phenyl-5-bromobarbiturate contain 9.11 and 11.80% nitrogen, respectively.

The 5-bromo-1-phenylbarbituric acid and butylamine in benzene under the above conditions gave some tar and a 10 to 15% yield of pure butylamine 5-bromo-1-phenylbarbiturate. The salt is unstable and decomposes to form a red tar at elevated temperatures or if exposed to moist air for any length of time. It melts with decomposition around 110–120°. Other aliphatic amines gave similar results.

Anal. Butylamine 1-phenyl-5-bromobarbiturate. Calcd. for $C_{14}H_{18}N_3O_3Br$: total N (Kjeldahl), 11.80; amine N, 3.93. Found: N, 11.73; N, 3.91. The amine nitrogen was determined by the procedure used by Cope.

The butylamine 5-bromo-1-phenylbarbiturate was treated with cold sodium carbonate solution in which it readily dissolved, liberating butylamine. The solution was filtered, acidified with hydrochloric acid, and the precipitate which formed collected on a Büchner funnel. This white solid melted at 213° and did not depress the melting point of a sample of 5-bromo-1-phenylbarbituric acid.

Both the mono and dibromo derivatives of 1,3-diphenylbarbituric acid and butylamine under the above conditions gave some tar on evaporation of the solvent but no crystals

of amine barbiturate, even when heated in a sealed tube with or without a solvent. Solvents such as ethyl alcohol and ether as well as benzene were used but with no better results.

When dibenzylamine reacts with dibromobarbituric acid, the crystals which separate rapidly from the alcohol solution are a mixture of the moderately soluble dibenzylamine hydrobromide and dibenzylamine 5-bromobarbiturate. When 1,3-diphenyl-5,5-dibromobarbituric acid was used, the solution turned a violet-red but no crystals separated. Concentration of the solution gave a small amount of colored crystals which on recrystallization were white and melted at 265°. The melting point of these crystals and dibenzylamine hydrobromide was also 265°. Some amine salt of monobromodiphenylbarbituric acid may be formed but is probably too unstable to isolate.

A comparison of rates of reaction of dibromobarbituric acid and 1-phenyl-5,5-dibromobarbituric acid with butylamine is difficult since they require different experimental conditions. Dibromobarbituric acid is only slightly soluble in hot benzene.

Halogen Barbituric Acids and Aniline.—Aniline reacts immediately in warm alcohol solution with dibromobarbituric acid to give an almost quantitative yield of *p*-bromoaniline and bromobarbituric acid. The 1-phenyl-5,5-dibromobarbituric acid (3.6 g.) was dissolved in hot alcohol and aniline (1 g.) added. There was no immediate reaction noticeable. After standing for several hours, the precipitate of 1-phenyl-5-bromobarbituric acid (m. p. 213°) which gradually separated was collected on a filter. The *p*-bromoaniline (m. p. 66°) was isolated from the filtrate. Yields were nearly quantitative.

The 1,3-diphenyl-5,5-dibromobarbituric acid and aniline formed some tar, but none of the monohalogen acid separated from the solution, even on long standing and evaporation of the solvent.

Halogen Barbituric Acids and Thioureas.—The mono and dibromo derivatives of barbituric acid and of 1-phenylbarbituric acid react rapidly with the thioureas to form the 8-thio-9-R- and 1-phenyl-8-thio-9-R-pseudouric acids, respectively. The halogen barbituric acid (1 mole) in alcohol solution is added to an alcohol solution of the thiourea (1 mole). Heat is evolved and the thiopseudouric acid precipitates rapidly. Yields are nearly quantitative. The thiopseudouric acids are soluble in hot water but insoluble in the common organic solvents, and decompose at their melting points.

8-THIO-9-R-PSEUDOURIC ACIDS

Thiourea used	Formula	°C., dec.	% nitrogen (Kjeldahl) Calcd.	Found
Phenyl	$C_{11}H_{10}N_4O_3S$	240	20.14	19.90
Allyl	$C_8H_{10}N_4O_3S$	270	23.14	23.16
o-Tolyl	$C_{12}H_{12}N_4O_3S$	275	19.18	19.04

1-PHENYL-8-THIO-9-R-PSEUDOURIC ACIDS

Thiourea used	Formula	°C., dec.	% nitrogen (Kjeldahl) Calcd.	Found
Thiourea	$C_{11}H_{10}N_4O_3S$	>300	20.14	20.16
Phenyl	$C_{17}H_{14}N_4O_3S$	280	15.82	15.94
Allyl	$C_{14}H_{14}N_4O_3S$	>300	17.61	17.62

When alcohol solutions of either 5-bromo- or 5,5-dibromo-1,3-diphenylbarbituric acid and the thioureas were mixed, no heat was evolved as with the other halogen barbituric acids, and no crystals separated even after long heating. Evaporation of the solvent gave some crude crystals which, from their nitrogen content and melting points, were apparently mixtures of some of the unchanged halogen barbituric acid and the thiourea. Recrystallization of this material gave the pure thioureas.

α-Naphthylhydrazine and the Dihalogen Barbituric Acids.—An alcohol solution of α-naphthylhydrazine hydrochloride (1 mole) was added to a hot alcohol solution of the nitrogen-substituted dibromobarbituric acid (1 mole). The brick-red hydrazone which separated rapidly was collected on a filter and washed with hot alcohol. These hydrazones are slightly soluble in hot alcohol and insoluble in the other common organic solvents.

	Formula	M. p., °C.	% nitrogen (Dumas) Calcd.	Found
1 - Phenylalloxan α - naphthylhydrazone	$C_{20}H_{14}N_4O_3$	292	15.64	15.49
1,3 - Diphenylalloxan α-naphthylhydrazone	$C_{26}H_{18}N_4O_3$	303	12.90	12.96

There was no observable difference in the rates of these reactions.

Methylene Condensations.—When either cinnamaldehyde or diphenylformamidine was added to a hot alcohol solution of either 1-phenyl- or 1,3-diphenylbarbituric acid, the slightly soluble cinnamylidene and anilinomethylene derivatives separated rapidly and quantitatively. There was no observable difference in the rate of reaction of a series of mono and diaryl nitrogen-substituted barbituric acids with these reagents.[7]

Summary

The replacement of one hydrogen by a phenyl group in dibromobarbituric acid decreases the rate of reaction with aniline and possibly with aliphatic amines. The amine salts of 1-phenyl-5-bromobarbituric acid are less stable than those of 5-bromobarbituric acid.

Amines and thioureas do not react appreciably with 1,3-diphenyl-5,5-dibromobarbituric acid under the conditions described.

Aryl nitrogen substitution seems to have little if any effect on the reactivity of the methylene groups in the aryl nitrogen substituted barbituric acids.

Solvation and the Determination of Molecular Weights by Means of the Svedberg Ultracentrifuge

BY WILLIAM D. LANSING AND ELMER O. KRAEMER

In a recent paper,[1] Professor McBain considers the error due to solvation in molecular weights determined by means of the ultracentrifuge and concludes that the error may amount to "hundreds of per cent." Although Professor McBain is not clear on this point, by emphasizing the dependence of sedimentation on a difference in the partial specific volumes of solvated and unsolvated molecules, he implies that solvation affects in a different manner molecular weights determined by means of the ultracentrifuge and by conventional methods such as osmotic pressure or change in freezing point, boiling point, or vapor pressure.

In contrast to this point of view, we shall show that the effect of solvation is the same for the ultracentrifuge as for conventional methods; that as a matter of fact, the error owing to solvation in binary systems is independent of the partial specific volumes of the components; and that in no case can the error amount to "hundreds of per cent." in a binary system for the reason that the apparent molecular weight, ignoring solvation, is always less than the true molecular weight of the unsolvated molecules, regardless of the values for the partial specific volumes. Furthermore, we shall show that whenever the molecular weight determinations are made in low concentrations, as is generally admitted to be necessary for valid results by any method, enormous solvations lead to a relatively small error. We therefore believe that, in practice, solvation very rarely, if ever, leads to any significant error in ultracentrifuge determinations of molecular weight on binary solutions.

The effect of solvation in a multicomponent system may be considerably more complicated than for a binary solution. Since Professor McBain discusses such systems also, without however presenting any mathematical treatment, we add a brief quantitative discussion of ternary systems in which combination occurs between the sedimenting component and one of the other two.

Solvation in Binary Systems.—Considering a binary solution, in which s grams of component 2 (solvent) combines with one gram of component 1 (solute), the following symbols and definitions may be set up

x_1, x_2 = number of grams of components 1 and 2 in solution.
$y_{12} = (s + 1)x_1$ = grams of compound (solvate) in solution.
$y_2 = x_2 - sx_1$ = grams of free solvent.
v = volume of solution; V = specific volume of solution $= v/(x_1 + x_2)$.
$\overline{V}_1$, $\overline{V}_2$ and $\overline{V}_{12}$ = partial specific volumes of solute, solvent and solvate respectively.

Remembering that $v = f\,(y_{12}, y_2)$, one obtains by partial differentiation

$$\frac{\delta v}{\delta x_1} = \overline{V}_1 = \frac{\delta v}{\delta y_{12}}(s + 1) - \frac{\delta v}{\delta y_2}s \qquad (1)$$

and

$$\frac{\delta v}{\delta x_2} = \overline{V}_2 = \frac{\delta v}{\delta y_2}$$

Combining these, and replacing the differentials by the corresponding specific volume symbols, one finds that

$$(s + 1)\overline{V}_{12} = s\overline{V}_2 + \overline{V}_1 \qquad (2)$$

That is to say, the partial specific volume of the solvate can be calculated only if the degree of solvation s is known.

Turning now to the question of molecular weights, it is apparent that

$$M_{12} = (s + 1)M_1 \qquad (3)$$

where M_1 is the molecular weight of the unsolvated solute and M_{12} is the molecular weight of the solvated solute. Since in calculating molecular weight by the usual equation for sedimentation equilibrium, the partial specific volume of the unsolvated solute is used, an "apparent molecular weight" M' is obtained, which is related to M_{12} and the partial specific volumes by the equation

$$M_{12}(1 - \overline{V}_{12}/V) = M'(1 - \overline{V}_1/V) \qquad (4)$$

Combining equation 4 with equations 2 and 3, and eliminating M_{12} and $\overline{V}_{12}$, we get

$$M_1 = M'\frac{(1 - \overline{V}_1/V)}{(1 - \overline{V}_1/V) + s(1 - \overline{V}_2/V)} \qquad (5)$$

Introduction of the definitions for $\overline{V}_1$ and $\overline{V}_2$ ex-

---

[1] J. W. McBain, THIS JOURNAL, **58**, 315 (1936).

pressed in terms of weight fractions, c_1 and c_2, for solute and solvent,[2] namely

$$\bar{V}_1 = V + c_2 \mathrm{d}V/\mathrm{d}c_1 \qquad (6)$$
$$\bar{V}_2 = V - c_1 \mathrm{d}V/\mathrm{d}c_1$$

finally gives

$$M_1 = M' \frac{1 - c_1}{1 - c_1 - sc_1} \qquad (7)$$

It may readily be shown that the same equation describes the effect of solvation on molecular weights by osmotic pressure and other conventional methods. This of course is to be expected in view of the thermodynamic equivalence of osmotic pressure and sedimentation equilibrium.[3]

From eq. 7 it is evident that the error due to solvation is independent of the partial specific volumes of the components for the ultracentrifuge method, as well as for osmotic pressure and related methods. Furthermore, inasmuch as the apparent molecular weight M' is always smaller than the true molecular weight M_1 of the unsolvated solute, the error can never amount to "hundreds of per cent." In fact, since low concentrations should always be used for molecular weight determinations by means of the colligative properties of solutions, quite enormous degrees of solvation have an insignificant effect on molecular weight. For example, from eq. 7, if c_1 is about 0.001, as it commonly has been in our ultracentrifuge work, the solvation would have to be about 990% to make an error of 1% in the molecular weight. We therefore believe that solvation needs never lead to any serious error in ultracentrifuge determinations of molecular weight for binary solutions.

Three-Component Systems with Solvation or Compound Formation.—Three-component systems containing but one sedimenting component and with no combination between the components may be considered as a binary system without solvation. If the sedimenting component combines with the other two components in the same proportions as they exist in the solution, the solution is equivalent to a binary solution with solvation, as treated above. If, however, combination occurs between the sedimenting component and one of the other components, or if the sedimenting component combines with both of the other components in proportions different from those in which they exist in the solution, a new case arises.

Calling the sedimenting or colloidal solute component 1, and considering the case where r grams of component 2 combines with one gram of component 1, we may set up the following definitions

$$y_{12} = (r + 1)x_1$$
$$y_2 = x_2 - rx_1$$
$$y_3 = x_3$$

where y_{12}, y_2, and y_3 are the grams of compound, free component 2, and component 3 in the solution.

By operations entirely similar to those used in the discussion of binary solutions, we obtain an equation which is analogous to eq. 2; namely

$$(r + 1)\bar{V}_{12} = r\bar{V}_2 + \bar{V}_1 \qquad (8)$$

and an equation which is analogous to eq. 5, namely

$$M_1 = M' \frac{(1 - \bar{V}_1/V)}{(1 - \bar{V}_1/V) + r(1 - \bar{V}_2/V)} \qquad (9)$$

In other words, the true molecular weight of component 1 in its uncombined state can be determined only if the component with which the colloidal solute combines, the composition of the compound, and the partial specific volumes of both components of the compound, are known. It may be noted that for this case, as well as for the binary solution, the error in molecular weight is not dependent on the partial specific volume of the compound formed by the colloidal solute.

The partial specific volumes in question are defined by a set of equations analogous to those of eq. 6 and similarly derivable

$$\bar{V}_1 = V + (1 - c_1)\frac{\delta V}{\delta c_1} - c_2 \frac{\delta V}{\delta c_2}$$
$$\bar{V}_2 = V - c_1 \frac{\delta V}{\delta c_1} + (1 - c_2)\frac{\delta V}{\delta c_2} \qquad (10)$$
$$\bar{V}_3 = V - c_1 \frac{\delta V}{\delta c_1} - c_2 \frac{\delta V}{\delta c_2}$$

where the partial derivative with respect to c_1 is taken with c_2 constant, and *vice versa*. Since $c_1 + c_2 + c_3 = 1$, changes in c_3 may be ignored. By substituting the values for $\bar{V}_1$ and $\bar{V}_2$ as given by eq. 10 into eq. 9, one may calculate the error corresponding to various values of r.

Whereas for the binary case, as Professor McBain points out, the partial specific volumes of the colloidal component and its compound with the solvent must necessarily differ if sedimentation is to occur, the same is not in general true for multicomponent systems. Specifically, in a ternary system, it is possible for the colloidal solute and its compound with one of the components to have

[3] A. Tiselius, *Z. physik. Chem.*, **124**, 449 (1926).

the same partial specific volume without eliminating the difference between $\bar{V}_{12}$ and V, which is the condition for sedimentation to occur. In such a case, as shown by eq. 8, $\bar{V}_1 = \bar{V}_2 = \bar{V}_{12}$, and as shown by eq. 9, the molecular weight calculated from ultracentrifugal data is then the true molecular weight of the *compound*. The relationship, under these conditions, between $\bar{V}_{12}$ and V may be shown from eq. 10 to be

$$\bar{V}_{12} = V + c_3(\delta V/\delta c_1) \qquad (11)$$

The question regarding the formation of a compound between the colloidal solute and another component of a solution has concerned us a good deal in connection with our ultracentrifugal studies of cellulose in cuprammonium.[4] Although these solutions contain at least four components, we have assumed that they could be considered as ternary systems with combination occurring between the cellulose and the copper. We know of no entirely satisfactory way of determining directly the composition of the compound or its partial specific volume, so our conclusions concerning the molecular weight of cellulose in cuprammonium involve other considerations. As pointed out above, however, if the partial specific volumes of cellulose and of the compound with copper happen to be the same, a true molecular weight of the compound is obtained. We attempted to give general expression to this thought in our previously cited paper, but unfortunately we did not limit our remark to ternary or more complicated systems, and we are in complete agreement with Professor McBain's criticism of our statement, in so far as binary systems are concerned.

From Professor McBain's remarks concerning "bound water" and its determination in ternary systems, it might be thought that his method offers a direct way of measuring at least the partial specific volume of the cellulose–copper compound. We fear, however, that such is not the case. The partial specific volume of the cellulose is considerably less than the specific volume of the solution. As a result, very considerable amounts of an additional substance with a definitely lower partial specific volume than the cellulose would have to be added to the solution in order to reduce the specific volume of the solution to equality with that of the cellulose–copper compound and thus to prevent sedimentation. Whether the elimination of sedimentation could actually be accomplished in this way we do not know, but if it could be done, we feel that there would in general be very little chance that the partial specific volume of the colloidal solute would remain unchanged, especially if the colloidal component formed a compound with some other component of the system.

However, whenever the partial specific volume of the compound containing the colloidal solute can be determined by Professor McBain's method, one may replace $\bar{V}_{12}$ of eq. 8 with the value of V, substitute the values of $\bar{V}_1$ and $\bar{V}_2$ as given by eq. 10, and calculate r. This assumes, of course, that $\bar{V}_1$, $\bar{V}_2$ and $\bar{V}_{12}$ are not changed by the additional component required to bring V and $\bar{V}_{12}$ into equality, that one knows which component combines with the colloidal solute, and that $\bar{V}_3$ and c_3 refer to the mixture of all components other than the colloidal solute and the component with which it combines.

Summary

For binary solutions the change in partial specific volumes resulting from solvation or compound formation does not affect molecular weights determined by the sedimentation equilibrium method in any way different from that for conventional methods, in spite of the fact that sedimentation equilibrium is dependent on differences in partial specific volumes. Under normal conditions, with a binary solution, solvation is probably rarely if ever great enough to lead to an appreciable error in molecular weights. For ternary and higher order systems, also, the error in molecular weight by the sedimentation equilibrium method may be evaluated quantitatively without considering the partial specific volume of solvates or compounds formed by sedimenting component.

Some Chromous and Chromic Ammines

BY J. H. BALTHIS, JR.,[1] AND JOHN C. BAILAR, JR.

In the course of some work on the stereochemistry of chromium, it has been necessary to know something of the stability of chromous ammines toward water and air. Very few chromous ammines have been studied in this respect; apparently no investigation has been made of the ones in which we are particularly interested—those containing ethylenediamine and its homologs.

Traube and Passarge[2] prepared chromous ammines by the action of hydrazine and of hydrazine sulfate upon chromous salts. These compounds were so stable that they showed no change on standing in the air for several days. Traube, Burmeister and Stahn[3] by treating chromous chloride and chromous formate with pyridine obtained complexes which absorb oxygen from the air, but which are stable, even when wet, if protected from the air. Barbieri and Tettamanzi[4] found that $[\mathrm{Cr\ dip_3}]\ \mathrm{Br_2{\cdot}6H_2O}$ (dip = dipyridyl) oxidizes slowly in the air. The same investigators prepared chromous complexes containing hexamethylenetetramine, and found them to be readily oxidized when wet. Chromous ammonia complexes are stable when dry[5] but when a solution of a chromous salt is treated with ammonium hydroxide and an ammonium salt, hydrogen is evolved and the chromic complex is formed.[6] We have found that ethylenediamine and its homologs behave in this same way, liberating hydrogen very rapidly.

When a solution of chromous chloride in an atmosphere of nitrogen was treated with a solution of ethylenediamine with or without the addition of ethylenediamine hydrochloride a transient blue precipitate formed. This was perhaps a chromous complex. Rapid oxidation to the chromic state prevented its isolation, however. As soon as the solutions were mixed, evolution of hydrogen began, and within an hour and a half the oxidation was practically complete.

The use of chromous acetate instead of the chloride gave essentially the same results. In this case an 80% yield of triethylenediamine chromic bromide $[\mathrm{Cr\ en_3}]\ \mathrm{Br_3{\cdot}3H_2O}$ was obtained by concentrating the solution and adding sodium bromide. A small amount of hexaethylenediamine-hexol-tetrachromic bromide $[\mathrm{Cr_4(OH)_6en_6}]\mathrm{Br_6{\cdot}4H_2O}$[7] was formed, also.

An unstable chromous ammine must have been formed before the oxidation took place, for the chromic ion will not react with ethylenediamine under these conditions. Although the conditions of the experiment were varied in many ways, no chromous compound could be isolated. In the hope of obtaining more stable compounds 1,2-propylenediamine and 2,3-butylenediamine (for which an improved method of preparation was developed) were substituted for the ethylenediamine. Again, only chromic compounds were obtained. Chromous ammines containing bases of this series are apparently too readily oxidized by water to be isolated from aqueous solution. This furnishes a much easier method of preparing the triethylenediamine chromic salts than any which has previously been described. A simplified procedure for this preparation is outlined in the Experimental Part.

We were led by these observations to study briefly the stability of chromous ammines containing bases with nitrogen in the ring. In agreement with the results of Barbieri and Tettamanzi, we found the dipyridyl complex to be quite stable. In the case of the pyridine complex the nitrogen to chromium bond is evidently less stable for the compound which we prepared, $[\mathrm{Cr\ py_2}]\mathrm{Cl_2}$, lost pyridine gradually on standing. Quinoline complexes are still less stable. Chromous chloride and acetate dissolved readily in quinoline to give deeply colored solutions, but the addition of alcohol precipitated the original chromous salt. None of the complex ions containing ring bases were oxidized by water.

Experimental

Most of the experiments were carried out in the apparatus shown in Fig. 1. A novel feature of this device is the combined stirrer-filter B. The shaft of this stirrer is a heavy-walled 8-mm. tube. The lower end is expanded to an

(7) Pfeiffer, *ibid.*, **58**, 272 (1908).

internal diameter of 10 mm. and is packed with glass wool. A short piece of glass rod is sealed to the shaft just above the expanded portion. During filtration the upper end of the shaft is connected (at C) to the vacuum line by a piece of light rubber tubing; when the device is used for stirring the rubber is disconnected from the vacuum line and closed by a piece of glass rod. By placing B very close to the bottom of the flask, practically all of the liquid can be drawn off. Liquids for washing precipitates are introduced through K and withdrawn through B. The apparatus is convenient and has proved to be very efficient.

Preparation of Chromous Acetate.—Chromic chloride is reduced by zinc and hydrochloric acid in F, the excess hydrogen escaping through the small Erlenmeyer, which is partially filled with water. When the reduction is complete, stopcock D is opened and rubber tube H is closed by a clamp. This forces the liquid in F through the glass wool filter A into the reaction flask G, through which a slow stream of oxygen-free nitrogen is passing. A concentrated solution of sodium acetate (excess) is added through K, and the precipitated chromous acetate is washed by stirring it with small portions of freshly boiled water. If it is to be removed from the apparatus it must be washed with alcohol and ether and dried by the stream of nitrogen. The yield is over 90%.

Chromous Chloride.—Eighteen grams of chromous acetate in the reaction chamber G is dissolved in 60 cc. of ice cold concentrated hydrochloric acid. With the flask immersed in an ice-bath, a steady stream of hydrogen chloride gas is passed into the flask with the nitrogen. (With undiluted hydrogen chloride, there is a tendency for water to be sucked in from flask L.) After about an hour, blue crystals of $CrCl_2 \cdot 4H_2O$ precipitate. The liquid is filtered off and the crystals washed with cold, concentrated hydrochloric acid. The yield is 90%, based on weight of chromous acetate, or 81% based on the weight of chromic chloride used.

Action of Ethylenediamine and its Homologs upon Chromous Chloride.—Solid chromous chloride tetrahydrate (from 15 g. of $CrCl_3 \cdot 6H_2O$) was dissolved in 30 cc. of freshly boiled ice-cold water in an atmosphere of nitrogen, and 30 cc. of an ice-cold saturated solution of ethylenediamine hydrochloride was added. Thirty cubic centimeters of a 65% solution of ethylenediamine was then added gradually with stirring. During the addition a pale blue precipitate formed, but soon redissolved. Even though the solution was kept at 0°, oxidation began at once and was complete in a few hours. Addition of alcohol to the cherry red solution precipitated $[Cr(NH_2CH_2CH_2NH_2)_3]Cl_3 \cdot 3.5H_2O$ as orange crystals. A second crop was obtained by evaporation. The total yield was 16 g. Dehydration over phosphorus pentoxide showed the compound to contain 15.65% water; (calcd., 15.69%). Analysis of the anhydrous material by ignition to Cr_2O_3 showed 15.7% chromium; calcd., 15.4%.

The substitution of 1,2-propylenediamine for ethylenediamine led to similar results, $[Cr(NH_2CH(CH_3)CH_2NH_2)_3]Cl_3 \cdot H_2O$ being obtained. Analysis for chromium: Found, 13.12%. Calcd., 13.05%.

In another experiment, a slight excess of butylenediamine was added to the solid chromous chloride, which had been freed from hydrochloric acid by washing with acetone. The results were the same as with the other bases. After oxidation was complete, the solution was poured into 50 cc. of concentrated hydriodic acid. The iodide precipitated in beautiful orange needles, which are soluble in water, alcohol and acetone, and were recrystallized from water. The loss in weight upon drying at 50° in a vacuum over phosphorus pentoxide was negligible. Analysis for iodide: Found, 54.85%. Calcd. for $[Cr(CH_3CH(NH_2)CH(NH_2)CH_3)_3]I_3$, 54.63%. This is the first member of the butylenediamine series to be described.

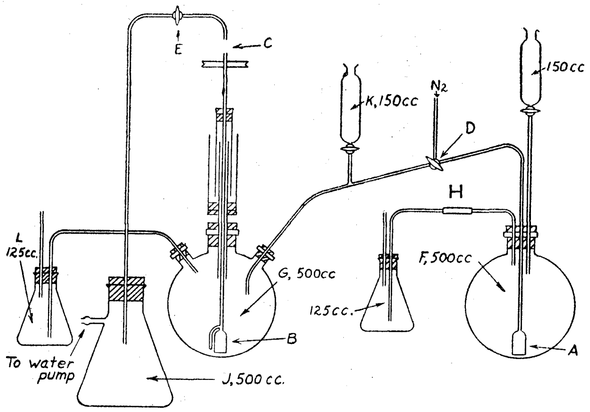

Fig. 1.

Action of Ethylenediamine upon Chromous Acetate.—When chromous acetate was dissolved in 65% ethylenediamine oxidation took place as with the chloride. Addition of sodium bromide followed by evaporation gave triethylenediamine chromic bromide and a small amount of hexaethylenediamine-hexol-tetrachromic bromide, $[Cr_4(OH)_6en_6]Br_6 \cdot 4H_2O$. These were separated through the difference in solubility in water and the tetrachromic salt was identified by analysis. Calcd.: Cr, 16.20; N, 13.8. Found: Cr, 16.13, 16.14; N, 13.7.

Action of Nitrogen Ring Bases upon Chromous Salts.—The directions of Barbieri and Tettamanzi[4] were followed in the preparation of the dipyridyl complex $[Cr\ dip_3]Br_2 \cdot 6H_2O$. In agreement with their report, we find the compound to be fairly stable toward water, and only slowly oxidized by exposure to the atmosphere.

An excess of pyridine was added to chromous chloride dissolved in water. The pale green precipitate which formed was filtered, washed successively with water, alcohol and ether, and dried by heating to 80° in a current of nitrogen. Analysis showed it to be $[Cr\ py_2]Cl_2$. Calcd.: Cr, 18.5; Cl, 25.1. Found: Cr, 18.0; Cl, 25.3. The compound undergoes slow oxidation when exposed to air. It has a faint odor of pyridine and evidently loses pyridine continuously. Since the completion of this work Chatelet[8] has reported the preparation of this compound from anhydrous chromous chloride and pyridine. Traube, Burmeister and Stahn[3] isolated this compound as the dihydrate.

Chromous acetate and chloride were dissolved in wet quinoline in an atmosphere of nitrogen to give deep red solutions. No oxidation was apparent after the solutions had stood for several days. Addition of alcohol to the solution reprecipitated the original chromous salt.

---

[8] Chatelet, *Compt. rend.*, **199**, 290 (1934).

Simplified Procedure for the Preparation of $[Cr(NH_2\cdot CH_2\cdot CH_2\cdot NH_2)_3]Br_3\cdot 3H_2O$.—A one-liter flask is equipped with a mercury sealed stirrer, a dropping funnel, an inlet for nitrogen and an outlet for escaping gases. Twenty grams of chromium in small pieces and 400 cc. of water are placed in the flask and the water is boiled to expel dissolved oxygen. Air is swept from the flask by a current of nitrogen. One hundred cubic centimeters of concentrated hydrobromic acid is added over a period of five minutes, followed immediately by 70 cc. of ethylenediamine monohydrate. The solution is allowed to stand with occasional stirring until oxidation is complete (eight to ten hours), is filtered and evaporated. The bromide crystallizes as orange needles. The yield in a typical run was 47 g. or 81% based upon the fact that 5.8 g. of chromium dissolved.

Preparation of 2,3-Butylenediamine.—Angeli[9] has described the preparation of 2,3-butylenediamine by reduction of an alcoholic solution of dimethylglyoxime. This method gives very poor yields, apparently because the sodium salt of dimethylglyoxime is insoluble in alcohol. The substance has been prepared also by the action of ammonia on 2,3-dibromobutane[10] and by the catalytic reduction of dimethylglyoxime dissolved in alcohol.[11] The catalytic reduction gives excellent yields of the base when very dilute solutions are used. Under these conditions it is difficult to obtain the material in large amounts. We have found that it is possible to obtain 2,3-butylenediamine readily by the following modification of Angeli's directions: dimethylglyoxime is acetylated by the method of Biltz.[12] Seventy grams of the diacetate is dissolved in two liters of anhydrous alcohol in a flask fitted with a stirrer and an efficient reflux condenser. One hundred and sixty grams of sodium in lumps the size of marbles is introduced rapidly. When the sodium has dissolved 200 cc. of water is added and the mixture is steam distilled. Most of the amine is obtained in the first three liters of distillate. Addition of a saturated solution of oxalic acid precipitates the oxalate. More of the oxalate can be obtained by concentrating the solution and adding alcohol and ether. The total yield is 27 g. or 40% of the theoretical. This material is pure enough for preparation of the free base. A sample, after recrystallization from water and drying over phosphorus pentoxide, melted at 235°. Angeli[9] reported 238°.

The base is liberated by mixing the oxalate with its own weight of sodium hydroxide in a small amount of water. Distillation gives a nearly quantitative yield of a fuming, somewhat viscous liquid with an odor similar to that of ethylenediamine. The hydrated base boils at 130°.

The major portion of the dimethylglyoxime not accounted for in the yield of diamine may be recovered from the original reaction mixture.

Summary

The stability of chromous ammines has been studied. Ammines containing ethylenediamine, 1,2-propylenediamine and 2,3-butylenediamine could not be isolated from water solution because of rapid oxidation to the chromic state by the water. On the other hand, when the chromous ion is coördinated with dipyridyl, pyridine or quinoline it is stable toward water, and in the case of the dipyridyl at least is somewhat stabilized to atmospheric oxidation.

A new and simple method for the preparation of triethylenediamino chromic salts and similar compounds has been presented.

An improved synthesis of 2,3-butylenediamine is described.

The Transference Number of Lanthanum Chloride as a Function of the Concentration

BY GRINNELL JONES AND LAURENCE T. PRENDERGAST

Introduction

The purpose of this paper is to test the general validity of several equations which have been proposed for the variation of the transference numbers of electrolytes with the concentration by the use of new data on lanthanum chloride covering a wide range of concentration. Although the old classical theory predicts that transference numbers should be independent of the concentration, it has long been known that variations do occur, especially among salts of polyvalent ions.

In 1924 Drucker and Riethof[1] found that the data for the transference numbers for the chloride ion in hydrochloric acid between 0.01 and 0.1 normal, inclusive, could be expressed by the two parameter equation: $t_- = 0.172(1 - 1/N^{0.51})$; where t_- is the transference number of the anion and N is the moles of water per mole of salt. The figures 0.172 and 0.51 were selected to fit the data, but the figure 0.172 obviously must be the limiting value of t as the concentration approaches

[1] C. Drucker and G. Riethof, *Z. physik. Chem.*, **111**, 20 (1924).

zero. No general validity for this form of equation was claimed and it aroused little interest but has been revived by Drucker[2] in his recent book "Elektrochemie" in the form

$$t_- = t_-^0\ (1 - 1/\sqrt{N})$$

which differs from the original only in the change of the exponent from 0.51 to 0.50. This change was perhaps influenced by the development of the Debye–Hückel theory in the meantime.

Soon after the original proposal of Drucker's equation Scatchard[3] used an equation for potassium chloride which is readily transformable into the form, $t_+ = 0.4975 - 0.014\sqrt{m}$, where m is the molality (moles of salt per 1000 grams of water) and the figure 0.4975 must be the limiting value at zero concentration if this equation is valid. This equation is of essentially the same form as Drucker's revised equation, except that it contains one more arbitrary parameter, namely, the coefficient of the last term. Scatchard regarded this equation as valid for potassium chloride up to 1.25 normal but makes no claim that it has general validity.

In 1929 Jones and Dole[4] found that an equation of the form $t_+ = A/(1 + B\sqrt{c}) - 1$ (where c is moles of salt per liter and A and B are parameters chosen to fit the data) held for barium chlorides solutions over the range of concentration from 0.001 to 1.0. It is evident from the form that if this equation is valid for extrapolation down to zero concentration then $t_+^0 = A - 1$.

In 1931 Jones and Bradshaw[5] found that this equation could be applied to lithium chloride from c = 0.001 to 3.0 normal.

Dole[6] has pointed out that the Jones and Dole equation has the same form as the limiting law derivable from the Onsager conductance equation but that the numerical coefficients are different.

Longsworth[7] has proposed and tested a two parameter equation for the variation of the transference number of uni-univalent salts with the concentration

$$t_+ = t_+^0 - \frac{(1 - 2t_+^0)\,\beta\sqrt{c}}{\Lambda_0 - (\alpha\Lambda_0 + 2\beta)\sqrt{c}} + Ac\left(1 + \frac{2\beta\sqrt{c}}{\Lambda_0 - (\alpha\Lambda_0 + 2\beta)\sqrt{c}}\right)$$

where α and β have a definite known numerical value from the Onsager conductance theory and Λ_0 must be estimated from the data on conductance so that only the limiting value of the transference number and the constant A are selected to fit the data. This equation was shown to be valid for potassium chloride between 0.001 to 0.1 normal and for sodium chloride and lithium chloride and hydrochloric acid between 0.01 and 0.1 normal.

The interionic attraction theory predicts that the variation of ionic mobilities with concentration should be greater for trivalent ions than for univalent or bivalent ions and therefore that the variation of the transference numbers of the ions with the concentration should be larger for a tri-univalent salt than for the simpler types of salts. This is supported by the fragmentary available data.

As Onsager[8] has pointed out, a qualitative prediction as to the sign of the change can be made from the Onsager theory beyond the range of concentration for which the conductance equation is valid. The interionic electric forces decrease the mobilities of the two ions in equal ratios and, therefore, do not affect the transference numbers. On the other hand, the absolute effect of electrophoresis in diminishing the mobility of an ion is proportional to its valence and independent of its mobility. For a 3-1 salt, this means that if the transference number of the trivalent ion at infinite dilution is more than 0.75, the theory predicts that it will increase with increasing concentration; and if it is less than 0.75 it will decrease with increasing concentration.

In order to test the various equations which have been proposed it seemed desirable to secure reliable data on some tri-univalent salt covering a wide range of concentration. Lanthanum chloride was selected because it is less hydrolyzed than any other chloride of a trivalent metal, is sufficiently soluble, and so far as is known does not form complex ions in solution. Moreover, conductance data on this salt have been obtained in this Laboratory.

The only published data known to us on the transference numbers of the ions of lanthanum chloride are by Proskauer.[9] His results are only given to two significant figures and show variations between the results obtained at the anode

and at the cathode of about 5% on the average. A few unpublished measurements have been made in this Laboratory by B. C. Bradshaw which agree well with the new data given below.

Experimental

The lanthanum chloride used in the early part of the work was originally separated from other rare earths by Professor Charles James and purified and dried by C. F. Bickford[10] as described in an earlier paper from this Laboratory. After this supply was used up the material was recovered from the used solutions by precipitation as the oxalate, ignition to the oxide and conversion into the chloride by the procedure used by Bickford. A concentrated solution of the salt gave a *p*H of 6.2 as determined by Phenol Red indicator, showing that the hydrolysis was so slight that even for the most dilute solution investigated the correction to the transference number due to hydrolysis was less than the experimental error.

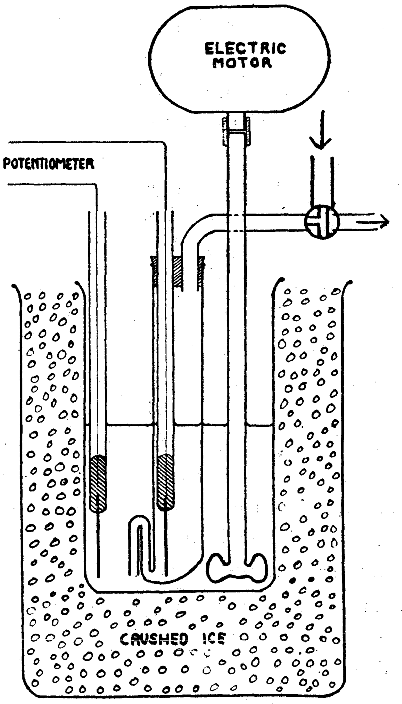

Fig. 1.

The transference numbers were determined by the analytical method using an apparatus of the type devised by Washburn.[11] The other details of the procedure were similar to those used by Jones and Dole, and Jones and Bradshaw with some modifications. The anode for solutions more concentrated than 0.01 normal was a roll of silver gauze, coated with spongy silver. This was made by covering the gauze with a paste of silver oxide in water, drying and heating to a low red heat. For very dilute solutions (0.01 molar and below), a roll of silver gauze without the spongy silver was used. This type of anode was more easily cleaned than the spongy silver type. During electrolysis these electrodes became covered with adherent silver chloride which could be easily washed, dried and weighed without loss. There was no evolution of oxygen or formation of acid at the anode in any of the experiments reported. These electrodes gave entire satisfaction, except that with dilute solutions there is a tendency for the silver chloride to be formed in colloidal suspension instead of adhering to the anode. This limits the current density which can be used and the total permissible transference. The formation of colloidal silver chloride in dilute solution is probably due to the fact that the chloride ions become depleted in the immediate vicinity of the anode so that silver ions may be formed and migrate away from the electrode before they meet a chloride ion and are precipitated. If the potential gradient in the solution is too high (more than 1 volt per centimeter) there may be evolution of oxygen and formation of acid. The anodes after being used could be prepared for reuse by cathodic reduction, followed by washing and drying.

The cathodes were made similar to the anodes and then were thickly coated with silver chloride by electrolysis in hydrochloric acid, thoroughly washed and dried at 105°. The silver chloride and reduced silver formed therefrom by electrolysis were so adherent that there was no loss of weight in handling the electrodes. For the more concentrated solutions, it was necessary to use very large electrodes weighing 30 g.

In order to prevent the formation of hydroxyl ion at the cathode when using these electrodes, it is necessary to remove the oxygen dissolved in the solution. This was done by bubbling oxygen-free nitrogen through the solution before pumping it into the transference cell. Then the cell was sealed with paraffin to exclude oxygen.

The analysis was carried out by differential potentiometric titration, similar to the procedure used by MacInnes and Dole. Our experience confirms the advantages of this method claimed by these authors. For the titration we have used the device shown in Fig. 1 which we have found to be more rapid and positive in its action than the air lift device used by MacInnes and Dole. The solution to be analyzed was added from a weight buret to a beaker immersed in an ice-bath. The sharpness of the end-point is greatly increased by chilling. The electrodes were platinum wires covered with silver by electroplating from a cyanide-bath. One electrode was inside a tube connected with the bath by a narrow gooseneck. A standard solution of silver nitrate was added from a weight buret until the end-point was near and then the titration completed by means of a very dilute solution added from a volumetric buret. After each addition of a drop of silver nitrate the solution in the beaker was thoroughly stirred and the change in potential was observed. The solution around the inner electrode was then mixed with the main body of the solution by making alternate connections with a pressure bottle and the outer air by means of a three-way cock as shown in the diagram. This method of electrometric titration is far more rapid than the gravimetric method and is sufficiently accurate for the purpose. The error in the analysis is probably not more than 0.01% except when applied to solutions less than 0.01 molar when the error increases somewhat.

Discussion of the Data

The experimental data presented above show that the transference number of the lanthanum ion in lanthanum chloride solutions decreases with the concentration from 0.4696 in 0.0038 molar solution to 0.3000 in 1 molar solution. This is a greater variation than has been observed for any strong electrolyte of the uni-univalent or uni-bivalent types.[12] This case is, therefore, especially well suited to test the general validity of the various proposals which have been made for the variation of transference numbers with the concentration. An important part of the problem is the estimation of the limiting value of the transference number at infinite dilution which requires that some law be assumed to be valid in the dilute range where reliable experimental data are not obtainable.

The results confirm the predictions of the Onsager theory both in regard to the great variability of the transference number with the concentration and to the sign of this variation.

Figure 2 shows a plot of the transference numbers of the lanthanum ion in lanthanum chloride against the square root of the concentration $\sqrt{c}$. This curve, although approximately straight, shows unmistakable positive curvature which makes extrapolation to zero concentration hazardous. Therefore, an equation of the form $t_+ = t_+^0 - A\sqrt{c}$ can only be a rough approximation over the entire range. This curvature is most pronounced in the middle range and tends to disappear in the dilute range and also in the concentrated range (0.2 to 1 molar). The four lowest points (0.0038 to 0.022) are on a straight line within the experimental error. There is no reason, either experimental or theoretical, to suspect that the curve could become more nearly horizontal as it approaches the axis which would require a change in the sign of the curvature at extreme dilution. Therefore, if we extrapolate the curve to zero concentration along the straight line determined by the last four points the result, $t_+^0 = 0.4881$, should be the minimum estimate of the transference number at zero concentration. The equation of this straight line is $t_+ = 0.4881 - 0.2946\sqrt{c}$, which agrees with the data within the experimental error up to $c = 0.022803$ but fails badly at the higher concentrations. This is shown in column 4 of Table II, which gives the difference between the experimental values and the values computed by this equation.

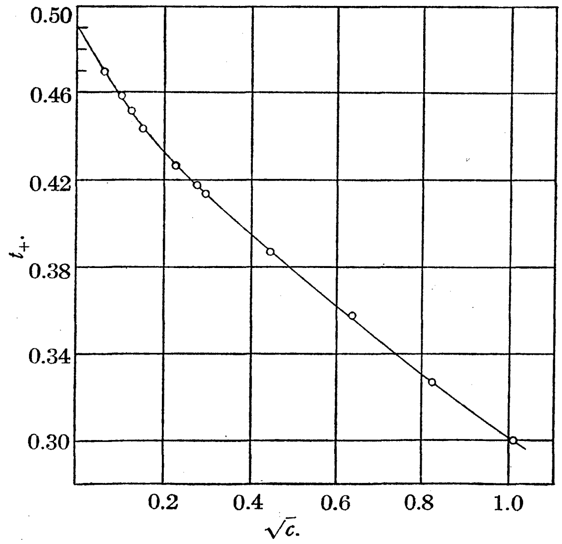

Fig. 2.

If the curve depicted by Fig. 2 has an appreciable curvature below the lowest concentration measured, then the limiting transference number would be higher than 0.4881.

We have tried the effect of adding a term proportional to the concentration, giving an equation of the form $t_+ = t_+^0 - A\sqrt{c} + Bc$, but the result was not satisfactory as it gives too great a curvature.

If we express the composition in terms of moles of salt per thousand grams of water (following Scatchard's suggestion) instead of concentrations,

---

(12) Although relatively greater changes in transference numbers have been observed for cadmium bromide and cadmium iodide, there is independent evidence that in the cases of these salts the cadmium is present partly in the form of a complex anion. Since the fraction of the cadmium present in the complex ion varies with the concentration, the decrease in the transference number of the cadmium is due to this cause.

the curvature of this plot is increased rather than decreased, so that there is no advantage for this purpose in this method of expressing the composition.

The Jones and Dole equation has been shown to hold for barium chloride and for lithium chloride over a wide range of concentration. This equation may be written $t_+ = A/(1 + B\sqrt{c}) - 1$; or $\frac{1}{1 + t_+} = \frac{1 + B\sqrt{c}}{A} = \frac{1}{A} + \frac{B\sqrt{c}}{A}$ where it is obvious that $t_+^0 = A - 1$. Figure 3 shows a plot of $1/(t + 1)$ against $\sqrt{c}$ which should give a straight line if the equation is valid. An inspection of this curve shows that a good straight line can be put through the points from $c = 0.05$ to 1.0, but that there appears to be a definite curvature in the more dilute range. The equation of this straight line is $1/(t_+ + 1) = 0.6815 + 0.08728\sqrt{c}$; or $t_+ = 1.4673/(1 + 0.128\sqrt{c}) - 1$.

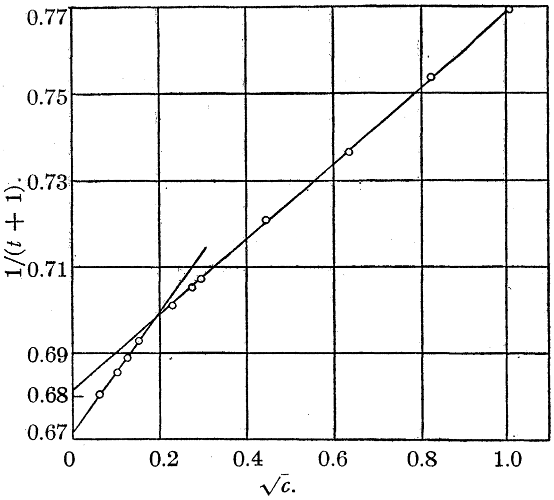

Fig. 3.

The differences between the experimental data and the figures computed by this equation are shown in column 5 of Table II. This is a good interpolation formula for the stronger solutions between the limit $c = 0.05$–1.0, but this equation fails in the dilute range. This equation leads to a value of $t_+^0 = 0.4673$, which is obviously too low since it is less than the observed transference number at $c = 0.0038$.

As is also shown in Fig. 3, we may put a straight line through the four lowest concentrations which gives $\frac{1}{t_+ + 1} = 0.6717 + 0.1388\sqrt{c}$, or $t_+ = 1.4887/(1 + 0.2067\sqrt{c}) - 1$, and hence $t_+^0 = 0.4887$. As will be seen from column 6 of Table II, this equation agrees with the data over the lower range but fails badly in the upper range.

A modified form of the Jones and Dole equation containing one more parameter selected to fit the data would be $t_+ = A/(1 + B\sqrt{c}) - D$. For barium chloride and lithium chloride the constant D was equal to 1, but this might not be generally true of all types of salts. We tried, therefore, evaluating the constant D by the method of least squares but the result was $D = 0.9998$ and there was no significant improvement

TABLE II

SUMMARY OF DEVIATIONS BETWEEN EXPERIMENTAL DATA FOR TRANSFERENCE NUMBERS OF LANTHANUM CHLORIDE AND RESULTS COMPUTED BY VARIOUS EQUATIONS

Column 4: $t = 0.4881 - 0.2946\sqrt{c}$

Column 5: $t = 1.4673/(1 + 0.1281\sqrt{c}) - 1$ (Jones and Dole)

Column 6: $t = 1.4887/(1 + 0.2067\sqrt{c}) - 1$ (Jones and Dole)

Column 7: $t = \frac{(0.4972 + 2.5702c)\,(\Lambda' + 880.24\sqrt{c}) - 660.18\sqrt{c}}{\Lambda'}$ (Longsworth)

Column 8: $\frac{1}{t + 1} = \frac{1}{0.4893 + 1} + 0.16563\sqrt{c} - 0.06835c + 0.07457c \log c$

in the agreement between the observed and computed result by replacing the term -1 by -0.9998.

Longsworth has recently proposed a method of extrapolating transference numbers to infinite dilution based on Onsager's limiting law for the variation of the conductance of ions with the concentration. Longsworth only claims that his method is valid for four univalent chlorides but it is of interest to test the method for salts of other valence types. Although Jones and Bickford have shown that Onsager's limiting law is not valid for lanthanum chloride even up to 0.001 molal, nevertheless if the influences which cause the failure of Onsager's law should affect the two ions proportionally a transference equation based on Onsager's law might be valid to much higher concentrations than Onsager's conductance equation. Longsworth's treatment may be readily generalized to apply to salts of any valence type. The mathematical details of this generalization are omitted to save space in printing. A plot prepared according to Longsworth's method was approximately straight up to 0.05 molar only. The corresponding equation is given in Table II and the difference between the experimental values and the values of t computed by this equation is given in column 7 of Table II. The deviations between the observed and computed values are not much greater than the experimental error up to $c = 0.051$, but the equation fails utterly at higher concentrations which indicates that it does not have the proper mathematical form to be regarded as generally valid. The values of t^0_+ are higher than those given by other methods of extrapolation.

Onsager and Fuoss[13] have suggested, without giving detailed mathematical proof, that any property of a solution of an electrolyte can be expressed as a function of the concentration by an equation of the form

$$\mathrm{F}\,(c) = \mathrm{F}\,(o) + A\sqrt{c} + Bc + Dc \log c + \dots$$

We have attempted to fit this equation to our transference data but the result was disappointing. The coefficient D of the $c \log c$ term came out nearly zero, thus reducing the equation to the form $t = t^0 + A\sqrt{c} + Bc$ which had already been found to be unsatisfactory. The next step was to try an equation of the form

$$\frac{1}{t+1} = \frac{1}{t^0+1} + A\sqrt{c} + Bc + Dc \log c$$

which may be regarded as an extension of the Jones and Dole equation since it reduces to the Jones and Dole equation as c approaches zero or if B and D are placed equal to zero. The equation

$$\frac{1}{t+1} = \frac{1}{0.4893+1} + 0.16563\sqrt{c} - 0.06835c + 0.07456c \log c$$

agrees with our data over the entire range better than any other equation known to us. Since this equation contains four parameters, it is to be expected that it can be made to fit better than the simpler forms discussed above. The differences between the experimental values and the values computed from this equation are shown in column 8 of Table II.

The data throw light on the difficult problem of the extrapolation of conductance data discussed by Jones and Bickford. The foregoing discussion makes it seem probable that the limiting value of the transference number must be at least as high as 0.4881 and may be as high as 0.4893. If the limiting value of the conductance of the chloride ion is 76.34 and $t^0_\pm = 0.4881$, then the conductance of lanthanum chloride at infinite dilution would be 447.4, whereas if $t^0_\pm = 0.4893$ then Λ_0 would be 448.4.

Jones and Bickford have found that if the conductance data for lanthanum chloride are extrapolated by the method of Shedlovsky the value for Λ_0 obtained was 432.7, which is much below the estimates based on the transference numbers. If the value 432.7 is correct the value of t^0 would be 0.4707. It seems clear from Fig. 2 that the curve would have to take an extremely improbable course to reach a value of t^0_+ as low as this. The extrapolation of the conductance data by the Jones and Dole conductance equation gives $\Lambda_0 = 442.97$ corresponding to a value of t^0_+ of 0.483. It is evident that these figures agree much better with the estimates based on the transference numbers. This evidence, therefore, indicates that for this case at least the Jones and Dole conductance equation is better than the Onsager or Shedlovsky equations for finding the limiting value of the conductance.

Summary

1. The transference numbers of the lanthanum ion in lanthanum chloride solutions have been determined by the analytical method at 25° at eleven concentrations over a range of 0.0038

---

(13) L. Onsager and R. M. Fuoss, *J. Phys. Chem.*, **36**, 2689 (1932).

to 1.0 molar. The transference number varies from about 0.47 to 0.30 over this range.

2. Several equations purporting to express the transference number as a function of the concentration and the problem of extrapolation of transference numbers to infinite dilution are discussed.

Polarization and Dielectric Constant of Liquids

BY JEFFRIES WYMAN, JR.

There is much evidence that the dielectric constant is a linear function of the polarization per unit volume in the case of the more polar liquids for which the Clausius–Mosotti relationship ceases to hold. This appears to be almost the only conceivable interpretation of the strikingly simple behavior of a variety of strongly polar molecules in solvents of high dielectric constant.[1] It is in accord with the temperature variation of the dielectric constant of polar liquids, and the change of dielectric constant with density, under pressure, at constant temperature (see below). If we suppose the linear function to approximate direct proportionality, it offers a ready explanation of such a simple empirical relationship as that submitted by Girard,[2] according to which for water and the aliphatic alcohols the product of molecular weight times the dielectric constant is nearly constant; for in these cases the electric moments and consequently the molecular polarizations are all about the same, and therefore the polarizations per cc. should be inversely proportional to the molecular volumes or, roughly, to the molecular weights.[3] Onsager, in the following paper in THIS JOURNAL, develops a theoretical argument for a linear relation between dielectric constant and polarization in strongly polar media.

The problem of determining the two constants of this inferred linear relationship between dielectric constant and polarization is of course of great interest and the present paper is an attempt to deal with it from a purely empirical point of view.[4] There are of course no cases of polar liquids in which we have exact independent knowledge of the polarization with which to correlate the dielectric constant. We may, however, calculate ideal or hypothetical values of the polarizations per unit volume for such liquids by making use of the values of the electric moments and molar polarizations obtained from measurements on the vapor or on dilute solutions in non-polar solvents and by taking account of the density. Clearly, such ideal, calculated values of the polarization per unit volume cannot be supposed in general to be realized more than approximately, but, nevertheless, apart from special cases of strongly associated liquids such as those forming hydrogen bonds, they may be expected to be fairly representative of the actual values. We may then try the effect of comparing these calculated values of the polarization with the observed values of the dielectric constant, to see whether or not the linear relation shows up. If it does, there is justification of our procedure of making use of the calculated values of the polarization and we may then proceed to determine the magnitude of the two constants. This in fact is what has been done.

By reference to the section of the "International Critical Tables" (Vol. VI) devoted to the dielectric constant of liquids and to the recent extensive table of electric moments and polarizations given in the *Transactions of the Faraday Society*,[5] it was possible to pick out about 140 cases of liquids with a dielectric constant greater than 5 and for which the electric moments and polarizations had been determined. In most of these the dielectric constant is pretty well known, although in some, accompanied in Table I below by a question mark, it has been measured only at very high frequencies, several times 10^8 cycles per second, and the values may be too low, the more so in the case of the larger molecules, owing to anomalous dispersion. On the other hand the

(3) As a matter of fact Cohn has pointed out that Girard's relationship is improved if we multiply the dielectric constant in each case not by the molecular weight but by the molecular volume. E. J. Cohn, "Annual Review of Biochemistry," Annual Review of Biochemistry, Ltd., Stanford University P. O., California, Vol. IV, 1935, p. 100.

(4) An attempted derivation of the relation based on a modification of the underlying assumptions of the classical theory with regard to the internal field has been suggested but appears far too special.[1]

(5) *Trans. Faraday Soc.*, **30** (1934).

values of the polarizations are much less certain, showing in some cases a twofold variation or more. This appears to be due in part to differences in the conditions under which the measurements were made and in part to experimental discrepancies. From these data were calculated the ideal values of the polarization per cc. for the liquids for comparison with the dielectric constant.

The results of the comparison are given in Table I and are shown graphically in Fig. 1, where the dielectric constant ϵ is plotted against p, the ideal value of the polarization per cc. The full curve at the left, which corresponds to the Clausius–Mosotti relation $p = (\epsilon - 1)/(\epsilon + 2)$ and is asymptotic to $p = 1$, is included for reference. It may be seen from the figure that the majority of the points are consistent with a linear increase of the dielectric constant with p described by the expression

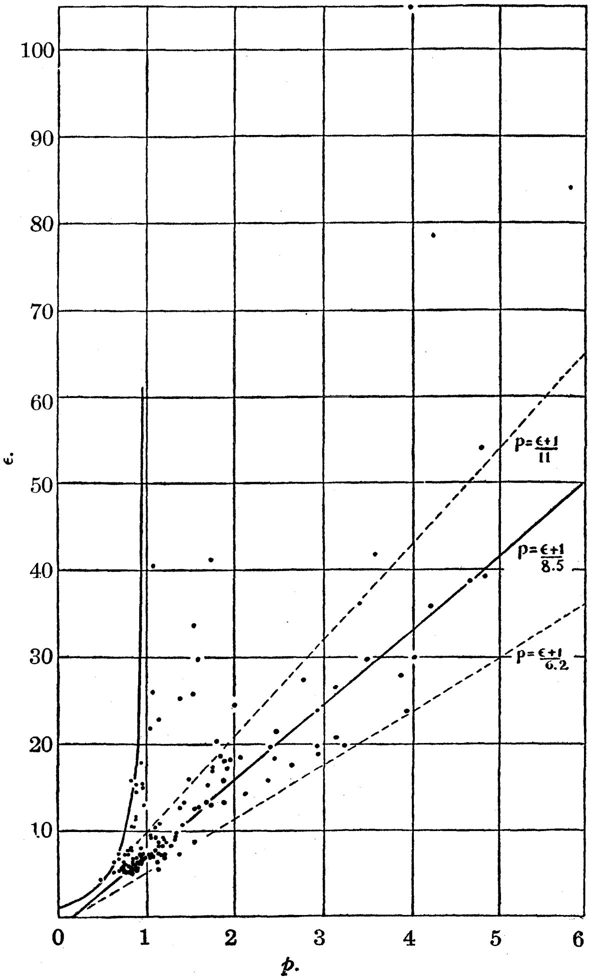

Fig. 1.

$$p = (\epsilon + 1)/8.5 \qquad (1)$$

corresponding to the full straight line. The figures 1 and 8.5 are of course only estimates (compare the dotted straight lines corresponding to a different choice of coördinates). The same thing is seen rather better by comparing columns 3 and 4 in Table I. For the most part the agreement between the two columns is fairly good.

On the other hand, hydrocyanic acid, formic acid, formamide, water, most of the alcohols, and a few other substances have dielectric constants much greater than corresponds to this empirical relation. Most of these will be recognized as liquids which are generally supposed to be strongly associated due to the formation of hydrogen bonds. Kumler has pointed out[6] that such liquids show abnormalities in regard to boiling point and dielctric constant, and it is not surprising that they should be exceptional in the present case. It would simply mean that the actual polarizations for the liquid state are quite different from the ideal values calculated from the moments taken from the literature.

In Fig. 2, values of the polarization per gram, calculated from the relation $p' = (\epsilon + 1)/8.5\rho$, ρ denoting density, are plotted against the reciprocal of the absolute temperature for a number of liquids for which data are available. The result should in each case be a straight line whose intercept on the axis of ordinates gives the sum of the atomic and electronic polarizations per cc. and whose slope gives the electric moment in accordance with the relation

$$\mu = 0.0127\sqrt{M\frac{\mathrm{d}p'}{\mathrm{d}1/T}} \times 10^{-18}\ \text{e. s. u.} \qquad (2)$$

where M is the molecular weight. The straight lines of the figure are in each case so drawn as to fit the data and at the same time give the correct intercept on the axis of ordinates (in accordance with optical or other data). Except for acetone and nitrobenzene, the nine liquids are in moderately good accordance with expectations. If we calculate the moments from the slopes of the lines as drawn we obtain the following values

Substance	μ cal. × 10^{18}	μ literature × 10^{18}
Chloroform	1.22	1.10–1.15
o-Toluidine	1.63	1.44–1.65
Ethylene chloride	1.96	1.12–1.75
Pyridine	2.24	2.11–2.21
Benzyl cyanide	3.27	3.47–3.56
Acetone	2.85	2.61–2.97
Nitrobenzene	4.29	3.66–4.08
Nitromethane	3.40	3.02–3.78
Water	2.77	1.88

The moments calculated in this way are in good agreement with the values from the literature, except for water, which, as was pointed out above, is in all probability much associated.

In the case of the ten liquids studied under

---

[6] Kumler, This Journal, 57, 600 (1935).

pressure by Danforth,[7] the variation of dielectric constant with density is very nearly linear and in accordance with the empirical relation presented above, except for the two non-polar liquids, pentane and carbon disulfide, and for ethyl ether and glycerol. For the others the quantity $(\epsilon + 1)/8.5\,\rho$ varies over the whole range by no more than about 3% at most, in some cases much less. This is probably almost within the experimental error. For ether and glycerol the variation is somewhat more than 10%.

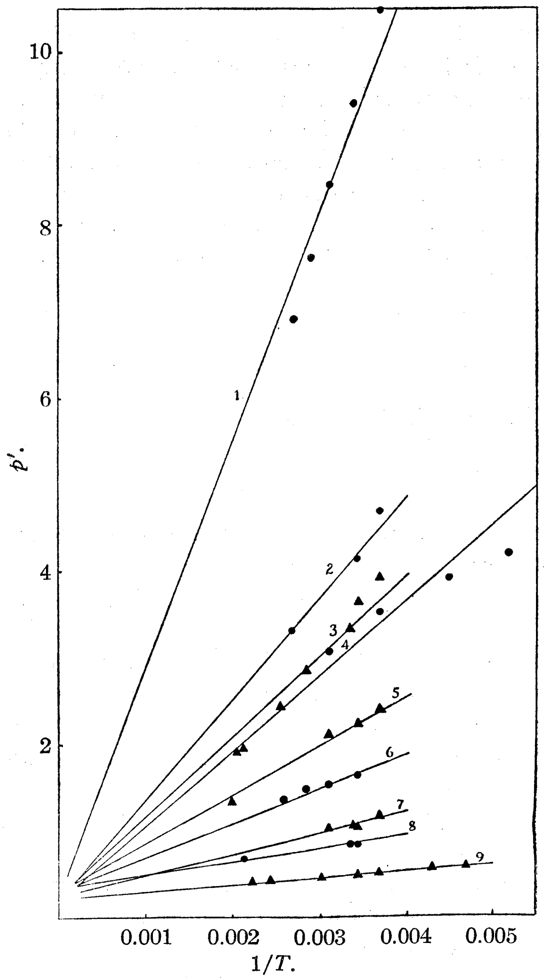

Fig. 2.—1, Water; 2, nitromethane; 3, nitrobenzene; 4, acetone; 5, benzyl cyanide; 6, pyridine; 7, ethylene chloride; 8, *o*-toluidine; 9, chloroform.

It is of interest to consider the meaning of the empirical relation just presented in terms of the internal field F. On the basis of the classical theory

$$F = E + (4/3)\pi I = E + pF \qquad (3)$$

where E is the electric intensity and I the electric moment per unit volume. Hence

$$F/E = 1/(1 - p) \qquad (4)$$

On the other hand, if the dielectric constant be linear in p

$$\epsilon = ap + b \qquad (5)$$

where a and b are constants.

But from the fundamental theory

$$E(\epsilon - 1) = 4\pi I = 3pF \qquad (6)$$

whence

$$\frac{F}{E} = \frac{1}{3}\left(a + \frac{b-1}{p}\right) \qquad (7)$$

The graphs of these two expressions are shown in Fig. 3 (b is taken as -1 and a as 8.5 in accordance with what we have found). Both curves are hyperbolas and we must suppose that the transition from one to the other occurs somewhat as shown by the dotted line, between $p = 0.3$ and $p = 1.3$ or between $\epsilon \cong 3$ and $\epsilon \cong 10$. It is of course always possible to calculate p from ϵ if F/E is known by means of the relation

$$p = \frac{E}{F}\frac{(\epsilon - 1)}{3} \qquad (8)$$

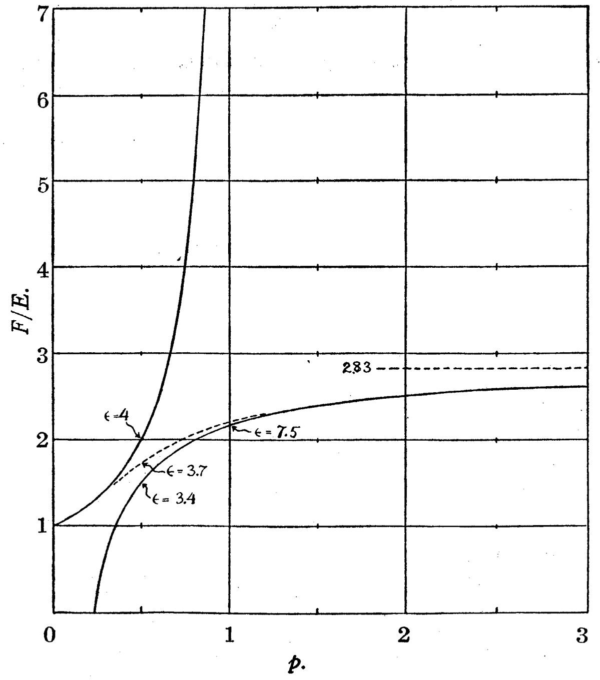

Fig. 3.—F/E, the ratio of the internal field to the electric intensity, as a function of the polarization per cc. (a) in accordance with the Clausius-Mosotti relation (left-hand full curve), (b) on the basis of the empirical equation 1 (right-hand full curve). The right-hand curve approaches $F/E = 2.83$ asymptotically.

---

[7] Danforth, *Phys. Rev.*, **38**, 1224 (1931).

which is general.[8]

It is of interest also to consider the moment of glycine calculated from the relation given above. On the basis of the observations in water at 25° the polarization is 3060 cc. and the moment 12.2 × 10^{-18} e. s. u. This would correspond to a dipole distance of 2.55 Å. Recent calculations based on a model proposed by Kirkwood[9] give a value of 3.17 Å. for this distance, or a moment of 15.2 × 10^{-18} e. s. u.

Summary

A correlation of the dielectric constant of a large number of polar liquids with assumed values of the polarization per cc. calculated by ascribing to the molecules in the liquid state the electric moments obtained from measurements on the vapor and on dilute solutions in non-polar solvents suggests an empirical relation between polarization and dielectric constant: $p = (\epsilon + 1)/8.5$. This relation is fairly satisfactory when applied to the variation of dielectric constant with temperature and with pressure in the case of a number of polar liquids for which data are available. The meaning of such a relation in terms of the internal field in the liquid is discussed.

---

[8] It may also be worth mentioning the implication of *any* linear relation between polarization and dielectric constant in the case of anomalous dispersion. According to the Debye treatment, based on the Clausius–Mosotti equation, the absorption index reaches a maximum at a frequency given by

$$2\pi\nu = \frac{1}{\tau}\,\frac{\epsilon_0 + 2}{\epsilon_1 + 2}\sqrt{\frac{\epsilon_1}{\epsilon_0}}$$

where τ is the relaxation time, ϵ_0 the dielectric constant at low frequencies and ϵ_1 the dielectric constant at frequencies above the region of dispersion. On the other hand, if the Clausius–Mosotti relation be replaced by any linear relation, the same for both ϵ_0 and ϵ_1, this expression reduces to

$$2\pi\nu = \frac{1}{\tau}\sqrt{\frac{\epsilon_1}{\epsilon_0}}$$

(see Debye, "Polar Molecules," Chemical Catalog Co., New York City, 1929).

Electric Moments of Molecules in Liquids

BY LARS ONSAGER

In its original, still generally accepted, form Debye's dipole theory[1] accounts quantitatively for the dielectric properties of gases, and qualitatively for those of liquids. In view of the extensive and consistent evidence the fundamental hypothesis of molecules possessing permanent electric moments is not in doubt.

When the theory is applied to liquids (and solids), the interaction of a molecule with its environment must be taken into account. For this purpose, Debye borrowed the theory of "internal field" which was developed by Clausius and Mosotti, one that has been applied universally and with remarkable success to aggregates of polarizable molecules. According to this theory, the "internal field" which polarizes a molecule in the dielectric equals the external field, augmented by $(4\pi/3)$ times the electric moment induced in a unit volume of the dielectric. Debye's implicit assumption is that the force-couple which tends to orient an electrically asymmetric molecule in a polarized dielectric is proportional to the same "internal field." This assumption leads to Debye's well-known formula for the dielectric constant (ϵ)

$$\frac{\epsilon - 1}{\epsilon + 2} = \frac{4\pi}{3}\sum N\left(\alpha + \frac{\mu^2}{3kT}\right) \qquad (1)$$

where α denotes the polarizability of the molecule, μ its permanent electric moment, kT the energy of thermal agitation, and N the concentration (molecules/cc.), and the summation is extended over all species of molecules present.

Formula (1) can be tested in a number of ways. When only a single species of molecules is present, one can compute the dipole moment μ, with the aid of Eq. 1, from the observed dielectric constant, and the test is whether the dipole moments computed for the liquid state or in liquid mixtures with a non-polar component remain the same as that observed in the vapor state. A more thorough analysis of the problem shows that one should not expect the dipole moment to remain quite constant, because all real molecules have a positive polarizability α. The polarization of the dielectric in the electric field of the molecule itself gives rise to a *reaction field*, which tends to enhance the electrical asymmetry.

---

[1] P. Debye, *Physik. Z.*, **13**, 97 (1912).

When Eq. 1 is compared with experience, one finds in general that for dilute solutions of polar substances in non-polar liquids the moments inferred with the aid of the formula come out approximately the same as in the vapor state, although with a systematic tendency for μ to decrease with increasing dielectric constant of the environment.[2] For pure polar liquids one computes very small moments; the discrepancy is more pronounced the higher the dielectric constant of the liquid. The reason for this remarkable result is the nature of the function $(\epsilon - 1)/(\epsilon + 2)$, which cannot exceed unity. Accordingly, Eq. 1 requires for any dielectric

$$(4\pi/3)\left(\alpha + \frac{\mu^2}{3kT}\right) \leqq \text{molecular volume}$$

The point of equality is known as the "Curie point"; it is characterized by an infinite dielectric constant. Beyond the Curie point, the theory predicts a stable state of permanent electric polarization, like the familiar permanent magnetic polarization of iron. Some bodies are actually capable of existing in such a "ferroelectric" state; the best known example is perhaps that of Rochelle salt, a solid. Nevertheless, the phenomenon is quite rare and certainly not, as one should expect from Eq. 1, a common occurrence with polar substances.

According to Eq. 1, a polar liquid with a high dielectric constant should necessarily be close to its Curie point, and, in this region its dielectric constant should be very sensitive to variations of all pertinent factors (temperature, pressure, field intensity), as seen from the formula

$$\Delta\epsilon = \frac{(\epsilon + 2)^2}{3}\,\Delta\left(\frac{\epsilon - 1}{\epsilon + 2}\right)$$

Like the Curie point, this predicted instability always fails to materialize; the observed variations of the electric susceptibility with temperature, pressure, volume and field intensity are of a smaller order of magnitude than those predicted by the theory.

This rather brief outline may suffice for a perspective of the difficulties which the original theory has encountered. Many authors have resigned themselves to the view that the consistent discrepancies were due to "association"; in other words, the forces between the polar molecules were so strong that their effects would not admit of any simple description.

J. Wyman[3] has shown that certain simple, general relations are approximately fulfilled by a large class of polar liquids, for example

$$(\epsilon - 1)\,T \sim \text{constant} \qquad (2)$$

Such a discovery belies the pessimistic expectations of the "association theory," and indicates that our theoretical understanding of polar liquids is capable of great advancement.

Without reference to any particular theory, by straightforward thermodynamic reasoning, Wyman's relation (2) implies quite simply that the polarization of the dielectric (by orientation) involves practically no change of the internal energy. According to Debye's theory, the polarization should be greatly enhanced by the internal field, and the consequent reduction of the energy should often be much greater than the work required to accomplish the polarization.

Analysis of the Internal Field

We shall show presently that the original Mosotti theory of the internal field is not applicable to permanent dipoles, in that only a certain part of it, which we might call the *cavity field*, contributes to the orienting force-couple. The remaining part of the internal field, the *reaction field*, is parallel to the dipole moment; it has therefore the very different effect of enhancing both the permanent and the induced dipole moments, in a ratio given by the polarizability of the molecule.

For cases where the electric polarization by orientation is but a small fraction of the whole, the modification of the theory involves the underlying picture more than the predicted results. For cases where the polarization is mainly due to orientation, the predictions of the new theory are very different; for example, no Curie point is expected.

Our molecular model will be the same as that of the Debye theory. While the shape of the molecules will affect the result, in the present article our concern shall be limited to spheres, whose radius will be denoted by a. Further pertinent characteristics of a molecule are its polarizability, α, related to an "internal refractive index" n as follows

$$\alpha = \frac{n^2 - 1}{n^2 + 2}\,a^3 \qquad (3)$$

and a permanent electric moment μ_0 (*in vacuo*). In an electric field, **F**, the total electric moment,

---

[2] H. Mueller, *Physik. Z.*, **34**, 689 (1933).

[3] Wyman, THIS JOURNAL, **58**, 1482 (1936).

is the vector sum of the permanent and the induced dipole moments

$$\mathbf{m} = \mu_0\mathbf{u} + \alpha\mathbf{F} \tag{4}$$

where **u** denotes a unit vector in the direction of the dipole axis. The statistical *a priori* expectation of **u** is isotropic.

First, let us consider an unpolarized medium of dielectric constant, ϵ, and introduce a rigid dipole of moment m into a cavity of radius a. For simplicity, let the dipole be a point singularity of the electric field, situated in the center of the spherical cavity. The potential ψ has to satisfy Laplace's equation

$$\Delta\psi = 0 \tag{5a}$$

and the formulation of the boundary conditions in polar coördinates is

$$\psi(r,\theta) - \frac{m\cos\theta}{r^2} = \text{continuous} < \infty \tag{5b}$$

$$\left(\frac{\partial\psi}{\partial r}\right)_{r = a - 0} = \epsilon\left(\frac{\partial\psi}{\partial r}\right)_{r = a + 0} \tag{5c}$$

The solution of this problem is

$$\begin{aligned} \psi &= \frac{m\cos\theta}{r^2} - Rr\cos\theta,\ (r < a) \\ \psi &= \frac{m^*\cos\theta}{\epsilon r^2},\ (r > a) \end{aligned} \tag{6}$$

whereby the coefficients m^* and R must equal

$$\begin{aligned} m^* &= \frac{3\epsilon}{2\epsilon + 1}\, m \\ R &= \frac{2(\epsilon - 1)}{2\epsilon + 1}\,\frac{m}{a^3} \end{aligned} \tag{7}$$

The former may be called the *external moment* of the immersed dipole; it determines the force (modified by the intervening medium), which the dipole will exert upon a distant charge in the dielectric. The coefficient R measures the electric field which acts upon the dipole as a result of electric displacements induced by its own presence, we shall refer to it as the *reaction field.*

For a neutral, spherical molecule with an arbitrary distribution of charges the above relations between m, m^* and R still maintain. In this more general case m is the actual dipole moment of the molecule, while m^* measures the dipole part of its external field, and R the homogeneous part of the reaction field. This important rule, that m^* and R are determined by m alone, independently of higher electric moments, admits of generalization to ellipsoidal molecules, whereby the coefficients naturally depend on the axes ($2a$, $2b$, $2c$) of the ellipsoid.

As a complement to this consideration of an immersed dipole in the absence of an external field, let us recall the familiar results for the modification of a homogeneous field E by an empty spherical cavity. The mathematical problem is the same as before, except that (5b) is replaced by

$$\psi(r,\theta) + Er\cos\theta = \text{continuous} < \infty \tag{8b}$$

and the solution is

$$\begin{aligned} \psi &= -Er\cos\theta - (M/r^2)\cos\theta,\ (r > a) \\ \psi &= -Gr\cos\theta \qquad\qquad\qquad\ ,\ (r < a) \end{aligned} \tag{9}$$

with the coefficients

$$\begin{aligned} M &= \frac{\epsilon - 1}{2\epsilon + 1}\, Ea^3 \\ G &= \frac{3\epsilon}{2\epsilon + 1}\, E \end{aligned} \tag{10}$$

In passing, we observe a reciprocal relation between this case and Eq. 7, namely

$$G/E = m^*/m = 3\epsilon/(2\epsilon + 1) \tag{11}$$

By combining the results (7) and (10) we now find the total field F which acts upon a spherical molecule in a polarized dielectric
