tone solution. No correction was necessary for initial dissociation of the cyanohydrin (Eqs. 2 and 3) for the calculation of the rate constant, since the dissociation was negligible due to the high acetone concentration. In these solvents equilibrium is reached when the reaction has proceeded about 60%, so that for each solvent the equilibrium was determined and used in the calculation of the rate constant. Table V presents typical data in which k_t has been calculated, using the equation

$$dx/dt = k_t(a - x)(b - x) - k_2x^2$$

where k_t and k_2 are specific velocity constants of the forward and reverse reactions, respectively.

The Rate Law in Alcohol. Catalysis by Acetone.—It is found in alcohol containing up to 1.4 *M* acetone that the rate constant calculated from the bimolecular rate law decreases as the initial concentration of the reactants increases. The rate of the reaction is actually independent of acetonecyanohydrin and at constant acetone concentration is proportional to the concentration of diethylamine as shown in Figs. 3 and 4. Since the acetone concentration is high,[9] the dissociation of cyanohydrin is small and may be considered to be constant over the small portion of the total reaction studied. The data are shown graphically in Figs. 3 and 4 where the logarithm of the diethylamine concentration is plotted against the time. The velocity constants, summarized in Table VII, were evaluated by multi-

[9] In Expt. E16 no acetone was added; that present was due to dissociation of the cyanohydrin. The initial reaction rate only was calculated, as the acetone concentration was not constant in this case.

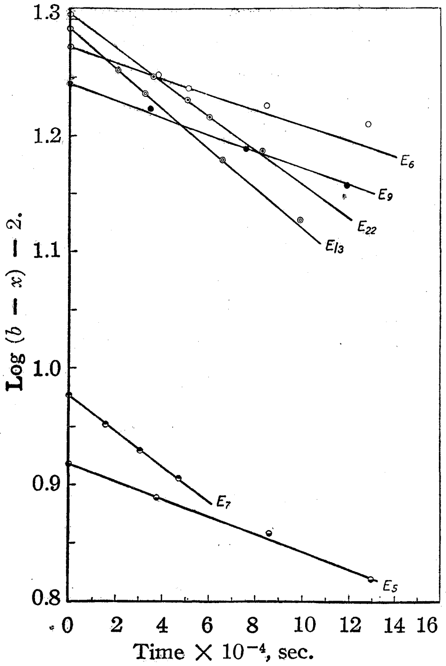

Fig. 3.—The reaction rate in ethanol.

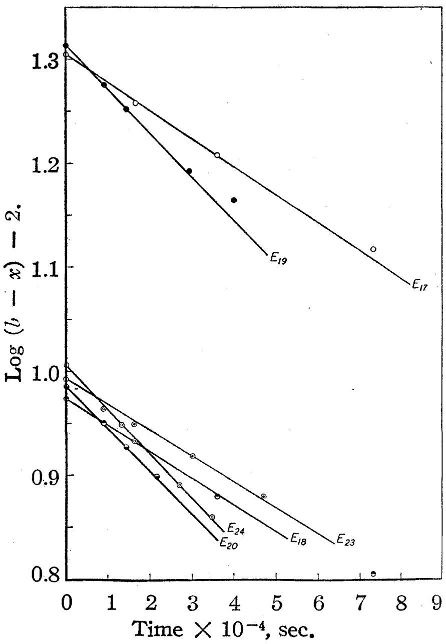

Fig. 4.—The reaction rate in ethanol.

plying the negative slopes of the straight lines by 2.303. In Fig. 5 the acetone concentration is plotted against the unimolecular rate constants of Table VII. The result indicates a reaction rate proportional to the acetone concentration.

Discussion of Results

Empirical rate laws have been obtained in solutions using acetone as solvent with varying amounts of alcohol present, and in solutions using alcohol as solvent with varying acetone content. For the first series the rate law found is

$$d(P)/dt = k''(\text{amine})(\text{cyanohydrin}) \qquad (A)$$

where P is the product of the reaction.

In ethanol as solvent a different rate law has been found

$$d(P)/dt = k'(\text{acetone})(\text{amine}) \qquad (B)$$

It is improbable that these rate laws should involve two fundamentally different mechanisms, and an attempt will be made to derive them from a simple mechanism.

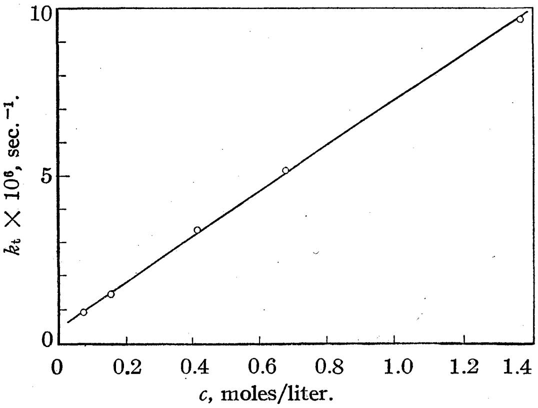

Fig. 5.—Effect of acetone concentration upon the specific reaction rate in alcohol.

The Reaction Mechanism.—Assume the existence of the reaction

$$R_2C{=}O + R_2NH \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R_2C(OH)NR_2 \qquad (13)$$

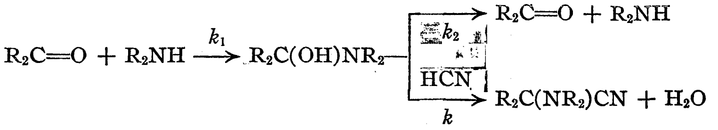
where k_1 is the specific rate of amino alcohol formation and k_2 its specific dissociation rate. We also assume that the mechanism of aminonitrile formation may be expressed

$$d(P)/dt = k(\text{amino alcohol})(\text{HCN}) \qquad (C)$$

The concentration of the hydrocyanic acid is determined by the equilibrium

$$R_2C(OH)CN \rightleftharpoons R_2C{=}O + HCN \qquad (14)$$

From these considerations the empirical rate laws above (Eqs. A and B) may be derived upon the additional assumptions that in acetone as a solvent the equilibrium between the amino alcohol, acetone and amine (Eq. 13) is maintained as the reaction proceeds, whereas in alcohol as a solvent the amino alcohol is no longer at its equilibrium concentration but a low steady state value. This value is determined largely by the acetone concentration. A low acetone concentration permits a higher hydrocyanic acid concentration (Eq. 14) and thereby decreases the probability that any amino alcohol formed will dissociate into its original constituents.



$$R_2C{=}O + R_2NH \xrightarrow{k_1} R_2C(OH)NR_2 - \begin{cases} \xrightarrow{k_2} R_2C{=}O + R_2NH \\ \xrightarrow[k]{HCN} R_2C(NR_2)CN + H_2O \end{cases}$$

The rates of appearance and disappearance of amino alcohol may be expressed

$$\mathrm{d(amino\ alcohol)}/\mathrm{d}t = k_1\mathrm{(acetone)(amine)}$$
$$-\mathrm{d(amino\ alcohol)}/\mathrm{d}t = k_2\mathrm{(amino\ alcohol)} + k\mathrm{(amino\ alcohol)\ (HCN)}$$

When the steady state is established, these rates are equal and

$$\mathrm{(amino\ alcohol)} = \frac{k_1\mathrm{(acetone)\ (amine)}}{k\mathrm{(HCN)} + k_2}$$

Therefore

$$\mathrm{d(P)}/\mathrm{d}t = \frac{k_1\mathrm{(acetone)\ (amine)\ (HCN)}}{k\mathrm{(HCN)} + k_2} \qquad \mathrm{(D)}$$

If k_2 is small and negligible in comparison with the factor k(HCN), Equation (D) becomes

$$\mathrm{d(P)}/\mathrm{d}t = k'\mathrm{(acetone)(amine)} \qquad \mathrm{(B)}$$

which is the empirically determined rate law, and implies that the major rate determining step is the rate of amino alcohol formation.

In acetone as the solvent, where the amino alcohol is maintained at or near its equilibrium concentration[10]

$$\mathrm{(amino\ alcohol)} = k_1/k_2\mathrm{(acetone)(amine)}$$

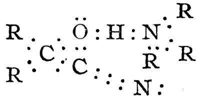
and from Equations C and 14

$$\mathrm{d(P)}/\mathrm{d}t = kk_1k_2\mathrm{(acetone)(amine)(HCN)} \qquad \mathrm{(E)}$$
$$= k''\mathrm{(amine)(cyanohydrin)} \qquad \mathrm{(A)}$$

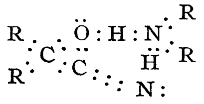
It is thus possible to use a single reaction mechanism (Eq. C) involving amino alcohol and hydrocyanic acid over the whole range of mixed solvents, and yet account in a simple way for the observed change in the rate law from an apparent bimolecular form in pure acetone, to a pseudo-monomolecular law in alcohol as a solvent.

The Catalytic Effect of Tertiary Amines and Alcohols.—The factor described as (HCN) in the rate determining steps (Eq. C) was evaluated from Eq. 14 as the ratio: (cyanohydrin)/(acetone). An equally valid evaluation would be the ratio: (amine cyanide salt)/(amine). Actually, hydrocyanic acid is present not only as such, but in various solvated forms; the cyanohydrin itself as well as a tertiary amine salt could be considered as belonging to the solvated hydrocyanic acid species of molecule, and as such enter the rate law. Each such variation of hydrocyanic acid would contribute to the total reaction rate in a specific and characteristic way. From the slopes of the curves in Figs. 1 and 2 the catalytic constants in acetone for the alcohols and amines appear in the order: ethanol, 4.0; methanol, 8.0; tri-*n*-propylamine, 89; and triethylamine, 154.

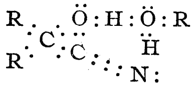
It is striking that there is no evidence of the secondary amine (one of the reactants) taking the place of the tertiary amine (a catalyst) and thereby entering the rate law to the second power. A ten-fold excess of diethylamine was used to test this, and any adequate hypothesis of this catalytic action should consider it. It is obvious that as bases, the tertiary and secondary amines are nearly equivalent, but in one respect their complexes with acetone cyanohydrin are very different.



I



II



III

Formulas II and III present chelated complexes between the cyanohydrin and secondary amine and alcohol. In these cases, the presence of the protons from the secondary amine and alcohol, respectively, offers opportunity for completion of a ring structure through hydrogen bond formation between the cyanide group and the nitrogen or oxygen atoms. The corresponding tertiary amine structure is not chelated, and, as discussed in the Introduction, its formation would increase the reactivity of the cyanide residue and thereby increase the availability of cyanide for replacement of the hydroxyl group of the amino alcohol (Eqs. 11 and 12). Chelation in II would both stabilize the complex, and in case of rupture of the carbon–cyanide bond, effectively reduce the activity of the cyanide ion by its association with the amine residue. The alcohol complex, on the other hand,

---

[10] The fact that pure acetone and diethylamine react only slightly to form the amino alcohol is indicated by the properties of their binary solution. Results of this study will appear in a separate communication.

is intermediate in its reactivity; as a chelated structure it might be reasonably stable and less reactive than the tertiary amine derivative; as an oxonium rather than an ammonium derivative it would offer a source of hydrocyanic acid far more reactive than the secondary amine complex. It is interesting that *t*-butyl alcohol and dioxane do not participate in this catalysis, a result which clearly indicates that these substances are no better proton acceptors than acetone, and very much poorer than the primary alcohols.[11]

The Reaction in Alcohol.—The pseudo first order reaction found in alcohol as a solvent is well supported. Doubling cyanohydrin concentration produces very little difference in the rate of the reaction, as measured by the slopes of the curves in Figs. 3 and 4. On the other hand, doubling the amine concentration doubles the actual rate but not the specific rate. Moreover, tertiary amines do not catalyze the reaction in alcohol, that is, under conditions where the rate determining step is primarily amino alcohol formation. Since the reaction probably comes to an equilibrium at close to 60% completion in alcohol, the measurements have been carried to but 25% in any one experiment. In Fig. 3, Curve E_{22}, there is evidence of a slower reaction than would be predicted from Curves E_7 and E_{13}, and this may be ascribed to the fact that amine is in excess in this experiment, with consequent increase in the steady state value of the amino alcohol concentration. The fact that in Fig. 5 where the specific reaction rate constant is plotted against the acetone concentration, the straight line does not pass through the origin, indicates that the steady state value of the amino alcohol concentration is not zero, but decreases relatively with decreasing acetone concentration. At any one acetone concentration k_2 is small compared to k_2 (HCN) as discussed above, and no interference arises with the apparent first order law. The accuracy of the data does not warrant an attempt to calculate specific values for k_1, k_2 and k_3 which would be required for a complete analysis.

Experimental

Materials.—The preparation of acetonecyanohydrin has been described already.[11] All amines were fractionated after standing over fused potassium hydroxide for at least one week. The fractions used distilled as follows: $(C_2H_5)_2NH$, 55.46° (corr.); $(C_2H_5)_3N$, 89.23° (corr.); and $(CH_3CH_2CH_2)_3N$, 156.47° (corr.). Acetone was refluxed for several days with solid potassium permanganate, distilled, dried over calcium chloride and fractionated in a 1-meter column of the Podbielniak type. The central fraction had a constant boiling point of 56.20° (corr.). Alcohols were treated as previously described.[11]

Experimental Procedure.—The diethylamine was dissolved in the dried solvent, pure acetone or acetone–alcohol mixtures, in known concentrations, and added to weighed portions of cyanohydrin in a thermostat. Aliquot parts of this solution were transferred at known time intervals to known volumes of 0.020 *M* silver nitrate in 0.20 *M* nitric acid solution and the mixture allowed to stand for an hour to complete the precipitation of silver cyanide. The latter was then filtered off, washed with water, and the filtrate titrated with standard thiocyanate using ferric alum as indicator. Accuracy in the end-point depends upon having an appreciable excess of silver nitrate in the filtrate and thorough removal of the precipitated silver cyanide.

The above analytical method for the determination of the amount of aminonitrile formed depends upon several factors. In the presence of appreciable acetone the cyanohydrin does not dissociate hydrocyanic acid, even in the presence of amines. In the solvents low in acetone allowance was made for such dissociation. Neither does the cyanohydrin lose cyanide ion to acidified silver nitrate. The rate at which aminonitrile loses cyanide ion depends upon the acidity. When the excess nitric acid is 0.05 *M*, half of a given amount of aminonitrile reacts in three minutes; when the excess acid is 0.13 *M* the half-life is about six and one-half minutes; no appreciable reaction occurs in 1 *M* nitric acid. It is important that no local concentration of alkali exist during the mixing of the alkaline reaction mixture and the acidified silver nitrate. To avoid this, vigorous stirring is employed and a concentration of acid greater than the concentration of amine is required.

Summary

The specific reaction rates of the reaction

$$(CH_3)_2C(CN)OH + (C_2H_5)_2NH \longrightarrow (CH_3)_2C(CN)N(C_2H_5)_2 + H_2O$$

have been measured in acetone and in alcohol as solvents, and the corresponding rate laws deduced. The two rate laws are, for the alcohol and acetone solvents, respectively

$$d(P)/dt = k'(\text{acetone})(\text{amine})$$
$$d(P)/dt = k''(\text{amine})(\text{cyanohydrin})$$

These have been shown to be related through a common reaction mechanism, and this in turn has been discussed from the general standpoint of the reactions of carbonyl systems.

The Reducing Action of Primary Grignard Reagents with Trimethylacetyl Chloride

By Frank C. Whitmore, R. E. Meyer, G. W. Pedlow, Jr., and A. H. Popkin

Recent studies have been made of the reducing action of Grignard compounds on acid chlorides.[1]

In the present work, the preparation of a series of secondary carbinols, for use in subsequent rearrangement studies, involved the addition of trimethylacetyl chloride to various primary Grignard reagents. The results, tabulated below, are in accord with previous reduction studies in this Laboratory.

Grignard reagent	% Yield of reduction products $(CH_3)_3CCH_2OH$	$(CH_3)_3CHOHR$
Ethyl[2]	None	69
n-Propyl	20	76
Isopropyl	23	53
n-Butyl[3]	28	71
Isobutyl	61	26
n-Amyl	20	75
Isoamyl[4]	15	71

The reduction of trimethylacetyl chloride to trimethylcarbinol by each of the Grignard reagents except ethyl is in sharp contrast to the failure to reduce *t*-butylacetyl chloride to neopentylcarbinol even by a tertiary Grignard reagent.[1] The obvious explanation that the reduction depends on the attachment of a tertiary group directly to the COCl group is unsound since *n*- and isobutyryl chlorides are reduced to the primary alcohols in 20 and 9% yields by *t*-butylmagnesium chloride.[1]

In these reactions, trimethylacetyl chloride was added to an excess of Grignard reagent. It has since been found that the reverse addition of a primary Grignard reagent to an excess of trimethylacetyl chloride produces carbinols in the form of the corresponding esters, with a marked change in the yield of reduction products. This is being investigated further.

Grignard solutions used in this study were filtered.

Experimental

The columns used were of the total condensation variable take-off type packed with single-turn glass helices. The dimensions (cm.) are of the packed portions: Column I, 45 × 0.9; II, 35 × 1.1; III, 43 × 0.5; IV, 67 × 1.3; V, 75 × 1.2.

Addition of Trimethylacetyl Chloride to Ethylmagnesium Bromide.—The ethylmagnesium bromide was prepared from 545 g. (5 moles) of ethyl bromide, b. p. 36° at 730 mm., $n^{20}D$ 1.4240, 121.5 g. (5 moles) magnesium and 900 cc. of dry ether. Addition of 181.5 g. (1.5 moles) of trimethylacetyl chloride, b. p. 57.6° at 150 mm., $n^{20}D$ 1.4125, prepared in 84% yield from thionyl chloride and trimethylacetic acid, required two and one-half hours for completion. The complex was then decomposed with ice, extracted with ether, and after removal of ether through column IV was fractionated through column I to give fractions: 1–3, 31.9 g. ether, b. p. 34–35° at 732 mm., $n^{20}D$ 1.3532; 4–5, 12.4 g., 50–130.5°, 1.4026–1.4205; 6, 14.6 g., 130.5–133°, 1.4218; 7–11, ethyl-*t*-butylcarbinol, 75.4 g., 133–134° at 732 mm., 1.4223–1.4225; 12, 9.8 g., 85–114° at 150 mm., 1.4292; 13–15, diethyl-*t*-butylcarbinol, 43.5 g., 114.5° at 150 mm., 1.4424–1.4427; residue 10 g.

Cut 4 on refractionation through column III gave: 16, 0.5 g., b. p. 33.5–60° at 735 mm., $n^{20}D$ 1.3696; 17, 1.5 g., 60–75°, 1.4057; 18, 1.1 g., 75–110°, 1.3825; 19, 0.6 g., 110°, 1.4142; residue 0.8 g. No indication of neopentyl alcohol could be found. The identity of fractions 6–13 was proved by m. p. and mixed m. p. of 109–110° for the α-naphthylurethan of ethyl-*t*-butylcarbinol. Fractions 13–15 were diethyl-*t*-butylcarbinol, b. p. 114.5° at 150 mm., $n^{20}D$ 1.4424, d^{20}_4 0.8524, in agreement with the constants given by Nasarow.[5]

Fraction 17 contained ethyl alcohol as shown by the m. p. and mixed m. p. of the 3,5-dinitrobenzoate, 93–94°.

Addition of Trimethylacetyl Chloride to *n*-Propylmagnesium Bromide.—The addition of 181.5 g. (1.5 moles) of trimethylacetyl chloride to 4.5 moles of *n*-propylmagnesium bromide in 1900 cc. of dry ether was completed in eighty minutes. The complex was decomposed with ice, extracted with ether, and the solvent removed through column IV. The product was then fractionated through column I to give: fractions 1–4, 59.8 g. ether, b. p. 32.5–42.0° at 739 mm., $n^{20}D$ 1.3529–1.3531; 5–7, 8.9 g., 45.0–107°, 1.3821–1.3953; 8, 3.2 g., 107–110°, 1.4010; 9–12, 24.1 g., 66.5–104° at 150 mm., m. p. 50°; 13–15, 19.0 g., 104–105.5° at 150 mm., 1.4245–1.4260; 16–20, 114.0 g., 105.5–106.5° at 150 mm., 1.4270–1.4276; residue 6.4 g.

Fractions 5–7 contained *n*-propyl alcohol as identified by the 3,5-dinitrobenzoate, m. p. and mixed m. p. 73–74°.

Fractions 8–12 were neopentyl alcohol, phenylurethan, m. p. and mixed m. p. 113–114°.

Fractions 13–20 were *n*-propyl-*t*-butylcarbinol, phenylurethan, m. p. and mixed m. p. 70.5–71.5°.

Addition of Trimethylacetyl Chloride to Isopropylmagnesium Bromide.—The addition of 181.5 g. (1.5 moles) of trimethylacetyl chloride to 4.5 moles of isopropylmagnesium bromide in 900 cc. of dry ether required three

hours. The product was decomposed and extracted in the usual manner and fractionated through column V to give: fractions 1, ether, b. p. 35–36° at 743 mm., $n^{20}\text{D}$ 1.3535; 2–7, 9.6 g., 43–99°, 1.3574–1.3840; 8–12, 30.3 g., 111° at 743 mm. and 73–75° at 150 mm., m. p. 50°; 13–14, 5.9 g., 81–96° at 150 mm., 1.4108–1.4212; 15–16, 11.6 g., 98–100° at 150 mm., 1.4277–1.4285; 17–25, 93.5 g., 100° at 150 mm., 1.4290–1.4295; residue 8.2 g.

Fractions 4–6 contained isopropyl alcohol as identified by the phenylurethan, m. p. and mixed m. p. 89–90°.

Fractions 8–12 were neopentyl alcohol, phenylurethan, m. p. and mixed m. p. 113–114°.

Fractions 15–25 were isopropyl-*t*-butylcarbinol, phenylurethan, m. p. and mixed m. p. 86–86.5°.

Addition of Trimethylacetyl Chloride to Isobutylmagnesium Bromide.—Addition of 181.5 g. (1.5 moles) of trimethylacetyl chloride to 4.5 moles of isobutylmagnesium bromide was completed in three hours. The complex was decomposed and extracted in the usual manner and fractionated through column V to give: fractions 1, ether, b. p. 34–35° at 735 mm., $n^{20}\text{D}$ 1.3535; 2–9, 13.3 g., 52–104°, 1.3574–1.3952; 9–18, 81.4 g., 106–111 and 76° at 150 mm., m. p. 50°; 19–20, 3.2 g., b. p. 100–109° at 150 mm., 1.4131–1.4212; 21–22, 12.2 g., 110–111° at 150 mm., 1.4270–1.4293; 23–27, 43.2 g., 111–112° at 150 mm., 1.4299–1.4302; residue 5.8 g.

Fractions 5–8, 7.8 g., contained isobutyl alcohol, phenylurethan, m. p. and mixed m. p. 83–84°.

Fractions 9–18 were neopentyl alcohol, phenylurethan, m. p. and mixed m. p. 113–114°.

Fractions 21–27 were isobutyl-*t*-butylcarbinol, phenylurethan, m. p. and mixed m. p. 112–112.5°, α-naphthylurethan, m. p. and mixed m. p. 103.5–104.5°.

Addition of Trimethylacetyl Chloride to *n*-Amylmagnesium Bromide.—The addition of 181.5 g. (1.5 moles) of trimethylacetyl chloride to 4.5 moles of *n*-amylmagnesium bromide in 1900 cc., of dry ether was completed in two hours. The complex obtained was decomposed with ice, extracted with ether, the solvent being removed through column IV and the product on fractionation through column II gave: fraction 1–2, 17.5 g. ether, b. p. 32–55.0° at 741 mm., $n^{20}\text{D}$ 1.3535–1.3545; 3–5, 26.9 g., 55–127.0°, solid; 6, 9.6 g., 127.0–176.5°, 1.4171; 7, 4.7 g., 39–61.5° at 18 mm., 1.4340–1.4342; 8–13, 22.1 g., 61.5–86.0° at 18 mm., 1.4176–1.4332; 14–17, 77.7 g., *n*-amyl-*t*-butylcarbinol, 86.0–88.0° at 18 mm., 1.4340–1.4342; 18–19, 62.3 g., b. p. 85–89° at 17 mm., 1.4345–1.4346; 20–23, 10.2 g., 85.0–134.0° at 14 mm., 1.4360–1.4484; residue 6.8 g.

Fractions 3–5 were neopentyl alcohol, identified by the phenylurethan, m. p. and mixed m. p. 113–114°.

Fractions 6–7 failed to produce any evidence of *n*-amyl alcohol. This fraction is probably a mixture of neopentyl alcohol, *n*-amyl alcohol, and the secondary alcohol (*n*-amyl-*t*-butylcarbinol).

Fractions 8–13 and 18–23 on refractionation through column I gave: fractions 24–25, 13.1 g., b. p. 42–67.8° at 7 mm., $n^{20}\text{D}$ 1.4199–1.4294; 26–30, 56.4 g., 67.8–72.5° at 7 mm., 1.4336–1.4348; residue 4.4 g.

Fractions 14–17 and 26–30 were *n*-amyl-*t*-butylcarbinol: *MR* found 49.80, calcd. 49.92.

Addition of Trimethylacetyl Chloride to Isoamylmagnesium Bromide.—The addition of 181.5 g. (1.5 moles) of trimethylacetyl chloride to 4.5 moles of isoamylmagnesium bromide required two hours. The complex was decomposed and extracted in the usual manner and fractionated through column I, to give: fractions 1–3, 25.3 g., ether, b. p. 34–35° at 742 mm., $n^{20}\text{D}$ 1.3535; 4–7, 26.8 g., 84–113° and 62–81.5° (150 mm.), 1.4000–1.4047; 8–12, 31.6 g., 81.5–128° at 150 mm., 1.4060–1.4130; 13–15, 50 g., 128–133.2° at 150 mm., 1.4284–1.4319; 16–18, isoamyl-*t*-butylcarbinol, 80.3 g., 133.2–133.5° at 150 mm., 1.4320–1.4323; 19–20, 31.9 g., 133.5–134° at 150 mm., 1.4325; 21–22, 24.4 g., 99–108° at 18 mm., 1.4407–1.4410; residue 1.6 g.

Fractions 4–7 were refractionated through column III to give: fractions 23–27, 3.4 g., b. p. 33–107° at 735 mm., $n^{20}\text{D}$ 1.3540–1.4080; 28–29, 20.5 g., 107–126°, solid; residue 2.2 g.

Fractions 8–12 were refractionated through column III to give: fractions 30–32, 8.4 g., b. p. 73–101 at 150 mm., $n^{20}\text{D}$ 1.4072–1.4080; 33–37, 14.2 g., 101–105.5° at 150 mm., 1.4098–1.4100; residue 1.7 g.

Fractions 30–32 contained isoamyl alcohol, phenylurethan, m. p. and mixed m. p. 54°.

Fractions 28–29 were neopentyl alcohol, phenylurethan, m. p. and mixed m. p. 113–114°.

Fractions 33–37 were olefins formed by the dehydration of isoamyl-*t*-butylcarbinol, d^{20}_4 0.7278; *MR* calcd. 47.43; found 47.37.

Fractions 13–20 were isoamyl-*t*-butylcarbinol d^{20}_4 0.8236; *MR* calcd. 49.92, found 49.74.

Fractions 21–22 were olefins from the dehydration of diisoamyl-*t*-butylcarbinol, d^{20}_4 0.7772; *MR* calcd. 71.03, found 71.34.

Summary

1. The reducing action of Grignard reagents with acid chlorides has been studied further by the addition of trimethylacetyl chloride to the Grignard reagents of ethyl, *n*- and isopropyl, *n*- and isobutyl and *n*- and isoamyl.

2. Neopentyl alcohol was obtained with all except the ethylmagnesium bromide. Even the latter gave reduction as represented by a 68% yield of ethyl-*t*-butylcarbinol.

The Action of Primary Grignard Reagents with *t*-Butylacetyl Chloride. II[1]

By Frank C. Whitmore, J. S. Whitaker, K. F. Mattil and A. H. Popkin

This is a continuation of the studies in this Laboratory on the reducing action of Grignard reagents.[2]

In the first paper of this title[1] the acid chloride was added to excess of Grignard solutions. The chief products isolated were tertiary alcohols of the type $(CH_3)_3CCH_2C(OH)R_2$ in which R was ethyl, *n*-propyl, *n*-butyl, or *n*-amyl, and the corresponding olefins $(CH_3)_3CCH{=}CR_2$ and their isomers. The other products were secondary carbinols of the type $(CH_3)_3CCH_2CHOHR$, in which R was *n*-propyl, *n*-butyl, or *n*-amyl. No reduction product of this type was found when ethylmagnesium bromide was used.

In the present study each of the four Grignard solutions was added to a slight excess of *t*-butylacetyl chloride in anhydrous ether.

Ethylmagnesium bromide gave the largest amount of the primary product, the ketone of the type $(CH_3)_3CCH_2COR$, giving about 51% of neopentyl ethyl ketone. The *n*-propyl, *n*-butyl, and *n*-amyl Grignard reagents gave 37, 34, and 29%, respectively, of the corresponding ketones.

Reduction by means of the Grignard reagent would convert these ketones to secondary carbinols $(CH_3)_3CCH_2CHOHR$. These would appear as the *t*-butylacetates. About 7% of such reduction took place with the ethyl Grignard solution. This is in contrast to the result of adding the acid chloride to the ethyl Grignard solution which gave no reduction.[1] The other three Grignard solutions gave about 20, 23, and 21% of the corresponding secondary alcohols as the *t*-butylacetates.

It is significant that these yields are nearly the same as those obtained by adding the acid chloride to an excess of the Grignard reagents.[1] As in the earlier experiments no trace of neopentylcarbinol or its ester was found even by extended searches. This is in contrast to the action of trimethylacetyl chloride which gives neopentyl alcohol in about 20% yields with *n*-propyl, *n*-butyl, and *n*-amyl Grignard reagents.[2]

A small amount of ethyl *t*-butylacetate was found in each of the four reactions. This was due apparently to interaction of the acid chloride with the solvent ether.

The Grignard solutions used were filtered from free magnesium under nitrogen pressure.

Experimental

The *t*-butylacetyl chloride, b. p. 76–77° at 140 mm., n^{20}_D 1.4212, used in these reactions was prepared, in 86% yield, from *t*-butylacetic acid and thionyl chloride.

The Grignard compounds were prepared from the corresponding alkyl bromides, magnesium, and dry ether in the usual way. They were filtered and titrated.

Addition of Ethylmagnesium Bromide to *t*-Butylacetyl Chloride.—Ethylmagnesium bromide (1.84 moles in 1 liter of ether) was added to 250 g. (1.86 moles) of *t*-butylacetyl chloride in 1200 cc. of ether, during fifty minutes. After standing overnight, the complex was decomposed with ice, extracted with ether, and the products after removing most of the solvent using column XII[3] were fractionated through column XI, using a solid carbon dioxide trap, to give: nos. 1–5, 71.4 g., b. p. 98–100° at 200 mm., n^{20}_D 1.4150–1.4163; residue 130 g.; trap contents 68 g. All fractions contained water, indicating dehydration.

The trap contents with nos. 1–5 were refractionated through column XI to give: 6, 27.5 g., 35° at 736 mm., 1.3580; 7, 1.4 g., 133°, 1.4060; 8–12, 46.5 g., 143°, 1.4150–1.4160. The main residue was added and fractionation continued to give: 13–22, 101.2 g., 62–110° at 23–74 mm., 1.4120–1.4163; 23–24, 14.5 g., 118° at 23 mm., 1.4253–1.4263; 25–27, 15.7 g., 118–135° at 23 mm., 1.4323–1.4500; residue 5 g.

Fractions 6–22, 25–27, and the residue were again refractionated, by parts, through column XI to give: 28–37, 123.2 g., 92° at 150 mm., 1.4130–1.4160; 38, 4.2 g., 105–134° at 150 mm., 1.4175; 39, 7.0 g., 134° at 150 mm., 1.4130; 40–43, 20.0 g., 124–166° at 90 mm., 1.4152–1.4500; residue 6.2 g.

Fraction 7, ethyl *t*-butylacetate, was saponified by aqueous potassium hydroxide to give ethyl alcohol, 3,5-dinitrobenzoate, m. p. and mixed m. p. 92°; and *t*-butylacetic acid, anilide, m. p. and mixed m. p. 130–131°.

Fractions 23, 24, and part of 25 represented a 7% yield of neopentylethylcarbinyl *t*-butylacetate. Alcoholic saponification gave neopentylethylcarbinol, previously reported,[1] b. p. 96° at 150 mm., n^{20}_D 1.4248, 3,5-dinitrobenzoate, m. p. and mixed m. p. 81–82°; and *t*-butylacetic acid, anilide m. p. and mixed m. p. 130–131°.

Fractions 28–37 represented a 51% yield of ethyl neopentyl ketone, m. p. and mixed m. p. of the dinitrophenylhydrazone 135–136°.

The high index of fraction 38 appeared to be due to the

[3] The fractionating columns used have been described: Whitmore, Popkin, Whitaker, Mattil and Zech, *ibid.*, **60**, 2459 (1938).

presence of diethylneopentylcarbinol or the corresponding olefins.[1]

Fraction 39 contained *t*-butylacetic acid, m. p. and mixed m. p. of the anilide 130–131°.

All attempts to find neopentylcarbinol and neopentylcarbinyl *t*-butylacetate failed.

Addition of *n*-Propylmagnesium Bromide to *t*-Butylacetyl Chloride.—The addition of 1.85 moles of *n*-propylmagnesium bromide, in 1 liter of ether, to 260 g. (1.94 moles) of *t*-butylacetyl chloride in 600 cc. of ether, was completed in forty-five minutes. The complex stood overnight and the products were isolated as above to give: 1–18, 166.3 g., b. p. 20–98° at 11 mm., $n^{20}D$ 1.4078–1.4250–1.4147; 19–22, 45 g., 111–112° at 13 mm., 1.4272–1.4181; 23–25, 7.5 g., 121–128° at 13 mm., 1.4340–1.4442; residue 3.8 g.; trap contents 37 g.

The trap contents on removal of the ether yielded 5.7 g. of oil, $n^{20}D$ 1.3985. This oil together with 1–18 was fractionated by parts through column X to give: 26–29, 14.9 g., 95–102° at 150 mm., 1.4032–1.4085; 30, 5.9 g., 107° at 150 mm., 1.4100; 31–32, 13.1 g., 109.5°, 1.4132–1.4140; 33, 4.8 g., 99–108°, 1.4105; 34–44, 83.5 g., 108–110°, 1.4132–1.4153; 45–47, 15.2 g., 51–58° at 7 mm., 1.4161–1.4273; 48–49, 7.9 g., 64–74° at 7 mm., 1.4315–1.4228; 50–51, 16.7 g., 78°, 1.4135–1.4122; residue 1 g.

Fractions 26–29 were identified as ethyl *t*-butylacetate. Aqueous saponification gave ethyl alcohol, 3,5-dinitrobenzoate m. p. and mixed m. p. 92°; and *t*-butylacetic acid, anilide m. p. and mixed m. p. 130–131°.

Fractions 31–32 and 34–44 were identified as neopentyl *n*-propyl ketone, semicarbazone m. p. and mixed m. p.[4] 93–94°, yield 36.7%.

Fractions 47–49 contained dodecenes, as previously reported,[1] obtained by dehydration of the tertiary alcohol.

Fractions 50–51 were *t*-butylacetic acid, anilide m. p. and mixed m. p. 130–131°.

Fractions 19–22 represented a 20% yield of neopentyl-*n*-propylcarbinyl *t*-butylacetate. Alcoholic saponification gave neopentyl-*n*-propylcarbinol,[1] b. p. 120–121° at 150 mm., $n^{20}D$ 1.4270, m. p. and mixed m. p. of phenylurethan 80–82°; and *t*-butylacetic acid, m. p. and mixed m. p. of anilide 130–131°.

All attempts to find neopentylcarbinol and neopentylcarbinyl *t*-butylacetate failed.

Addition of *n*-Butylmagnesium Bromide to *t*-Butylacetyl Chloride.—The addition of 2.01 moles of *n*-butylmagnesium bromide, in 1 l. of dry ether, to 292 g. (2.18 moles) of *t*-butylacetyl chloride, in 600 cc. of ether, was completed in eighty minutes. After standing overnight the products were isolated to give: 1–18, 173.6 g., b. p. 34° at 742 mm. to 59° at 4 mm., $n^{20}D$ 1.4070–1.4195; 19–23, 27.6 g., 68–95° at 4 mm., 1.4232–1.4415–1.4365; 24–29, 55.2 g., 98–99° at 4 mm., 1.4300–1.4315; 30, 6.1 g., 109° at 4 mm., 1.4430; residue 5.1 g.; trap contents 18.6 g.

The trap contents, on removal of ether, yielded 8.9 g. of oil. This and 1–18 were fractionated by parts through column X to give: 31–32, 2.7 g., 48–52° at 150 mm., 1.4332–1.4300; 33–38, 22.6 g., 63–102°, 1.4030–1.4098; 39–43, 38.6 g., 127°, 1.4192–1.4195; 44–49, 55.0 g., 126–127°, 1.4182–1.4178; 50–53, 39.6 g., 130–134°, 1.4170–1.4150; 54–55, 8.0 g., 134–155° at 150 mm., 1.4270–1.4400; residue 2.0 g.

Fractions 33–38 were ethyl *t*-butylacetate.

Fractions 39–52 were identified as a mixture of neopentyl *n*-butyl ketone, m. p. and mixed m. p.[5] of semicarbazone 82–84°, and *t*-butylacetic acid, anilide m. p. and mixed m. p. 130–131°; which contained 105.2 g. of the ketone and 28.0 g. of the acid, as determined from a composition—index of refraction curve. This represented a 34% yield of neopentyl *n*-butyl ketone.

The index of refraction of 20–23 corresponded to tetradecenes.[1]

Fractions 24–29 with part of fraction 23 represented a 23% yield of neopentyl-*n*-butylcarbinyl *t*-butylacetate. Alcoholic saponification gave neopentyl-*n*-butylcarbinol,[1] b. p. 92° at 100 mm., $n^{20}D$ 1.4295–1.4305, phenylurethan m. p. and mixed m. p. 84–85°; and *t*-butylacetic acid, anilide m. p. and mixed m. p. 130–131°.

All attempts to identify neopentylcarbinol and its *t*-butylacetate failed.

Addition of *n*-Amylmagnesium Bromide to *t*-Butylacetyl Chloride.—Addition of 1.9 moles of *n*-amyl Grignard solution to 271 g. (2 moles) of *t*-butylacetyl chloride in fifty minutes as above gave: 1–16, 161.7 g., 67–145° at 150 mm., $n^{20}D$ 1.4240–1.4090–1.4235; 17–18, 21.8 g., 128–132° at 20 mm., 1.4342–1.4450; 19–22, 42.3 g., 133–144°, 1.4450; 23–27, 54.1 g., 146–147°, 1.4332–1.4350; 28, 7.1 g., 147°, 1.4412; residue 3 g.; trap contents 91 g.

The trap contents with fractions 1–17 gave: 29–30, 9.8 g., 65–90° at 150 mm., 1.4370–1.4210; 31–34, 45.1 g., 90–103°, 1.4060–1.4080; 35–42, 44.6 g., 103–134°, 1.4160–1.4140; 43–52, 76.3 g., 122–138°, 1.4212–1.4280; residue 1 g.

Fractions 31–34 were identified as ethyl *t*-butylacetate.

Fractions 35–42 were largely *t*-butylacetic acid, anilide m. p. and mixed m. p. 130–131°. The other component was identified as neopentyl *n*-amyl ketone, semicarbazone m. p. and mixed m. p. 99–102°.[1]

Fractions 43–52 were largely neopentyl *n*-amyl ketone. This together with an estimate from fractions 35–42 represented a 29% yield of this ketone.

Fractions 19–22 were hexadecenes.[1]

Fractions 23–27 represented a 21% yield of neopentyl-*n*-amylcarbinyl *t*-butylacetate. Alcoholic saponification of 26–27 gave neopentyl-*n*-amylcarbinol,[1] b. p. 132° at 100 mm., $n^{20}D$ 1.4340–1.4347, phenylurethan m. p. and mixed m. p. 62–63°; and *t*-butylacetic acid, anilide m. p. and mixed m. p. 130–131°.

All attempts to identify neopentylcarbinol and its *t*-butylacetate failed.

Preparation of Neopentylcarbinyl *t*-Butylacetate.—A solution of 0.8 mole of neopentylmagnesium chloride was prepared from neopentyl chloride, b. p. 82° at 740 mm., $n^{20}D$ 1.4042. An excess of dry formaldehyde, generated by heating dry paraformaldehyde, was passed into the solution during four hours. The complex was decomposed with ice and 30% H_2SO_4 and fractionated through column X to give 48 g. (0.47 mole) of neopentylcarbinol, b. p. 140–146° at 739 mm., $n^{20}D$ 1.4120–1.4034.

---

(4) This ketone and the semicarbazone prepared by H. C. Crafton, Jr., of this Laboratory.

(5) Unpublished work of E. Rohrmann, this Laboratory.

Heating 22.2 g. (0.22 mole) of the above carbinol for two hours with 29 g. (0.2 mole) of *t*-butylacetyl chloride, b. p. 79° at 150 mm., $n^{20}D$ 1.4215, and fractionation through column X gave: 1–2, 7.7 g., b. p. 78–140° at 150 mm., $n^{20}D$ 1.4050–1.4190; 3–5, 22.2 g., 104° at 26 mm., 1.4198–1.4202; residue 4.8 g.

Fractions 3–5 represented a 57% yield of neopentylcarbinyl *t*-butylacetate. Saponification of 16.0 g. of this ester with alcoholic potassium hydroxide gave neopentylcarbinol, α-naphthylurethan m. p. and mixed m. p. 81–82°; and *t*-butylacetic acid, anilide m. p. and mixed m. p. 130–130.5°.

Preparation of Ethyl *t*-Butylacetate.—A mixture of 57.5 g. (0.54 mole) of *t*-butylacetic acid, $n^{20}D$ 1.4096, 125 cc. of absolute ethyl alcohol, and 25 cc. of concd. sulfuric acid was refluxed fifteen hours. The mixture was dissolved in ether, washed with water and dilute potassium carbonate solution, dried over magnesium sulfate, and fractionated through column X to give 60.1 g. or a 77% yield of ester of b. p. 102° at 740 mm., $n^{20}D$ 1.4032–1.4040.

Summary

1. Ethyl, *n*-propyl, *n*-butyl, and *n*-amyl Grignard solutions, when added to a slight excess of *t*-butylacetyl chloride, gave ketones of the type $(CH_3)_3CCH_2COR$ in about 51, 37, 34, and 29% yields, respectively. They also gave esters of the type $(CH_3)_3CCH_2CHROCOCH_2C(CH_3)_3$. The latter were obtained in about 7, 20, 23, and 21% yields, respectively, from the four Grignard solutions.

2. Ethyl *t*-butylacetate and neopentylcarbinyl *t*-butylacetate have been prepared.

STATE COLLEGE, PENNA. RECEIVED AUGUST 24, 1938

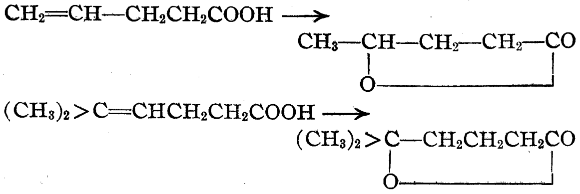
Lactone Formation in the Addition Product of Maleic Anhydride and Bicyclohexenyl

BY ROGER ADAMS AND E. E. GRUBER[1]

The addition of maleic anhydride to bicyclohexenyl takes place readily with the formation of $\Delta^{4a,5a}$ - dodecahydrophenanthrene - 9,10 - dicarboxylic acid anhydride (I).[2] During the course of the study of this compound, several reactions were noted which have a general bearing upon lactone formation of γ,δ-unsaturated acids. Linstead has demonstrated[3] that the ease and direction of lactonization of aliphatic γ,δ-olefinic acids depend on the substituents on the δ-carbon. The formation of a γ-lactone is favored if hydrogens, a δ-lactone if alkyl groups, are present. Lactonization is promoted by mineral acids and in some cases merely by heating the olefinic acids.



$$CH_2{=}CH{-}CH_2CH_2COOH \longrightarrow \begin{array}{l} CH_3{-}CH{-}CH_2{-}CH_2{-}CO \\ \qquad\;\; \lfloor O \rule[0.5ex]{6em}{0.4pt} \rfloor \end{array}$$

$$(CH_3)_2{>}C{=}CHCH_2CH_2COOH \longrightarrow \begin{array}{l} (CH_3)_2{>}C{-}CH_2CH_2CH_2CO \\ \qquad\quad\;\; \lfloor O \rule[0.5ex]{6em}{0.4pt} \rfloor \end{array}$$

When I or its anhydride (V) is esterified with absolute ethanol and hydrogen chloride, a monoethyl ester lactone (II) is obtained. Saponification of this compound gives a sodium salt of an hydroxy acid (III) which on acidification results not in the hydroxy dibasic acid but in a lactone acid (IV). By the action of heat or acetic anhydride, I forms the anhydride (V) which upon treatment with cold sodium ethylate leads to an ester acid (VI). Hot sodium ethylate, however, results in a complicated reaction, the character of which was not determined. The ester acid (VI) can be hydrolyzed by boiling with dilute alkali to the dibasic acid (I). Heating I alone gives a mixture of anhydride (V) and lactone (IV).

Of significance is the fact that the action of bromine in carbon tetrachloride differentiates between the dibasic acid derivatives and the lactone acid derivatives. Thus, compounds I, V and VI absorb bromine while compounds II and IV do not.

As lactonization of one of the carboxyls results when I or V is esterified and no diethyl ester may be isolated, it is obvious that lactonization of the second carboxyl is the more rapid of the competing reactions. Lactonization also takes place merely by heating the acid (I) in acetone solution in presence of hydrochloric acid; lactone (IV) is formed.

The structures of the lactones obviously may be either those given in II and IV or the isomeric γ-lactones. Stereochemically the γ- or δ-lac-

tones might form with equal ease. It seems likely, in view of Linstead's work, that the factors which lead to δ-lactone formation are probably more influential than those which lead to the γ-lactone.

Unfortunately, all of the reactions described are accompanied by side-products of an oily character which exclude quantitative studies.

Experimental

$\Delta^{4a,5a}$-Dodecahydrophenanthrene-9,10-dicarboxylic Acid.—The preparation of this product and its lactone was described previously.[2] The anhydride is also conveniently formed from the acid by the action of acetic anhydride.

$\Delta^{4a,5a}$-Dodecahydrophenanthrene-9,10-dicarboxylic Acid Anhydride.—A solution of 2 g. of dibasic acid in 20 cc. of acetic anhydride was refluxed for five hours. The acetic anhydride and acetic acid were removed by distillation *in vacuo* and the residue extracted with 125 cc. of hot ligroin (b. p. 60–110°). Upon filtering and evaporating to 75 cc., a tan precipitate separated on cooling. Purification from cyclohexane gave colorless crystals of m. p. 121°. The yield was low.

Monoethyl Ester of Hydroxytetradecahydrophenanthrene-9,10-dicarboxylic Acid Lactone (II).—Dry hydrogen chloride was bubbled through a solution of 11 g. of $\Delta^{4a,5a}$-dodecahydrophenanthrene-9,10-dicarboxylic acid in 150 cc. of absolute ethanol for one and one-half hours and the mixture was then refluxed on a steam cone for one hour. About 50 cc. of ethanol was distilled off and the residue poured into 200 cc. of ice water. The oil was extracted with benzene, the solution washed with dilute aqueous sodium carbonate and 10% sulfuric acid, then evaporated and the oil distilled *in vacuo*, b. p. 225–250° at 13 mm.; yield 8.2 g. (68%). After standing in a desiccator for several days, it solidified and was recrystallized from cyclohexane; white microcrystals, m. p. 109–110°.

Anal. Calcd. for $C_{18}H_{26}O_4$: C, 70.54; H, 8.56. Found: C, 70.29; H, 8.61.

The product is insoluble in cold or warm 10% aqueous sodium hydroxide but goes into solution on prolonged boiling.

A second procedure using the anhydride follows: dry hydrogen chloride was bubbled for three-quarters of an hour through a solution of 2 g. of dodecahydrophenanthrene-9,10-dicarboxylic acid anhydride in 30 cc. of absolute ethanol. After refluxing for about twenty-four hours on a steam cone, the alcohol was evaporated by means of a stream of warm air and the residue poured into water. Extraction with benzene and purification as described above gave the same product.

Tetradecahydrophenanthrene-9,10-dicarboxylic Acid Lactone (IV). Compound III as Intermediate.—A solution of 1.5 g. of the ethyl ester of the lactone in 10 cc. of 5% sodium hydroxide was refluxed for a few hours until all the solid had dissolved. Upon cooling, a solid precipitated. This proved to be a disodium salt.

Anal. Calcd. for $C_{16}H_{22}O_5Na_2$: Na, 13.51. Found: Na, 13.81.

The sodium salt, as well as the filtrate from the sodium salt, on acidification gave a precipitate, which still contained sodium. If, however, it was warmed with hydrochloric acid, a crystalline product separated on cooling. After purification from dilute acetone, it formed long blunt prisms, m. p. 246–247°.

Anal. Calcd. for $C_{16}H_{22}O_4$: C, 69.02; H, 7.97; neut. equiv., 278. Found: C, 69.14; H, 8.09; neut. equiv., 278.

Monoethyl-$\Delta^{4a,5a}$-dodecahydrophenanthrene-9,10-dicarboxylate (VI).—To a cold solution of 0.2 g. of sodium in 20 cc. of absolute ethanol was added 3 g. of $\Delta^{4a,5a}$-dodecahydrophenanthrene-9,10-dicarboxylic acid anhydride. After standing a day at room temperature, the alcohol was evaporated by means of a stream of air. The solid residue was dissolved in 35 cc. of water and acidified with dilute hydrochloric acid. The clumpy precipitate was allowed to dry and any material that gradually separated from the acidified solution added to it. Crystallization from cyclohexane, followed by several crystallizations from dilute acetone, gave small white plates, m. p. 127–128°.

Anal. Calcd. for $C_{18}H_{26}O_4$: C, 70.54; H, 8.56; neut. equiv., 306. Found: C, 70.71; H, 8.52; neut. equiv., 323.

Effect of Heat upon $\Delta^{4a,5a}$-Dodecahydrophenanthrene-9,10-dicarboxylic Acid.—A sample of 0.9 g. of acid was heated in a test-tube at 200–210° for fifteen minutes. Upon cooling, 30 cc. of cyclohexane was added and the mixture heated to boiling. Insoluble material was filtered from the hot solution. This solid product was crystallized from dilute acetone and prisms were obtained which proved to be lactone acid (IV).

Heating the acid (I) above its melting point, and direct extraction of the reaction mass with petroleum ether gave a small amount of crystalline material, m. p. 123–123.5°, which proved to be anhydride.

Conversion of $\Delta^{4a,5a}$-Dodecahydrophenanthrene-9,10-dicarboxylic Acid to Tetradecahydrophenanthrene-9,10-dicarboxylic Acid Lactone (IV).—To a solution of 2 g. of dicarboxylic acid in 50 cc. of acetone was added 10 cc. of concentrated hydrochloric acid. After refluxing for four to five hours the solution was poured into ice water and filtered. The filtrate upon evaporation left a brown crystalline residue which was recrystallized from dilute acetone; m. p. 213°.

Since the neutral equivalent determination indicated that the material was probably impure lactone acid, it was recovered and subjected to three more recrystallizations. This treatment yielded long blunt prisms, m. p. 242–244°, which proved to be the lactone acid by mixed melting point.

Summary

$\Delta^{4a,5a}$ - Dodecahydrophenanthrene - 9,10 - dicarboxylic acid and its anhydride are converted into a lactone ester and not into a diester upon esterification. Saponification of this lactone ester with alkali gives the alkali salt of an hydroxy dibasic acid which on acidification gives a monobasic acid monolactone. It is assumed by analogy to previous results on the study of γ,δ-olefinic acids that in these molecules a δ-lactone probably has formed.

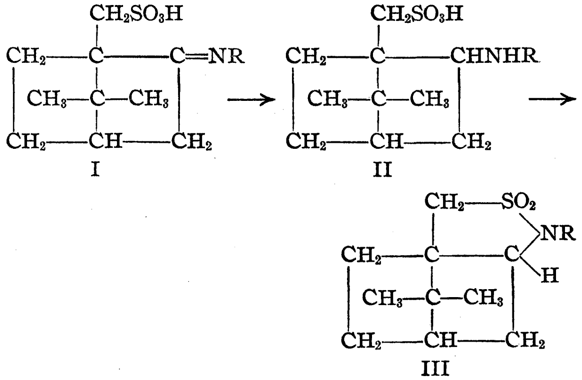
Anomalous Mutarotation of Salts of Reychler's Acid. VI. Synthesis and Structure of the Sultam of 2-(N-Methylamino)-*d*-camphane-10-sulfonic Acid

BY R. L. SHRINER, JAMES A. SHOTTON AND HARRY SUTHERLAND

One of the reactions used to establish the ketimine structure (I) of the dehydration products of primary amine salts of Reychler's acid[1] was reduction to the substituted amino sulfonic acid (II). The two forms of the latter underwent dehydration, producing compounds whose analyses and properties indicated the sultam structure,[1c] (III).



I

II

III

The purpose of the present investigation was to synthesize one of these sultams by an independent method in order to establish this structure.

Accordingly, use was made of an observation by Reychler[2] that *d*-camphor-10-sulfonamide (IV) underwent dehydration to an anhydro compound to which Armstrong and Lowry[3] had assigned the structure shown in formula V. In the present work this anhydramide was reduced catalytically with hydrogen and Raney nickel to the sultam, VI. Although the latter may exist in two diastereoisomeric forms, since carbon atom 2 is now asymmetric (*), only one form actually was produced. The sodium salt of this sultam was treated with methyl iodide and the N-methyl sultam, VII, obtained. Hydrolysis by means of concentrated hydrochloric acid opened the heterocyclic ring and produced the α-form of 2-(N-methylamino)-*d*-camphane-10-sulfonic acid (VIII). Although Reychler's acid and its amide are dextrorotatory, all the derivatives V, VI, VII and VIII were levorotatory; the specific rotations being −32, −33, −59 and −98°, respectively.

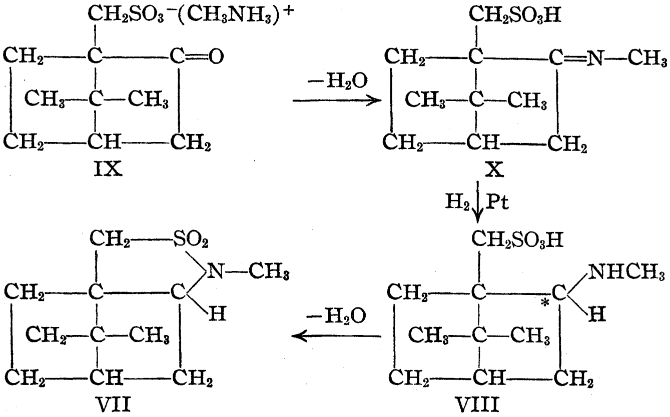
[2] Reychler, *Bull. soc. chim.*, **19**, 127 (1898).

[3] Armstrong and Lowry, *J. Chem. Soc.*, **81**, 1448 (1902); Lowry and Desch, *ibid.*, **95**, 1340 (1909); Richards and Lowry, *ibid.*, **127**, 1503 (1925).

Samples of the N-methyl sultam (VII) and its hydrolytic product (VIII) were next prepared from the methylamine salt of Reychler's acid (IX) which was dehydrated to the ketimine (X).



Catalytic reduction produced the two diastereoisomeric forms of 2-(N-methylamino)-*d*-camphane-10-sulfonic acid (VIII). These isomers were separated by fractional crystallization and the α-form possessed the same decomposition point and specific rotation as the sample of compound VIII obtained by the first series of reactions. By refluxing this α-form with acetic anhydride the N-methyl sultam (VII) was obtained which was identical in melting point with the N-methyl sultam described above.

These two series of reactions not only establish the structure of these sultams but also serve to confirm Lowry and Armstrong's formula for *d*-camphor-10-sulfonanhydramide.

Experimental

***d*-Camphor-10-sulfonanhydramide** (V).—A mixture of 25 g. of *d*-camphor-10-sulfonic acid and 5 cc. of thionyl chloride was warmed on the steam-bath until the reaction started and then another 30 cc. of thionyl chloride was added slowly. The mixture was heated on the steam-bath for four hours, cooled and poured slowly into a mixture of 100 cc. of concentrated ammonium hydroxide and 400 g. of cracked ice. The crude anhydramide was filtered and recrystallized from 95% ethanol. The aqueous mother liquor deposited additional crops of crystals of the anhydramide after standing overnight. Concentration of the ethanol mother liquor above yielded a product which melted at 126°, being an impure form of *d*-camphor-10-sulfonamide. When this material is warmed for ten minutes with concentrated hydrochloric acid, it is converted into the anhydramide. By working up all these fractions there resulted a total yield of 19.1 g. (90%) of colorless crystals of *d*-camphor-10-sulfonanhydramide which melted at 224° (corr.) and possessed a specific rotation[4] of −32° in chloroform (*c*, 5). These values check closely those given by Armstrong and Lowry.[3]

Sultam of 2-Amino-*d*-camphane-10-sulfonic Acid (VI).—A mixture of 10 g. of the anhydramide, 10 g. of Raney nickel catalyst and 150 cc. of warm 95% ethanol was shaken with hydrogen under 45 lb. (3 atm.) pressure. The anhydramide was only partially in solution at the start but dissolved as the reduction proceeded. The reduction was complete in one and one-half hours after which time the catalyst was removed by filtration and the filtrate concentrated. The sultam which separated melted at 181–182°. It was subjected to fractional crystallization but all the fractions melted at 181–182°, showing that only one form had been produced. The sultam was soluble in dilute aqueous sodium hydroxide and was precipitated upon acidification. It had a specific rotation in chloroform (*c*, 5) of −33.0°.

Anal. Calcd. for $C_{10}H_{17}O_2NS$: N, 6.51; S, 14.88. Found: N, 6.62; S, 14.83.

Sultam of 2-(N-Methylamino)-*d*-camphane-10-sulfonic Acid (VII).—A solution of 0.5 g. of sodium in 10 cc. of absolute ethanol was added to a solution of 5 g. of the above sultam (VI) in 25 cc. of absolute ethanol. To this solution was added 2.5 cc. of methyl iodide and the mixture refluxed for two hours. It was then poured into 50 cc. of water and acidified with hydrochloric acid. An oil separated which solidified on stirring and rubbing. The solid was removed by filtration and the filtrate concentrated to obtain an additional crop of crystals. The crude N-methyl sultam was recrystallized from hot water. A total yield of 4.5 g. (89%) of colorless crystals was obtained which melted at 80° and possessed a specific rotation in chloroform (*c*, 5) of −59.6°.

Anal. Calcd. for $C_{11}H_{19}O_2NS$: N, 6.11; S, 13.96. Found: N, 6.07; S, 14.10.

Hydrolysis of the N-Methyl Sultam (VII).—Three grams of the above N-methyl sultam was refluxed with 50 cc. of concentrated hydrochloric acid for twenty-four hours. The mixture was evaporated to dryness and the residue recrystallized from absolute ethanol. An 83% yield of the α-form of 2-(N-methylamino)-*d*-camphane-10-sulfonic acid was obtained which decomposed at 325–326° on the Maquenne block. Its specific rotation in ethanol (*c*, 1) was −98.0°.

Anal. Calcd. for $C_{11}H_{21}O_3NS$: N, 5.66; S, 12.95. Found: N, 5.43; S, 13.10.

2-(N-Methylimino)-*d*-camphane-10-sulfonic Acid (X).—One sample of this ketimine was prepared according to the method previously described.[1b] Fifty grams of Reychler's acid was added to an ethanol solution of 9.2 g. of methylamine and the salt obtained by evaporation to dryness. Dehydration was effected by heating the salt for six hours at 184° *in vacuo*. Four recrystallizations from absolute ethanol with the use of Norite were necessary in order to obtain a pure product.

A modified procedure proved simpler and yielded a product more easily purified. To a solution of 6.8 g. of methylamine in 100 cc. of ethanol were added 30 g. of Reychler's acid and 150 g. of ethylene glycol. The mixture was dis-

---

[4] All rotations were taken at 25° with sodium D light. The concentration in grams per 100 cc. of solution is denoted by *c*.

tilled until the volume of the residue was about 50 cc. This residual solution was cooled and the ketimine filtered and washed with cold ethanol. Recrystallization from absolute ethanol gave 12.8 g. of colorless crystals which melted at 312–313° (Maquenne block) and possessed a specific rotation of −137.6° in ethanol (*c*, 1). These constants checked with those previously obtained.[1b]

2-(N-Methylamino)-*d*-camphane-10-sulfonic Acid (XI).—2-(N-Methylimino)-*d*-camphane-10-sulfonic acid (18.8 g.) was dissolved in 150 cc. of absolute ethanol and catalytically reduced with hydrogen and platinum-oxide platinum black. It was necessary to use two successive portions of 0.5 g. of catalyst in order to secure complete reduction, which required about twenty-four hours. The catalyst was removed by filtration and the filtrate concentrated. The crude product was fractionated by a series of systematic crystallizations from 95% ethanol. The two diastereoisomers were isolated as colorless crystals.

α-Form.—This form had a decomposition point of 320° and a specific rotation in ethanol (*c*, 1) of −98.6°. *Anal.* Calcd. for $C_{11}H_{21}O_3NS$: C, 53.41; H, 8.56; N, 5.66. Found: C, 53.51; H, 8.54; N, 5.54.

β-Form.—This isomer decomposed at 338–343° and had a specific rotation in ethanol (*c*, 1) of +38.8°. *Anal.* Calcd. for $C_{11}H_{21}O_3NS$: C, 53.41; H, 8.56; N, 5.66. Found: C, 53.52; H, 8.49; N, 5.65.

The α-form was identical with the compound obtained by hydrolysis of the N-methyl sultam (VII).

Conversion of the α-Form of 2-(N-methylamino)-*d*-camphane-10-sulfonic Acid to the Sultam (VII).—One-tenth of a gram of the α-form of 2-(N-methylamino)-*d*-camphane-10-sulfonic acid was heated with 3 cc. of acetic anhydride for eighteen hours. The mixture was then poured into 5 cc. of water and evaporated to dryness. Three cubic centimeters of acetic anhydride was added and the mixture again heated to the boiling point. The mixture was cooled and then 3 cc. of water was added. This mixture was then evaporated to dryness. Two cubic centimeters of water was added and the white crystals collected on a filter. The substance melted at 79°. The mixed melting point with the methyl sultam (VII) was 79–80°.

Summary

The sultam of 2-(N-methylamino)-*d*-camphane-10-sulfonic acid was synthesized by alkylation of the sultam of 2-amino-*d*-camphane-10-sulfonic acid which was obtained by catalytic reduction of *d*-camphor-10-sulfonanhydramide. The sultam was hydrolyzed to 2-(N-methylamino)-*d*-camphane-10-sulfonic acid. The latter was shown to be identical with the α-form obtained by catalytic reduction of 2-(N-methylimino)-*d*-camphane-10-sulfonic acid. This α-form was converted to the N-methyl sultam by acetic anhydride.

The Determination of Dissolved Oxygen by Means of the Dropping Mercury Electrode, with Applications in Biology

BY HAROLD G. PETERING AND FARRINGTON DANIELS

The measurement of respiration constitutes but one of the many demands for an accurate and rapid method for the quantitative determination of oxygen. The differential pressure manometer such as the Warburg–Barcroft manometer is widely used for this purpose. The Winkler process is another standard method. The results of this investigation show that for many purposes the concentration of dissolved oxygen can be determined with great simplicity, accuracy, and rapidity by means of the dropping mercury electrode.

The method described here is a modification of the polarographic method, shown by Vitek[1] to be applicable to the determination of oxygen. The recording features of the polarograph are dispensed with and the apparatus is constructed from ordinary laboratory materials in such a way that readings of oxygen concentration in water or other conducting solvents can be made in a few seconds. It is especially useful for studying systems which involve a changing oxygen concentration.

This method may be regarded merely as an empirical analytical procedure which has been checked against chemical standards. On the other hand, theoretical interpretations of the polarographic method have been proposed.

Theory

The use of the dropping mercury electrode for analytical purposes depends on the fact that solutes (electrolytes or non-electrolytes) are reduced (or oxidized) when a current is passed through the solution at voltages above the decomposition potential. The current flowing de-

---

(1) Vitek, *Chimie et Industrie*, **29**, 215 (1933); *Coll. Czech. Chem. Comm.*, **7**, 537 (1935).

pends on the rate of diffusion of the material to the electrode, and this in turn depends on the concentration. The dropping mercury electrode gives reproducible results because a fresh surface of the electrode is being exposed continuously. At low voltages a small residual current flows, and then as the voltage is increased above the decomposition potential the current depends directly on the voltage in accordance with Ohm's law. As the voltage is still further increased, a point is reached after which the current is limited by the rate of diffusion of the reducible substance into the surface of the dropping mercury cathode. The current–voltage curve then becomes flat in the ideal case, and the current remains constant and independent of the voltage until the voltage becomes high enough to produce some other chemical reaction at the electrode.

The dropping mercury electrode was originally used by Kucera[2] to measure the interfacial tension of polarized mercury. Heyrovsky[3] is responsible for its extensive use in analytical chemistry. He devised the sensitive, self-recording polarograph which enables one to obtain easily and accurately the current–voltage curves of any dissolved reducible (or oxidizable) material—electrolyte or non-electrolyte. The decomposition potentials corresponding to breaks in the curve are used for qualitative analysis and the magnitude of the current at the "waves" is used for quantitative analysis.

There are several complications in the quantitative determination of a solute by this method. Other materials which have decomposition potentials in the same voltage range as oxygen will also give diffusion currents. As in any analytical procedure, these materials must be eliminated or corrected for. In this case, the readings are calibrated with a chemical method which is specific for oxygen, or these extraneous materials are determined when oxygen is removed by bubbling hydrogen through the cell. Again, these materials do no harm if only differences in oxygen concentration are being determined. When electrolytes are being determined the migration current of the ions affects the observed galvanometer readings, but this difficulty is removed by adding an excess of an indifferent electrolyte[4] such as potassium chloride (about 0.1 mole per liter). In the case of oxygen, which is a non-electrolyte, this migration current is not a factor.

Another complication is due to the (electrostatic) adsorption of reducible molecules on the surface of the mercury, which then causes a current to flow which is greater than the limiting current set by the diffusion rate. This phenomenon is evident in the maximum shown in the dotted line of Fig. 1A. These maxima are reproducible, but they may not be proportional to the reducible matter in solution, and it becomes necessary to eliminate them by the addition of small amounts of adsorbable material which are not reduced at the given potentials. Materials used to suppress these maxima are colloids such as proteins and carbohydrates, polymers, soaps, dyes, and alkaloids.[5] The adsorption of these materials tends to prevent the adsorption of the reducible material, and it does not affect the readings because they have a different decomposition potential than the material in question. It has been found in this investigation that for the analysis of oxygen there is sufficient material of this type in most biological samples and even in water which has been passed through filter paper to eliminate or greatly suppress the adsorption maximum of oxygen. The elimination of the objectionable maximum by the addition of algal cells is shown in Fig. 1B, while

(4) For a discussion of the migration current, *cf.* Ilkovic, *Coll. Czech. Chem. Comm.*, **6**, 498 (1934).

(5) This subject is fully treated by Heyrovsky in "Actualités scientifiques et industrielles," No. 90, Hermann et Cie, Paris, 1934. It has been found in this work on dissolved oxygen that the alkaloids do not lead to the same diffusion current as the colloids do when the maximum is suppressed. Gelatin and ethyl cellulose are good agents for suppressing the maximum.

the dotted line A for a smaller concentration of algal cells shows that the maximum has been only partially suppressed.

As already stated, oxygen was determined with a polarograph by Vitek.[1] He showed that the absorption coefficients of oxygen in water, ethanol, and methanol, were proportional to the wave heights (*i. e.*, diffusion currents corresponding to the flat parts on the polarographic records) for oxygen in these three solvents. He gave the precision of the method as 4% and the range of dissolved gas capable of being measured as 0.04 mg. per liter up to saturation, but he did not report quantitative measurements on the absolute concentrations of oxygen. No further application of the method seems to have been published since that time.[6]

The object of the present research has been to simplify the method and to show how it can be used to advantage in a number of problems, particularly to those of biology. The simplification consists in dispensing with the recording features of the polarograph and in determining the current only at two voltages which have been determined previously by experiment.

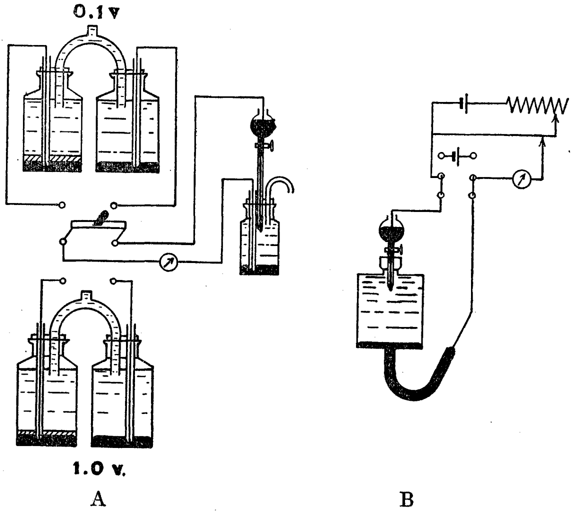

Fig. 2.

According to present practice, quantitative analysis by means of the dropping mercury electrode involves the determination of the whole current–voltage curve either by graphic or by automatic recording as in the polarograph. In some cases the difference in currents between two adjacent flat parts of the curve is taken as a measure of the concentration of the material whose decomposition potential falls in this range. In another method, parallel tangents are drawn at a definite angle above and below the region of the diffusion current, and the difference in current between the points of tangency is taken as the significant diffusion current which is proportional to the concentration.[7] The interpretation of the polarograms is fully discussed by Hohn.[8] It is much simpler, however, to determine the current at a predetermined voltage slightly less than the decomposition voltage of the electrode reactants, and again at a second voltage above the decomposition potential in the region of the diffusion current but below the decomposition voltage of a second electrode reaction. The difference between the currents flowing at these two voltages is proportional to the concentration of the substance (oxygen) taking part in the first electrode reaction. The results of this investigation show that this procedure is adequate, provided that the voltages are predetermined by experiment and the calibration curve is shown to be reproducible. The experimental apparatus then becomes extremely simple.

Apparatus

The apparatus, shown in Fig. 2B, consists merely of a stream of mercury dropping from a capillary tube into a solution in a closed bottle. The mercury stream is made the cathode and the pool of mercury the anode in a circuit which contains a storage battery, adjustable resistance and a galvanometer. The potential is varied by means of the resistance and measured with a simple potentiometer. The galvanometer need not be of the most expensive type, a sensitivity of 5×10^{-7} amp. per scale division being sufficient. A portable box type with a light and scale will do if the scale is long enough (6–10 cm.).

Since a study of the whole current–voltage curve showed that only two voltages are necessary for the analysis, it is evident that even the potentiometer may be dispensed with and two large capacity standard cells substituted for it as shown in Fig. 2A. The standard cells are made from two eight-ounce square bottles taped together, closed with rubber stoppers, and connected with a salt bridge. Connections are made with the mercury or amalgams, at the bottom of the bottles, by means of platinum wire fused to copper wire and sealed into glass tubes fitting into the stoppers. In the 1.0-v. Weston cell one bottle contains 100 g. of 13% cadmium–mercury amalgam. (The cadmium dissolves more quickly if its surface is in-

---

(6) After this manuscript was completed it was learned that Baumberger and O. H. Müller reported an application of the polarographic method to respiration measurements at the meeting of the Western Society of Naturalists in 1935.

(7) Borcherdt, Adkins and Meloche, THIS JOURNAL, **59**, 2171 (1937).

(8) Hohn, "Chemische Analysen mit dem Polarographen," Verlag von Julius Springer, Berlin, 1937.

creased by cautiously pouring the molten metal into water.) The other bottle contains about the same amount of pure mercury covered with a paste of mercurous sulfate in 2 molar cadmium sulfate. Both bottles are then filled to the top of the bridge with approximately 2 molar cadmium sulfate and the opening at the top of the bridge is closed. Such a cell maintains a constant potential of about 1.04 v. over long periods of time and is unaffected by ordinary currents during continued usage.

The 0.1-v. cell is a cadmium–lead cell[9] in a similar double-bottle. One electrode contains 10% lead in 90% mercury over which stands a solution of about 1 molar cadmium iodide saturated with lead iodide. The other electrode contains 11% lead, 9% cadmium and 80% mercury in a solution of about 1 molar cadmium iodide.

As shown in Fig. 2A a double pole-double throw switch is used for throwing in first the 1.0-v. cell and then the 0.1-v. cell. The difference in galvanometer readings with the two cells gives the desired measurement which is proportional to the concentration of dissolved oxygen.

The dropping mercury cathode must be adjusted carefully to give maximum galvanometer deflections with minimum oscillation and without clogging of the capillary tube. A separatory funnel is connected with a capillary tube from a broken thermometer through a minimum length of pure gum rubber tubing or rubber which has been boiled with sodium hydroxide to remove sulfur. The rubber tube is wired on and reinforced if necessary with a wrapping of tape. A 50-cm. head of mercury is satisfactory and the tip is so made that the mercury drops off at the rate of about one drop every one or one-half seconds.

Several different types of cells were used in this work. The cells are completely filled with the liquid, leaving no gas space. In one type (Fig. 2A) the solution overflows as the mercury flows in. In another type (Fig. 2B) the mercury pool at the bottom is kept at a constant level, by allowing the mercury to overflow. In still another type the anode was a calomel electrode connected through a bridge of potassium chloride (1.0 *N*) solution. In the photochemical work the sides of the cell were made of polished glass and care was taken to place the mercury cathode in the center of the cell.

Calibration

In using the dropping mercury electrode it is necessary to calibrate the galvanometer readings directly against the concentration of the substance being analyzed under the same conditions, and in the simple method proposed here it is necessary first to determine empirically at what voltage the galvanometer readings should be taken in order to give a straight line when the concentration is plotted against deflections. Using the same tip and the same apparatus, then the concentration of an unknown solution is obtained readily by interpolation on this straight line or by simply multiplying the galvanometer readings by a constant, *i. e.*, by the slope of the calibration line.

In Fig. 3 are shown current–voltage curves at 18° for various concentrations of oxygen in a solution containing some suspended algae. The full curve is shown at a concentration of 3.00×10^{-4} mole per liter while for the other concentrations the range only from 0.7 to 1.0 v. is shown. When the currents at 0.7, 0.8, 0.9, 1.0 v. are plotted against the concentration of oxygen, only the points at 1.0 v., marked with double circles, give a straight line, as shown in A of Fig. 4. It is clear from an inspection of Fig. 3 that if a straight line is produced at 1.0 v., a straight line cannot be produced at the other voltages.

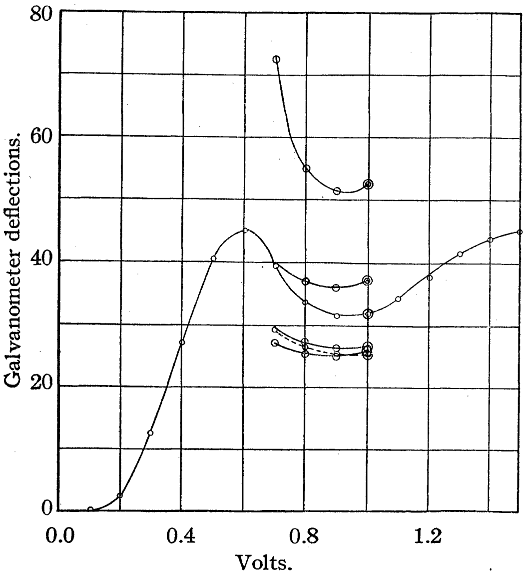

Fig. 3.

In these calibrations the oxygen concentration was determined by titration with sodium thiosulfate using the standard Winkler method[10] with manganous sulfate and potassium iodide. The oxygen concentration was controlled by equilibrating the nutrient solution in which the chlorella were suspended (or just the salt solution, for example 0.1 *N* potassium chloride) with air at the specified temperature, and then passing through this solution oxygen, or nitrogen, or gases containing some oxygen. The closed vessel, containing the solution with dissolved oxygen, was fitted with a siphon, and the samples were withdrawn quickly for chemical analysis and for analysis with the dropping mercury electrode under conditions giving a minimum of change in the oxygen concentration.

Four different calibration curves (A, B, C, and D) obtained by the first method are shown in Fig. 4. These curves illustrate the necessity for separate calibrations for each tip and for each temperature as well as for each galvanometer and electrical circuit. Calibrations A, B, and C were all made with the same dropping mercury cathode tip, but at different temperatures—namely, 18, 22, and 28°, respectively. Calibration D was made with a different tip and at 25°.

An examination of these calibration curves shows the high sensitivity of this method of analysis. Assuming that the galvanometer can be read to at least one-half of a scale division (0.5 mm.), the corresponding limit of error in the oxygen concentration is of the order of 5 ×

10^{-7} mole per liter. The experimental points fall on the straight line within these limits. It is quite convenient to use the dropping mercury electrode with samples of about 10 cc.; and for a sample of this size the actual change which can be measured is of the order of 5×10^{-9} mole total change in oxygen concentration. At room temperatures this corresponds to 1.2×10^{-4} cc. or to 0.112 cu. mm., or 1.6×10^{-7} g. Expressed in another way the dissolved oxygen can be determined to 0.016 part per million by weight. These estimates of the sensitivity of the method are substantiated by the curves and particularly the data of Table I.

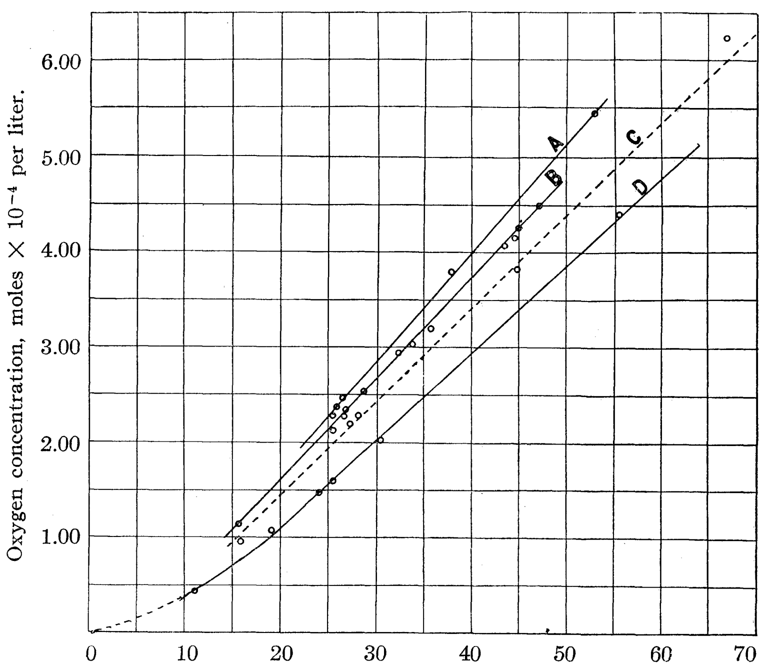

Fig. 4.

A simple calculation shows that the passage of current during the reading of the galvanometer deflections is far too small to cause detectable change in concentration by electrolysis.

The straight line relation between concentration and current apparently fails to hold below a concentration of about 5×10^{-5} mole per liter. The straight lines do not extrapolate to zero current at zero concentration, an observation which has been discussed by several investigators. In curve D of Fig. 4 special effort was made to determine the relation between concentration and current in this region. The Winkler method loses its sensitivity at these low concentrations and hence the true situation is difficult to determine. The curve bends toward the axis so that it extrapolates to zero, and this fact has been checked by other determinations. Despite this complexity, it is possible to use the method outlined here for low concentrations of oxygen by interpolating on the curve even where the straight line relationship does not hold.

The limitations of this simplified method should be summarized. The substitution of two empirically-determined voltages for the complete polarogram is possible only after a complete voltage–current curve has been plotted, and the proper voltages checked by independent chemical or physical determinations of the concentration of dissolved oxygen. However, after these voltages have been established it is no longer necessary to determine these complete curves. The preliminary curves can be prepared, manually, with simple apparatus. Calibration must be carried out for each cell and tip, and for each new type of solution unless it can be shown that no interfering substances are present. However, such calibrations are necessary, also, in the complete polarographic method. Calibration can be effected by direct chemical analysis as with the Winkler method, or by removal of oxygen by the bubbling of hydrogen and the addition of measured quantities of oxygen. It might be argued that, with this calibration method, a single voltage rather than two voltages would be sufficient, but the zero point of the galvanometer fluctuates with temperature and accidental variations in the amount of iron and other easily reducible substances give large fluctuations in the galvanometer deflections even at 0.1 volt. The fluctuations are cancelled out by taking the difference between two voltages, 1.0 and 0.1 v., for example, when analyzing for oxygen. The maximum deflections of the galvanometer are taken at a given voltage and these maxima are read easily when the mercury is dropping at the rate of one drop every second or second and a half. Although this rate may be considered somewhat rapid for producing a "theoretical" curve, it has been shown to be entirely satisfactory for the method described here.

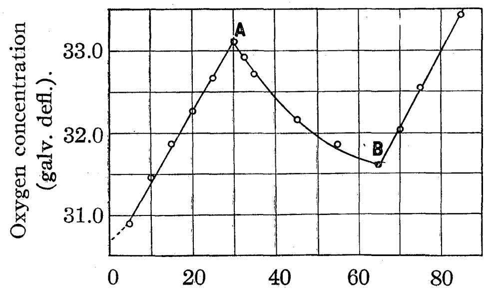

Fig. 5.

Applications

The accuracy and the quick response of this method is clearly shown in Fig. 5 where the photosynthesis of algae is protrayed. In this experiment light from a 500-watt projection lamp was filtered through 9 cm. of 0.025 *N* cupric sulfate and a Corning No. 243 filter. This red light at about 3500 ergs per second per sq. cm. was passed into a vessel containing *chlorella pyrenoidosa* suspended in Warburg nutrient solution, 16,000,000 cells per cc. The steady evolution of oxygen is indicated by the straight line with a positive slope. At point A, the light was turned off and photosynthesis stopped, but the respiration of the algae continued. The negative slope shows that oxygen is being consumed by the respiration. It is of interest to note that the rate of respiration, *i. e.*, the slope of the line, is greatest just after removal of the light. It was, in fact, to study this rate of respiration just after the exposure to light that this method was developed. Chemical analysis and differential manometric methods have failed to give information of any degree of definiteness or consistency about this rate of respiration immediately after exposure to light. When the light is turned on again at B, the photosynthesis immediately releases oxygen and the net effect of respiration and photosynthesis is a uniform increase in concentration of oxygen as before. The slopes of the oxygen concentration–time curves during exposure to light are identical within experimental error.

Before using this method it was necessary to prove that mercury is not toxic to chlorella—at least not in the concentration to which this method subjects the algae. Algae were cultured in the presence of 1 cc. of purified mercury of the grade used in the dropping mercury electrode. The algae grew normally along with many controls which were a part of the regular culture stock maintained for experimental purposes. No differences were noticed in the appearance of the algae grown in the presence of and in the absence of mercury, nor was there any noticeable difference in the total growth at the end of seventeen days. The algae which were grown in the presence of mercury respired and photosynthesized in the same way as those which were grown in the absence of mercury. Likewise, Mr. Albert E. Dimond of the Botany Department, who furnished the yeast used in some of these experiments, found that yeast is not affected by the presence of the mercury in these experiments.

Other applications of the analysis of oxygen by the dropping mercury electrode method are given in Fig. 6. Curves A, B, C, and D are for the respiration of yeast. They show how the respiration rate increases with the concentration of cells and with the addition of glucose. Curve E is for the oxygen uptake of homogenized rat liver tissue in the presence of sodium succinate four hours after the rat had been killed. The volt–current curve for this material is shown in Fig. 1, D. Curves F and G give the respiration rates of red blood cells from chickens. F and G are for the same cells, but G was obtained with a suspension in which the concentration of cells is about one-third that of F. Curve H shows the respiration of the red cells of dog's blood in vitro and it is particularly interesting because the respiration is so slight that it can be followed by other methods only with great difficulty. Accordingly, the de-

20	32.20	45	31.15

tails of the experimental measurements are given in Table I and the volt–current curve for the dog's blood is shown in Fig. 1 at curve C.

When the chicken and dog blood are put on the same basis of concentration of cells, it is seen that chicken blood takes up in thirty minutes twenty times as much oxygen as the dog blood. The cells of the chicken bloods are nucleated while those of the dog blood are not.

Measurements were made on the dog blood cells at the same time using a Barcroft–Warburg manometer. However, the oxygen uptake was too small to be measured with any accuracy by the manometric method.

Another application of the method described here lies in the determination of the oxygen content of soils. This analysis has been beset with many difficulties and the values which have been obtained have little significance according to many workers in soil culture. The methods described here may be used, by determining first the oxygen content of a given volume of 0.1 *N* potassium chloride solution, and then determining the oxygen content after adding a sample of soil and allowing equilibrium to be established. In one sample of loam, 33 cu. mm. of oxygen was found to be associated with 1 g. of soil with a moisture content estimated as 30%.

The apparatus is portable and it can be made adaptable to field use such as determining the oxygen content of lakes at different depths.

There are other fields of study in biology which might be attacked with this precise method of oxygen analysis such for example as the study of the border line between aerobic and anaerobic bacterial action, the respiration of small amounts of tissue and nerve material, the accurate measurement of the respiration of cancer cells and the study of the influence of drugs and various diseases on the respiration of blood.

Although this investigation has been limited to the determination of dissolved oxygen, it is likely that other substances can be determined in the same simple way. Calibration curves with galvanometer deflections plotted against concentration are plotted at several different voltages and that voltage (or rather the difference in current between two voltages) is selected which gives a straight line for a calibration curve. Aside from giving the confidence which results from a straight line relationship over a wide range of concentration, this method renders unnecessary any expensive recording apparatus and enables one to make an analysis on systems undergoing rapid chemical or biological change.

The authors are glad to acknowledge the support given this investigation by the Research Committee of the Graduate School and the Wisconsin Alumni Research Foundation. They are indebted to Professor B. M. Duggar of the Botany Department in whose laboratory much of the work was done. They wish to thank Professor V. W. Meloche for his helpful interest and for the use of a polarograph in a preliminary test. They appreciate the help given by Mr. A. Axelrod in the measurements with the Barcroft manometer and by Mrs. N. Dimond in preparing the algal cultures.

Summary

1. A method using simple apparatus is described for measuring the concentration of dissolved oxygen. A dropping mercury electrode is used and galvanometer deflections are measured at two predetermined voltages. The deflections are plotted against solutions of known concentrations giving a calibration curve which is a straight line.

2. The limitations of the method are pointed out and the method is illustrated with the photosynthesis and respiration of algae and with the respiration of yeast and blood cells and with animal tissue.

Salted-Out Protein Films

BY IRVING LANGMUIR AND VINCENT J. SCHAEFER

Proteins can be adsorbed from aqueous solutions onto a plate, covered by barium stearate multilayers, which has been conditioned[1,2] by previously dipping it into a solution of thorium nitrate. When a 1% solution of insulin is applied in this way to a conditioned plate and this is then washed in distilled water, and dried, a film of a thickness of about 45 Å. is obtained. However, if the protein solution is washed off the plate with an 0.8% sodium chloride solution instead of with water and the plate is then washed with distilled water and dried, the film thickness is much greater, ranging from 70 to about 200 Å. The variations in thickness seem to depend upon the rapidity of mixing the salt solution with the underlying protein solution.

These results suggested that the increased thickness due to the application of the salt solution directly to the protein solution on the plate was caused by the concentration gradient in the solution while the salt diffused into the insulin solution. Confirmation of this hypothesis was obtained from experiments in which 0.8% sodium chloride was added to the insulin solution before applying this to the conditioned plate. After washing this off with sodium chloride solution and then with water, the normal thickness of about 45 Å. was found.

The effect seems to be analogous to the Ludwig–Soret effect in which a temperature gradient causes a migration of a solute to the cold part of a solution. The theory of this phenomenon has not been satisfactorily worked out. A simple explanation often given is that the molecules of the solute are bombarded by the solvent molecules with greater intensity on the high temperature side than on the low temperature side. Such an explanation seems particularly useful in accounting for the Soret effect in air commonly manifested by the slow accumulation of dust particles at cold spots on the ceiling of a room.

According to S. Chapman[3] particles having a large diameter compared to the free path of the molecules in a liquid should distribute themselves in such a way that cD is constant throughout the solution, c being the concentration of the particles and D the diffusion coefficient. Thus, since the diffusion coefficient increases with temperature, the concentration should be less in the hotter parts. Bruzs[4] attempts to develop a thermodynamic theory and concludes that the Soret coefficient σ depends upon the entropy and the partial molar specific heats. There are, however, practically no experimental data for checking this theory.

Hartley,[5] after discussing the preceding theories, advances reasons for believing that the relative solubilities of the solute in the solvent, at different places in the tube, are important in determining the Soret coefficient.

In a second paper,[6] Hartley considers the distribution of solute molecules in a solvent of graded composition. Apparently in all cases if there is one component A originally uniformly distributed throughout a solvent, the effect of a concentration gradient in a second component B is to drive the molecules of A toward the region where B has a low concentration. We shall designate this as the carrying effect.

Hartley believes that there are three factors that determine the magnitude of this forced migration. First there is the Chapman effect, according to which the particles should migrate toward the region where the diffusion coefficient is lowest. Thus, if the presence of a substance B increases the diffusion coefficient of substance A, A should tend to move into the region where B has a low concentration. It seems improbable, however, that the general effect of dissolved substances should be to raise the diffusion coefficient of other substances, so that Chapman's theory seems inadequate as a general explanation of the carrying effect.

As a second factor, Hartley considers the effect of the added substance B on the solubility of A.

The third factor he describes as a "push effect." The larger molecules are subjected to greater bombardment by diffusing molecules than small ones.

Hartley assumes that the pressure exerted is approximately proportional to the mean cross-sectional area of the large molecules. Thus an enormous push effect is to be expected in the case of colloidal particles. This simple explanation of the "push effect" cannot be generally valid, for it would indicate that a sphere the size of a baseball placed at the boundary between a molar salt solution and overlying pure water should be forced upward with a force of about 1000 lb. It is obvious, however, that any pressure difference greater than that due to gravity will be equalized by a flow of liquid. It is only when the particles are of a size comparable to the free path of the molecules of the liquid that an appreciable push effect can exist.

Recently Seastone[7] found it impossible to spread monolayers of tobacco mosaic virus by Gorter's method on the surface of water adjusted to a *p*H corresponding to the isoelectric point of the protein. At *p*H 1 there was a small amount of spreading corresponding to about 0.1 sq. m. per mg. Since the protein solution when applied sank to the bottom of the tray and so could diffuse only slowly to the surface, Seastone attempted to spread the protein on a solution of higher density, using for this purpose a 25–90% saturated ammonium sulfate solution. The protein solutions, and even distilled water, spread with almost explosive rapidity on such strong salt solutions, for these have surface tensions that exceed that of pure water by several dynes per cm. With 90% saturated ammonium sulfate at *p*H 7.1, a film of virus covering an area of 0.06 sq. m. per mg. was obtained. Measurements of the virus activity proved that little or none of the tobacco virus remained in the liquid under the film. If this film has a density 1.3 and if it contains all the protein applied to the solution, its thickness should be 126 Å. In another case Seastone reports that a film of a thickness of 1000 Å. was obtained by applying tobacco mosaic virus to a 50% saturated ammonium sulfate solution. He suggests that these thick films may correspond to monolayers in which the rod-shaped molecules of diameter 150 Å. lie flat in the surface in some cases and lie with their long axes perpendicular to the surface in other cases.

The work of Gorter and Philippi shows that many proteins spread to give films of thicknesses from 7 to 20 Å. under compressions to 0 to 10 dynes per cm. Some samples of tobacco virus sent to us over a year ago by Dr. Stanley gave films of approximately this thickness. About six months ago, Dr. Stanley sent us some new samples of 1.9% tobacco virus purified by ultracentrifuge sedimentation. With a spreading technique which we had used previously, which was a modification of Gorter's, we were unable to obtain monolayers. When this solution of tobacco virus was spread upon ammonium sulfate solution we obtained very thick films, ranging from 100 to 2000 Å.

Our experiments showed clearly that the film thickness was not determined by the molecular diameter but depended on the concentration of the salt solution and on the amount of protein applied in relation to the area available for spreading.

When a drop of tobacco virus solution is placed upon a concentrated ammonium sulfate solution, the drop spreads over the surface because the surface tension of the water is less than that of the salt solution. We have observed that one drop of distilled water (0.05 ml.) spreads on a saturated ammonium sulfate solution to form a film 5×10^{-4} cm. thick and of an area of about 100 sq. cm., as shown by the pushing back of a film of indicator oil on the surface of the solution. A pressure of only one dyne per cm. causes the immediate collapse of the circular area covered by the water film.

The rate of diffusion of salt from a solution into an overlying layer of initially pure water can be calculated by methods used in problems of heat conduction.[8]

Consider a salt solution of concentration c_0 on which is placed at time $t = 0$, a layer of water of thickness b. Then, if x is the depth below the surface, the concentration c is initially 0 between $x = 0$ and $x = b$, and is c_0 for $x > b$. The concentration gradient has a maximum value at $x = b$ which is given (for not too large values of t) by

$$\mathrm{d}c/\mathrm{d}x = (c_0/2)(\pi D t)^{-1/2}$$

where D is the diffusion coefficient of the salt.

For values of x small compared to b, the concentration gradient is at first very small but rises to a maximum and then decreases toward zero. The maximum value of $\mathrm{d}c/\mathrm{d}x$ occurs when $t = b^2/6D$ and is given by

$$(\mathrm{d}c/\mathrm{d}x)_{\text{max.}} = 0.93 c_0 x/b^2$$

---

[7] C. V. Seastone, *J. Gen. Physiol.*, **21**, 621 (1938).

[8] Ingersoll and Zobel, "Mathematical Theory of Heat Conduction," Ginn and Co., New York, N. Y., 1913; see especially Eq. (25) on p. 70.

At this time the concentration at the surface $x = 0$ is only $0.084c_0$; at $x = b/2$ it is $0.198c_0$ and at $x = b$ it is $0.5003c_0$. The concentration gradient at $x = b/2$ is then $0.45c_0/b$.

The diffusion coefficient D for salts in water is of the order of magnitude of 10^{-5} cm.^{2}/sec. Thus the maximum concentration gradients close to the surface will occur within less than a second, even if the water film has a thickness as great as 0.08 mm., which corresponds to 0.8 ml. per 100 sq. cm.

Although the concentration gradient reaches its maximum within such a short time, the actual concentration of salt in the surface (at $x = 0$) approaches its limiting value very slowly. Thus to reach $0.9c_0$ will require a time $32b^2/D$ and to reach $0.99c_0$ takes $t = 3200b^2/D$. With $b = 5 \times 10^{-3}$ cm., $D = 10^{-5}$ cm.^{2}/sec. One hundred and sixty seconds would be required for $c = 0.9c_0$ and four and one-half hours for $c = 0.99c_0$.

The thick films of tobacco virus observed by Seastone and confirmed by our experiments thus appear to be essentially salted-out films in which the protein is forced to the surface by the concentration gradient of the salt until the protein concentration becomes so high as to cause a crystallization of the protein into a thin sheet.

Recent work[9,10] has shown that highly purified tobacco virus solutions, if stronger than 2%, separate into two phases on standing. The lower layer, usually water clear, is liquid crystalline; the upper layer, which is slightly turbid, shows, on gentle agitation, anisotropy of flow.

X-Ray examination has shown that in the denser phase the rod-shaped molecules lie with their axes parallel, but in a plane perpendicular to this direction the molecules are arranged in a hexagonal close packed lattice with a spacing which varies continuously from 150 to 600 Å., depending upon the concentration of the solution. The lower limit of 150 Å., obtained when the water content is very low apparently corresponds to the diameter of the molecular rods.

The forces that hold the molecules apart in the hexagonal lattice are recognized as being electrostatic forces associated with the negative charges on the molecules. The intervening water must therefore carry an excess of ions of the opposite polarity. The spindle-shaped crystals of tobacco virus observed by Stanley and others have been shown to have a similar structure and are thus tactoids in which the distance between molecules depends on the water content.

We believe that in our experiments the concentration gradient of ammonium sulfate forces the tobacco virus to the surface in such concentration that this denser phase appears. Probably the molecules are arranged with their axes parallel to the surface and in transverse directions are packed in a hexagonal lattice.

Films Salted-Out onto Plates.—The salted-out films of insulin produced on a plate by applying a few drops of insulin solution and then washing this off by pouring over it a salt solution were very non-uniform in thickness. We attempted in several ways to develop a technique of producing uniform films.

Using one method, we saturated filter paper, blotting paper or silk fabrics with an insulin solution, applied this in one or more layers onto a wet, conditioned barium stearate multilayer and placed on top of this other layers of porous paper or fabric wetted with salt solution. After two minutes the layers of paper were lifted off, the film was washed with water and dried, and the thickness was determined by matching the color of the specularly reflected light with that given by a barium stearate stepped color gage.[11,12] With 0.05 ml. of 0.1% insulin on 3 sq. cm. filter paper covered with paper saturated with 90% saturated ammonium sulfate solution, a film 220 Å. thick was produced.

This represents nearly 20% of the protein applied to the paper. With more concentrated insulin solutions (up to 10%) film thicknesses, in some cases as great as 650 Å. were obtained, but the fraction recovered was much less. The films produced by this method were usually of unsatisfactory uniformity.

The best method we have found for producing salted-out films directly on a plate is as follows. A prepared plate covered with barium stearate multilayers is conditioned by thorium nitrate so as to render it hydrophilic and it is then dipped into a solution of the protein. It is important that the plate first should be rendered hydrophilic for otherwise when it is dipped into the protein solution a film is deposited on the down trip.

The plate is lifted from the protein solution at a rapid uniform rate, the adhering liquid is allowed to drain for a few seconds and the surplus removed from the lower corner of the plate by filter paper. The plate is then quickly immersed into a strong salt solution in a beaker and allowed to stand for a few minutes. It is then taken out of the salt solution and dipped successively for twenty seconds into each of several beakers containing 1% tannic acid solution. The plate is then washed thoroughly in distilled water, dried and the thickness of the protein film is measured optically.

The tannic acid renders the protein film insoluble so

[11] K. B. Blodgett and I. Langmuir, *Phys. Rev.*, **51**, 964 (1937).

[12] I. Langmuir, V. J. Schaefer and H. Sobotka, THIS JOURNAL, **59**, 1751 (1937).

that it can be washed with water without loss. Salted-out films of insulin, however, suffer no loss, even without the tannic acid treatment. When tannic acid is used with insulin the film is 12 Å. thicker. We assume that with other proteins the use of tannic acid gives a similar increment of thickness.

The thicknesses of films of insulin, salted-out from a 0.5% insulin solution by applying sodium chloride solutions, increase from 90 Å. with 0.3% salt to a maximum of 340 Å. with 1% salt, decreasing to 190 Å. at 3% and to 140 Å. with salt solutions between 10 to 35%. Variation of the *p*H of the salt solution between 4 and 7 gave little or no change in thickness.

Salted-out films of pepsin (Eli Lilly's, 8000 units per gram), formed by using saturated ammonium sulfate solutions at *p*H from 2 to 5 gave 100 Å. from a 0.1% protein solution, and up to 600 Å. with a 5% protein solution. With a 0.5% pepsin solution, thicknesses of only 50 Å. were obtained with ammonium sulfate up to 25% saturated, and the thickness increased from 150 to 225 Å. as the concentration of the sulfate solution was raised from 50 to 100% saturation.

The salted-out films produced in this way were very uniform, but scattered a good deal of light (more than the films produced by the use of impregnated filter paper).

Films Salted-Out on the Surfaces of Salt Solutions.—A tray is filled with a strong solution of some salt such as ammonium sulfate, or magnesium sulfate and its surface is cleaned in the usual way. Barriers are placed across the tray to delimit a definite area.

A graduated 1-ml. hypodermic syringe is filled with the protein solution and by a micrometer screw the plunger is forced down a definite distance so as to deliver a given volume of solution. By Gorter's method the protein solution is introduced from the needle just under the surface of the salt solution. Because of the relatively high density of the salt solution, it is equally satisfactory to let drops of the protein solution fall upon the surface. Another method, which we call the "band method," consists in distributing the protein solution along a line near the edge of a thin nickel or platinum band which has a length equal to the width of the tray and has been cleaned by heating in a flame. Before the protein solution has dried, the band is lowered slowly edgewise into the tray close to one end of the delimited area.

The protein solution applied by either of these methods spreads rapidly over the salt solution, and the protein is driven to the surface by the concentration gradient. If the bottom of the tray has been made black (by black Bakelite varnish, baked on, or by a sheet of black glass) and the thickness of the protein film on the solution exceeds about 200 Å., it is visible because of the increased reflection from the surface. There is usually a part of the surface farthest from the point of application that is covered by an invisible monolayer, 10–20 Å. thick, which was formed from the first portion of the applied protein solution and which was pushed against the barriers and so retarded the further spread of the protein solution. A surface pressure of about 15 dynes per cm. can be observed against a movable barrier under these conditions.

The salted-out film on the surface should be allowed to age for two minutes so that it may reach its maximum thickness and stability.

Optical Measurement of Thickness.—Sometimes the salted-out protein films on the salt solutions are so thick, 1000–7000 Å., that interference colors are seen. There are two convenient methods of producing films of known thickness on water which serve as comparison standards. A few drops of 10% sulfuric acid applied to the edge of a barium stearate multilayer (49 to 120 layers) on glass creeps under the film and detaches it so that it may be floated off onto water in a tray. Since water has a lower refractive index (n = 1.33) than the film (n = 1.50), the interference colors are complementary to those observed when the same film is on chromium or on glass of refractive index higher than 1.55.

Table I gives the number of layers and the thickness of barium stearate multilayers on water which give various colors when examined at an angle of incidence of 45°.

The second method consists in spreading a weighed amount of indicator oil (partially oxidized lubricating oil) on water and compressing the film between barriers to confine it to known areas so that the thickness can be calculated. The relation between the thickness and the color of the oil films was approximately the same as that of the stearate films given in Table I.

TABLE I

COLORS OF THIN OIL OR STEARATE FILMS ON WATER OBSERVED WITH UNPOLARIZED LIGHT AT i = 45°

Color	No. of layers	Thickness, Å.
Gray	33	800
Faint yellow, first order	49	1200
Yellow	57	1400
Dark yellow	65	1600
Yellow-red	73	1800
Bluish-red	81	2000
Purple-blue	89	2200
Blue	97	2400
Bluish-green	105	2600
Yellow-green	115	2800
Yellow, second order	122	3000

A salted-out film produced by applying 0.3 ml. of a 1% solution of commercial egg albumin in successive drops to the central portion of a 100-cm. area of a 90% saturated ammonium sulfate solution gave at the point of application a disk of about 5-cm. diameter showing a light yellow color, while on the solution. The film around this disk showed only a gray color. Some of the film from the colored disk, transferred to a chromium plate by the "lift method" (to be described later), fixed by dipping into 1% tannic acid, then washed and dried, gave a purple-blue, about the same as that given by 45 layers of barium stearate on chromium observed at i = 50°. A portion of the same film transferred to a fused quartz plate, n = 1.46, showed a yellow color. On a microscope slide (n = 1.51), the color was light blue, while on lead glass (n = 1.6) the film gave an intense blue color. These data show that the film had a refractive index between 1.46 and 1.51, probably close to 1.48, and that the thickness was about 1100 Å. The refractive index of protein calculated from that of solutions is usually found to be approximately

1.58. It has been shown previously[13] that built-up films of egg albumin gave a refractive index for Na light of 1.50. Thus it is probable that the salted-out films and the built-up films contain water or air which lowers the refractive index. Experiments show that paper wet with a drop of octane held above a thick salted-out protein film on water or over the same film deposited on a chromium plate produces striking changes of color just like those observed by bringing these vapors in contact with skeletonized barium stearate films. These facts seem to indicate that these thick protein films are skeleton films which contain a considerable proportion of water or air.

Similar films of 1200 Å. thickness were produced by applying 0.5 ml. of a 1% solution of crystalline pepsin (Northrop) to 90% saturated ammonium sulfate.

Dr. W. M. Stanley gave us a 1% solution of some centrifuged monodispersed tobacco mosaic virus. When 0.1 ml. was applied to 100 sq. cm. of 90% saturated ammonium sulfate solution, a grayish colored film of considerable rigidity was formed covering an area of about 55 sq. cm. This was deposited upon a chromium plate and fixed in 1% tannic acid. After washing and drying, the film, when examined with the R_s ray at large angles of incidence, showed a second-order yellow corresponding to a thickness of 120 barium stearate layers or 2900 Å. At an angle of incidence $i = 45°$, this gives a purple color. Thus we should expect the film on water before deposition on the plate to have shown the complementary color, *viz.*, a second-order yellow (see also Table I). During the growth of the film, the colors should have changed from first-order yellow through purple, blue-green, to second-order yellow. Actually, however, the films on water show only a strong grayish reflection, which forms a strong contrast with a clean water surface.

The probable explanation of the absence of interference colors of the tobacco virus films on water is a graded lower boundary which does not provide the definite reflection needed for interference. When the film is deposited on a plate, fixed, washed and dried, the upper surface which was previously the lower surface now has a definite boundary and gives good interference colors.

With several proteins, egg albumin, pepsin, urease, edestin and horse globulin, we have observed that the salted-out films formed are of a composite type. Thus, if a drop of a 1% solution of one of these proteins is applied to the center of the clean surface of a 90% saturated ammonium sulfate solution about 100 sq. cm. in area, a faintly visible gray film instantly covers the surface followed within a few seconds by the formation in the central part of a circular area 2 to 5 cm. in diameter which first appears black (similar to a clean surface). This area is soon filled in with a grayish film, starting at the outer edge and gradually filling the interior with a uniform film which gradually increases in reflecting power. A second drop applied to the same place sinks into the salt solution and then rises and dissolves this film, producing a black region as previously described. This is followed by the appearance of a film similar to the previous one in formation but much thicker, often showing intense interference colors extending even into second- or third-order colors, depending largely on the purity and concentration of the protein solution used.

A large area of the film on the surface, including the colored spot, is now deposited on a chromium plate and is fixed by gently flooding over the surface a 1% tannic acid dissolved in 90% ammonium sulfate saturated solution. After washing and drying, it is usually found that interference colors are seen not only on the central disk but also far out into the surrounding area. Within the disk the thickness of the film as determined by the colors observed after deposition agrees with that determined from the color seen on the salt solution. The portions surrounding the disk, however, now give colors which correspond to very great thicknesses, often as large as 7000 Å.

These phenomena seem to show that these salted-out protein films are essentially composite and consist of two layers, a *diffuse layer* which has an indefinite lower boundary and thus produces no interference effects while on the solution, and a second or *compact layer* which overlies the diffused layer on the solution and which has a definite lower boundary giving good interference colors. The compact layer is of uniform thickness within the central disk and gradually decreases with increasing radii over the surrounding surface. The diffuse film is far thicker than the compact film and decreases steadily in thickness as the radius increases. Originally, while the film is on the solution, the diffuse film has a maximum thickness under the central disk; but while depositing this on the plate and subsequently fixing it with tannic acid, the thickest parts of this diffuse film usually break away, within a circular area, leaving within this only the compact film on the plate. By agitating the salt solution under the film or by more vigorous treatment with tannic acid fixing solution, the area from which the diffuse film is removed may be increased greatly without altering the thickness of the compact film.

The thickest compact films are obtained by using protein solutions of very high purity. For example, we find that solutions of pure crystalline egg albumin (given by Dr. P. A. Levene) give far thicker compact films and form them in far less time than when an impure egg albumin is used.

The compact film, which is usually very uniform in thickness over the central disk, acts as though it were a single crystal sheet; the diffuse film frequently may be seen upon stirring the underlying solution as a veil which scatters an appreciable amount of light and can be moved about under the compact film. It perhaps consists of a suspension of very fine crystals.

With insulin we have not been able to produce these composite films. When this protein is applied to a 90% ammonium sulfate solution, a white cloudy precipitate is formed but no coherent film. On 1% ammonium sulfate the insulin spreads to form a monolayer. When a 1% insulin solution is applied to an unlimited area of a 1% sodium chloride solution, an insulin monolayer is formed, but with a restricted area the pressure builds up to $F = 18$ dynes per cm. and a circular grayish area appears, which after deposition on a plate gives a thickness of 115 Å. It is not necessary to fix this deposited film with tannic acid, for it can be washed gently with water without loss. However, the salted-out film formed on the salt solution gradually decreases in thickness to 50 Å. if left for five minutes before deposition.

---

[13] K. B. Blodgett, *J. Phys. Chem.*, **41**, 975 (1937); see p. 980.

In many experiments we have made estimates of the total amount of protein which can be recovered in the salted-out films by transferring them to metallic surfaces, or we have determined the protein content per sq. cm. by a method which we shall describe later involving the production of monolayers on another water surface. In general, with pure crystalline egg albumin, tobacco virus and pepsin, there is a very high recovery in the film.

With impure proteins such as commercial egg albumin or pepsin, the fraction of applied protein which is recovered in the salted-out film is much lower. Apparently there is a purification of the crystallizable protein involved in the formation of the salted-out film, so that the yield serves to measure the crystallizable protein content.

Properties of Salted-Out Films.—The thick salted-out films of protein, particularly the compact ones, possess considerable mechanical strength and are relatively incompressible. When subjected to moderate pressure, they can be lifted off the solution on a loop of platinum wire.

A film produced from crystalline egg albumin, on an ammonium sulfate solution, having a thickness of 1000 Å. and showing a light yellow interference color, was found to be under a pressure of $F = 23$ dynes per cm. at the time it was formed. On raising the pressure to 30 dynes per cm. the area decreased only 2%, corresponding to a compressibility of 0.0030 for each dyne per cm. On raising the compression to $F = 50$, the area decreased 17%, corresponding to a compressibility of 0.0080. At this higher pressure groups of parallel wrinkles began to appear, especially when slight shearing stresses were applied. At $F = 54$, the whole surface became wrinkled and collapse set in. For comparison we note that a monolayer of egg albumin on water decreases to half its area when F is raised from 1 to 25 and to one-quarter the original area at $F = 34$. In the F range from 23 to 30 the compressibility was 0.07 for the monolayer as compared to 0.003 for the salted-out film.

Transference of Salted-Out Films to a Water Surface.—If a piece of nickel or platinum foil cleaned and made hydrophilic by heating in a Bunsen flame, is lowered into a salt solution covered by a salted-out protein film under compression of $F = 30$ dynes per cm. produced by a drop of oleic acid, and is then raised out of the solution, the film is deposited on the foil as a hydrous B-film. If, now, before the water film under the protein film has dried, the foil is lowered into clean water in another tray, the protein film escapes onto the water surface.

Salted-out films of many proteins, such as pepsin, insulin and egg albumin, when transferred in this way to water, which preferably has its *p*H adjusted to the isoelectric point of the protein, spread out apparently without appreciable loss to form typical monolayers. By measuring A_2, the area of the monolayer at some value of F, such as 16 dynes per cm., and determining the thickness T_2 of the monolayer at the same compression, we can calculate the weight, W_2, of the protein transferred to the water by the relation

$$W_2 = 1.3 \times 10^{-5} A_2 T_2 \qquad (1)$$

where W_2 is expressed in mg. and T_2 in Å.

The thickness T_2 can be measured optically after depositing the monolayer on a barium stearate multilayer film of critical thickness (45–47–49 layers), preferably by the "lift method" in which the plate is lowered horizontally onto the monolayer (H-layer) and then after the surface has been cleaned, raised from the water. By this method a single monolayer of A_L-type is deposited.

The thickness T_1 of the original salted-out film can now be calculated from the equation

$$T_1 = A_2 T_2 / A_L \qquad (2)$$

where A_L is the area of the "lifted film" taken from the salted-out film. Our experience has been that this is usually a more accurate method of determining T_1 than a direct optical measurement of the salted-out film on the water or on a plate upon which it may be deposited. The reason for this is that the optical measurements are often difficult because of a relatively large amount of scattered light from the thick protein films. The method, however, is not applicable to tobacco virus and other proteins which do not spread to form monolayers.

Table II gives a summary of data obtained in studies of salted-out films of various proteins on 90% saturated ammonium sulfate solutions. The insulin (L) was a pure crystalline product obtained from Eli Lilly and Company, while the pepsin (L) was a commercial grade from the same source having an activity (skim milk test) of 8000 units per gram. A similar test of the activity of Northrop's crystalline pepsin (N) gave 50,000 units per gram. The egg albumin (L) was also an impure commercial product.

The third column gives the concentration of the protein solution in percentage by weight. A measured volume of this solution (for example, 0.18 ml. in Experiment 1, and 0.033 ml. in Experiment 2) which contained the weight W_1 of protein as given in mg. in Col. 4 was applied in the middle of the delimited area (Col. 5) by Gorter's technique. The sixth column gives the approximate area of the salted-out film that was produced; Col. 7 gives A_L, the area of the salted-out film that was deposited onto a plate and subsequently transferred to the surface of water (at the isoelectric point of the protein) in another tray where it gave the area A_2 (Col. 8) when subject to a

compression of $F = 16$ dynes per cm. The thickness T_2 was found in the various experiments to range from 15 to 18 Å., so we have taken the average value $T_2 = 16$ Å. The thickness T_1 of the salted-out film, as given in Col. 9, was calculated by Eq. (2) from A_2, T_2, and A_L.

The last column gives β, the fraction of the protein applied to the salt solution which was recovered in the salted-out film. This was calculated by the equation

$$\beta = 1.3 \times 10^{-5} A_1 T_1 / W_1 \qquad (3)$$

Examination of the data in the table shows that with a large delimited area, Experiments 1 to 3, from 77 to 94% of the insulin was found in the salted-out film, but with the L-pepsin only from 8 to 17% was recovered, the highest fraction being obtained with the most dilute protein solution. The fraction recovered was not greatly dependent on the amount of protein solution applied (Experiments 6, 7 and 8). The thickest films were obtained with the most concentrated solutions (Experiments 3 and 6) and when the largest amounts of the protein solution were applied (Experiments 6, 7 and 8). In Experiments 9 to 14 the delimited areas were purposely varied. The fraction recovered is somewhat less when the available spreading area is restricted, but the thickness T_1 is made greater in this way (Experiments 9 and 12).

The high percentage of recovery from the insulin compared with pepsin suggested that this might be due to the difference in purity of the two proteins. We therefore made some experiments with a crystallized egg albumin obtained from P. A. Levene and a crystallized pepsin from J. H. Northrop. With these very high percentages of recovery were obtained. Films of various thicknesses, ranging from 100 up to 7000 Å., could be obtained by regulating the amount of protein in the delimited area.

The Activity of Pepsin in Salted-Out Films.—Uniform salted-out films of pepsin were produced by applying pepsin solutions to 90% saturated ammonium sulfate solutions. The thickness of the film was measured optically after depositing it on a chromium plate. Another portion of the film was deposited on a plate of known area and the protein was washed off with 2 ml. of 0.1 *M* acetate buffer, *p*H 5, into a test-tube containing 1 g. of powdered skim milk in 4 ml. of the same acetate buffer, and the clotting time at 37° was noted. The weight of the protein on the plate was calculated from the area, and thickness, assuming a density 1.3. In this way the activity per gram was determined. Similar tests of activity were made by introducing known weights of protein directly into the milk solution.

The results showed that Northrop's pepsin (50,000 units per gram) gave salted-out films having at least 90% of the activity of the original protein. On the other hand, with a commercial grade of pepsin (8000 units per gram) salted-out films were obtained which gave (per gram) four times the activity of the impure pepsin applied to the salt solution, although they were still only about 60% as active as the crystalline pepsin.

The production of salted-out films may thus prove to be a rapid and convenient microtechnique for purifying small amounts of various proteins. By the choice of the proper salt and concentration it should be possible to separate proteins from one another and to measure the amounts.

Summary

When a glass or metal plate is dipped into a protein solution, then into a concentrated solution of a salt such as ammonium, sodium or magnesium sulfate, or sodium chloride, a compact film of protein often 200–1000 Å. thick is salted out onto the plate. This can be fixed by 1% tannic acid and can then be washed with water without loss. After it has dried the thickness can be determined optically by interference colors. Insulin films, formed by using 1% sodium chloride solution, need no tannic acid treatment.

Salted-out protein films, in some cases up to 7000 Å. in thickness, are formed on the surface of salt solutions by applying a few drops of the protein solution. These can be deposited as hydrous B-films or as lifted A_L films onto plates or small pieces of metal foil, and they can thus be transferred to clean water surfaces where the amount of the protein can be measured from the area of the monolayer produced, or they can be fixed by tannic acid, washed and dried and the amount of protein per sq. cm. determined optically.

The refractive index of dried salted-out films of crystalline egg albumin was found to be 1.48. This low value and the power of the film to absorb hydrocarbon vapors indicate that the dried film has a skeleton-like structure.

The formation of these films at the surface of the solution or on a plate is aided by the concentration gradient in the salt solution. This carrying effect is analogous to the Ludwig–Soret phenomenon by which a solute originally uniformly distributed through a solution tends to concentrate in a portion of the solution which is cooled.

NOTES

Esters of Chlorosulfonic Acid[1]

BY W. W. BINKLEY WITH ED. F. DEGERING

While the lower alkyl esters of chlorosulfonic acid have been prepared, they have not been purified by redistillation and there is some disagreement in the values of the physical constants which have been reported.[2] We have therefore again prepared these substances and have purified them by careful rectification using a modified Podbielniak column and have redetermined with care certain of their physical constants.

The esters were prepared by adding dropwise one-fifth mole of the absolute alcohol to one-fifth mole of sulfuryl chloride contained in a test-tube 20 cm. long immersed in an ice-bath, the sulfuryl chloride being agitated by a brisk current of dry air drawn through it. A rough separation of the alkyl chlorosulfonate from the dialkyl sulfate was first accomplished by distillation under diminished pressure at the lowest possible temperature. The distillate was then rectified under diminished pressure in a jacketed electrically heated column which has a continuous nichrome wire gage No. 18 for packing.[3] An average yield of 50% based on the alcohol was obtained. The characteristic physical constants for these esters and other analyses are collected in Table I.

The chlorine content was estimated by a modified Fajans method[4] after the ester was allowed to decompose in a pressure bottle containing calcium carbonate. Sulfur was determined by the method of Carius.

All the lower normal esters of this series are lachrymators. The tear-producing effect decreases as the length of carbon chain is increased.

Nitrogen-Terminated Conjugated Systems and Maleic Anhydride

BY FELIX BERGMANN

The ability of 9-vinylphenanthrenes to condense with maleic anhydride[1] induced us to investigate whether conjugated systems consisting of a cyclic C–N double bond and an exocyclic ethylenic linkage would add maleic anhydride. 2-Styrylquinoline gave a well-defined reaction product, which, however, besides the components, contained one molecule of water, and therefore was styrylquinolinium maleate. This became obvious in its reaction with diazomethane, yielding dimethylpyrazoline-4,5-dicarboxylate.[2] Analogous observations have been made recently by La Parola[3] in the case of antipyrine and pyramidone. For comparison purposes, we studied the interaction between maleic anhydride and cinnamylidene-aniline, which contains the nitrogen-terminated conjugated system entirely in an open chain. Here, too, the reaction involves one molecule of water (from the air), but the maleate, presumably formed as above, is unstable and decomposes spontaneously into cinnamic aldehyde and maleanilic acid, HOOCCH=CHCONNH-C_6H_5.

Experimental

2-Styrylquinoline[4] (1.2 g.) and **maleic anhydride** (0.5 g.) were heated on the water-bath or in xylene solution for some minutes. The mixture turned yellow at once and deposited on cooling yellow crystals, which were recrystallized from xylene or butyl acetate. 2-Styrylquinolinium maleate formed long, silky needles, m. p. 165–167°. *Anal.* Calcd. for $C_{21}H_{17}O_4N$: C, 72.6; H, 4.9. Found: C, 72.8; H, 5.3. The salt was kept in contact with an excess of ethereal diazomethane solution; on evaporation a crystalline mass was obtained which was triturated with light petroleum (b. p. 80–100°) and recrystallized from the same solvent. Dimethyl pyrazoline-4,5-dicarboxylate was obtained in the form of leaflets, m. p. 103–105°. *Anal.* Calcd. for $C_7H_{10}O_4N_2$: C, 45.2; H, 5.4; N, 15.1. Found: C, 44.8; H, 5.5; N, 15.6.

Cinnamylidene-aniline[5] (1 g.) and **maleic anhydride** (0.5 g.) were heated together on the water-bath; the mixture turned brown, then red and an intense odor of cinnamic aldehyde developed. After fifteen minutes, benzene was added, whereupon maleanilic acid crystallized, yield 300 mg.; from butyl acetate as rhombohedra, m. p. 210°.[6] *Anal.* Calcd. for $C_{10}H_9O_3N$: C, 62.8; H, 4.7; N, 7.3. Found: C, 62.5; H, 4.5; N, 7.7. Diazomethane gave as above the expected methyl ester-anilide of pyrazoline-4,5-dicarboxylic acid, from xylene or butyl acetate; crystals, m. p. 175° (dec.). *Anal.* Calcd. for $C_{12}H_{13}O_3N_3$: N, 17.0. Found: N, 17.4.

The Calculation of the Dissociation Constant of Weak Acids in H_2O–D_2O Mixtures

BY FRANK BRESCIA

From the exchange equilibria

$$2DCl + QH_2 = 2HCl + QD_2 \qquad K_1 = 14.64 \quad (1)$$

$$QH_2 + D_2O = QD_2 + H_2O \qquad K_2 = 0.96 \quad (2)$$

$$H_2O + D_2O = 2HDO \qquad K_3 = 3.27 \quad (3)$$

Korman and La Mer[1] have calculated the equilibrium constant for the process, $D^+ + H_2O = H^+ + HDO$, to be $K_4 = 7.1$. Their derived equation for the calculation of dissociation constants of weak acids in H_2O–D_2O mixtures

$$K_M = K_D \left[1 + 7.1 \frac{C_{H_2O}}{C_{HDO}} \Big/ 1 + 7.1 \left(\frac{K_D}{K_H}\right) \frac{C_{H_2O}}{C_{HDO}}\right] \quad (5)$$

contains, therefore, the factor 7.1. K_M is the dissociation constant of the acid in the mixtures of H_2O–D_2O, K_D is the dissociation constant of

---

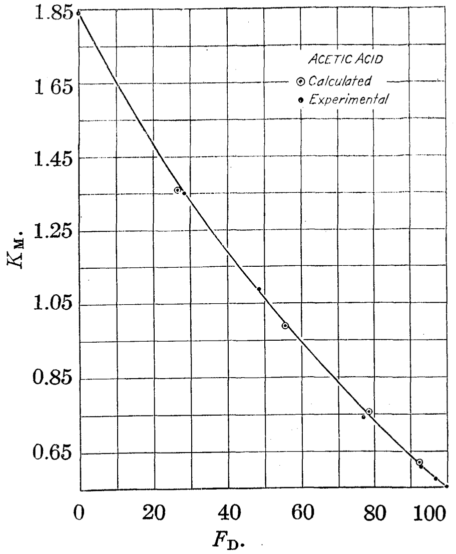

Fig. 1.—Acetic acid: ◉, calculated; ●, experimental.

the heavy acid, and K_H is the dissociation constant of the light acid. This equation, tested by Chittum and La Mer,[2] does not give the same K_M constants as those calculated from the conductance data. The sag of the experimental curve for acetic acid is opposite from that predicted by equation (5).

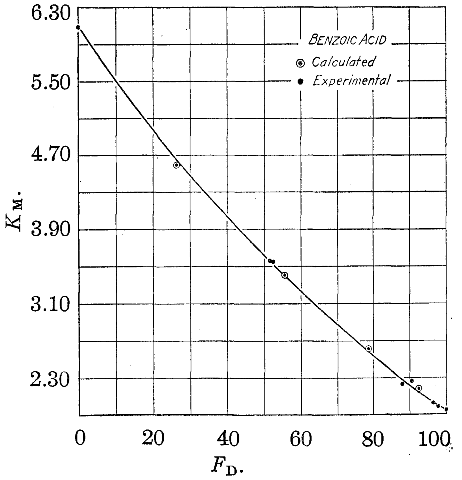

Fig. 2.—Benzoic acid: ◉, calculated; ●, experimental.

The value of K_4 can now be arrived at by an independent method. K_4 (column 4, Table I) has been calculated from the customary $K_3 = 3.27$[3] and from the values of C_{H^+} and C_{D^+} (columns 2 and 3, Table I), obtained through kinetic measurements of a specific hydrogen-ion catalyzed reaction: hydrolysis of ethyl orthoformate in mixtures of $H_2O–D_2O$.[5] The average value thus obtained, 3.76, is much smaller than the previous value, 7.1. Equation (5) is, therefore, corrected to

$$K_M = K_D \left[1 + 3.76 \frac{C_{H_2O}}{C_{HDO}} \Big/ 1 + 3.76 \left(\frac{K_D}{K_H}\right) \frac{C_{H_2O}}{C_{HDO}}\right] \tag{6}$$

The K_M values, calculated from the revised equation (6), are now in very good agreement with the experimental results. These are summarized in Table II and plotted in Figs. 1, 2, and 3. The predicted slope for chloroacetic acid is given in Fig. 4; no experimental data for comparison are available. The value of K_D for salicylic acid is extrapolated with equation (6) from the average value $K_M = 0.24 \times 10^{-3}$, a. d. 12%, at $F_D = 91.7$, and from the average $K_H = 0.98 \times 10^{-3}$, a. d. 2%, determined by Korman and La Mer.[1] The K_D thus calculated is 0.21×10^{-3} which also has not yet been determined experimentally.

It is apparent that true values of hydrogen and deuterium ion concentrations are obtainable from kinetic data when tested by means of acid dissociation constants.

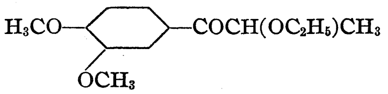
The Structure of Lignin

BY A. B. CRAMER, M. J. HUNTER AND HAROLD HIBBERT

In a recent note[1] the isolation of a new aromatic ketone ($C_{13}H_{18}O_4$) was described. This has now been identified (by direct synthesis and mixed melting point determination) as α-ethoxypropioveratrone



The synthesis (after numerous unsuccessful attempts, and using a variety of methods) was accomplished as follows:

Veratrole + propionyl chloride ⟶ Propioveratrone ⟶
α-Brompropioveratrone ⟶ Acetate of α-hydroxypropioveratrone
↙ ↘
α-Hydroxypropioveratrone ⟶ α-Ethoxypropioveratrone

The synthetic compound melted at 81–82°; a mixed melting point with natural compound gave no depression. The melting point of the 2,4-dinitrophenylhydrazone of the natural compound is 134–136°; synthetic compound, 134–136°; the mixed melting point also showed no depression.

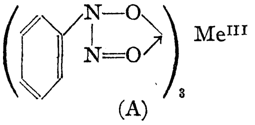
The Classification of Chelating Groups

BY HELMUT M. HAENDLER AND BRADFORD P. GEYER

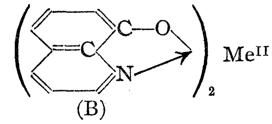
In the course of preliminary work on organic analytical reagents which form inner complex compounds with metal ions, it was found advisable to devise a system for the classification of chelating groups present in various organic compounds to serve as a basis of comparison. The available classifications, in particular that of Diehl,[1] are too unwieldy for rapid grouping and comparison. In addition to classifying the organic compounds now known, any system should also present information concerning possible reagents. The common method of indicating the number of members in the completed chelate ring is too cumbersome, in view of the recent increases in both number and variety of compounds possessing groups capable of chelation.

TABLE I

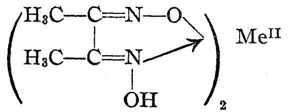
Group designation	Representative compound
C-N, SH	Mercaptobenzothiazole
C-NH, SH	Rubianic acid
C-NOH, OH	Benzohydroxamic acid
N-$NONH_4$, O	Cupferron (A)
C,C-N, NOH	Phenyl α-pyridyl ketoxime
C,C-N, OH	8-Quinolinol (B)
C,C-N, SH	8-Quinolinethiol
C,C-NH, SH	Thionalide
C,C-NH_2, OH	Glycocoll
C,C-NOH, NOH	Dimethylglyoxime (C)
C,C-NOH, O	α-Nitroso-β-naphthol
C,C-O, OH	Oxalic acid
C,C-O, SH	Thioglycolic acid
C,C-OH, OH	Catechol
C,C-OH, S	Thiohydantoic acid
C,N-NH, NOH	Nitrosoguanidine
C,N-NH_2, OH	Hydrazinecarboxylic acid
C,N-NH_2, SH	Dithizone (D)
C,C,C-N, NH	Chlorophyll type
C,C,C-NOH, OH	Salicylaldoxime (E)
C,C,C-O, OH	Alizarin
C,C,N-N, NH	Phthalocyanine
C,C,N-NH, NH	Biguanidine
C,C,N-NH, NH_2	Biuret
C,C,N-NH, O	Dicyandiamidine (F)



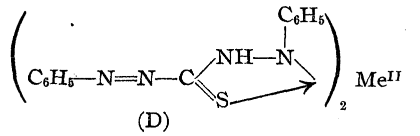
(A)



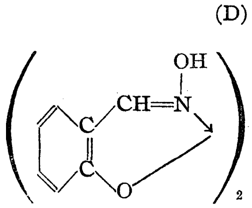
(B)



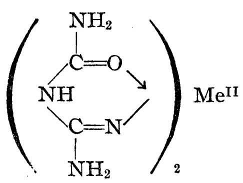
(C)



(D)



(E)



(F)

In this classification the two functioning groups, which supply the primary and secondary valences involved in the general formation of a chelate ring, and the atom or atoms linking these two groups form the basis of the system. Compounds with identical chelating groups have the same group designation, regardless of the structure of the remainder of the molecule. The group designation is derived as follows: (*a*) The atom or atoms connecting the two functional groups are expressed by their conventional symbols, arranged alphabetically. (*b*) The functioning groups are given by their symbolic representations in alphabetical order of the atoms by which they are attached to the original compound before chelation.

In salicylaldoxime, for example, the functional groups are linked by three carbon atoms, and these functional groups are the oxime and hydroxyl radicals. Consequently, the classification is C,C,C-NOH, OH.

The accompanying list gives in order of increasing complexity the designations of the more common chelating groups and the names of representative compounds containing such groupings. For the sake of clarity, structural formulas illustrating some of the inner complexes formed are also given. It is evident that exact knowledge of the structure of the chelate compound formed is not essential for this method, insofar as the primary and secondary valence connections are concerned. No attempt is made to designate these linkages as to type, and compounds are arranged solely on the basis of general structure.

Dynamic Isomerism of Acetaldehyde 2,4-Dinitrophenylhydrazone

BY W. M. D. BRYANT

In earlier papers the writer[1,2] presented conclusive evidence based on optical crystallographic measurements that there are at least two distinct crystalline modifications of acetaldehyde 2,4-

---

[1] Bryant, THIS JOURNAL, **55**, 3201 (1933).

[2] *Ibid.*, **58**, 2335 (1936).

dinitrophenylhydrazone, and refuted the contention of Campbell[3] that the second modification is merely a product contaminated with the dinitrophenylhydrazone of another carbonyl compound. On the basis of the evidence then available the relationship between these two crystal modifications was assumed to be one of polymorphism. However, a new melting point study using a Kofler and Hilbck micro heating stage[4] has been completed and the results indicate dynamic isomerism rather than polymorphism as the true relationship. This explanation was proposed by Allen and Richmond[5] on the basis of some work by Bredereck[6] with substituted furfural derivatives, and is in accord with the new experimental results.

Experimental

The new melting point observations were made using a Kofler and Hilbck micro heating stage[7] mounted on the object stage of a chemical microscope equipped with a 10X Reichert heat resisting objective. By this means thermal changes in individual crystals could be followed and the temperatures read by means of a calibrated thermocouple. Melting points by this method were found accurate to ±2° and precise to ±0.5°. The samples of acetaldehyde 2,4-dinitrophenylhydrazone employed were prepared during the two earlier investigations.

Acetaldehyde 2,4-dinitrophenylhydrazone I (previously called the "stable form") recrystallized five times from 95% ethanol[1] was found to melt sharply without transition at 168–170° in agreement with 168.5° obtained previously by the more precise macro method. Above 115° in the initial heating a slight sublimate of orange lozenge-shaped crystals appeared and was recognized as the II modification (previously designated as "metastable"). These crystals melted at 156–157°. A few of these crystals in contact with modification I began melting at slightly lower temperature. The resulting liquid noticeably eroded plates of the I form below their regular melting temperature. In another experiment the sublimate was the I form (plates) and melted at the higher temperature (168–170°). On slowly cooling the liquid phase after complete fusion, the II form often reappeared first, usually at 130–140°; on reheating, this form was in equilibrium with the liquid at 148°, a slight change of temperature being sufficient to induce either growth or solution. In cases where the I form reappears first, the fusion or solution process begins at 150–155° and complete solution occurs between 155 and 160°. The above behavior is typical of a system in which the two compounds are, strictly speaking, different chemical entities but mutually convertible one into the other.

A sample of derivative recrystallized once from benzene[2] had an initial melting point of 148–151°. Crystals (mainly the II modification) reappeared at 131° and were completely fused (or dissolved) at 149.5°. After several repetitions the fusion temperature was lowered to 142°.

The above observations indicate that acetaldehyde 2,4-dinitrophenylhydrazone exists in two chemically different forms (dynamic isomers), the ordinary form (I) melting sharply near 169° and a form (II) obtained by sublimation melting at 157°. Crystallization of the melt produces a mixture (probably an equilibrium mixture) melting near 148°. The derivative recrystallized from benzene although optically identical with the I modification melts near 149° as does the "equilibrium mixture," hence must contain traces of a catalyst (possibly sulfuric acid) capable of inducing a rapid isomerization. This accounts for the low melting points sometimes observed.[2] In the writer's earlier experiments[1] slow isomerization was mistaken for a more fundamental thermal breakdown and hence not given the attention it deserved.

Structure of Lignin

BY M. J. HUNTER, A. B. CRAMER AND HAROLD HIBBERT

In a recent note[1] the isolation of an aromatic ketone, $C_{13}H_{18}O_4$, from spruce wood by organic solvent extraction was reported and the additional presence of derivatives containing the syringyl group from hard woods noted.

Using maple wood and similar organic solvent extraction, there is obtained a mixture of two ketones, having in the pure state the empirical formulas $C_{12}H_{16}O_4$ and $C_{13}H_{18}O_5$, respectively, which can be readily separated by conversion into their *p*-nitrobenzoates.

One of these corresponds to the ester from the ketone previously reported, while the new crystalline *p*-nitrobenzoate is derived from the second ketone, the latter being related to the former by possessing an additional methoxyl group. They are apparently present in approximately equal amounts.

The theoretical conclusion drawn previously that hard woods differ from soft in having present in the building unit not only the guaiacyl but also the syringyl radical has thus been substantiated.

The Dimerization of 3-Phenylindene

BY C. S. MARVEL AND H. A. PACEVITZ

Blum-Bergmann has reported[1,2] a dimer of 3-phenylindene (m. p. 207–209°) as a by-product in a reaction in which 3-phenylindene was treated with lithium. No exact method of producing or isolating the dimer was described. We have tried to obtain the same compound for comparison with an isomeric hydrocarbon melting at 210–211°.[3] Various combinations of conditions have been used but none yielded the dimer reported. A different dimer melting at 157° has, however, been obtained.

Dimer of 3-Phenylindene.—A mixture of 30 cc. of 47% hydrogen iodide solution and 2 g. of 3-phenylindene was shaken for sixteen hours. A dark brown solid separated out. This was separated and dissolved in about 400 cc. of low-boiling petroleum ether (b. p. 40–60°). The ether solution was concentrated to about 100 cc., at which point some crystals separated. The product was twice recrystallized from petroleum ether. The yield was 1.9 g. of a product melting at 156–157°.

Anal. Calcd. for $C_{30}H_{24}$: C, 93.6; H, 6.4; mol. wt., 384. Found: C, 93.55, 93.48; H, 6.36, 6.45; mol. wt. (Rast), 357, 359.

In a similar manner 2 g. of 3-phenylindene and 25 cc. of fuming stannic chloride gave 1.7 g. of dimer melting at 156–157°.

Heating 3-phenylindene with equal parts of sirupy phosphoric acid and water, with glacial acetic acid, with concentrated sulfuric acid or a mixture of sulfuric acid and hydrochloric acid did not cause it to dimerize.

Treating a benzene solution of 3-phenylindene with metallic lithium in an atmosphere of nitrogen for several days did not produce a dimer.

Heating the dimer to 350° caused some charring but no 3-phenylindene was found in the distillate.

[1] Blum-Bergmann, *Ann.*, **484**, 26 (1930).

[2] Through the kindness of Dr. E. Bergmann we have obtained a sample of the dimer of 3-phenylindene melting at 210–211°. This product proved to be a different hydrocarbon from the hydrocarbon of the same composition and melting point reported by Farley and Marvel,[3] since a mixture of the two melted at 185–190°.

[3] Farley and Marvel, THIS JOURNAL, **58**, 32 (1936).

The Dimerization of 3-Phenylindene

BY E. BERGMANN

The preceding Note by Marvel and Pacevitz has been made accessible to me through the courtesy of the Editor. The dimeric 3-phenylindene had only occasionally been obtained and its structure therefore had not been elucidated. Although the mechanism by which indene is dimerized[1] would lead only to one dimer of 3-phenylindene, there may be other ways, too, of dimerization. An experiment has shown that the two substances, m. p. 210–211° and 156–157°, respectively, are not allyl isomeric forms, as they are not interconvertible by means of sodium ethylate solution.

β,β′,β″-Trichlorotriethylamine

BY J. PHILIP MASON AND DALE J. GASCH

In the course of some other work, we had occasion to make trichlorotriethylamine and its hydrochloride. By a slight modification of the procedure used by Ward,[1] we were able to increase the yield of the hydrochloride from 70 to 92%.

Two moles (238 g.) of thionyl chloride dissolved in 150 ml. of benzene was added to 0.5 mole (92.7 g.) of triethanolamine hydrochloride in a 1-liter round-bottomed flask equipped with a reflux condenser and a gas absorption trap. The mixture was heated to 55° and kept at that temperature for three hours. The benzene and excess thionyl chloride were distilled under diminished pressure at 50°. In order to decompose the last portion of thionyl chloride, about 50 ml. of ethyl alcohol was added. The mixture was warmed for

---

[1] Ward, THIS JOURNAL, **57**, 914 (1935).

ten to fifteen minutes and then the alcohol was distilled. This step was found desirable because otherwise charring occurred when acetone was added to recrystallize the product. The residue was recrystallized from boiling acetone; yield, 106.3 g. (88%). By concentrating the acetone filtrate, a second crop of crystals (4.5 g.) was obtained, bringing the total yield up to 92%. McCombie and Purdie[2] made trichlorotriethylamine hydrochloride directly from triethanolamine and thionyl chloride, using chloroform as a solvent, and obtained a yield of 73.8%.

The free trichlorotriethylamine, obtained in the usual way from the hydrochloride, had a b. p. of 143–144° at 15 mm., which is 6° higher than that reported by McCombie and Purdie[2] at the same pressure.

Anal. Calcd. for $C_6H_{12}Cl_3N$: Cl, 52.1; mol. wt., 204.5. Found: Cl, 51.6, 51.8; mol. wt. (benzene), 205.9.

The amine was almost colorless when freshly distilled, but turned to a light brown color on standing for sixty hours. The color darkened on longer standing. Crystals, which were not identified, appeared in the liquid after standing for a month. Ether solutions of the amine darkened more slowly and no crystals were observed. Instead, a small amount of dark brown material was deposited from an ether solution which had been kept for two months. No attempt was made to identify this material.

The Catalytic Reaction between Sodium Nitrite and Dichlorodiethylenediamine Cobaltic Chloride

BY J. P. MCREYNOLDS AND JOHN C. BAILAR, JR.

In the course of stereochemical studies on the complex inorganic compounds, it was observed that racemic dichlorodiethylenediamine cobaltic chloride reacts almost instantaneously with sodium nitrite according to the equation $[Coen_2Cl_2]^+ + 2NaNO_2 \longrightarrow [Coen_2(NO_2)_2]^+ + 2NaCl$[1] but that the material which has been resolved into its optical antipodes reacts very slowly. This resolution is carried out through the α-bromocamphor-π-sulfonate, which is reconverted to the chloride by means of hydrochloric acid in alcohol and ether. The active product is then washed with alcohol and ether.[2] It was found that washing the racemic material with alcohol and ether caused it to lose its reactivity toward sodium nitrite. The washings contained cobaltous ion. That cobaltous ion catalyzes the reaction in question was demonstrated easily.[3]

Werner has noted[4] briefly that traces of acids catalyze this reaction but no other example of such catalytic substitution has been reported for compounds of this type. A study was therefore made to determine the mechanism of the reaction. Two compounds which seemed possible intermediates are sodium cobaltinitrite, $Na_3Co(NO_2)_6$, and sodium cobaltonitrite, $Na_2Co(NO_2)_4$. Sodium cobaltinitrite was found to have no catalytic effect in this reaction. On the other hand, the cobaltonitrite ion could be precipitated (as the potassium salt) from mixtures which had been catalyzed artificially by addition of cobaltous ion. This seems to point to the intermediate formation of sodium cobaltonitrite.

The mechanism postulated for this catalysis must explain the very rapid replacement of chloro by nitro groups and the apparent absence of oxygen to cobalt linkages at any step in the reaction. This latter requirement is evidenced by the fact that at no time is there any indication of a red coloration such as is found in nitrito cobalt compounds. The isolated intermediate and the almost instantaneously formed product both have the yellow color characteristic of the nitrogen to cobalt bond. Further, nitrite complexes of trivalent cobalt have been prepared and characterized. They are stable in solution for a considerable period, changing to nitro complexes quite slowly.

The explanation offered here involves a shift of the electrons upon the nitrogen to allow it to form a coördinate bond to both trivalent and bivalent cobalt. This is a very unstable arrangement and is broken up immediately, leaving the nitrogen attached to the trivalent cobalt. This latter step seems quite logical since the trivalent cobalt complexes are very much more stable than those of bivalent cobalt. It must be assumed that

---

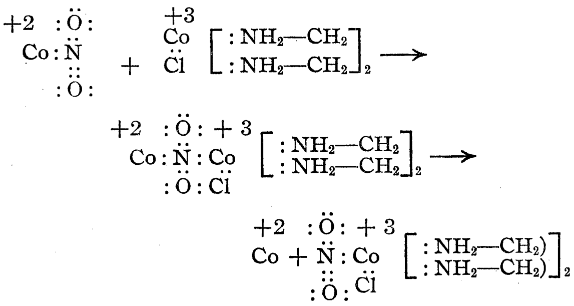
[1] The symbol "en" represents ethylenediamine.

[2] Bailar and Auten, THIS JOURNAL, **56**, 774 (1934).

[3] The traces of cobaltous ion present in the racemic material evidently are produced during the conversion of the *trans* form of the complex to the *cis* form by evaporation of the solution and subsequent heating of the residue in the oven. A dry sample of optically active material unreactive to sodium nitrite became reactive after several hours of such heating. It lost a large part of its optical activity during the heating.

[4] Werner, *Ber.*, **34**, 1734 (1901).

one chloride group ionizes from the cobaltic complex momentarily or that the coördination number of the cobaltic ion may exceed six, at least for an instant. On the first assumption, the mechanism of the catalytic reaction may be as follows



$$\overset{+2}{\mathrm{Co}}:\underset{:\ddot{O}:}{\overset{:\ddot{O}:}{\ddot{N}}} + \overset{+3}{\mathrm{Co}}\,\mathrm{Cl}\left[\begin{matrix}:NH_2-CH_2\\ :NH_2-CH_2\end{matrix}\right]_2 \longrightarrow$$

$$\overset{+2}{\mathrm{Co}}:\underset{:\ddot{O}:}{\overset{:\ddot{O}:}{\ddot{N}}}:\overset{+3}{\underset{\mathrm{Cl}}{\mathrm{Co}}}\left[\begin{matrix}:NH_2-CH_2\\ :NH_2-CH_2\end{matrix}\right]_2 \longrightarrow$$

$$\overset{+2}{\mathrm{Co}} + \underset{:\ddot{O}:}{\overset{:\ddot{O}:}{\ddot{N}}}:\overset{+3}{\underset{\mathrm{Cl}}{\mathrm{Co}}}\left[\begin{matrix}:NH_2-CH_2)\\ :NH_2-CH_2)\end{matrix}\right]_2$$

It is possible that the familiar coördination compounds of metal ions with ethylene compounds and with azo compounds are formed in the same way—by the shift of a pair of electrons from the double bond to an adjacent atom.

The catalyzed reaction, when applied to optically active starting material, lends further evidence in favor of such a mechanism since the product always has a much lower activity than that formed through the uncatalyzed reaction.

A further investigation was carried out to determine the possibilities of extending this type of catalysis to other substitutions. All attempts to catalyze the substitution of oxalate or thiocyanate groups for chloro groups by the addition of metallic ions failed to show positive results. The ions used were nickelous, ferric, aluminum, stannous and cobaltous, all of which tend to form unstable complex ions. This study showed that cobaltous ion is unique among those tried in producing the catalytic substitution of the nitro group.

Ammonium Chloride–Sodium Sulfide Solutions for Organic Nitro Reductions and for Inorganic Qualitative Analysis

BY M. J. MURRAY AND D. E. WATERS[1]

Two disadvantages in the use of ammonium sulfide as reducing agent for organic nitro compounds have been: (1) the length of time consumed in saturating the ammonium hydroxide with hydrogen sulfide, and (2) the indefinite amounts of materials used. Both of these disadvantages are overcome by preparing a solution containing equivalent amounts of ammonium chloride and crystalline sodium sulfide ($Na_2S\cdot 9H_2O$). This solution is added to the nitro compound dissolved in ammonium hydroxide or alcohol and ammonium hydroxide. The mixture can be heated at once until excess hydrogen sulfide has escaped, and from this point the isolation of the reduction product is the same as in standard procedures.

The reagent was tested most thoroughly on the reduction of *p*-nitrobenzoic acid. The yields were consistently higher than on parallel runs using hydrogen sulfide and ammonium hydroxide. The melting point and the neutralization equivalent showed the product to be one of high purity. Reduction by sodium polysulfide, sodium sulfide alone, and sodium hydrogen sulfide gave yields inferior as to both quality and quantity. Other compounds reduced by the sodium sulfide–ammonium chloride reagent were: *p*-nitrophenylacetic acid,[2] 3-nitrophthalhydrazide,[3] and *m*-dinitrobenzene.[4] In each case the yield equaled or exceeded that reported in the reference given.

A second use of this rapid method for the preparation of ammonium sulfide is in the making up of solutions of ammonium polysulfide for inorganic qualitative analysis. A solution of approximately known strength can be prepared in a few minutes as follows: equivalent amounts of ammonium chloride and crystalline sodium sulfide ($Na_2S\cdot 9H_2O$) are dissolved in a small volume of water, powdered sulfur is added, and the mixture warmed to promote solution. Then ammonium hydroxide is added and the solution diluted to the desired strength. Concentrations are not given here because textbooks do not agree as to the optimum strength.[5] Attention should also be directed to the fact that few laboratory assistants make up the ammonium polysulfide solutions as strong as called for because of the difficulty of completely saturating the ammonium hydroxide with hydrogen sulfide. For this reason solutions prepared by the short method just described will be, in general, considerably more concentrated than ordinarily

The Interaction between Methylene Radicals and Hydrogen

BY CHARLES ROSENBLUM

The photolysis of ketene in the presence of hydrogen points to a reaction between methylene radicals and hydrogen, in contrast with the relative stability[1] of methylene toward ketene itself and toward ether vapor. The reactants, 100 mm. of ketene and 225 mm. of hydrogen, were irradiated in a cylindrical quartz vessel (volume 130 cc.) by a "hot" mercury arc for about forty-five minutes, and the resultant gas mixture analyzed. Although a constricted arc was used throughout, a hydrogen–mercury vapor filter[2] for resonance radiation was interposed as an added precaution against the lamp as a source of hydrogen atoms. A mixture of ethylene and hydrogen did not react when exposed to the arc under these conditions.

Irradiation of ketene alone[3] results in an increase in volume due to the formation of carbon monoxide and ethylene as the sole gaseous products, this increase falling below the theoretical value after longer exposures because attendant polymerization creates a gaseous hydrocarbon deficiency. The reaction which occurs in the presence of hydrogen differs markedly from the above in that it is characterized by a volume decrease. This can be accounted for only if the gaseous hydrocarbon is saturated and some saturated liquid (or solid) hydrocarbons of low vapor pressure are formed, which implies a disappearance of hydrogen.

Analysis confirmed these expectations fully. Of the ketene decomposed in the presence of hydrogen at 35°, 1% yielded methane, 74% was recovered as a gas with an average composition[4] $C_{2.56}H_{7.12}$, and 25% yielded a residue of low volatility. At 200° the methane content corresponded to 9.6% of the decomposed ketene, the gaseous fraction with a mean composition[4] $C_{2.68}H_{7.36}$ represented 69%, and the residue accounted for 21% of the ketene present originally. In both cases, the average composition of the residual polymeric product was C_4H_{10}. The mean composition and quantity of this polymer were deduced from the carbon and hydrogen deficiencies in the balance sheet of initial and final gaseous components of the reaction system. The amounts of condensed product calculated in this manner agreed well with the observed volume decreases.

The experiments indicate that the direct association of methylene radicals and molecular hydrogen to form methane is inappreciable. The profound change in the nature of the products when hydrogen is present suggests that the interaction in question is

$$CH_2' + H_2 = CH_3 + H$$

Such a reaction yielding methyl radicals and atomic hydrogen would account for the formation of saturated and higher molecular weight hydrocarbons.[5] The methylene radical has been represented as energy rich (CH_2') since present accepted views as to bond energies would suggest that the reaction of a normal methylene radical with hydrogen would be endothermic. The energy of the radical must arise from the photoenergy absorbed during the dissociation process.

A secondary source of methyl radicals might be a reaction between methylene radicals and methane already formed

$$CH_2 + CH_4 = 2CH_3$$

This would be less endothermic than the reaction with hydrogen. The low yields of methane, increasing at higher temperatures, do not appear to support this view.

The source of methane is probably an interaction of methyl radicals with hydrogen[6] or hydrocarbons[7] which is known to take place readily at or above 150–160°. The recombination of methyl radicals to form ethane would account for the

prominence of this constituent in the gaseous product.

Details of the temperature effect, which so far indicates a very small temperature coefficient for the photo-decomposition of ketene in hydrogen,[8] as well as the influence of varying concentrations of reactants and the addition of hydrocarbons, are being investigated.

Potassium Acid Phthalate as a Buffer for Use with the Hydrogen Electrode

BY JOHN RUSSELL AND R. ELIOT STAUFFER

Several investigators[1] have reported in the literature that accurate measurements on 0.05 molar potassium acid phthalate cannot be made with the hydrogen electrode. On the other hand, Clark[2] states that repeated experiments have shown measurements on phthalate buffers to be reliable. Recently, MacInnes and co-workers[3] again have intimated that phthalate solution is unstable and cannot be measured satisfactorily with the hydrogen electrode, especially at 38°.

Our experience in this connection definitely supports Clark's statement, and, since the 0.05 *M* phthalate is so convenient a buffer for use in *p*H standardization, we are submitting the following data as evidence for the stability and reproducibility of hydrogen electrode potentials observed in it. We have used the following type of cell for *p*H measurements in these Laboratories (Pt) H_2; Solution X: 3.5 *N* KCl: 3.5 *N* KCl, satd. Hg_2Cl_2; Hg_2Cl_2; Hg, with 0.05 *M* phthalate as solution X in this cell both at 25 and 40°.

An essential feature in the design of the cell, which we hope to describe in detail later in connection with other studies, is the possibility of creating a very reproducible and constant junction between the potassium chloride bridge solution and solution X. Equally important in the obtaining of consistent and accurate measurements is the elimination of rubber connections in contact with the hydrogen supply or solution X, and the use of hydrogen prepared electrolytically in glass and passed over a hot platinum gauze catalyst in a fused silica tube. As a result, the cell in question has yielded highly reproducible and constant e. m. f. values with phthalate and other buffers. A few of these for phthalate at 40° are given in Table I.

TABLE I

ELECTROMOTIVE FORCE MEASUREMENTS OF POTASSIUM ACID PHTHALATE (0.05 *M*) WITH THE HYDROGEN ELECTRODE AT 40°

Reference half-cell	Phthalate soln.	E. m. f., v.	Date
A	1 X	0.49500	8-28-36
B	2 Y	.49504	9-21-36
B	2 Y	.49503	9-24-36
B	2 Y	.49496	9-28-36
B	3 X	.49503	9-25-36
B	3 X	.49501	9-28-36
C	4 Z	.49494	1-20-37
D	5 X	.49502	5- 5-37
	Average	.49500	

These measurements cover a period of about nine months during which four different calomel half-elements and bridging solutions were prepared, and five different phthalate solutions from three commercial sources of potassium acid phthalate were used. Each value in the table represents an average of values obtained by two or more platinum electrodes whose differences were rarely more than a few hundredths of a millivolt. Table II taken from a typical page of data shows that the e. m f. of the cell using phthalate as solution X remains substantially constant for periods as long as four hours after creating the liquid junction. The junction was formed as soon as the solution reached the temperature of the thermostat (*ca.* fifteen minutes).

TABLE II

CONSTANCY OF HYDROGEN ELECTRODE AND JUNCTION POTENTIALS WITH 0.05 *M* PHTHALATE BUFFER AT 40°

Hours after formation of junction	E. m. f., v.
0	0.49495
0.5	.49501
1	.49504
2	.49505
4	.49506

These data indicate that in our experience 0.05 *M* potassium acid phthalate can be used very satisfactorily as a buffer with the hydrogen elec-

The Preparation of *m*-Bromobenzaldehyde

By Floyd T. Tyson

For work in progress in this Laboratory it was necessary to prepare *m*-bromobenzalaminoacetal by the interaction of *m*-bromobenzaldehyde with aminoacetal. The *m*-bromobenzaldehyde was prepared by the reduction of *m*-nitrobenzaldehyde by stannous chloride and hydrochloric acid, followed by diazotization and conversion to bromobenzaldehyde by the Sandmeyer method as originally described by Einhorn and Gernsheim[1] and modified by Buck and Ide.[2] In these procedures, no attempt is made to isolate the intermediate *m*-aminobenzaldehyde from admixture with stannic chloride and hydrochloric acid.

Analysis of the *m*-bromobenzalaminoacetal yielded uniformly low results for halogen calculated as bromine and very high results for carbon and hydrogen. These analytical values were in accord with the assumption that much of the chloro compound was present with the bromo compound.

The *m*-bromobenzaldehyde used for the preparation of the impure *m*-bromobenzalaminoacetal was analyzed for halogen and the halogen calculated as bromine. The analytical values obtained were in agreement with the theoretical values for bromobenzaldehyde. However, analyses of the *m*-bromobenzaldehyde preparations for both chlorine and bromine proved the presence of both chlorine and bromine. The amounts of chlorine indicated a percentage of chlorobenzaldehyde ranging from 20 to 72 depending upon details of procedure.

Since *m*-nitrobenzaldehyde should be a convenient source for the preparation of pure *m*-bromobenzaldehyde, a procedure has been devised which will be published elsewhere, in which the presence of chlorides in the reaction mixture was avoided.

Experimental

The following table summarizes data obtained in the analysis of products resulting from the attempted preparation of pure *m*-bromobenzaldehyde from *m*-nitrobenzaldehyde as described in the literature. The preparations analyzed were fractionated; b. p. 92–97° (6 mm.).

Table I

Prepn.	Analyses, % Cl	Analyses, % Br	Calcd. % chlorobenzaldehyde present
1	18.17	11.86[3]	72.0
	18.31	11.57[4]	
2	5.11	34.50[3]	20.3
3	6.78	31.58[3]	26.9

Preparation No. 1 was made as described by Buck and Ide.[2] Preparation No. 2 was made as No. 1 except that the hydrobromic acid was added to the cuprous bromide mixture before mixing with the diazotized solution. Preparation No. 3 was made as described by Einhorn and Gernsheim.[1]

The analytical results reported in the following table were calculated on the erroneous assumption that the mixtures of silver chloride and bromide actually obtained in the analyses of preparations No. 1, 2 and 3 (Table I) were pure silver bromide. The satisfactory agreement with the values for *m*-bromobenzaldehyde may explain the fact that the preparations as recorded in the literature[1,2] were reported as essentially pure.

Table II

Prepn.	% Br found as assumed	% Br calcd. for *m*-bromobenzaldehyde
1	43.12	43.19
2	43.18	
3	43.25

The Optical Rotation of a Grignard Reagent

By Frank C. Whitmore and Benjamin R. Harriman

Frequent use is made of the Grignard reaction in preparing optically active compounds from optically active halogen compounds, but not to our knowledge has the rotation of an optically active Grignard reagent been measured previously. Porter[1] observed a very small rotation in an ethereal solution of methyl-*n*-hexylmagnesium

---

(1) Porter, This Journal, **57**, 1436 (1935).

bromide which he had prepared from active methyl-*n*-hexyl bromide. He ascribed this activity to unchanged bromide.

Since the position of the functional halogen atom relative to the asymmetric carbon atom determines the degree to which the product is racemic, we sought a halide in which the halogen was on the carbon atom next to the asymmetric carbon atom. Optically active 1-bromo-2-methylbutane, "active amyl bromide," was selected because it was prepared easily from the readily available optically active 2-methyl-1-butanol, which J. H. Olewine of this Laboratory has obtained by the fractionation of fusel oil through a 100-plate column.[2] Since the conversion of this bromide to another compound through the intermediate Grignard reagent gives a product which is only partly racemic, it was thought that rotation measurements on Grignard reagents made from this and similar halides might throw light on the mechanism of such racemizations and on the structure of the Grignard reagent itself. With this in mind a manipulative procedure for measuring the rotation of the Grignard reagent was evolved.

Obviously it was necessary to be assured of the absence of any excess halide. This could be done either by using an excess of magnesium or by removing the excess halide after the Grignard reagent was made. Grignard reagents were made by the first method under the most careful conditions for the exclusion of air and moisture, and a special polarimeter tube with optical Pyrex sealed-in windows was made to hold the volatile ethereal solution. However, what appeared to be finely dispersed magnesium rendered the solutions too dark for measurement.

The alternative method of using an excess of the optically active halide produced clear Grignard reagent solutions. Di-*n*-butyl ether (b. p. 141°) was used as the solvent so that the excess active amyl bromide (b. p. 120°) could be removed by distillation under reduced pressure. The Grignard reagent solution freed from excess halide was then transferred with a pipet to an ordinary polarimeter tube, in which measurement of its optical rotation readily was made. Specific rotations were calculated from data obtained by titrating the Grignard reagent with standard hydrochloric acid. Molecular rotations are given below as being non-committal as to the structure of the Grignard reagent. It is significant that the molecular rotation of the Grignard reagent was slightly greater than that of the active amyl bromide from which it was prepared.

The following is a typical run. Active 1-bromo-2-methylbutane, $[M]^{25}_D$ +5.06°, was prepared with phosphorus tribromide from active 2-methyl-1-butanol $[M]^{25}_D$ −4.35°. Using an excess of this bromide with di-*n*-butyl ether as the solvent, the corresponding Grignard reagent was then prepared in the ordinary way. After distilling off the excess bromide under reduced pressure, a clear active Grignard reagent, $[M]^{25}_D$ +5.36°, was obtained.

COMMUNICATIONS TO THE EDITOR

THE STRUCTURE OF CELLULOSE ETHERS OBTAINED BY THE METHYLATION OF CELLULOSE MATERIALS DISPERSED IN QUATERNARY AMMONIUM BASES

Sir:

The methylation of cellulosic materials dispersed in certain quaternary ammonium bases has been reported[1] to proceed as a homogeneous molecular cellulose reaction. The structure of the apparently homogeneous water-soluble methylcellulose prepared in this manner was thought to be similar to the water-soluble methylcellulose obtained by Traube, Piwonka and Funk[2] on methylating a cellulose–copper hydroxide–sodium hydroxide complex. However, since no chemical evidence was presented to substantiate this conclusion, researches on the structure of these partially methylated cellulosic materials have been undertaken in this Laboratory.

The methylation of both wood pulp and ash-free viscose rayon dispersed in 1.8 *N* dimethyldibenzylammonium hydroxide with dimethyl sulfate, according to the procedure of Bock,[1] yields methylated cellulosic materials containing 12 to 16% methoxyl, corresponding to 0.7 to 0.9 methyl group to each $C_6H_{10}O_5$ unit of cellulose. Acetylation of this material with acetic anhydride in pyridine solution, followed by methyl alcoholysis at 125° in the presence of 1% dry hydrogen chloride gave a mixture of partially methylated methylglucosides and α- and β-methylglucosides. The latter crystalline constituents were isolated from the mixture in yields of 30–35%, which after purification was found to be largely α-methylglucoside, m. p. 164–165°; sp. rot. +157.8° (H_2O). The sirupy constituents representing 65–70% of the total alcoholysis mixture, after acetylation with acetic anhydride in pyridine solution, were subjected to distillation under high vacuum. The following fractions were obtained:

Fraction	B. p., 0.1 mm.	% OCH_3	% Yield[a]
I	130–140°	29.5	25–30
II	140–150°	22.5	20–25
III	160–175°	19.5	5–10

[a] Yield based on original weight of acetylated product.

Evidence that Fraction I contained traces of trimethylmonoacetyl methylglucoside (OCH_3, 44.6%) mixed with the predominating dimethyldiacetyl methylglucoside (OCH_3, 30.4%) was shown by the fact that further fractional distillation yielded a fraction (b. p. 130–140°) with a methoxyl content of 31.7%. Fraction II yielded a small amount of crystalline 2-methyltriacetyl α-methylglucoside (OCH_3, 18.5%) with melting point 120–121°, remaining constant when mixed with an authentic specimen.[3] Fraction III yielded crystalline 2-methyltriacetyl α-methylglucoside (m. p. 120–121°), tetraacetyl β-methylglucoside (m. p. 104–105°) and a sirupy product presumably dimethyldiacetyl methylglucoside.

Acetolysis of the methylated wood pulp and viscose rayon (OCH_3, 13.5%) in a manner similar to that described by Lieser[4] gave a 5% yield of cellobiose octaacetate (m. p. 224–225°; sp. rot., +41.5° ($CHCl_3$)).

These experiments confirm the assumption of Bock[1] that the "water-soluble" methylated cellulosic materials obtained by use of the quaternary ammonium bases are very similar in structure to those obtained by Traube, Piwonka and Funk.[2] The results indicate, however, that methylation proceeds by diffusion of dimethyl sulfate into a particle structure, from which it follows that the cellulose component of these materials is not molecularly dispersed in quaternary ammonium bases but rather is dispersed as particles. Slit ultramicroscopic observations[5] of cellulosic materials dispersed in quaternary ammonium bases and of the methylated product dispersed in water verify the above conclusion by showing the presence of microscopic particles approximately 1 μ in diameter.

This work is being extended to other partially methylated cellulosic materials.

THE RELATIVELY INERT OXYGEN ATOM OF DIGOXIGENIN, SARMENTOGENIN AND THE STEROID COMPOUNDS OF THE ADRENAL CORTEX

Sir:

We have recently described [THIS JOURNAL, **60,** 1493, 2566 (1938)] a series of *etio*-cholanic acids and esters with oxygen atoms at C-3 and C-12. Steiger and Reichstein [*Helv. Chim. Acta*, **21,** 828 (1938)] have prepared from digoxigenin a similar series of acids which were thought to have oxygen atoms at C-3 and C-11. Since the 3,*x*-diketo-4-*etio*-cholenic acids derived from digoxigenin and from corticosterone proved to be different, they considered it doubtful that an oxygen atom occupied C-11 in the acids derived from digoxigenin. Through the courtesy of Professor Reichstein we have been able to compare directly the methyl diketo-*etio*-cholanates and the methyl diketo-4-*etio*-cholenates from the two sources. The results given in the table show that the properties of the esters from the two sources are identical. We conclude that Reichstein's acids are identical with those derived from desoxycholic acid and that the inert oxygen atom of digoxigenin, which was assigned to C-11 by Tschesche and Bohle [*Ber.* **69,** 793 (1936)], is actually at C-12.

	Acid or ester	From digoxigenin		From desoxycholic acid	
		M. p., °C.	$[\alpha]^{19}D$	M. p., °C.	$[\alpha]^{25}D$
1	Methyl diketo-*etio*-cholanate	171–172[a]	138.3 ± 2	169–170[a]	142 ± 3
2	Methyl diketo-4-*etio*-cholenate	236–238[b]	185 ± 2	236–238[b]	190 ± 6
3	Diketo-*etio*-cholanic acid	170		178	
4	Dihydroxy-*etio*-cholanic acid	280–286		283–286	
5	Methyl dihydroxy-*etio*-cholanate	180–183		145–146	

[a] Mixtures melted at 169–170°.

[b] Mixtures melted at 236–237°.

The other comparisons of the table are less satisfactory since the specific rotations of these compounds of Reichstein were not known and specimens were not available for mixed melting point determinations. The melting points of the diketo-*etio*-cholanic acids are in reasonable agreement, since we have found, as has Reichstein, that the acid is very difficult to purify. The methyl dihydroxy-*etio*-cholanates appear to be different since the melting point of our ester was sharp and could not be raised by distillation or recrystallization. Accepting this difference, epimerism at C-12 is indicated since the configuration of both esters at C-3 is α (no precipitation with digitonin). This difference is not certain, however, since the corresponding acids melt at the same point.

It has been generally accepted since the work of Tschesche and Bohle [*Ber.* **69,** 2497 (1936)] that digoxigenin and sarmentogenin differ only in the configuration at C-9. Inasmuch as some of the adrenal steroids contain an oxygen atom which corresponds in almost all respects with the inert oxygen atom of sarmentogenin, it has been assumed [Marker, THIS JOURNAL, **60,** 1725 (1938)] that they had a configuration at C-9 like that of sarmentogenin which was supposed to have a *cis* linkage of rings B and C instead of the normal or *trans* linkage. Marker [THIS JOURNAL, **60,** 1061 (1938)] has made the same assumption for his urane compounds. There is now no need to assume such a configuration at C-9 for sarmentogenin to explain its difference from digoxigenin, although such a possibility is by no means excluded. Consequently, such an assumption for the adrenal compounds has no basis. Indeed, all the evidence [Reichstein, *Helv. Chim. Acta*, **19,** 402 (1936); **20,** 978 (1937); **21,** 161 (1938)] points to a normal steroid skeleton with an oxygen atom at C-11.

ABSENCE OF COMBINED FATTY ACID IN CEREAL STARCHES

Sir:

The common cereal starches contain fatty material which cannot be extracted by solvents such as petroleum ether, ethyl ether or carbon tetrachloride. From this behavior, T. C. Taylor and his co-workers assumed that the fatty acid must be present as an ester of the carbohydrate substance. His later work indicated that the α-amylose fraction of the starch was characterized by—and owed its insolubility to—this esterification with fatty acid.

Recent investigations in these Laboratories show that the fatty acids in corn, wheat and rice starches can be removed completely by Soxhlet extraction with certain water-miscible fat solvents, particularly methanol, the cellosolves, and 80% dioxane. The de-fatted starch retains its characteristic granule structure and optical birefringence, and gelatinizes in hot water to give a paste of normal high viscosity. By treatment with alcoholic oleic acid, such de-fatted starch can be reimpregnated with fatty acid, and this added fat cannot be extracted by hydrocarbon type solvents.

Hence, it appears that free fatty acid is distributed throughout the starch granule as an extraneous impurity. To explain selective extraction, it is suggested that only those fat solvents bearing hydrophilic groups can penetrate into the granule, hydrocarbon types merely washing the surface. This investigation is being continued, and final results will be reported in detail at an early date.

PANTOTHENIC AND NICOTINIC ACIDS AS GROWTH FACTORS FOR LACTIC ACID BACTERIA

Sir:

In a previous publication the preparation of highly active concentrates (1 unit in 0.5 γ) of an essential growth factor for lactic acid bacteria has been described [Snell, Strong and Peterson, *Biochem. J.*, **31,** 1789 (1937)]. Considerable difficulty has been encountered in attempts to further purify this factor, and a long series of fractionation procedures resulted in only about a two-fold increase in activity (1 unit in 0.20 γ).

Recently, information became available [R. J. Williams, papers presented before the American Chemical Society at Milwaukee, Wisconsin, Sept. 5–9, 1938, and private communications] which revealed a striking similarity between the properties of the above growth factor and pantothenic acid [Williams, *et al.*, THIS JOURNAL, **55,** 2912 (1933)]. Both are water-soluble, nitrogenous, organic, hydroxy acids, easily destroyed by aqueous acids or alkalies, but relatively resistant to the action of light, nitrous acid, bromine, and mild oxidizing agents. Through the kindness of Dr. R. J. Williams it has now been possible to subject two samples of pantothenic acid to our bacterial test. One preparation, A, contained approximately 40%, and the other, B, 83% calcium pantothenate. The following results were obtained on *Lactobacillus casei* as the test organism:

	γ Added per 10 cc. medium				Cc. 0.1 *N* acid produced per 10 cc. medium			
Supplement	a	b	c	d	a	b	c	d
Sample A	0.0	0.05	0.1	0.5	0.5	1.4	3.5	7.0
Sample B	.0	.02	.05	.3	.5	1.3	3.3	7.8

These and other tests indicated that sample A contained one unit in approximately 0.13 γ, and that B possessed about twice this activity.

Sample B was further tested on *Bacillus lactis acidi*, *Lactobacillus arabinosus*, *Lactobacillus pentosus*, *Lactobacillus delbrückii*, *Bacillus brassicae*, *Streptococcus lactis*, *Leuconostoc mesenteroides*, and *Propionibacterium pentosaceum*, and proved to be highly active for each organism. All of these organisms had previously been shown to require the growth factor. It appears certain that the active substance in our concentrates is identical with pantothenic acid, and that our best preparation contained approximately 26% pantothenic acid.

In addition to pantothenic acid some lactic acid bacteria seem to require nicotinic acid as well. Six species tested were found to grow very poorly or not at all in an acid-hydrolyzed casein medium containing both riboflavin and pantothenic acid. When small amounts of nicotinic acid were added to this medium, a marked improvement in growth and acid production occurred in some cases.

	γ Nicotinic acid added per 10 cc. medium				Cc. 0.1 *N* acid produced per 10 cc. medium			
Organism	a	b	c	d	a	b	c	d
L. casei	0.0	0.1	0.3	0.5	2.2	4.1	5.4	6.6
L. arabinosus	.0	.1	.3	.5	1.7	4.7	...	5.2

From the above data it appears that nicotinic acid is also an essential growth factor for at least two species of lactic acid bacteria.

ORIENTATION OF HIGH MOLECULAR WEIGHT LINEAR POLYMERS IN UNSTRETCHED FILMS

Sir:

Recent electron diffraction studies by Storks[1] furnish definite evidence that unstretched films of polyethylene sebacate consist of relatively small crystallites which are oriented with their long axes approximately in the plane of the film, and with limited rotation around this axis, "probably due in part to the presence of carbonyl groups along the chain." Further, Storks points out that such films will probably show a preferred orientation until the film thickness exceeds the average chain length; only beyond this point do high molecular weight linear polymers exhibit truly amorphous Debye–Scherrer ring patterns,

---

(1) Storks, THIS JOURNAL, **60,** 1753 (1938).

This work is in complete accord with a theory of partially oriented film structure proposed by us, which was advanced to explain qualitatively the results of film continuity studies.[2]

We have shown previously that the minimum coating weight of certain linear polymers on several metals varies essentially inversely as the average chain length.[2] If the chains made a 90° angle with the surface, a direct ratio of minimum coating weight to chain length would obviously be approximated. A system of oriented chains *parallel* to the surface would give a minimum coating weight independent of chain length. At any angle between zero and 90° which the chains make with the surface, a fixed chain length would give a coating weight directly related to the sine of the angle with the surface. Now, it is obvious from the work of Langmuir and others that a chain having only a single terminal polar anchoring group would tend to stand on end; with additional polar groups along the chain, the effective polarity gradient along the polymer would vary with the type and distribution of such groups. Assuming a relatively uniform distribution along the chain,[3,4] then the chain would incline at an angle with the surface which was directly related to the polarity gradient. Finally, with uniform distribution of polar groups along the chain, the longer the chain the smaller would be this polarity gradient. Accordingly, the longer the chain the smaller would be the angle it makes with the surface and as a result, an increase in chain length would reduce the minimum coating weight. This was actually found by experiment.[2]

This line of reasoning had already led us to make electron diffraction studies, with inconclusive results. Storks' results obviously reopen this method of attack. They furnish independent confirmation of our theory of partial orientation in what are usually considered to be wholly amorphous films.

Unfortunately, our film continuity studies depend upon a specific method, namely, that of conductivity through discontinuous films. In the near future attempts will be made to get an independent check of this work by studying the diffusion of hydrogen through thin films on palladium and of helium through thin films on glass.

NEW BOOKS

Catalysis from the Standpoint of Chemical Kinetics. By GEORG-MARIA SCHWAB, University of Munich. Translated from the First German Edition, with additions from the recent literature by the author, by HUGH S. TAYLOR, Princeton University, and R. SPENCE, Leeds University. D. Van Nostrand Company, Inc., 250 Fourth Ave., New York, N. Y., 1937. xi + 357 pp. 39 figs. 16 × 23.5 cm. Price, $4.25.

The German edition [reviewed in THIS JOURNAL, **54**, 3017 (1932)] of Dr. Schwab's "Katalyse," which appeared in 1931, ably filled the need for an ordered and condensed theoretical treatment of the whole field of catalysis, both homogeneous and heterogeneous. The present translation, delayed by "the difficult economic conditions in the world," closely adheres to the original arrangement and purpose, but has been brought up to date by the addition of new material to the extent of some 15%. The result is a book admirably suited to graduate courses in catalytic theory, and useful to the prospective investigator as an orientation into the many unsolved problems in this field.

The reader is assumed to be familiar with the principles of theoretical chemistry, including the kinetics of uncatalyzed reactions, and with elementary mathematics. The emphasis is on the significance of theories as applied to selected examples rather than on formal mathematical statements. The treatment of the various types of catalysis is organized on a systematic rather than historical basis. Experimental examples are frankly chosen for their value in illuminating general principles, and details are naturally minimized. The book is about equally divided between homogeneous catalysis (in gases and solutions) and heterogeneous catalysis (of gas reactions). Bio-catalysis is treated briefly; technical aspects of catalysis are excluded, as is also experimental technique.

Some idea of the current activity in catalytic investigation may be obtained from the fact that the 457 citations to the literature in the original text have grown in six years to 735. The increase is especially marked in heterogeneous catalysis, where new sections on "activated adsorption," "quantum mechanics of activated adsorption," etc., appear. All the original citations are retained but in the main the effort to incorporate the newer material into the old has been reasonably successful. The translation is mostly clear in spite of the fact that few liberties have been taken with the original text.

A few points are discussed in a way which may seem inadequate to the specialist, for example: entropy of activation, *absolute* rates of adsorption and of catalysis, determination of surface areas, adsorption by poisoned catalysts, catalysis of gas–solid reactions by solids. But on the whole the book should be as stimulating to the specialist as it will be indispensable to others interested in an authoritative survey of this vigorous branch of theoretical chemistry.

Arthur F. Benton

Lehrbuch der Chemie. Teil II. Organische Chemie. (Textbook of Chemistry. Part II. Organic Chemistry.) By Walter Hückel, Professor at the University and Institute of Technology, Breslau. Akademische Verlagsgesellschaft m. b. H., Markgrafenstrasse 6, Leipzig C 1, Germany, 1937. xvi + 602 pp. 38 figs. 16.5 × 24 cm. Price, RM. 16; bound, RM. 18.

This text is an introduction to organic chemistry for the general student, with special attention given to the needs of the pre-medical group. Sections of importance for these students are marked.

The special quality of this book lies in its spirit and choice of material, rather than in any novel order of presentation. The material is chosen with unusual discrimination. The classification by homologous series is well explained, and thereafter only examples of live current interest are used to illustrate types of compounds. The work is distinguished by the logical presentation which would be expected by all who know Professor Hückel's writings. There is frequent reference to the experimental methods behind the structures and interpretations presented.

While it may not be practicable to use a German text in the instruction of first-year American students, this book will be welcome for the way in which it combines an interesting story with the teaching of a logical science.

P. D. Bartlett

(1) **Collateral Readings in Inorganic Chemistry.** (2) **Readings in Elementary Organic Chemistry.** Edited by L. A. Goldblatt, University of Pittsburgh. D. Appleton-Century Co., 35 West 32d St., New York, N. Y., 1937 and 1938. 21.5 × 27.5 cm. (1) viii + 225 pp. Price, $1.35. (2) viii + 150 pp. Price, $1.25.

A chemistry major student on departing from a small college or large university should carry with him a thorough grounding in the fundamentals of chemistry and a humble realization that there is much more to his chosen science than has been given in his lectures and textbooks. The one is a function of faculty and curriculum; the other requires in addition a judicious consultation of the original literature, and its acquisition frequently is rendered difficult by linguistic and library limitations as well as the problem of intelligent selection. In these photo-reproductions of the original articles (with notes and translations where needed), Professor Goldblatt has gone far toward solving the problem, presenting a comprehensive selection of recent inorganic and organic papers ranging from the "Fathers of the Chemical Revolution" to the Dow Process for Bromine from Sea Water, and from Wöhler's "Artificial Preparation of Urea" to the Use of Isotopes in the Study of Intermediary Metabolism, with plentiful dashes of general seasoning in the form of Nobel Laureates, Eminent Chemists, Summary Articles and Market Reports. The experiment seems worth while and its continuance, by revised selection editions, will depend upon the academic acceptance accorded these two inexpensive paper-bound volumes.

Allen D. Bliss

Traité de Pharmacie Chimique. (Treatise on Pharmacological Chemistry.) By P. Lebeau, Professor in the Faculty of Pharmacy of Paris, and G. Courtois, Assistant in the Faculty of Pharmacy of Paris. Vol. I. Chimie Minérale et Chimie Organique. Vol. II, Parts 1 and 2. Chimie Organique. Second edition. Masson et Cie., Éditeurs, 120 Boulevard Saint-Germain, Paris VI^e, France, 1938. 17.5 × 25 cm. Vol. I: xxviii + 1206 pp. Price, fr. 280. Vol. II: xxviii + 2128 pp. Price, fr. 460.

The rapid development during the last few years of the study of chemical medication compelled the authors considerably to increase the bulk of the second edition of their textbook on pharmacological chemistry. It is presented now in three volumes, a total of 3334 pages.

The first volume is still, as in the previous edition, devoted to the study of therapeutical material classified under inorganic chemistry and the acyclic part of organic chemistry, excluding the nitrogen derivatives.

The second volume consists of two parts. The first one deals with pharmaceutical substances of the cyclic group, both cyclic and acyclic nitrogen compounds, terpenic derivatives, and finally with the chemically well-defined substances of the hormone, vitamin and organo-mineral group. The second volume describes the therapeutically valuable substances of the heterocyclic, the alkaloid, the glucoside and the proteic groups.

The authors give special consideration in their work to phytopharmacy, to which they lend a very particular importance. The profession of pharmacist, in France, is quite distinct from what it is in this country so that it is evident that the requirements of a textbook on pharmaceutical chemistry will be different also.

The present work is primarily intended as a textbook and corresponds to a regular course in pharmaceutical chemistry as given at the Faculty of Pharmacy of the University of Paris.

Rather complete references to the literature are given so as to allow for more thorough study of the properties of the different pharmaceutical compounds. This makes the Treatise of equal value to both the student and the pharmaceutical practitioner.

The first part of the work, dealing with mineral chemistry, is different from the usual textbook on general chemistry only in that more emphasis is given to the pharmaceutical aspect of the different substances described. It seems as if it would have been wise to pay even more attention to the pharmacological side and to reduce considerably the description of chemical properties and modes of preparations. The sequence of descriptions follows closely the trend in books of general chemistry. The relation between chemical structure and physiological activity has, however, been stressed by the authors as often as possible.

The recent advances in the field of vitamin and hormone investigation are only briefly described and the achievements of the last two years are practically entirely omitted. It might be stated once more, in this respect, that the aim of the authors was not to publish a monograph, but to provide the student with a textbook as a help to his course on the subject. Sufficient bibliography, including reference to more specialized textbooks, is given, however, so as to provide the student with all facilities for further study on a given subject.

The presentation of the subject matter of this book is very good indeed.

V. DESREUX

A Textbook of Biochemistry. By ROGER J. WILLIAMS, Ph.D., D.Sc., Professor of Chemistry, Oregon State College. D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, N. Y., 1938. x + 525 pp. 17 figs. 14.5 × 22 cm. Price, $6.00.

The book includes five sections: biochemical materials, Chapters 2–5; tissue composition, Chapter 7; food composition, Chapter 8; bodily mechanisms for promoting and regulating chemical change, Chapters 9–14; metabolism, Chapters 15–23. There is a glossary and an index.

The conventional description of fats, proteins, and carbohydrates is well balanced with proper attention to chemical properties on the one hand and biochemical significance on the other. Other materials of biochemistry usually are considered in relation to function rather than structure to the bewilderment of the student accustomed to the orderly system of organic chemistry. The author has wisely arranged these diverse substances in Chapter 5 according to chemical constitution, postponing until later questions of function.

Tables showing the chemical make-up of tissues are assembled in Chapter 6 from 166 sources. There are a few errors, some data of doubtful validity and no analyses are reported of extra- and intracellular phases of muscle, but it is a unique and valuable compilation.

Excellent chapters in the later sections cover the subjects of permeability, chemical mediation of nerve impulses and chemotherapy. It is the opinion of the reviewer that the first of these could be improved by including, with some elaboration, the discussion of colloid osmotic pressure given in Chapter 6—Colloidal Properties. Concealed in the latter chapter is an incomplete account of the physicochemical properties of proteins. Neither here nor elsewhere is the role of proteins as buffers explained except for the special case of hemoglobin.

There are remarkably few errors. On p. 179, Steffanson's experiences are said to indicate that very high protein diets may be quite satisfactory. Actually, Steffanson became sick on a lean meat diet but thrived on a fat meat diet despite a moderate ketosis. His protein intake did not exceed that of the American soldier in active service. On p. 346, the small intestine is said to be 30 feet long. This is the length after death; a sound passed naturally through the gastro-intestinal tract of a healthy man shows a length of 7 or 8 feet from mouth to rectum. On p. 487 it is said that Cinchona bark has been used to treat malaria for two centuries. Presumably it had been used for centuries by the Indians before the first authenticated use in treating the wife of the governor of Peru about 1630.

The author is tolerant in his discussion of new theories and shows good judgment in evaluating current trends in biochemistry. He questions, for example, the validity of the assumption that the faster the rate of growth and the greater the body size, the better for the race, whether of rats or men.

D. B. DILL

Textbook of Organic Chemistry. By GEORGE HOLMES RICHTER, Assistant Professor of Organic Chemistry, the Rice Institute. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1938. viii + 711 pp. 83 tables. 15.4 × 23.5 cm. Price, $4.00.

Professor Richter set himself the task of writing a book "directed specifically to that large body of ambitious students who wish to study beginning organic chemistry and gain more than a superficial knowledge of the subject." He has accomplished his purpose admirably; his book should prove most useful in a full year's elementary course; indeed, it contains far more material than one could hope to cover in the usual first course.

The order of the subject matter is the conventional one: after a very brief introduction in which types of valence and structural formulas are discussed, follow aliphatic hydrocarbons, saturated and unsaturated, alcohols, ethers, aldehydes and ketones, etc. The various homologous series are well illustrated by excellent tables giving pertinent physical properties of the more important members, with the result that such data are kept at an absolute minimum in the text with a consequent increase in readability.

Adequate consideration is given to compounds of industrial significance and to naturally occurring substances; these are to be found as illustrations of the particular classes to which they belong. Granting that this method of treatment is desirable up to a certain point, we are not entirely sure that the very early introduction of formulas as complex as those of the carotenes and the sex hormones is not objectionable from the pedagogic standpoint.

An unusually large number of substances find mention, and the choice of material is, on the whole, good. If Professor Richter has erred at all, he has attempted to give too complete a picture of organic chemistry in a book written specifically for ambitious beginners. Each chapter closes with a list of review questions which cover the subject matter very fully.

In one minor respect the author is not consistent: he points out carefully the objections to the formulation of the nitro group as  $-\mathrm{N}{\genfrac{}{}{0pt}{}{\nearrow \mathrm{O}}{\searrow \mathrm{O}}}$, and of sulfonic acids, etc., as  $-\mathrm{S}{\genfrac{}{}{0pt}{}{\nearrow \mathrm{O}}{\searrow \mathrm{O}}}\!-\mathrm{OH}$, and then proceeds to use the rejected formulas freely.

The book is clearly and interestingly written, it contains very few typographical errors, and is a very complete and accurate survey of the chemistry of organic compounds with emphasis on their nomenclature, structure synthesis, reactions and properties.

NATHAN L. DRAKE

Introduction to Physiological Chemistry. By MEYER BODANSKY, Ph.D., M.D. Fourth Edition. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1938. ix + 686 pp. 15.5 × 24 cm. Price, $4.00.

The Fourth Edition brings this very satisfactory "Introduction to Physiological Chemistry" largely up to date. In each chapter some of the material has been rewritten, and several chapters have been entirely rewritten. As a whole, it takes into account work published in 1937, both in the text and in the many references. All this has been done with the addition of only twenty-five pages, but, as the type is smaller, the actual addition is substantially greater than appears at first sight. There are very few typographical errors or errors of commission, and, although any reader having intimate knowledge of the subjects included would probably write the subject coming within his special competence differently, it is none the less a thoroughly sound and satisfactory introduction to the wide variety of subjects covered under the general title bio-chemistry.

RONALD M. FERRY

Organic Syntheses. An Annual Publication of Satisfactory Methods for the Preparation of Organic Chemicals. Vol. XVIII. By R. C. FUSON, C. F. H. ALLEN, W. H. CAROTHERS, L. F. FIESER, W. W. HARTMAN, J. R. JOHNSON, C. R. NOLLER and A. H. BLATT. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1938. v + 103 pp. 15.5 × 24 cm. Price, $1.75.

Like the preceding members of this series, the present volume contains carefully tested methods for the preparation of a selected group of organic compounds. As will be noticed from the table of contents, the continued increase in biochemical interest is represented by several classical examples. Here, under "Barbituric Acid" might have been mentioned Hakon Lund's recently (1935) described method of condensation by means of magnesium methylate. As further indication of modern trends, the introduction of fluorine, and of selenium, into organic compounds is exemplified each by one substance.

The list of new preparations is as follows: 2-acetothienone, acetylenedicarboxylic acid, allylamine, barbituric acid, betaine hydrazide hydrochloride, β-bromoethylamine hydrobromide, α-chloroanthraquinone, α,β-dibromosuccinic acid, 4,4′-difluorobiphenyl, 3,4-dihydro-1,2-naphthalic anhydride, diphenyl selenide, diphenylselenium dichloride and triphenylselenonium chloride, ethyl benzoylacetate, ethyl α-phenylacetoacetate, *n*-ethyl-*m*-toluidine, *l*-histidine monohydrochloride, α-hydrindone, malonic acid, methyl benzyl ketone, methyliminodiacetic acid, 1,2-naphthalic anhydride, *p*-nitrobenzaldehyde, phenoxthin, α-phenylacetoacetonitrile, 2-phenylpyridine, potassium anthraquinone-α-sulfonate, protocatechualdehyde, taurine *p*-tolylcarbinol.

A recent number of "Nature" contains a review of this volume, and it is a pleasure to endorse the statement, "In all respects this latest member of the series maintains the high standard of its predecessors."

M. GOMBERG

The Origin of Life. By A. I. OPARIN. Translated with Annotations by SERGIUS MORGULIS. The Macmillan Company, New York, 1938. 270 pp. $2.75.

Probably there is no biologist or philosopher who has not at some time considered the basic question of biology, "How did life come to be?" In general they must be satisfied with the statement that somehow, somewhere on the surface of the earth special conditions, and perhaps an "accident," started the stream of life in motion. Few have attempted to expand the discussion past the limits of a few paragraphs. Oparin, however, has evolved a fascinating hypothesis and has expanded it into an exceedingly readable volume, one which challenges and provokes the thought of the scientist and which unquestionably will stimulate a certain amount of experimental investigation, although Oparin does not hold out much hope that experimental investigations based on the hypothesis will lead to its confirmation or rather will lead to the creation of life.

Oparin's viewpoint is radically different from most discussions of the subject of which the reviewer is aware. Most discussions presuppose an atmosphere in which carbon dioxide is highly concentrated and from which enormous quantities of carbon dioxide could be drawn by plants with the corresponding liberation of oxygen by the photosynthetic process. The great rise of the plant kingdom, culminating in the carboniferous era, is thus explained, and most hypotheses account for the tropical temperatures at that time by assuming a blanketing effect of the higher carbon dioxide content of the atmosphere.

Oparin begins his discussion of the origin of life by discussing the origin of the planetary systems. He points out that if the planets arose from the sun because of tides raised on the sun by the passage of another star, the gaseous masses which eventually became the planets would have had to pass through a progressive evolution as the masses cooled. He points out that the primary atmosphere of the earth must have been devoid of oxygen because the earth's crust is still far from being saturated with oxygen, and at the higher temperatures this lack of oxygen saturation by the lithosphere must have been still more pronounced. He, therefore, regards the free oxygen in the atmosphere as having arisen in a much later epoch and to have been formed secondarily as the result of the activity of living organisms. Furthermore, he regards the nitrogen of the atmosphere as being principally of secondary origin and concludes that the nitrogen must originally have been present in the form of nitrides and of ammonia. He points out that at high temperatures carbon and hydrogen would preferentially unite to form hydrocarbons and that carbon would react with mineral elements to form carbides. As the temperatures became lower, water vapor and superheated water would react with the carbides to form hydrocarbons and with the nitrides to form ammonia. His primary atmosphere would then consist of a great variety of hydrocarbons, of ammonia, and of water vapor. As the cooling proceeded, the water would condense into the oceanic pools, the ammonia would largely dissolve in the water, and this mixture would be saturated with a variety of hydrocarbons.

As supporting evidence of this portion of his thesis, he cites Russell to the effect that the original oceans on Jupiter probably consisted of aqua ammonia, and as the temperature fell still lower, the water froze out, so that today at a temperature of −100°, ice exists at the bottom of Jupiter's oceans and that this ice is covered with liquid ammonia, that the clouds on Jupiter are apparently clouds of ammonia snow, and that when we pass to Neptune at −200° the ammonia is solidified and the clouds now are clouds of methane snow.

Up to this point Oparin has introduced no radically new hypothesis. He now points out, however, that the biocatalysts or the enzymes characteristic of living organisms in general only speed up reactions which take place very slowly in the absence of the catalyst. In the evolution of the planets there would be the opportunity for hydrocarbons and their oxidation products, aldehydes, alcohols, ketones, and organic acids, to interact with each other in an aqueous ammoniacal medium over long eons of time. He therefore believes that under the conditions which then prevailed most of the types of organic compounds, and which we now know to be characteristic of plants and animals, originated by the processes of this chemical interaction. This evolutionary process lasted for an incalculably long period of time. Condensations and polymerizations built up complex organic molecules. These probably reached colloidal size long before that phenomenon which we know as life came into being. Oparin suggests that relatively complex proteins may have originated *de novo* in this manner. He even accounts for the origin of optically active organic compounds and the specialized groupings around an asymmetric carbon atom by calling attention to the fact that sky light is plane polarized and that when this passes into an aqueous medium it is transformed into circularly polarized light, and then he cites experimental evidence that circularly polarized light preferentially decomposes either the *d*- or the *l*-form of a racemic mixture of organic compounds having appropriate absorption bands.

He continues with his thesis, assuming that certain of these organic colloids are positively charged and that others are negatively charged, and argues from the observation of Bungenberg de Jong that coacervate droplets would separate as a distinct phase. Here then we have what are essentially single cells but as yet incapable of self-propagation. He concludes, however, that since enzymes are in all probability chemical compounds with particular space configurations, there should be no essential reason why enzymes should not arise in the same way that the primary organic compounds arose and that a coacervate system containing enzymes possibly represents the primary living cell.

From this point on the argument is somewhat more hypothetical and is based on the assumption that those coacervate systems more nearly adapted to the environment tended to persist and become stabilized, whereas those coacervate systems less adapted to the environment were eliminated and disappeared by a process of "natural selection." Those systems which persisted probably grew at the expense of the nutrilites in the aqueous environment, and those which possessed enzymes characteristic of anaerobic respiration found a source of energy in the interaction of organic substances with water molecules. In this way carbon dioxide and other products of fermentation were liberated into the atmosphere. This started a new cycle of reactions, since new building stones were available, and from these new series of reactions Oparin postulates the synthesis of certain special pigments which, when possessed by the coacervate system, rendered that particular system capable of utilizing the energy of sunlight for initiating and controlling chemical reactions. Such systems became the primitive life forms.

The above is only a very brief and cursory review of a very fascinating hypothesis. Many chemists will want to read this volume over and over again. Every physiologist and biochemist should call it to the attention of his students, for while it is purely a hypothesis, there are many proven facts interwoven into the network, and in some places where the gaps in knowledge are great, it may be possible to supply at least a part of the missing links by further investigations.

ROSS AIKEN GORTNER

Colorimetric Methods of Analysis Including Some Turbidimetric and Nephelometric Methods. Vol. II. Organic and Biological. By FOSTER DEE SNELL and CORNELIA T. SNELL. D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, N. Y., 1937. xxiv + 815 pp. 49 figs. 16.5 × 23.5 cm.

In this second volume the authors have collected methods of colorimetric and nephelometric analysis applicable to organic and biological substances. They have also collected methods for the comparison and evaluation of the colors of various products such as oils and sugar solutions. The book is complete up to 1936.

As in the first volume, a number of methods are given for each substance, five, for example, being given for benzene. The general plan of Volume I is also continued. After a brief general description of each method, detailed directions for the preparation of samples are given. Then the procedure is described carefully and finally there are directions for preparing standards.

Although complete critical treatment of all of the methods described is impossible in a volume of this scope, a great deal of very valuable criticism and discussion of interferences has been collected from the literature and included in the book. Thus thirteen references are quoted on the determination of methanol and methoxy groups as formaldehyde by Schiff's reagent, and no less than sixty-four on the determination of cholesterol by acetic anhydride. Incidentally, this bibliography in the form of footnotes is most convenient and accessible. Would that all compilers of chemical information would thus make short the path from datum to reference! The index is also complete and accurate.

The first chapter on hydrocarbons is followed by one on alcohols and then by a chapter on sterols. Next there are three chapters on aldehydes and ketones and then thirteen chapters on acids and related compounds, ranging from formic to abietic acid. Then follow chapters on hemoglobin, proteins, nitrogen in various forms, phenols, urea and related compounds, miscellaneous amines, imines, and nitro compounds. Five chapters on carbohydrates, four on alkaloids and one each on glucosides, halogen derivatives, and compounds with inorganic radicals, are included. Then there are two chapters on enzymes, one on hormones and one on vitamins. Finally a chapter on the measurement of bleaching power introduces a section of nine chapters on the measurement of color and turbidity itself in oils, sirups, extracts, pigments, etc. In this section various special instruments adapted to particular types of color measurement are described.

The authors may feel sure that a wide circle of chemists will be grateful to them for the labor of preparing this very useful and comprehensive survey of colorimetric and nephelometric methods.

C. H. Greene

An Outline of Organic Chemistry. By Ed. F Degering, Purdue University, R. E. Nelson, Purdue University, and J. R. Harrod, Ohio Northern University, and seventy-seven Assistant Editors. Revised edition. Barnes and Noble, Inc., 105 Fifth Avenue, New York, N. Y., 1937. 317 pp. 14 × 21.5 cm. Price, $2.25.

If at first one is inclined to regard this volume as just a soft short-cut for the student to a pass mark in a course in organic chemistry, a careful perusal of the book promptly corrects such a view. It represents a sincere effort on the part of a group of teachers to aid students in understanding what is to many a difficult subject, but it is no sugar-coated pill. Sixteen standard texts have been drawn upon in preparing the outline, and a pagination chart enables one to use it with any one of these texts in lieu of note taking in class. Throughout an effort has been made to indicate conditions and reagents requisite for the performance of each reaction. In addition to the usual material referred to in a one-year course, the book contains excellent special chapters contributed by authorities. The chapter on nomenclature, edited by Patterson, should aid in the gradual, and welcome, unification and simplification of naming schemes employed by American chemists. *Chemical Abstracts* usage is recommended. Lucas' excellent chapter on electronics makes evident to the beginning student in organic chemistry the fact that a knowledge of electrons and protons should not be relegated to limbo after a good course in Freshman chemistry. Careful attention to the brief, but good, section on pronunciation will spare users from censure (readily recalled by the reviewer from his student days) for the use of "damned Teutonisms." An excellent, *informative*, 17-page index is included. The publishers present with the book an "omission list," the use of which, without change, would in the reviewer's opinion lead to a pretty thin broth kind of elementary organic chemistry course. The outline, with no omissions, presents somewhat too much "red meat" for most students to digest in one year. The material given is very well organized, misprints and other errors are remarkably few, and the book work is very well done.

This little volume is interesting, stimulating, and should prove helpful to students and instructors alike.

G. Albert Hill

Qualitative Analyse mit Hilfe von Tüpfelreaktionen. Theoretische Grundlagen, praktische Ausführung und Anwendung. (Qualitative Analysis with the Aid of Spot Tests. Theory, Development and Application.) Third, revised edition. By Dr.-Ing. Fritz Feigl, Professor in the University of Vienna. Akademische Verlagsgesellschaft m. b. H., Sternwartenstrasse 8, Leipzig C 1, Germany, 1938. xii + 554 pp. 27 figs. 16 × 24 cm. Price, RM. 28; bound, RM. 30.

All chemists who are familiar with the first (1930) [This Journal, **53**, 1621 (1931)] and second (1935) [*ibid.*, **58**, 863 (1936)] editions of this valuable work will be gratified to note the publication of this third edition. Although the total number of pages has increased from 513 (2nd edition) to 554 (3rd edition), yet substantial improvements in the typographical arrangements of the numerous tables have permitted the inclusion of much more material than would correspond to the page increase alone.

As in the previous editions the book is divided into two major divisions designated as theoretical (140 pp.) and special (373 pp.). Both are generously documented with references to the original literature. The first will be particularly welcomed since it was omitted completely from the recent English translation of the second edition [*ibid.*, **60**, 734 (1938)]. Following a brief but adequate description of the general technique of "spot testing," the special part devotes itself to the particular methods for the detection of metals (127 pp.), the detection of acids (66 pp.), systematic investigation of inorganic mixtures (21 pp.), application of spot tests to qualitative organic analysis (104 pp.), tests for purity, technical testing and mineral examination (50 pp.) and finally to an extensive tabular review of the content of the special part.

As a work to which continual reference will gladly be made by workers in organic as well as inorganic chemistry, the present edition well deserves the attention of all chemists who may hitherto have overlooked this valuable assistant.

E. H. Huntress

Second Report on Viscosity and Plasticity. Prepared by the Committee for the Study of Viscosity of the Academy of Sciences at Amsterdam. Nordemann Publishing Company, Inc., 215 Fourth Avenue, New York, N. Y., 1938. viii + 287 pp. 80 figs. 19 × 27 cm. Price, $7.50.

The book consists of a series of six articles surveying various topics relating to the viscous and plastic deformation of liquids and solids. The contributors are J. M. Burgers, F. M. Jaeger, R. Houwink, C. J. van Niewenburg, and R. N. J. Saal.

In the first article, Chapter I, recent investigations on the structure of liquids are reviewed by Burgers. The results of X-ray scattering studies and the calculation of radial distribution functions receive particular attention. In the article by Jaeger, viscosity data on pure liquids and liquid mixtures are discussed in connection with a number of theoretical and semi-empirical formulas. Certain problems relating to the theory of lubrication are touched upon.

The article by Burgers, Chapter III, on the motion of small particles suspended in a viscous liquid is of particular interest to chemists because of its bearing on the molecular shape of proteins and of polymers of high molecular weight. The author develops in a rather simple manner an approximate theory of the influence of elongated particles on the viscosity of a liquid in which they are suspended. By employing a method due to Oseen for the calculation of the velocity field in a viscous liquid in laminar flow, under the influence of external forces, he is able to avoid much of the intricacy of the exact hydrodynamical treatment of Jeffery and others.

In Chapter IV, by Houwink, the various factors influencing the yield value of crystalline solids, amorphous solids, and suspensions are investigated. The last two chapters are concerned with the techniques of plasticity and viscosity measurements. In the article on plastometers by van Niewenburg a survey of the types of instruments in use is undertaken, and the significance of plasticity measurements is discussed. The author concludes that no plastometers of present design allow an unambiguous determination of the fundamental relation between the rate of shear in an element of the sample and a simple shearing stress acting through it. In the final chapter by Saal, types of technical capillary viscosimeters in current use are described.

The report provides a unified and critical survey of a large amount of material on viscous and plastic phenomena. It will certainly prove to be a source of useful information on the subject. It is perhaps to be regretted that certain of the latest theoretical developments in the theory of viscosity have not been included.

JOHN G. KIRKWOOD

Tables of Reagents for Inorganic Analysis. In English, German and French. First Report of the "International Committee on New Analytical Reactions and Reagents" of the "Union Internationale de Chimie": C. J. van NIEUWENBURG (Delft) President, W. BÖTTGER (Leipzig), F. FEIGL (Vienna), A. S. KOMAROVSKY (Odessa), N. STRAFFORD (Manchester). Akademische Verlagsgesellschaft m. b. H., Sternwartenstrasse 8, Leipzig C 1, Germany, 1938. xxiv + 409 pp. 18 × 25 cm. Price, RM. 34; bound, RM. 36.

It should be clearly understood that this report deals only with reagents for use in *qualitative* inorganic analysis, and that the reagents that are covered are those that have been introduced in the period 1911–1936, inclusive. Spectroscopic methods, flame color reactions and methods of separation or concentration are not mentioned. Neither are the older standard reagents, unless they have been reinvestigated during this period.

The types of reactions described are those involving precipitation, color, catalysis, and certain miscellaneous operations. The procedures cover spot tests on drop plates or paper, micro tests under the microscope or in the micro test tube, and macro tests in the ordinary test tube.

Data are presented by an extensive use of symbols and abbreviations under the six general columns (1) cation or anion, (2) name and formula of the reagent, (3) type of reaction, (4) procedure, (5) sensitivity, and (6) remarks on compounds that are known to yield similar reactions or to interfere in the test. Extensive references to the literature are given under each test.

The section on cations deals with tests for some 57 elements plus the ammonium ion, while that on the anions covers some 38 anions. Finally, there is a very complete subject index listing the reagents and the tests in which they are used.

The book is a very worth while addition to texts on inorganic analysis, and is a mine of information for those who are prospecting or working in the field of qualitative analysis.

G. E. F. LUNDELL

The Elements of Physical Chemistry. By F. W. GODDARD, M.A., F.C.S. and E. J. F. JAMES, M.A., D.Phil. Longmans, Green and Co., 114 Fifth Avenue, New York, N. Y., 1938. viii + 251 pp. 66 figs. 13.5 × 20 cm. Price $1.80.

The two British authors state in their preface: "This introduction to the study of Physical Chemistry is intended for the use of students preparing for Higher Certificate, First Medical, and University Entrance Scholarship Examinations. It is assumed that such students will have acquired a knowledge of elementary physics and chemistry up to the standard of School Certificate on Matriculation." In American colleges and in teacher training schools it could well find a place in a course following general chemistry, or as an introduction to the regular course in physical chemistry. The book is distinctly an elementary treatment of the subject. Little, if any, calculus is involved. The pitch is about right for our American type of pre-medical courses in physical chemistry, but the dearth of illustrative material drawn from the biological field probably renders this text unsuited for such a purpose It is a bare skeleton outline cut almost to the bone.

The scope of the book is indicated by the chapter headings: I, The Atomic and Molecular Theory; II, Valency and the Structure of Atoms; III, The Gaseous and Liquid State; IV, Solution; V, Osmotic Pressure and Allied Phenomena; VI, Law of Mass Action; VII, Thermochemistry; VIII, Electrolysis and Electrolytic Dissociation; IX, Catalysis; X, Colloids.

The exposition is extremely clear, and the whole book is well organized. Every chapter is followed by a well-chosen list of good questions and problems (two hundred and fifty altogether). The answers are supplied at the end of the book. There is also a supplementary list of miscellaneous questions. An author index, subject index, and atomic weight, four-place log and anti-log tables, are also given.

EDWARD MACK, JR.

Laboratory Methods of Physical Chemistry. By JOSEPH J. JASPER, Assistant Professor of Chemistry, Wayne University. Houghton, Mifflin Company, 2 Park Street, Boston, Massachusetts, 1938. xix + 312 pp. 34 figs. 15 × 22.5 cm. Price $2.50.

This textbook is one of the series edited by Professor H. T. Briscoe. Following the Editor's Introduction, a Preface, Table of Contents and List of Figures, there are Preliminary Remarks to the Student, and the Chapters: I, Errors of Measurement and Corrections; II, Gases; III, Liquids; IV, Optico-Chemical Methods; V, Solutions; VI, Colloidal Systems; VII, Thermochemistry; VIII, Homogeneous Equilibrium; IX, Chemical Kinetics; X, Phase Equilibrium in Chemical Systems; XI, Electrical Conductance; XII, Transference Numbers; XIII, Electromotive Force; XIV, Photochemistry; Bibliography and Index. Altogether, Professor Jasper gives directions for about sixty experiments. The directions are clear and adequate and are featured by (1) the excellent figures, (2) helpful discussion of the pertinent theory at the beginning of every experiment, and (3) by specific instructions for treatment of results at the end.

It is perhaps somewhat surprising, or perhaps not surprising, to teachers of physical chemistry to find that several of the available laboratory manuals are constructed so nearly on the same pattern. Resemblances in the skeleton outline of book structure may be inevitable because of the necessity of acquainting the student with a representative set of the highly standardized laboratory techniques of the physical chemist. The author of such a textbook no doubt feels almost compelled to present the usual type of directions for making the classical measurements of molecular weight, surface tension, viscosity, electrical conductivity, hydrogen ion concentration, etc., etc., through the whole list.

If a dozen, or several dozen, authors and their publishers are to give birth to laboratory manuals of physical chemistry, it is to be hoped that some distinctive flavor of originality may be found in a few of the new-born. Surely the vast literature of experimental physical chemistry, with its enormous wealth of illustrative material suitable for textbook use, has scarcely been sucked quite dry. Nor have the resources upon which the alert pedagogue may draw for setting forth the meaning and limitations and possibilities of the experimental method, and for arousing and sustaining the interest of the student, necessarily been exhausted.

The present book is a good one. It should find a wide adoption and usefulness, as have some of the other books which it resembles.

The author, the editor and the publishers are to be congratulated on its very fine appearance, and on the excellent job of book-making that they have done.

EDWARD MACK, JR.

The Fine Structure of Matter. Part II. Molecular Polarization. Part III. The Quantum Theory and Line Spectra. By C. H. DOUGLAS CLARK, D.Sc., A.R.C.S., A.I.C., D.I.C., Assistant Lecturer in Inorganic Chemistry in the University of Leeds. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1938. 14.5 × 22.5 cm. Part II: lxxii + 241 pp. 35 figs. Part III: lxxii + 185 pp. 29 figs. Price, $4.50 each.

The chapter headings in the two volumes under review are the following: Part II, Molecular Polarization: Dielectric Constants, The Debye Theory of Polarization, Molecular Refraction, Polar Molecules, Molecular Fields; Part III, The Quantum Theory and Line Spectra: The Quantum Theory, The General Principles of Line Spectra, The Multiple Structure of Lines, Line Spectra and the Periodic Classification.

In the opinion of the reviewer, a reader unfamiliar with the subjects could not gain an understanding of molecular polarization and line spectra by the study of these books, although the author in his preface suggests that Part III might serve as an introduction to the study of spectra. The style in which the books are written is incoherent and confusing, and the author has not given a consecutive account of the topics treated. Unrelated subjects are grouped together as, for example, on page 285, where reference is inserted in a section on the additivity of molecular refraction values to a method of calculating the refractive index of nickel arsenide from its reflective power in air and in cedarwood oil. The lack of clarity in the discussions is due in part to the inclusion of references to outmoded suggestions as well as to the more satisfactory recent theories and to unreliable as well as reliable values of experimental quantities.

The theoretical parts of the books are poor; although a detailed mathematical discussion (pages 452–455) is given of Debye's old calculation, now unimportant, of the value 64° for the H–O–H angle in the water molecule (the actual value being 105°), no derivation of the Debye fundamental equation relating molecular polarization and dipole moment is given in the chapter headed "The Debye Theory of Polarization" or elsewhere in the book. In several pages of discussion of the Clausius–Mossotti equation mention is made of the electric displacement in cylindrical cavities, but the significant step of evaluating the factor $^1/_3$ in the equation with use of a spherical cavity is omitted, the reader being left unenlightened as to the nature of the "certain assumptions, in accordance with the classical theory," which are involved.

The volumes are made somewhat unsatisfactory for reference purposes by the Author's selection of 1934 as the closing date for literature references, and by the existence of many errors. Fluorescent scattering and Raman scattering are said to require a decrease in frequency of the light. A figure showing experimental values of the molecular refraction of alkali halide crystals is confusingly described as based on estimates of $R_{\text{crystal}} - R_{\text{free gas ion}}$. Typographical errors such as CH_2OH for CH_3OH, SiF_6 for SeF_6, $Te(NO_3)_2$ for $Te(NO_3)_4$, and HeII for HeII occur rather frequently.

The books are not recommended either to readers interested in learning about the subjects treated or to those seeking a convenient guide to the literature.

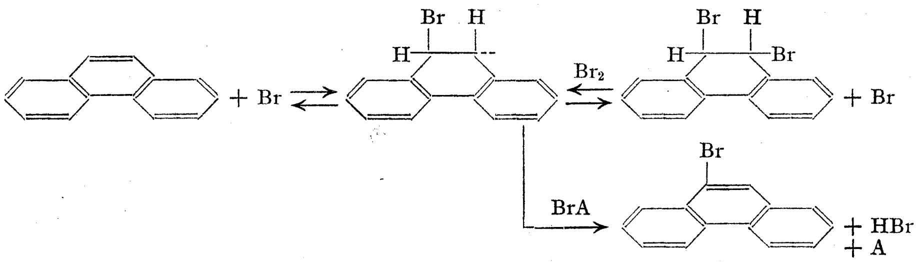
The Mechanism of Aromatic Bromination[1]

BY CHARLES C. PRICE AND CLYDE E. ARNTZEN

From previous investigations of the effect of iodine on the reaction between bromine and phenanthrene[2] it was concluded that the bromine substitution reaction proceeded in the following manner, A representing the necessary bromination catalyst.



Since the central ring of phenanthrene obviously differs from the usual aromatic type in that it forms a stable addition product, it remained to prove that this mechanism could be applied to aromatic compounds in general.

It was pointed out in a previous paper[2] that Bruner's[3] extensive measurements of the iodine-catalyzed bromination of benzene with this reactant as solvent could be reinterpreted very accurately according to the rate expression

$$d[C_6H_5Br]/dt = k[Br_2]^{3/2}[I_2]^{5/2}$$

Any dependence of the rate on the benzene concentration could not be detected in his experiments since the benzene was in such excess as to remain essentially unchanged during the course of the reaction.

A study of the iodine-catalyzed bromination of phenanthrene has shown it to obey the same kinetics as the similar reaction of benzene investigated by Bruner. The only difference is that it was not feasible to work with a large enough excess of phenanthrene for its concentration to remain unchanged during the course of the reaction. The rate expression therefore includes dependence on the hydrocarbon concentration as well as bromine and iodine.

$$d[C_{14}H_9Br]/dt = k[C_{14}H_{10}][Br_2]^{3/2}[I_2]^{5/2}$$

The values for the constant, *k*, calculated with the concentrations expressed in moles per liter, are summarized in Table I for various bromine, iodine and phenanthrene concentrations. The fact that for both benzene and phenanthrene the rate of bromination is dependent on the bromine concentration to the three-halves power and the iodine concentration to the five-halves power proves beyond reasonable doubt that the mechanisms for the two reactions are identical. We may therefore write the bromination of benzene according to the following scheme, omitting, of course, a dibromide such as is formed in the case of phenanthrene.

The catalyst may function in the reaction not only, as has been indicated, by the removal of hydrogen from the active intermediate, but also in the production of the active bromine which acts as the initiator of the reaction by producing this active intermediate. Thus the total effect of iodine on the rate of reaction may be divided into an effect on the equilibrium of the first step, the formation of the intermediate, in addition to catalysis of the second step, the removal of the hydrogen.

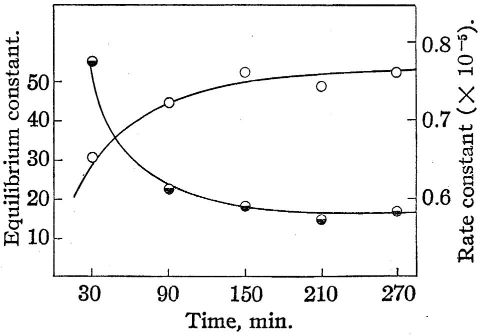

Fig. 1.—Phenanthrene and bromine concentration 0.0322 *M*; iodine 0.0102 *M*; equilibrium constant for addition ○; rate constant for substitution ◒.

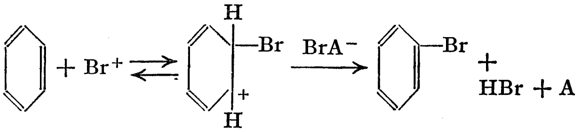
Since iodine has a decidedly inhibitory effect on the addition of bromine to phenanthrene,[2] which is a photochemical[4] chain reaction propagated by bromine atoms, it may well be that the iodine-catalysis of the first step in the bromination is the production of positive bromine *ions* rather than bromine atoms. The intermediate in this case would have a positive charge and would be that proposed by Pfeiffer and Wizinger.[5]



The fact that benzene reacts with bromine photochemically to form an addition product while the catalytic reaction leads to substitution is in agreement with this proposal. The photochemical addition most certainly proceeds by an atomic mechanism, leaving an ionic intermediate as the most probable for catalytic substitution in the absence of light.

The kinetics of the reaction are incapable of distinguishing between the atomic and the ionic mechanisms, proving only that the same mechanism holds for both benzene and phenanthrene.

The experiments were all performed in the dark using painted flasks to exclude light. Bromine was purified as in previous experiments;[6] the iodine was resublimed and the phenanthrene prepared from its recrystallized dibromide by treatment with zinc dust in alcohol,[4b] m. p. 99–99.5°.

Standard solutions of the three reagents were mixed and the samples for individual titrations immediately placed in small (5-cc.) glass-stoppered flasks and sealed with paraffin to prevent loss of hydrogen bromide. After a specified interval the flasks were opened under distilled water containing potassium iodide. The liberated iodine was titrated with sodium thiosulfate to the disappearance of its color, then the acid with carbonate-free sodium hydroxide using phenolphthalein as indicator. From these data the course of both addition and substitution can be determined since the decrease in bromine concentration is a measure of both reactions while the acid is produced by substitution alone.

It was found in every case that the rate constant for the substitution reaction did not become truly constant until the equilibrium of the addition reaction had been established. In Fig. 1 are plotted the rate and equilibrium constants at various times for a typical experiment to illustrate this point. The rate constants of Table I are, therefore, the average of the individual con-

[4] (a) Kharasch, White and Mayo, *J. Org. Chem.*, **2**, 574 (1038); (b) Price, Arntzen and Weaver, THIS JOURNAL, **60**, 2837 (1938).

[5] Pfeiffer and Wizinger, *Ann.*, **461**, 132 (1928).

[6] Price, THIS JOURNAL, **58**, 1834 (1936).

stants for each experiment after the attainment of the equilibrium of the addition reaction.

In Table I the penultimate column lists the values for the equilibrium constants for the addition of bromine to phenanthrene at the various iodine concentrations. They show a steady decrease with increasing iodine concentration which may be accounted for by the reaction of bromine and iodine to form a bromoiodide

$$Br_2 + I_2 \rightleftharpoons BrI$$

which would reduce the actual concentration of bromine molecules but not the bromine titer. Insertion of the titer value for bromine, a larger value than is actually effective, would cause a variation in the manner noted for the equilibrium constant.

In fact, since the true value for the equilibrium constant, $K_{25} = [C_{14}H_{10}Br]/[C_{14}H_{10}][Br_2] = 230$, is known, and since the concentrations of both the phenanthrene and its dibromide may be calculated from the experimental data, it is possible to calculate from this the value for the free molecular bromine concentration. With this value known, as well as the total iodine and total bromine concentrations (Br_2 + BrI) it is possible to calculate the equilibrium constant, $K_{IBr} = [BrI]/[Br_2]^{1/2}[I_2]^{1/2}$, for the bromine–iodide reaction in carbon tetrachloride solution, the values for which are given in the final column of Table I. The calculation is for the last determination in each experiment, which should be at equilibrium. No calculation could be made for the experiments at lower iodine concentration since the equilibrium of the addition reaction had not been established at the last measurement.

Bodenstein and Schmidt[7] have determined the value for this equilibrium constant at elevated temperatures in the gas phase and derived the following expression for its dependence on the temperature

$$\log \frac{1}{4K^2} = \frac{3.676}{4.57 \times T} - 0.50$$

Calculation of the equilibrium constant at 25° from this expression gives a value of 19.9, agreeing well with the experimentally determined values, especially since a fairly large experimental error (10–15%) could easily be involved.

Summary

The kinetics of the iodine-catalyzed bromination of phenanthrene have been determined as identical with those of benzene. This is offered as proof of the identity of mechanism for the bromination of aromatic compounds in general with that previously proposed for phenanthrene.

This mechanism involves addition of a positive bromine ion to the unsaturation of the aromatic nucleus followed by catalytic elimination of a hydrogen ion to yield the substitution product.

It has been found that the equilibrium for the bromine-iodine reaction in carbon tetrachloride solution agrees with the determinations of Bodenstein and Schmidt for the gas phase reaction at considerably higher temperatures.

The Reaction of Bromine with Various Samples of Phenanthrene

BY CHARLES C. PRICE, CLYDE E. ARNTZEN AND CLAY WEAVER

No entirely satisfactory method for the purification of phenanthrene has as yet been developed. Selective oxidation with nitric acid[1] and with chromic acid,[2] as well as treatment with maleic anhydride,[3] have been recommended for the removal of anthracene. Treatment with sodium has been found effective for the removal of fluorene[4] or sulfur-containing compounds.[5]

We have found the following series of reactions convenient for preparing samples of phenanthrene of a high degree of purity from relatively impure starting material.

$$C_{14}H_{10} + Br_2 \longrightarrow C_{14}H_{10}Br_2 \xrightarrow[\text{alcohol}\ (60°)]{\text{Zn dust in}} C_{14}H_{10} + ZnBr_2$$

The chief advantage offered is that the phenanthrene dibromide may be recrystallized to remove impurities which could not be separated from phenanthrene itself by crystallization. The prod-

uct so obtained (A) melted at 99–99.5°, three degrees higher than the starting material, which had been purified by oxidation[2] but not by treatment with sodium.

Dihydrophenanthrene was a possible impurity in this product since some of the dibromide might decompose with evolution of hydrogen bromide even though the temperature was kept well below its usual thermal decomposition point (90–100°). Consequently some of the material (A) was treated with selenium for eight hours at 300–320°, distilled and twice recrystallized. This treatment raised the melting point only half a degree but completely altered the behavior of the material toward bromine.

Phenanthrene purified from coal tar as described previously[6] and the sample (A) prepared by the present method react with bromine photochemically[7] at nearly the same rapid rate. The sample from selenium treatment, however, in spite of the higher melting point, was found to react only very slowly, although it finally attained the same equilibrium for the addition reaction as the other samples. This is in agreement with experiments using synthetic phenanthrene,[8] which also had been treated with selenium. This material was found to melt high (m. p. 100.7–101°), and to react with bromine only very slowly.

That the difference in the behavior of these various samples of phenanthrene was not due to the absence of fluorene or anthracene in the selenium-treated samples (which may have been present as an impurity in the material reacting with bromine), was demonstrated by addition of these hydrocarbons to such samples, the mixtures showing the same characteristics as the original material.

It was of interest to note that anthracene, which catalyzes several reactions of bromine in the dark,[9] did not cause the chain addition of bromine to phenanthrene. The course of the reaction of bromine with a mixture of phenanthrene and anthracene appeared, in this case, to be the addition of one molecule of bromine to phenanthrene for each molecule reacting with anthracene. The results of these experiments are summarized in Table I. The fact that all the phenanthrene samples behave similarly in this instance indicates that the material which inhibits the photochemical addition (bromine atom mechanism) has no effect on the dark, anthracene-catalyzed reaction (bromine cation mechanism).

[a] Phenanthrene sample (A). [b] Phenanthrene sample (A) treated with selenium. [c] Gesellschaft für Teerverwertung phenanthrene.

Furthermore, it was found that addition of selenium-treated phenanthrene to that reacting with bromine gave a mixture which would not react. These various facts are interpreted as indicative of the presence of an inhibitor in the phenanthrene treated with selenium, in spite of its higher melting point. However, since the photobromination of this hydrocarbon is a chain reaction of considerable length,[6] it would require but small amounts of a chain-breaking impurity to account for the results.

Several qualitative tests have been made for the purity of the various samples of phenanthrene. These are summarized in Table II.

These color tests indicate that the samples prepared by the present method are much purer than the starting material and seem quite similar to a sample of the highly purified hydrocarbon from the Gesellschaft für Teerverwertung.

Experimental

Crude phenanthrene (10 g.) with a melting point of 94–96° was dissolved by warming in 50 cc. of purified[6] carbon tetrachloride[10] and, after cooling in ice, treated with 4 cc. of bromine in portions. The reaction mixture was allowed to stand in sunlight at 0° for an hour. The dibromide, 13 g. (65%), was recrystallized by dissolving in the minimum amount of benzene (150 cc.) at 40–45°,[11] adding an equal amount of petroleum ether (60–90°), and cooling in an ice-salt bath to −15°. The pure dibromide, crystallizing as colorless plates with a greenish tinge, was collected by filtration, yield 10 g., m. p. 98–99°, with decomposition. Its

[c] Martin, THIS JOURNAL, **58,** 1438 (1936).

solution in 200 cc. of alcohol was treated with 7.5 g. of zinc dust at 50–60° for twelve hours, the reaction mixture filtered while hot, evaporated to 50–60 cc. and set aside to crystallize. The yield was 4.6 g. (90%) of colorless plates melting at 99–99.5° after one recrystallization.

A portion of this material was heated with selenium to 300–320° for eight hours, distilled under diminished pressure and twice recrystallized from alcohol to give a sample melting at 99.5–100°.

Summary

Phenanthrene of a high degree of purity may be obtained by conversion to the dibromide followed by regeneration of the hydrocarbon on treatment with zinc dust.

Phenanthrene which has been treated with selenium apparently contains an impurity inhibiting the photochemical addition of bromine.

Anthracene has been found to catalyze an equimolecular but not a chain addition of bromine to phenanthrene in the dark.

A Chemically-Catalyzed cis-trans Isomerization

BY CHARLES C. PRICE AND RALPH S. THORPE

The anthracene-catalyzed bromination of dioxane[1] can be accounted for only by assuming that the reaction between bromine and anthracene produces active bromine. Since many photochemical reactions of bromine presumably proceed through active bromine atoms produced by the dissociation of a bromine molecule on absorption of light, and since the same intermediate has been proposed for several reactions of hydrogen bromide in the presence of peroxides,[2] it was proposed to use one of these reactions to test the possibility that the active bromine produced by the anthracene–bromine reaction in the dark might behave in a similar manner.

The particular reaction studied was the conversion of a maleic ester to the corresponding fumaric ester. Wachholtz and Schmidt[3] have reported previously the photochemical isomerization of the ethyl and methyl esters, respectively, in the presence of bromine. Both investigators agree that the mechanism must be a chain reaction with a length of several hundred, initiated by the photochemical dissociation of bromine molecules to atoms. They represent the course of the reaction as

$$Br_2 + h\nu \longrightarrow 2Br$$
$$M + Br \longrightarrow (MBr) \longrightarrow F + Br$$

More recently Kharasch[2] has proposed a bromine atom intermediate for the peroxide-catalyzed rearrangement of isostilbene to stilbene in the presence of hydrogen bromide, and, on this basis, has extended this proposal of a bromine atom mechanism to the well-known effect of peroxides in reversing the usual mode of addition of hydrogen bromide to many olefinic double bonds.

The investigation reported herein is on the conversion of ethyl maleate to ethyl fumarate by bromine and anthracene in carbon tetrachloride solution.

Experimental.—The reactions were all carried out in purified carbon tetrachloride solution.

(3) (a) Wachholtz, *Z. physik. Chem.*, **125,** 1 (1929); (b) Schmidt, *bid.*, **B1,** 205 (1930).

Ethyl maleate was prepared from the anhydride according to the directions of Wachholtz.[3a] Bromine and anthracene were added to a solution of 1 cc. of the ester in 2.5 cc. of carbon tetrachloride in a painted flask. The bromine color had always faded completely at the end of the reaction so the mixture of the two isomeric esters was obtained by fractional distillation under diminished pressure. The effective removal of carbon tetrachloride was demonstrated by the index of refraction of the ester mixture. Analysis for the percentage conversion was most convenient according to the method developed by Kistiakowsky and Smith[4] with the modification that no special apparatus was necessary for the determination. The production of cloudiness in the clear solution of 0.4 cc. of ester mixture in 0.6 cc. of liquid petroleum could be reproduced readily to within 0.5° using only the naked eye in ordinary daylight. Analysis by this method was accurate to within 1% and scarcely more difficult than an ordinary melting point determination. The results of these various determinations are summarized in Table I.

TABLE I

CONVERSION OF ETHYL MALEATE TO ETHYL FUMARATE BY BROMINE AND ANTHRACENE IN CARBON TETRACHLORIDE

16, 17[b]	2.6	1.3	.5	18, 22

[a] These experiments were exposed to light. [b] In these experiments the bromine-anthracene reaction was completed *before* the ester was added.

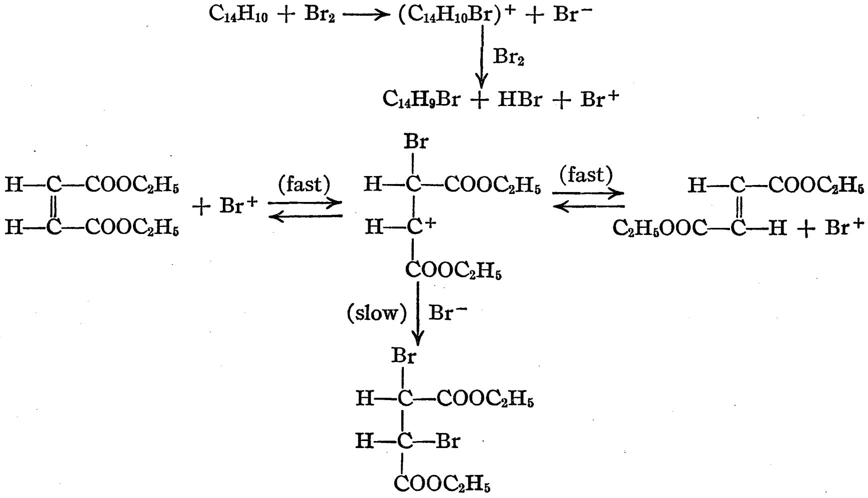
Discussion of Results.—Inspection of this table shows that ethyl maleate was converted rapidly in good yield to ethyl fumarate by the combined action of bromine and anthracene in carbon tetrachloride solution with light rigorously excluded. That the isomerization was indeed due to the combined effect of bromine and anthracene is demonstrated by Experiments 6 and 18 in which bromine alone caused no isomerization in the dark, even after a week, while the reaction in the presence of anthracene requires at most but a few minutes. The photochemical reaction reported by Wachholtz and Schmidt was observed in Experiments 5 and 19 in which bromine alone, exposed to sunlight, caused complete isomerization.

The small proportion of anthracene (1.3%) which was capable of isomerizing a large portion of the maleate is indicative of a fairly long chain mechanism for the conversion in agreement with the previous reports for the photochemical reaction.[3]

Two mechanisms appear plausible for this *cis-trans* isomerization. A bromine atom, as in the photochemical reaction, may be the active intermediate. If such were the only alternative, anthracene must react with bromine in the dark to produce bromine atoms.

$$C_{14}H_{10} + Br_2 \longrightarrow C_{14}H_{10}Br + Br$$

An alternative mechanism, however, involves a bromine cation as active intermediate. In this regard, it may be mentioned that the bromination of dioxane in the presence of anthracene may be best accounted for on the basis of the production



---

(4) Kistiakowsky and Smith, THIS JOURNAL, **56**, 638 (1934).

of an active bromine cation by the reactions between anthracene and bromine in the dark. On this basis, the conversion of *cis* to *trans* isomers in the dark might then be represented by the series of reactions shown.

The isomerization would thus be a true chain reaction since the bromine cation is constantly regenerated after each conversion.

These results indicate that bromine cations, as well as bromine atoms, may cause rapid isomerization about an olefinic bond. This latter reaction, therefore, must be applied with reservation as a criterion for the presence of bromine atoms.

Summary

The reaction of bromine with anthracene in the dark has been found to catalyze the isomerization of ethyl maleate to ethyl fumarate.

The mechanism of this conversion has been formulated with a positively charged bromine ion as an intermediate.

The subsequent limitation of *cis–trans* isomerization as a criterion for the presence of bromine atoms is pointed out.

[A CONTRIBUTION FROM THE PEARSON MEMORIAL LABORATORY OF TUFTS COLLEGE]

The Action of Ammonia and Aromatic Amines on 4-Methylnitrostyrene and Related Compounds

BY DAVID E. WORRALL

Nitrostyrene has been shown[1] to react with aniline in a manner characteristic of α,β-unsaturated compounds, forming ultimately a saturated β-anilino derivative. That the additive capacity of the unsaturated system toward such substances is slight became apparent when it was discovered that comparatively few reacted in this way, if at all. An attempt[2] to facilitate the reaction by working with a substance incapable of polymerization, namely, bromonitrostyrene, was fruitless as the presence of halogen promoted the formation of Schiff bases. Similar results were obtained by Musante[3] working with nitrostyrenes containing methoxy or oxymethylene groups. A study has now been made of the effect of substituents on the alkylated nitrostyrene, $CH_3C_6H_4CH{=}CHNO_2$ (I).

The ability to add organic bases is entirely lost on the introduction of a methyl group into the ring of nitrostyrene, although the tendency for polymerization or hydrolysis is not greatly changed. It is true that a condensation product of the amine and aldehyde is formed when I reacts with an alcoholic solution of phenylenediamine or benzidine, a reaction that may be interpreted as resulting from the decomposition of an intermediate addition product. Since no reaction takes place with anhydrous benzene as a solvent, it seems apparent that the product is rather the result of hydrolysis and condensation. The additive power of I is not increased by the introduction of bromine in the side chain, but the presence of a nitro group in the ring partially restores the lost reactivity. Addition compounds are formed with aniline and *p*-toluidine, but not with phenylhydrazine.

(II)  (III)

$$NO_2(CH_3)C_6H_3CH{=}CHNO_2 + C_6H_5NH_2 \longrightarrow NO_2(CH_3)C_6H_3\underset{NHC_6H_5}{\underset{|}{CH}}CH_2NO_2$$

p-Phenylenediamine reacts in a similar manner, both functional groups being involved. With ammonia the reaction is somewhat different inasmuch as the primary addition product reacts further with a second molecule of II.

$$2NO_2(CH_3)C_6H_3CH{=}CHNO_2 + NH_3 \longrightarrow IV$$
$$(NO_2(CH_3)C_6H_3CH[CH_2NO_2])_2NH$$

The introduction of bromine into the side chain of II again cuts down the ability to form addition compounds. No reaction takes place in the absence of water and with wet reagents only unchanged components or products resulting from hydrolysis or destructive decomposition are present.

The nitrostyrene (V) obtained from nitroethane and toluic aldehyde contains an alkyl group in the side chain next to the nitro group as well as in the ring. It shows no tendency to

---

[1] Worrall, THIS JOURNAL, **49**, 1598 (1927). This particular substance was first prepared, in another manner, by Tönnies, *Ber.*, **20**, 2986 (1887), although the true structure was pointed out later by Wieland, *ibid.*, **36**, 2564 (1903).

[2] Worrall, THIS JOURNAL, **43**, 919 (1921).

[3] Musante, *Gazz. chim. ital.*, **67**, 579 (1937).

polymerize or form addition compounds. The introduction of bromine into the side chain on carbon next to the ring has no effect but nitration produces a substance again capable of reacting, by addition, with *p*-toluidine. The presence of the methyl group in the side chain, however, has a hindering effect as the nitro derivative does not form an addition compound with *p*-phenylenediamine.

The introduction of a phenyl group into the side chain produces a nitrostilbene, a substance showing no tendency to react by addition or polymerization. It is converted by alcoholic ammonia into an isoxazolone oxide.[4]

Experimental

α-Nitro-β-[4-methylphenyl]-ethylene I.—While toluic aldehyde may be condensed with nitromethane through the action of alkali,[5] it was found more convenient in working with smaller quantities (0.25 to 0.5 g. mole) to use a modification of the method of Knoevenagel.[6] The two components were heated under a reflux condenser by steam in the presence of 5% of the equivalent amount of amylamine for forty minutes. The yield by either method after crystallization from two volumes of alcohol was slightly better than 60%. A much better yield was obtained on heating with alcoholic amylamine but the product was contaminated with a small amount of polymer difficult to remove. I separated from alcohol in long light yellow needles, m. p. 102°.

Anal. Calcd. for $C_9H_9NO_2$: C, 66.3; H, 5.5. Found: C, 66.0; H, 5.5.

A gelatinous precipitate difficult to filter separated from a warm alcohol solution of I in the presence of ammonia or an aliphatic amine. Considerable discoloration may take place especially with ammonia. No good solvent was found for the polymer which dried out after thorough washing with hot alcohol to a white powder. It gradually decomposed above 230°.

Anal. Calcd. for $(C_9H_9NO_2)x$: C, 66.3; H, 5.5. Found: C, 66.5; H, 5.6.

Ammonia did not react with a dry benzene solution of I. Amylamine in the absence of solvents reacted vigorously, producing a tar from which 4-methylbenzalamylamine and nitromethane were isolated and identified.

I gave no evidence of reacting with aniline. On long standing the oily residue was found to consist of a mixture of unchanged components. Similar results were obtained with phenylhydrazine and *p*-toluidine. No reaction took place between I and *p*-phenylenediamine dissolved in dry benzene even after the mixture had been heated to boiling and then kept at room temperature for a day. Unchanged amine separated out. These same substances did react in warm alcohol, but as the product was insoluble in alcoholic potash and was unchanged on heating with this same reagent, it was not an addition product but a Schiff base. Recrystallized from glacial acetic acid, it appeared as tiny brownish-yellow needles, m. p. 188–189°.

Anal. Calcd. for $C_{22}H_{20}N_2$: C, 84.6; H, 6.4. Found: C, 84.3; H, 6.5.

Similar results were obtained with benzidine.

α-Nitro-β-(4-methylphenyl)-ethylene Dibromide.—Ten grams of I was brominated in chloroform by heating for an hour under a reflux condenser. The oily residue after removal of solvent hardened on cooling. A small portion was crystallized from ligroin, separating in colorless tablets, m. p. 79–80°.

Anal. Calcd. for $C_9H_9O_2NBr_2$: Br, 49.5; Found: Br, 49.3.

α-Nitro-α-bromo-β-[4-methylphenyl]-ethylene.—The crude dibromide reacted spontaneously and smoothly with a warm alcohol solution of potassium acetate. After standing for a short time the new substance was isolated, separating from alcohol as lustrous yellow plates, m. p. 67–67.5°.

Anal. Calcd. for $C_9H_8BrNO_2$: Br, 33.1. Found: Br, 32.8.

It did not polymerize in the presence of alcoholic ammonia, neither was it observed to react with *p*-toluidine or *p*-phenylenediamine. The corresponding chlorine derivative obtained in a similar manner as narrow yellow plates melting at 78–78.5° was also non-reactive.

Anal. Calcd. for $C_9H_8ClNO_2$: C, 54.7; H, 4.1. Found: C, 54.3; H, 4.2.

α-Nitro-β-[2-nitro-4-methylphenyl]-ethylene.—The product obtained by nitrating 25 g. of I using fuming acid and maintaining the temperature slightly below 20° was recrystallized from alcohol: yield 23 g.; m. p. 121–122°, after several crystallizations. It was identified as the 3-nitro derivative of I by an analysis and an examination of the oxidation product, obtained by the action of potassium permanganate, which did not depress an authentic sample of 3-nitro-*p*-toluic acid. The substance previously prepared by Hanzlik and Bianchi[7] by the nitration of *p*-methylcinnamic acid and recorded as melting at 117–118° probably contained some of the 2-nitro isomer. The original filtrate yielded 8.5 g. of material melting at 70–75°. By repeated crystallizations a small quantity of tiny pale yellow needles was obtained that had a constant melting point, 96–97°.

Anal. Calcd. for $C_9H_8N_6O_4$: C, 51.9; H, 3.8. Found: C, 51.5; H, 3.9.

It was unchanged by nitric acid while the melting point was depressed by the 3-nitro isomer. It seems safe to conclude that the substance was the 2-nitro derivative of I, although it still may have contained some of the isomer.

α-Nitro-β-anilino-β-[3-nitro-4-methylphenyl]-ethane III was obtained by heating, until solution was complete, the two components in the presence of alcohol. Crystals gradually formed on standing. III separated from alcohol as small yellow prisms, m. p. 98–99°. As with all of these addition compounds, some decomposition took place at the melting point which accordingly varies depending upon the rate of heating. III was soluble in alcoholic potash.

Anal. Calcd. for $C_{15}H_{15}N_3O_4$: C, 59.8; H, 5.0. Found: C, 59.5; H, 5.0.

---

[4] Worrall, This Journal, **57**, 2299 (1935).

[5] *Org. Syntheses*, **9**, 66 (1929).

[7] Hanzlik and Bianchi, *Ber.*, **32**, 2287 (1899).

α-Nitro-β-toluidino-β-[3-nitro-4-methylphenyl]-ethane.—Prepared in a similar manner it separated from alcohol as bright yellow sparkling plates, m. p. 135–136°, dec.

Anal. Calcd. for $C_{16}H_{17}O_4N_3$: C, 61.0; H, 5.4. Found: C, 60.7; H, 5.4.

N,N′-(α,α′-[3-Nitro-4-methylphenyl]-β,β′-dinitro-diethyl)-*p*-phenylenediamine.—Yellow crystals quickly formed on heating II and *p*-phenylenediamine in alcohol until dissolved. No good solvent was found although the substance crystallized from acetone as tiny pale yellow plates, melting with decomposition at 152–153°. It was dissolved readily by alcoholic potash.

Anal. Calcd. for $C_{24}H_{24}N_6O_8$: C, 55.0; H, 4.6. Found: C, 55.4; H, 4.8.

II readily formed a polymer with alcoholic ammonia, an amorphous powder melting with decomposition at 198–200°. It was not examined further.

α,α′-([3-Nitro-4-methylphenyl]-β,β′-dinitrodiethyl)-amine, IV.—It was obtained by dissolving 2 g. of II in 100 cc. of dry benzene which was then saturated with dry ammonia. The mixture after standing for several hours in a closed container was allowed to evaporate spontaneously to a small bulk. The nodular crystalline aggregates that appeared were crystallized from alcohol. This must be done cautiously and in small lots as the substance is destroyed easily by hot alcohol solutions. Small colorless flat needles melting at 147° with decomposition were obtained. IV was insoluble in alcoholic potash and was not observed to form a salt with acids, although it was soluble in concd. hydrochloric acid.

Anal. Calcd. for $C_{18}H_{19}N_5O_8$: C, 49.9; H, 4.4. Found: C, 50.1; H, 4.5.

α-Nitro-β-bromo-β-[3-nitro-4-methylphenyl]-ethylene.—Ten grams of the bromine derivative of I was nitrated, the product crystallizing from a moderately large volume of alcohol in clumps of small pale yellow needles, m. p. 105°.

Anal. Calcd. for $C_9H_7BrN_2O_4$: C, 37.6; H, 2.4. Found: C, 38.1; H, 2.7.

Repeated crystallization from alcohol of the residue left in the original mother liquor produced eventually a substance that separated from ligroin as tiny yellow needles, m. p. 82–83°. This isomer, the 2-nitro derivative, on analysis gave data identical with those reported for the 3-nitro compound and in the one experiment tried did not form an addition compound. Only negative results were obtained in attempts to form addition compounds of the new 3-nitro derivative with aromatic amines, or to obtain a polymer. The odor of bromonitromethane was evidence that some hydrolysis occurred, but even with phenylenediamine no Schiff base was isolated from the black tar that formed.

α-Nitro-β-chloro-β-[3-nitro-4-methylphenyl]-ethylene.—Nitration of the chlorine derivative of I resulted in small pale yellow needles (from alcohol), m. p. 107–108°.

Anal. Calcd. for $C_9H_7ClN_2O_4$: C, 44.5; H, 3.3. Found: C, 44.9; H, 3.1.

No search was made for the isomer probably present. All attempts to form addition compounds with the chloro derivative were fruitless.

α-Nitro-α-methyl-β-[4-methylphenyl]-ethylene, V.—This substance obtained from nitroethane and toluic aldehyde using amylamine separated from petroleum ether as yellow prismatic needles, m. p. 55°; yield approximately 50%.

Anal. Calcd. for $C_{10}H_{11}NO_2$: C, 67.8; H, 6.2. Found: C, 67.4; H, 6.1.

All attempts to form addition compounds using ammonia, *p*-toluidine and *p*-phenylenediamine failed, also attempts to prepare a polymer. A small amount of V was brominated in the customary manner and the oil-like product heated under a reflux condenser with potassium acetate for four to five hours. The mixture was worked up yielding a pale yellow oil. With this impure sample only negative results followed attempts to form an addition compound with toluidine.

α-Nitro-α-methyl-β-(3-nitro-4-methylphenyl)-ethylene, VI.—Nitration of V gave a substance separating from ligroin as narrow yellow plates, m. p. 72–73°.

Anal. Calcd. for $C_{10}H_{10}N_2O_4$: C, 54.1; H, 4.5. Found: C, 54.0; H, 4.7.

α-Nitro-α-methyl-β-(*p*-toluidino)-β-[3-nitro-4-methylphenyl]-ethane.—*p*-Toluidine formed an addition compound with VI after several hours. It separated from alcohol in clusters of bright golden platelets, m. p. 109–110°, dec.

Anal. Calcd. for $C_{17}H_{19}N_3O_4$: C, 62.0; H, 5.8. Found: C, 62.1; H, 5.8.

On mixing VI with a warm alcohol solution of *p*-phenylenediamine a black tar quickly formed from which, by digestion with warm alcohol, a crystalline product was obtained. It crystallized from acetone in tiny hair-like pale yellow crystals, m. p. 254–255°. As it was stable toward alkali and therefore not an addition compound, the substance was not examined further.

3,5-Diphenyl-4-(4-methylphenyl) Isoxazolone Oxide.—A suspension of 10 g. of 4-methylnitrostilbene in 50 cc. of alcohol was saturated with ammonia. The melting point of the product, removed at the end of an hour, indicated a mixture. It was heated with hydrochloric acid to destroy the condensation product of aldehyde, phenylnitromethane and ammonia otherwise difficult to remove.[6] The residue separated from a large volume of alcohol in long slender needles, m. p. 171–172°.[8]

Anal. Calcd. for $C_{22}H_{19}O_2N$: C, 80.2; H, 5.8. Found: C, 80.2; H, 5.9.

Dibenzoyl-4-methylphenylmethane Monoxime.—The filtrate from VII after steam distillation and crystallization from ligroin yielded a small amount of needle-like crystals, easily soluble in alcohol, m. p. 160–161°.

Anal. Calcd. for $C_{22}H_{19}NO_2$: C, 80.2; H, 5.8. Found: C, 79.8; H, 5.9.

It is quickly changed by hot hydrochloric acid into the corresponding isoxazole.

---

[8] Meisenheimer and Matarbeiter, *Ann.*, **468**, 254 (1929), obtained, as a by-product in the preparation of 4-methylnitrostilbene, a small amount of white needle-like crystals melting at 168° and sparingly soluble in methyl alcohol. Based on an analysis the formula $C_{21}H_{19}NO_2$ was deduced for the unknown substance, which was probably VII.

3,5-Diphenyl-4-(4-methylphenyl)-isoxazole was obtained from VII by the action of hot alcoholic potash as needles, m. p. 198°.

Anal. Calcd. for $C_{22}H_{17}NO$: C, 84.9; H, 5.5. Found: C, 84.7; H, 5.5.

5-(4-Bromophenyl)-4-(4-methylphenyl)-3-phenylisoxazolone Oxide.[9]—A suspension of 3 g. of *p*-bromophenylnitromethane and VII in 50 cc. of alcohol was saturated with ammonia. The product after an hour was dissolved in alcohol separating as feathery needles, m. p. 182–183°; yield 2.5 g.

Anal. Calcd. for $C_{22}H_{18}NO_2Br$: C, 64.7; H, 4.4. Found: C, 65.1; H, 4.6.

5-(4-Bromophenyl)-4-(4-methylphenyl)-3-phenylisoxazole.—Obtained from the isoxazolone oxide it separated from alcohol in hair-like needles, m. p. 175°.

Anal. Calcd. for $C_{22}H_{16}BrNO$: C, 67.7; H, 4.1. Found: C, 67.6; H, 4.3.

Summary

It has been shown that the presence of an alkyl group in the aromatic ring of nitrostyrene prevents addition reactions with ammonia and aromatic amines, but does not stop polymerization. An alkyl group in the side chain partially blocks the addition reaction and completely stops the tendency to polymerize. Halogen has a similar effect. Both reactions are suppressed by a phenyl group in this position. The presence of a nitro group in the ring partially restores the addition tendency, but has no noticeable influence on polymerization.

MEDFORD, MASS.

RECEIVED SEPTEMBER 21, 1938

[9] It has been assumed that this substance resulted rather than the isomeric 3-(4-bromophenyl)-5-phenyl derivative; see Kohler and Richtmyer, THIS JOURNAL, **50**, 3092 (1928).

[A CONTRIBUTION FROM THE PEARSON MEMORIAL LABORATORY OF TUFTS COLLEGE]

The Action of *p*-Toluidine and *p*-Phenylenediamine on Substituted Nitrostyrenes

BY DAVID E. WORRALL AND FREDERIC BENINGTON

It was shown in a previous communication[1] that the tendency of a nitrostyrene to form an addition compound with an aromatic amine, which is rather limited in the mother substance, may be modified by the introduction of certain groups into the molecule. In the hope of finding a more active combination, a number of unsaturated nitro compounds have been prepared and a study made of their additive power. *p*-Toluidine and *p*-phenylenediamine, most powerful of the primary aromatic amines for reactions of this type, were selected to test the reactivity.

The results clearly indicate that an addition reaction between an aromatic amine and a substituted nitrostyrene is relatively uncommon and even more circumscribed than with the parent substance. No reaction takes place with the unsaturated nitro compounds prepared from aldehydes containing hydroxy, methoxy or methylene oxy groups. The presence of a nitro group in the ring on the contrary enhances the additive capacity and even may restore the lost activity of a substituted nitrostyrene. Halogen also has a favorable influence as the most active substance in the list contains a chlorine as well as a nitro substituent. *p*-Phenylenediamine is more reactive than *p*-toluidine with these particular substances.

α-Nitro-β-(2-methoxyphenyl)-ethylene.—This substance, prepared by condensing *o*-methoxybenzaldehyde with nitromethane in the presence of triethylamine,[2] separated from alcohol in the form of yellow prismatic crystals, m. p. 50°.

Anal. Calcd. for $C_9H_9NO_3$: C, 60.3; H, 5.0. Found: C, 60.1; H, 5.1.

α-Nitro-β-(2-methoxy-4-nitrophenyl)-ethylene.—The product obtained by the action of fuming nitric acid crystallized from alcohol as yellow plates, m. p. 175–176°.

Anal. Calcd. for $C_9H_8N_2O_5$: C, 48.2; H, 3.6. Found: C, 48.7; H, 3.9.

The isomeric 2-nitro-4-methoxy compound obtained in a similar manner formed microscopic canary yellow crystals from alcohol, m. p. 145–146°.

Anal. Calcd. for $C_9H_8N_2O_5$: C, 48.2; H, 3.6. Found: C, 47.9; H, 3.8.

The following procedure was used in testing the addition ability of the nitrostyrenes with *p*-phenylenediamine and *p*-toluidine. To a filtered solution containing the correct amount of the base in alcohol was added 1 g. of the unsaturated compound. The mixture was heated until all of the solid phase had disappeared, adding more solvent if necessary. The addition product usually appeared within a few minutes. No good solvent was found for the phenylenediamine derivatives although they are somewhat soluble in acetone. The crude products were purified by thorough extraction with hot alcohol. The 2-nitro and 3-nitro derivatives may have contained traces of colored impurities. All melted with decomposition and were dissolved readily by alcoholic potash. Shaking

with concd. hydrochloric acid caused disappearance of color. The white microscopic crystals of the salt that promptly appeared were analyzed in one instance (3-nitro derivative) and found to agree with the calculated value.

α-Nitro-β-(*p*-toluidino)-β-(2-nitro-4-chlorophenyl)-ethane.—Obtained in the customary manner it crystallized from alcohol in the form of brownish-yellow plates, m. p. 136–137°, dec. It was observed to form a hydrochloric acid salt.

Anal. Calcd. for $C_{15}H_{14}ClN_3O_4$: C, 53.4; H, 4.2. Found: C, 53.1; H, 4.1.

No reaction was observed between toluidine and the other nitrostyrenes reacting with *p*-phenylenediamine. Negative results with both *p*-toluidine and *p*-phenylenediamine followed attempts at addition with the following: 2-methoxy, 4-methoxy, 2-nitro-4-methoxy, 2,4-dimethoxy, 2,4-dimethoxy-6-nitro, 3-methoxy-4-hydroxy, 3,4-oxymethylene and 4-chloronitrostyrenes. Furfurylidene also was without action.

Summary

p-Phenylenediamine forms addition compounds with the three mononitro, 2-methoxy-4-nitro and 2-nitro-4-chloronitrostyrenes. *p*-Toluidine acts similarly with 2-nitro-4-chloronitrostyrene. Neither substance reacts with other nitrostyrenes prepared from the common aldehydes.

The Action of Aromatic Amines on 4-Nitro-2-chloronitrostyrene

BY DAVID E. WORRALL

In a recent investigation relating to the additive capacity of substituted nitrostyrenes,[1] it was disclosed that the 2-nitro-4-chloro derivative represented an unusually active combination as measured by *p*-toluidine and *p*-phenylenediamine. The isomeric 2-chloro-4-nitro compound (II) has been found to be much more reactive, so the present communication is concerned with a study of this capacity toward a variety of organic bases containing mobile hydrogen.

II is decidedly more reactive in some respects than nitrostyrene itself. It forms, for example, addition compounds with *o*- and *m*-toluidines as well as *p*-anisidine. On the other hand, it does not react, at least under similar experimental conditions, with aniline or β-naphthylhydrazine, both of which add to nitrostyrene. It is believed that the failure to obtain similar compounds with II is the consequence of an increased tendency for destructive oxidation–reduction reactions originating in the nitro groups. This also explains the formation of black tars when II is heated with hydrazine or hydroxylamine and the rapid destruction of the ammonia addition product by alcohol.

Experimental

α-Nitro-β-(2-chlorophenyl)-ethylene (I).—Obtained by the action of triethylamine[2] it crystallized from alcohol as long yellow needles, m. p. 48°.

Anal. Calcd. for $C_8H_6ClNO_2$: C, 52.3; H, 3.3. Found: C, 52.1; H, 3.5.

α-Nitro-β-(2-chloro-4-nitrophenyl)-ethylene (II).—The product from the nitration of 10 g. of I separated from alcohol in the form of slender pale yellow needles, m. p. 149–150°, yield 7.5 g.

Anal. Calcd. for $C_8H_5ClN_2O_4$: C, 42.0; H, 2.2. Found: C, 41.9; H, 2.5.

α-Bromo-α-nitro-β-(2-chloro-4-nitrophenyl)-ethylene (III).—Five grams of II after bromination was treated with alcoholic potassium acetate producing after crystallization from alcohol 3.5 g. of yellow prismatic needles, m. p. 132–133°.

Anal. Calcd. for $C_8H_4BrClN_2O_4$: C, 31.2; H, 1.3. Found: C, 31.1; H, 1.6.

In a similar manner I was changed into the monobromo derivative, yellow needles melting at 60–61°.

Benzidine	$C_{28}H_{22}Cl_2N_6O_8$	Yellow microscopic	137–138	52.4	3.4	52.7	3.6

Anal. Calcd. for $C_8H_5BrClNO_2$: C, 36.6; H, 1.9. Found: C, 37.0; H, 2.2.

N,N'-(α,α'-Di-(2-chlorophenyl)-β,β'-dinitrodiethyl)-*p*-phenylenediamine.—*p*-Phenylenediamine, but not *p*-toluidine, formed an addition compound with I, separating from an alcohol solution of the components as irregular yellow plates melting with decomposition at 147–148°.

Anal. Calcd. for $C_{22}H_{20}Cl_2N_4O_4$: C, 55.6; H, 4.2. Found: C, 56.1; H, 4.5.

α-Bromo-α-nitro-β-(2-chloro-4-nitrophenyl)-β-*p*-toluidino-ethane.—III reacted in alcohol with *p*-toluidine producing gold yellow platelets, m. p. 138°, dec. A slight odor of monobromonitromethane was noticed.

Anal. Calcd. for $C_{15}H_{13}BrClN_3O_4$: C, 44.3; H, 3.1. Found: C, 43.5; H, 3.3.

No addition reactions were observed with aniline or *m*-toluidine, but *p*-phenylenediamine produced tiny brownish needles. This material which melted indefinitely with marked decomposition gave a poor analysis and was not examined further.

A uniform procedure was used with II. Five-tenths gram of the nitro compound was weighed out carefully, together with the equivalent amount of the base and a few cc. of alcohol. The mixture was heated until solution was completed. The reaction, if it went at all, usually started in a few minutes. The phenylenediamine reaction started in less than one minute, while the *o*-toluido compound did not form for an hour. The products were recrystallized from alcohol, except those obtained with the diamines which were thoroughly washed with hot alcohol. The substance obtained from ammonia, using dry benzene as a solvent,[3] was decomposed rapidly by alcohol; therefore it was crystallized from a benzene-ligroin mixture. All of the above-mentioned addition products melted with decomposition.

Negative results ensued with aniline, *m*-anisidine, β-naphthylamine, β-naphthyl- and *m*-tolylhydrazines, and *m*-phenylenediamine. Destructive decomposition occurred with hydroxylamine, hydrazine, and piperidine.

Summary

4-Nitro-2-chloronitrostyrene is unusually reactive with aromatic amines and for the first time (with a nitrostyrene) addition compounds have been obtained with *o*- and *m*-toluidines as well as *p*-anisidine.

The Mechanism of Carbohydrate Oxidation. XXIV.[1] The Action of *aldehydo-d*-Glucose and of *aldehydo-d*-Galactose in Alkaline Solutions[2]

BY ROY JOSEPH PLUNKETT AND WILLIAM LLOYD EVANS

When *d*-glucopyranose and *d*-galactopyranose are treated with aqueous solutions of potassium hydroxide, lactic acid is formed in amounts which are dependent upon the concentration of the alkali used and the temperature employed. Shaffer and Friedemann[3] have found that the yields of lactic acid obtained from alkaline solutions of dihydroxyacetone are also a function of the concentration of the triose.

The reaction mechanism, which has been used to account for lactic acid formation in alkaline solutions of certain hexoses and other carbohydrates, involved a rupture of the oxidic structure with the resulting intermediate formation of the corresponding aldehydo structure. The next stage of the reaction assumed the fragmentation of the hypothetical hexose enediols[4] derived from the *aldehydo* sugar thus formed, an action which has been postulated as the third one in the series of changes resulting in lactic acid formation. This latter step should yield pyruvic aldehyde, the precursor of lactic acid, and, in addition, other products of fewer carbon atoms than the original carbohydrate. This has been found to be true. Nef[4] and Schmidt[5] have postulated mechanisms for the rupture of the hypothetical enediols formed by alkaline solutions of reducing sugars.

The discovery of *aldehydo-d*-glucose and *aldehydo-d*-galactose pentaacetates by Wolfrom[6] has made it possible to test the validity of the postulate that the *aldehydo* sugars, if formed as intermediates in the alkaline fragmentation of reducing carbohydrates, should yield lactic acid as one of the reaction products. To establish the validity of this assumption experimentally was the principal objective of this study.

Experimental Part

1. ***aldehydo-d*-Glucose Pentaacetate and *aldehydo-d*-Galactose Pentaacetate.**—These compounds were prepared according to the methods of Wolfrom.[6]

2. **Reagents.**—All reagents used throughout these experiments were examined for their purity by appropriate physical and chemical methods.

3. **Apparatus.** (a) **Volatile Acid Distillation.**—A 500-ml. round-bottomed flask, bearing a small separatory funnel and an aspirator, was connected through a Kjeldahl bulb and an adapter to the top of an upright coil condenser. The delivery end of the condenser dipped into a layer of water about 1 cm. in thickness contained in a 750-ml. suction flask. Heat was supplied through a water-bath and the whole system was evacuated by means of a water pump.

(b) **Extraction Apparatus.**—Modified Soxhlet[7] apparatus was used to extract the lactic acid.

(c) **Volumetric Apparatus.**—All volumetric apparatus was carefully calibrated by the usual well-known methods.

4. **Analytical Procedures.** (a) **Determination of Lactic Acid.**—The procedure for lactic acid was essentially the same as that reported by Nadeau, Newlin and Evans.[8] Only the procedure used for *β-d*-glucopyranose pentaacetate will be described since the same procedure with slight modifications was used throughout this work.

A small glass vial (18 × 50 mm.) was charged with *β-d*-glucopyranose pentaacetate (2.4385 g. = $^1/_{160}$ mole) and placed upright in a 150-ml. carbon dioxide flask containing 12.5 ml. of potassium hydroxide solution of the desired concentration. The flask was closed with a rubber stopper bearing two outlet tubes and a copper wire. The wire was used to hold the vial and its contents in an upright position until the time of mixing. The flask was then evacuated and filled with nitrogen gas, which had been scrubbed with ferrous sulfate and alkaline pyrogallol to remove any oxygen. The evacuation and introduction of nitrogen was repeated twice. The flask and its contents were then placed in the thermostatically controlled water-bath and then allowed to come to the temperature equilibrium. After ten minutes the copper wire was pulled out and the contents of the vial spilled into the potassium hydroxide solution. The flask and contents were agitated in the thermostat for a period of forty-eight hours (except in the case of the time runs) after which the flask was removed, a 5-ml. sample of the contents pipetted into a tared weighing bottle and the density determined. After the density determination the sample was returned to the flask, the stopper, pipet and bottle washed with distilled water, and the potassium hydroxide neutralized with 12.5 ml. of phosphoric acid of the appropriate molarity.

The vial was then removed and the neutral solution treated with carboraffin, filtered, transferred to a 500-ml. round-bottomed flask and evaporated to dryness under a water pump vacuum at 50°. Forty ml. of water (in 10-ml. portions) were added to the residue and evaporated off to effect the completeness of the removal of acetic and formic acids. The residue was dissolved in a small amount of water (50–100 ml.) and transferred to the Soxhlet extractor, after which the aqueous solution was extracted for forty-eight hours with ether. The Sy flask contained a few grams of zinc carbonate and 50 ml. of water in addition to the ether. At the end of the forty-eight hour period the ether was evaporated off and the aqueous solution treated with carboraffin and boiled for a few minutes to complete the reaction between the zinc carbonate and lactic acid. The carboraffin and excess zinc carbonate were filtered off and the filtrate transferred to a 4-inch (10-cm.) evaporating dish and evaporated to dryness on a water-bath maintained at a temperature of about 50°. The crystallized zinc lactate trihydrate was treated with a minute amount of cold water and about 2 ml. of cold 95% ethanol and cooled to 0°. The crystalline salt was transferred to a tared Gooch crucible and washed with a few ml. of anhydrous ether. The salt was dried at 40–45° in a vacuum oven and examined quantitatively for its water of hydration and zinc oxide content. The filtrate and washings were evaporated for a second crop of zinc lactate trihydrate.

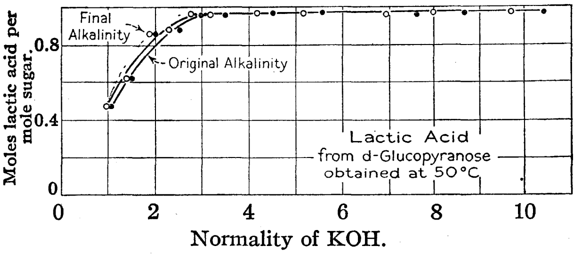

Fig. 1.—Lactic acid yields from *d*-glucopyranose expressed as a function of the original alkali normality and the final normality obtained after applying the necessary correction due to the expansion of the reaction mixture.

(b) **Saccharinic Acids.**—The aqueous solutions remaining after the extraction of lactic acid were evaporated to dryness and the residue freed from moisture by drying in a vacuum oven at 65°. The dried residue was placed in a bottle, covered with about 50 ml. of absolute ethanol, the bottle stoppered, and then allowed to stand for several days at room temperature. The mixture was next digested on the hot-plate for two to three hours and filtered through a Büchner funnel, the phosphate residue being washed with absolute ethanol. The filtrate and washings were transferred to a 250-ml. beaker, water added, and the alcohol evaporated off. An excess of zinc carbonate was added and the mixture digested on the hot-plate for several hours. This was necessary because it was found by titration that the saccharinic acids were present in the form of their lactones, which hydrolyzed slowly. After the completion of the reaction between the saccharinic acid and zinc carbonate the excess zinc carbonate was filtered off, the filtrate concentrated to low volume and transferred to a tared crucible. The liquid in the crucible was evaporated to dryness, the crucible weighed and the zinc saccharinate roasted to zinc oxide and the crucible reweighed. The ratio of zinc oxide/zinc saccharinate indicated that the saccharinic acids were largely $C_6H_{12}O_6$, *i. e.*, rearranged hexoses.

5. **Effect of Expansion on Alkali Normality.**—In comparing the lactic acid yields obtained from the pentaacetates of *d*-glucopyranose and *d*-galactopyranose with those of *d*-glucopyranose and *d*-galactopyranose themselves, it was desired to plot the amount of lactic acid produced as a function of the normality of the alkali. To make the data comparable it was necessary to apply a correction factor to the alkali concentration used with the pentaacetates to account for the potassium hydroxide used up in neutralizing the acetic acid formed by the hydrolysis of the acetates.

In this manner, using equivalent quantities of the various sugars, it was thought that the amount of sugar and the alkali concentration in the solutions were comparable. However, in some preliminary experiments by Mr. L. C. Kreider,[9] of this Laboratory, and ourselves, it was noted that when β-glucopyranose pentaacetate was dissolved in potassium hydroxide there was an appreciable expansion in volume. Thus it became necessary to determine experimentally the magnitude of this expansion for the acetylated sugars and for the sugars themselves and to make suitable corrections for the change in alkali normality before strict comparisons could be made.

From the density of the solutions and the weight of materials originally used, the volume and the potassium hydroxide concentration of the reacting solution were calculated easily. This value is only as accurate as our method used in determining the density. The density measurements could be reproduced within 1%, which is sufficiently accurate for this work. The expansion in all cases for the pentaacetyl derivatives was found to be approximately 18%, while that of *d*-glucopyranose was approximately 8%. Our experience shows that the volume change was inappreciable during the time of the experiment.

In Fig. 1 are shown the effects of the correction for such expansion on the character of the lactic acid curve obtained from *d*-glucopyranose at 50°, while in Fig. 2 similar data are plotted for β-*d*-glucopyranose pentaacetate. The curves for *d*-glucopyranose and β-*d*-glucopyranose pentaacetates are not greatly changed, except in the points being shifted in a direction parallel to the potassium hydroxide axis. However, the curve for *aldehydo*-*d*-glucose pentaacetate is altered quite appreciably (Fig. 3). The same relationships are true at least qualitatively for all of the experimental data herein reported.

In connection with the density determinations it should be pointed out that Powell[10] in studying the velocity of decomposition of dextrose and fructose by alkalies, measured the change in volume during the reaction by means of a very delicate dilatometer. He noted that for a reaction volume of about 15 ml. (sugar concn. = 0.4 *M*) the expansion was of the order of magnitude 0.15 ml. This expansion would lie within our experimental error.

[9] Harry Gehman, L. C. Kreider and W. L. Evans, THIS JOURNAL, **58**, 2388 (1936).

[10] C. W. R. Powell, *J. Chem. Soc.*, **107**, 1335 (1915).

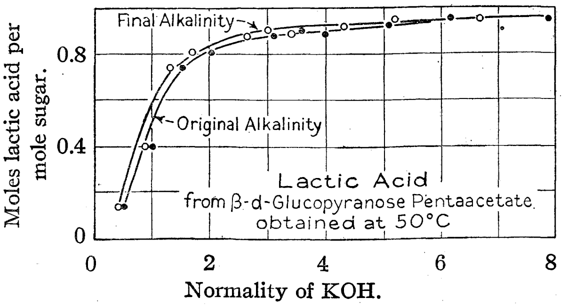

Fig. 2.—Lactic acid yields from *β-d*-glucopyranose pentaacetate expressed as a function of the original alkali normality and the final normality obtained after applying the necessary correction due to the expansion of the reaction mixture.

The increase in volume of our solutions caused a decrease in the sugar concentration. We were interested to learn if this decrease would have any effect on the lactic acid production. To check this point, varying amounts of *d*-glucopyranose (2.0000–2.5000 g.) were treated with 25 ml. of 3.221 N potassium hydroxide. The amount of lactic acid produced is 0.95 mole per mole of *d*-glucopyranose over this range of concentration. Thus the lowering of the sugar concentration by the increase in volume had no effect on lactic acid production, under our experimental conditions. These results are in quantitative agreement with those of Shaffer and Friedemann,[3] who found that the yield of lactic acid from 5 N sodium hydroxide solutions containing 100–500 mM. equivalents of glucopyranose is 1.05–1.01 moles. The concentration of sugar in our experiments was in no case far removed from 500 mM. equivalents.

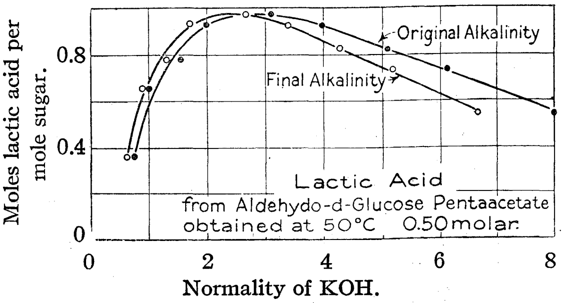

Fig. 3.—Lactic acid yields from *aldehydo-d*-glucose pentaacetate expressed as a function of the original alkali normality and the final normality obtained after applying the necessary correction due to the expansion of the reaction mixture.

The Effect of Time on the Lactic Acid Production.—In a comparative study of this type it is necessary that the reactions proceed to completion. At first it was thought that the differences in lactic acid production might be due to different reaction rates. This point was cleared up by running *d*-glucopyranose, *β-d*-glucopyranose pentaacetate and *aldehydo-d*-glucose pentaacetate in approximately 3 N potassium hydroxide for various periods of time from five minutes to forty-eight hours. Reference to Fig. 4 shows that the yield of lactic acid increases rapidly with time, reaching a constant value in about four hours. The quantitative differences between the three curves are obvious in Fig. 4. The data show definitely that the reaction was completed in the forty-eight-hour period.

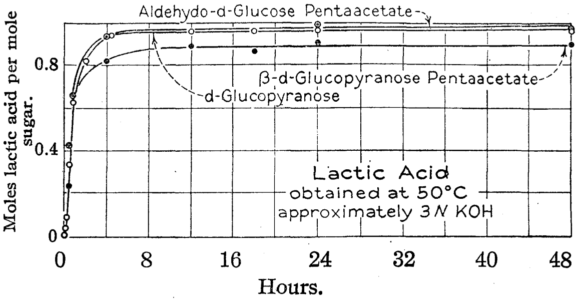

Fig. 4.—Lactic acid yields obtained from alkaline solutions of *d*-glucopyranose, *β-d*-glucopyranose pentaacetate and *aldehydo-d*-glucose pentaacetate expressed as a function of time.

Discussion

Lactic Acid Formation from *aldehydo*-Hexoses.—The data obtained in this experimental study concerning the behavior of *aldehydo-d*-glucose pentaacetate and *aldehydo-d*-galactose pentaacetate in alkaline solutions show conclusively that lactic acid is formed in these reactions under the same conditions as were used in obtaining this acid from *d*-glucopyranose and *d*-galactopyranose, respectively. *Therefore, it is clear that the mechanism which postulates the intermediate formation of aldehydo structures from the respective pyranoid structures in the production of lactic acid from the sugars seems to be well founded.*

Marchlewski[11] and collaborators found that alkaline solutions of glucose, galactose, maltose and arabinose give strong absorption bands in the ultraviolet, but after neutralization the original continuous spectrum is restored. The band in the region of about 2700 Å. is characteristic for alkaline solutions of the above carbohydrates and is attributed to the formation of an aldehyde group.

Effect of Temperature and Alkali Normality on Lactic Acid Formation.—Since it was necessary to use *aldehydo-d*-glucose pentaacetate and *aldehydo-d*-galactose pentaacetate in these experiments, it followed that one each of the *d*-glucopyranose pentaacetates and *d*-galactopyranose pentaacetates should be employed throughout for comparative purposes. We chose *β-d*-glucopyranose pentaacetate and the *β-d*-galactopyranose

---

[11] (a) Gabryleski and Marchlewski, *Biochem. Z.*, **261**, 393 (1933); *C. A.*, **27**, 4218 (1933); (b) Marchlewski and Urbanczyk, *Biochem. Z.*, **262**, 248 (1933); *C. A.*, **27**, 5004 (1933).

pentaacetate in each case by reason of their more favorable solubilities.

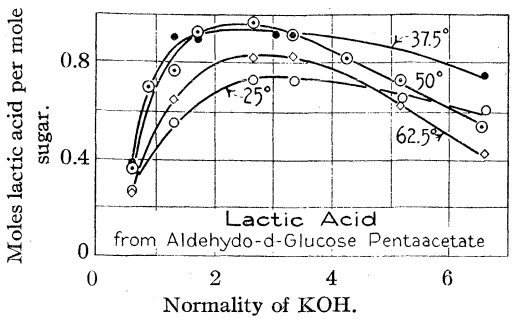

Fig. 5.—Lactic acid yields obtained from alkaline solutions of *aldehydo-d*-glucose pentaacetate at 25, 37.5, 50 and 62.5°.

(a) The yields of lactic acid obtained from the *aldehydo-d*-glucose pentaacetate under varying alkali normalities at 25, 37.5, 50 and 62.5° are shown in Fig. 5, while the comparative data obtained from *β-d*-glucopyranose pentaacetate under the same experimental conditions are shown in Fig. 6.

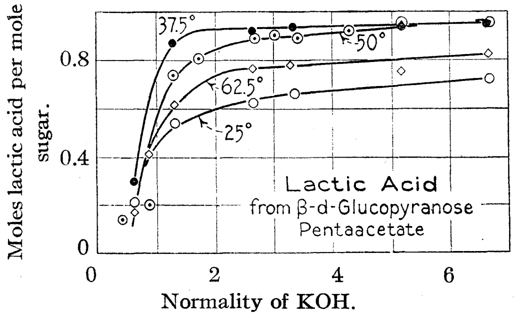

Fig. 6.—Lactic acid yields obtained from alkaline solutions of *β-d*-glucopyranose pentaacetate at 25, 37.5, 50 and 62.5°.

From these two figures it is seen that in some respects *d*-glucopyranose pentaacetate and *aldehydo-d*-glucose pentaacetate differ quite markedly in their behavior in alkaline solutions of the same alkali normality and the same temperature. The diminishing yields of lactic acid from the aldehydo form of the sugar after the range 2–3.5 N has been passed are in marked contrast to those obtained from the pyranoid form. From limited experimental data available in this Laboratory it has become increasingly evident that these diminishing yields of lactic acid from *aldehydo-d*-glucose pentaacetate are compensated for by the increasing yields of saccharinic acids, while the increasing yields of lactic acid obtained from *d*-glucopyranose pentaacetate are on the contrary accompanied by diminishing yields of the saccharinic acids.[3] This relationship is shown in Fig. 7 for which the data have been gathered by a method which leaves much to be desired. This same general relationship was observed by Gehman, Kreider and Evans[9] in a study of the products obtained by the action of mixtures of cellobiose octaacetate and dihydroxyacetone monoacetate in alkaline solutions. In this connection it also should be noted that Hoff[7] obtained crystalline *d*-galacto-α-saccharinic acid lactone from alkaline solutions of *d*-galactopyranose in yields which increased with the temperature and the alkali normality.

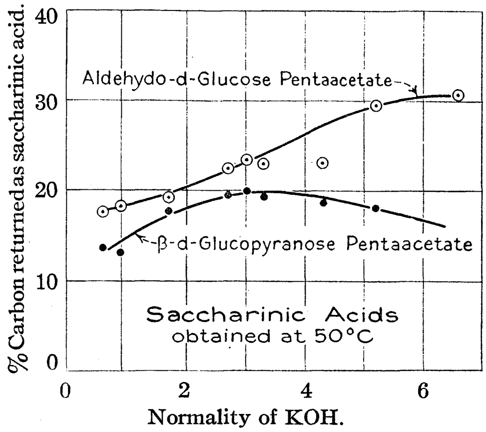

Fig. 7.—Saccharinic acids obtained from alkaline solutions of *aldehydo-d*-glucose pentaacetate and *β-d*-glucopyranose pentaacetate.

We may classify the reactions of reducing sugars in alkaline solutions into the following general groups: (1) they may undergo rearrangement to form saccharinic acids; (2) they may undergo the Lobry du Bruyn and Alberda van Ekenstein rearrangement to form other reducing sugars; (3) they may rearrange to form hypothetical enediols; (4) they may mutarotate; (5) they may form polymers; (6) they may fragment. The general relationship existing between the yields of lactic and saccharinic acids may be regarded as due to differences or equalities in the rates of the two reactions here shown

Fragmentation $\longleftarrow$ Reducing sugar $\longrightarrow$ Rearrangement

The fragments may undergo rearrangement to give acetic, lactic, C_4 and C_5 saccharinic acids, while the sugar itself may at the same time rearrange to the C_6 saccharinic acids. It has been pointed out by Hockett[12] that glycol aldehyde, a

---

(12) W. L. Evans and R. C. Hockett. THIS JOURNAL, **52**, 4065, ref. 14 (1930).

theoretically possible fragmentation product of the saccharides, must be regarded as one of the possible sources of acetic acid when this simplest of all carbohydrates is reacted upon by alkalies, *i. e.*, acetic acid must be considered the saccharinic acid of glycol aldehyde in quite the same way as lactic acid may be regarded as the saccharinic acid of glyceric aldehyde and dihydroxyacetone.

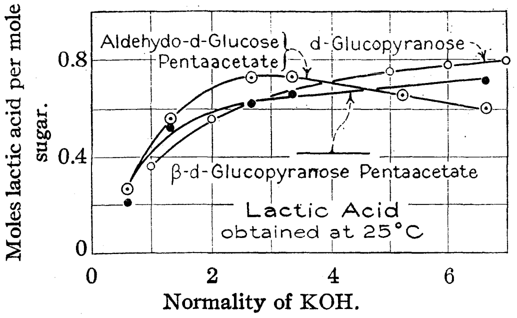

Fig. 8.—Comparison of lactic acid yields obtained from alkaline solutions of *d*-glucopyranose, *β*-*d*-glucopyranose pentaacetate and *aldehydo-d*-glucose pentaacetate at 25°.

From the above discussion it is evident that the relationship between the yields of C_6 saccharinic acids and those containing less carbon atoms must depend on many experimental factors among which are temperature, alkali normality and concentration of sugar studied. From Figs. 5 and 7 it is clear that approximately 73% of the *aldehydo-d*-glucose pentaacetate carbon has been recovered at 50° between 2–3 *N* potassium hydroxide as lactic and saccharinic acids. This is our maximum value in this series of studies. These reactions are accompanied by tar formation. Work is now in progress in this Laboratory to extend our knowledge of these complicated systems. (b) From the data in Figs. 5 and 6 it is seen that the lactic acid yields from *aldehydo-d*-glucose pentaacetate and *d*-glucopyranose pentaacetate are not necessarily at a maximum at the highest temperatures. At 37.5° and in the region of lower alkali normalities, the two compounds seem to be more sensitive than at the other temperatures studied and tend to give as high yields of lactic acid as under more drastic conditions of alkalinity.[3] This is more especially true with the pyranoid structure, while with the aldehydo form the yields at 37.5 and 50° from 0.6 *N* to approximately 4 *N* are almost the same. It is to be noted that the yields of lactic acid are lower from both compounds at 62.5°, a fact in harmony with previous studies[13] on *d*-glucopyranose, *d*-mannopyranose and *d*-fructopyranose at 75°. The lactic acid data obtained by a comparative study of *aldehydo-d*-glucose pentaacetate, *d*-glucopyranose, and *β*-*d*-glucopyranose pentaacetate at 25° are shown in Fig. 8.

Although no extensive experimental studies have been made of the effect of temperature and different alkali normalities on the formation of saccharinic acids containing six carbon atoms from the hexoses except that of Hoff,[7] it may be concluded safely that the data obtained by such an inquiry will be found in general to be in accord with the views expressed above with reference to lactic and saccharinic acid formation at 50° with various alkali normalities. (c) The yields of lactic acid obtained from *aldehydo-d*-galactose pentaacetate, *d*-galactopyranose pentaacetate and *d*-galactopyranose at 25 and 50° are shown in Figs. 9 and 10, respectively. It is seen that the *aldehydo* structure seems to be more reactive than either of the two pyranoid structures which were used for comparative purposes. The *aldehydo* structure reaches a maximum production of lactic acid at a lower alkalinity at 50° than it does at 25°.

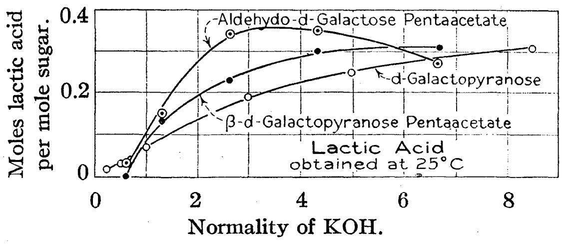

Fig. 9.—Comparison of lactic acid yields from alkaline solutions of *d*-galactopyranose, *d*-galactopyranose pentaacetate and *aldehydo-d*-galactose pentaacetate at 25°.

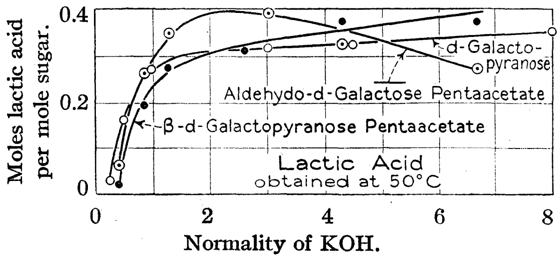

Fig. 10.—Comparison of lactic acid yields from alkaline solutions of *d*-galactopyranose, *d*-galactopyranose pentaacetate and *aldehydo-d*-galactose pentaacetate at 50°.

---

[13] (a) W. L. Evans and J. E. Hutchman, THIS JOURNAL, **50**, 1496 (1928); (b) W. L. Evans and D. C. O'Donnell, *ibid.*, **50**, 2543 (1928).

(d) Although the galactose series does not yield as much lactic acid as the glucose series under our experimental conditions the data obtained by Hoff[7] show that the formation of *d*-galacto-α-metasaccharinic acid at 50° increases rapidly with increasing alkali normalities, a fact in harmony with the views expressed above. Whether there is a higher concentration of the *aldehydo* form of galactose under these conditions has not been established.

Effect of Potassium Acetate on Lactic Acid Formation.—Since potassium acetate is formed in all of these reaction mixtures, it became necessary to determine the extent of its influence on the formation of lactic acid. This was done by studying the yields of this acid obtained from *d*-glucopyranose, *aldehydo*-*d*-glucose pentaacetate, β-*d*-glucopyranose pentaacetate, and a mixture of *d*-glucopyranose and potassium acetate equal to that produced by the hydrolysis of the pentaacetates, at 50° and at various alkali normalities. The data obtained in these experiments are shown in Fig. 11. An examination will show that in general there is a close correspondence in the results obtained in the pyranoid structures, especially in the case of the two pentaacetates. At the higher alkalinities the yields of lactic acid from the pyranoid structures tend to become more nearly identical, *i. e.*, the data are within the limits of the experimental error.

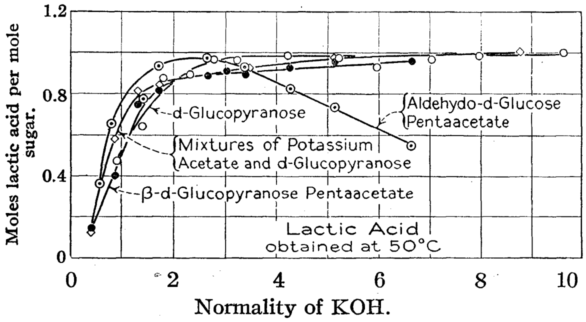

Fig. 11.—Comparison of the yields of lactic acid obtained from alkaline solutions of *d*-glucopyranose, β-*d*-glucopyranose pentaacetate, *aldehydo*-*d*-glucose pentaacetate, and mixtures of potassium acetate and *d*-glucopyranose.

Acknowledgment.—The authors wish to express their indebtedness to Drs. Leonard C. Kreider and Harry Gehman for valuable assistance rendered during the progress of this work.

Conclusions

1. (a) A comparative study has been made of the yields of lactic acid obtained from *d*-glucopyranose pentaacetate and *aldehydo*-*d*-glucose pentaacetate at 25, 37.5, 50 and 62.5° in potassium hydroxide solutions ranging from 0.5–6 *N*. (b) A similar study was made with *d*-galactopyranose pentaacetate and *aldehydo*-*d*-galactose pentaacetate at 25 and 50°.

2. Lactic acid was obtained as a reaction product from the *aldehydo* structures as well as from the pyranoid structures, a fact which supports the postulate that pyranose sugars are converted into *aldehydo* ones as intermediate compounds in the mechanism involved in the formation of lactic acid in alkaline solutions.

3. The most striking difference in the yields of lactic acid obtained from the pyranoid and *aldehydo* structures of both glucose and galactose lies in the maximum point reached by the *aldehydo* structures after which there is a marked decrease in the yield of this acid.

4. (a) In the glucose series the difference in lactic acid yields between the *aldehydo* and pyranoid structures has been attributed to a concurrent production of the isomeric saccharinic acids at such rates as to produce this effect. (b) At 50°, it was found that the yields of lactic acid obtained from *d*-glucopyranose pentaacetate and *aldehydo*-*d*-glucose pentaacetate bear an inverse relation to their respective yields of the saccharinic acids.

5. At 50°, the *aldehydo*-*d*-glucose pentaacetate yielded the maximum amount of its carbon as lactic and saccharinic acids, namely, approximately 73% between 2–3 *N* potassium hydroxide.

6. At 37.5° and the lower alkali normalities, *d*-glucopyranose pentaacetate seems to be more sensitive toward alkalies than at either 25, 50 or 62.5°.

The Composition of the Seeds of *Asimina triloba*

BY J. L. RIEBSOMER, JOHN BISHOP AND CHARLES RECTOR

The mature fruit of *Asimina triloba* (common name papaw) required for this investigation was collected from woodlands in Putnam County, Indiana, about October 1, 1937, and the seeds were extricated from the pulp almost at once and allowed to air dry at room temperature. Each fruit contains from two to twelve flat, oblong, dark brown seeds, the average weight of which is 0.7 g. The air-dried seeds were ground carefully and dried at 100–110° for an hour in a carbon dioxide atmosphere. The loss in weight indicated a moisture content of 5.1%. The dried material was then extracted quantitatively with petroleum ether (b. p. 30–60°) and found to contain about 38% of a reddish-brown fatty oil. The unextracted residue was a slightly gray powder.

Experimental

Analysis of the Fatty Oil of Papaw Seed.—The usual physical and chemical characteristics of this oil were determined by standard methods[1] and are as follows: sp. gr. (25°/25°), 0.9296; ref. ind. (Abbe 25°), 1.4728; iodine no. (Hanus), 113.5; sap. value, 194.0; mean mol. wt. satd. acids, 307.9; mean mol. wt. unsatd. acids, 308.2; iodine no. unsatd. acids, 117.8; iodine no. satd. acids, 14.0; unsatd. acids (basis of oil) (by the lead-salt method) (corrected %), 85.5; satd. acids (basis of oil) (corrected %), 5.6; unsap. matter, %, 0.80; Reichert–Meissl no., 1.05; acid value, 6.4; acetyl value, 18.11.

Composition of the Unsaturated Acids.—The unsaturated acids (270 g.) were converted into the methyl esters and distilled at 4 mm.: yield 228 g.; b. p. 175–182°. The narrow boiling point range indicated that the mixture contained acids with the same number of carbon atoms.

Two and one-half grams of the unsaturated methyl esters was reduced catalytically with hydrogen. The product was saponified and the acid thus produced, recrystallized once from 95% alcohol, melted at 68–70°. The unsaturated acids were thus shown to consist of only eighteen-carbon-atom acids.

Linolenic and more highly unsaturated acids were found to be absent by adding bromine to a cold ether solution of the unsaturated acids. Another sample was dissolved in petroleum ether, cooled to −5° and bromine added slowly with stirring. A precipitate formed, was filtered off and recrystallized once from glacial acetic acid. The melting point of the product was 112.5–113.5°. This indicated qualitatively the presence of linoleic acid.

The ozonolysis method of Riebsomer and Johnson[2] was applied to 175 g. of the unsaturated methyl esters, and the methyl esters from this process fractionally distilled from a modified Claisen flask with the following results: at a pressure of 14 mm., the fractions had boiling points and weights of (1) 53–57°, 7.4 g.; (2) 57–88°, 4.7 g.; (3) 88–99°, 15.8 g. At a pressure of 4–5 mm., the fractions had boiling points and weights of (4) 60–121.5°, 21.8 g.; (5) 121.5–127.5°, 54.8 g.; (6) 127.5–155°, 30.0 g.; (7) 155–167°, 11.9 g.; (8) 167–177°, 9.4 g.; undistillable, 15.4 g.

Fractions 3 and 4 were put together and redistilled into three fractions which are designated as fractions 3a, 3b, and 3c. At a pressure of 14.5 mm., these fractions had boiling points and weights of (3a) 85–91°, 5.4 g.; (3b) 91.5°, 21.1 g.; (3c) residue, 11 g.

For the examination of the various fractions densities were determined at 20°, converted to densities at 4°; refractive indices were determined at 20° using the Abbe refractometer. The refractive index and density of fraction 1 were 1.407, 0.8858. The ester was saponified and the acid distilled, b. p. 106–107° at 18 mm.; found for the refractive index and density of the acid, 1.4150, 0.9211; reported for caproic acid, 1.4138, 0.927. The anilide prepared from this acid melted at 94.5–95°. Mixed m. p. of known caproic anilide (m. p. 96°) was 94.5–95.5°. These data established the identity of fraction 1 as methyl caproate.

Fractions 2 and 3a were small and each boiled over a wide range. Their refractive index, density and saponification equivalents all indicated them to be a mixture of methyl caproate and methyl pelargonate found in fraction 3b.

For fraction 3b the refractive index and density were 1.4210 and 0.8792. The ester was saponified and the acid distilled, b. p. 142–144° at 18 mm.; neut. equiv. acid, found 157.0; calculated for pelargonic acid, 158.1; refractive index and density: 1.4309, 0.905; reported for pelargonic acid; 1.433, 0.907. The anilide prepared from this acid melted at 55–55.5°. Reported for the anilide of pelargonic acid 56°. These data indicated this fraction to be methyl pelargonate.

Fraction 3c.—The b. p. of fraction 3c and its saponification equivalent (137.6) indicated it to be a mixture of the methyl esters of pelargonic and azelaic acids.

The refractive index and density for fraction 5 were 1.4361, 0.9974; reported for dimethyl azelate, 1.436, 1.005. The ester was saponified and the acid recrystallized from water. It melted at 106.5°; mixed m. p. with known azelaic acid (m. p. 106.5°) showed no depression; neut. equiv. of the acid 95.1; calculated for azelaic acid 94.1. Fraction 5 was thus shown to be dimethyl azelate.

In a similar manner, fraction 6 was demonstrated to be essentially dimethyl azelate.

Fractions 7 and 8 were relatively small and boiled over large ranges. Saponification equivalents, refractive indices, and density determinations indicated them to con-

[1] Jamieson, "Vegetable Fats and Oils," Monograph Series No. 58, The Chemical Catalog Co., Inc., New York, 1932.

[2] Riebsomer and Johnson, THIS JOURNAL, **55**, 3352 (1933).

sist largely of dimethyl azelate admixed with the methyl esters of some 18 carbon monobasic acids which had not been cleaved by ozonolysis.

The three significant fractions for establishing the composition of the original unsaturated acids are 1, 3c, and 5, which were shown to contain, respectively, caproic, pelargonic, and azelaic acids.

Using the same reasoning as employed by Riebsomer and Nesty[3] these products were taken to mean that the only acids present in the unsaturated acids were oleic and linoleic. This is another case in which the double bonds in the natural occurring linoleic acid are found in the 9, 10, and 12, 13, positions, which is in accord with previous findings.[3]

The iodine number of the unsaturated acids was 117.8, which makes it possible to calculate the percentage of oleic and linoleic acids.

	In unsatd. fraction	In oil % acid	In oil % glyceride
Oleic acid	69.5	59.4	62.1
Linoleic acid	30.5	26.1	27.1

The Saturated Acids

The neutral equivalent of the saturated acids (307.9) indicated that the mixture contained some acids with more than 18 carbon atoms. Twenty grams of the saturated acids was converted into the methyl esters and were fractionally distilled at 4 mm. using a modified Claisen flask. The fractions had boiling points, weights, and saponification equivalents of (1) 160–175°, 12.5 g., 208.0; (2) 175–190°, 5.5 g., 317.7; residue 1.5 g.

The saponification equivalent of fraction 1 suggested a mixture of methyl palmitate and methyl stearate. This material was redistilled into three fractions. The first 1.2 g. of distillate (fraction 1a) was collected, the next 6.5 g. (fraction 1b) was collected, and the last 2.0 g. to distil was collected separately (fraction 1c). Fraction 1a was saponified and the acid recrystallized three times from ethyl alcohol. The m. p. of the acid was 60–61°. Mixed m. p. with palmitic acid was 61–62°; the m. p. of the anilide 88–88.5°. Mixed m. p. with known anilide of palmitic acid showed no depression. Fraction 1c was saponified and recrystallized from alcohol. The m. p. of the acid was 67–69°. Mixed m. p. with stearic acid 68–70°. These data were interpreted to mean that fraction 1 consisted of palmitic and stearic acids.

Fraction 2 (b. p. 175–190°) was saponified and, after three crystallizations of the acid from ethyl alcohol, a small amount of acid was left with a m. p. of 68–70°. A mixed m. p. with stearic acid showed no depression. The saponification equivalent (317.7) of this fraction indicated that another acid with a molecular weight greater than that of stearic acid was present, but it was not isolated from this fraction.

The residue (1.5 g.) was saponified, the acid dissolved in ethyl alcohol, decolorized with charcoal, and allowed to crystallize. On the second crystallization 0.3 g. of an acid was isolated; m. p. 76–77°. A mixed m. p. with an authentic specimen of arachidic acid (m. p. 76–77°) showed no depression, from which it was concluded that arachidic acid was present.

These data do not permit a very accurate calculation of the percentages of the saturated acids, but if we assume fraction 1 to be a mixture of palmitic and stearic acids, fraction 2 to be a mixture of stearic and arachidic acids, and the residue to be largely arachidic acid it is then possible to obtain the percentages shown in the accompanying table. These assumptions are admittedly not entirely valid, especially since no account has been taken of the small amount of unsaturated acids present.

	In satd. fraction	% acid	% glyceride
Palmitic acid	41.5	2.3	2.4
Stearic acid	31.8	1.8	1.9
Arachidic acid	26.6	1.5	1.54

Glycerol was shown to be present by conversion into the tribenzoate.

Estimation of Nitrogen, Crude Fiber, and Ash Content of the Seeds.—A Kjeldahl nitrogen determination on the ground dried seeds showed 0.1805% of nitrogen present. This would correspond to 1.128% of protein.

Crude fiber was determined on the dried meal after extraction of the oil. The percentage of crude fiber calculated on the basis of the dried seeds was 20.0%.

The ash content calculated on the basis of the dried seeds was 1.3%.

The authors wish to express their appreciation to Dean William M. Blanchard of this department who was instrumental in securing funds for this work from the National Research Council and from Mr. J. K. Lilly of Indianapolis, Indiana.

Summary

1. The seeds from *Asimina triloba* have been analyzed.

2. These seeds contain about 38% of a fatty oil which consists of the glycerides of oleic, linoleic, palmitic, stearic, and arachidic acids.

3. The protein, crude fiber, and ash content of the seeds have been determined.

Further Studies on the Electrical Properties of Stearate Films Deposited on Metal

BY ELIOT F. PORTER AND JEFFRIES WYMAN, JR.

I. Introduction

In two previous communications[1,2] we have discussed a variety of phenomena associated with the contact potentials of multilayer stearate films built on metal slides by dipping the slides through stearate monolayers spread on liquid surfaces. Langmuir[3] recently has pointed out the advantages of interpreting these phenomena on the hypothesis that the potentials are due to the production of surface charges. He also has outlined a mathematical analysis of the electrostatic forces brought into play in consequence of the potentials while the films are being dipped. This analysis suggests that by introducing an arbitrary voltage between the submerged metal slides and the liquid it should be possible to modify the behavior of the films and to control the potentials which they develop, and Langmuir refers to observations pointing to this. Thus, speaking in terms of the surface charge hypothesis, he states that "By applying potentials of a few volts between the plate and the metallic tray during the deposition of stearate monolayers it has been found possible to alter the surface charge σ on X or Y films and to obtain either positive or negative values of σ over wide ranges of *p*H."

In the present paper we describe a variety of experiments which reveal new phenomena associated with the films, and which have a bearing on the problem of the source and nature of the potentials, particularly in relation to the surface charge hypothesis.

II. Effects of Liquids on Potentials Associated with the Films

In this section we discuss studies on the effect of dipping films into various liquids, as well as electromotive force measurements involving films covered with liquids. In these electromotive force measurements, owing to the very high resistance of the circuits due to the films themselves and in some cases to the liquids as well, it was impossible to make direct measurements with a potentiometer. For this reason we employed a bridge circuit of the type described by Du Bridge,[4] involving an F. P. 54 Pliotron.

We already have pointed out[2] that dipping an X film of high contact potential into water or the aqueous substrates from which films are obtained does not greatly alter its subsequent contact potential in air. Nevertheless while the film is under the liquid its electrical behavior is like that of a film of zero potential. The same is true of Y films and X films of lower potential. Thus the e. m. f. of the arrangement

X or Y film/liquid/X or Y film

is always very close to zero, irrespective of the contact potentials of the films. This is illustrated by the case of two X films of potentials 1.79 and 0.175 v. separated by a few drops of a solution used for forming X films. The voltage of the combination was close to zero, *i. e.*, 0.055–0.075. If we think of the potential as due to internal charges, or to the orientation of dipoles within the film, the effect may be interpreted as due to the accumulation of a layer of compensating free charge, or of oriented dipoles, at the outer face of the film while it is in contact with the liquid. On the other hand, if we regard the potential as due to the presence of a layer of free charge on the surface, we may think of this effect as due to the surface being discharged by contact with the liquid. It is then, of course, necessary to assume that the surface of the film is recharged by the act of separating it from the liquid, since contact potentials persist after the slides are dipped into aqueous solutions. This result at once raises the question whether a similar neutralization takes place when other liquids are substituted for water or aqueous solutions. We have made a number of observations to answer this question.

When films are immersed in benzene there is no evidence of neutralization of the potentials. This is illustrated by the case of an X film originally of potential 5.6 v. separated from a Y film of potential 0.19 v. by a layer of benzene. The voltage from left to right[5] of the combination

X film (5.6 v.)/C_6H_6/Y film (0.19 v.)

---

[1] Porter and Wyman, THIS JOURNAL, **59**, 2746 (1937).

[2] Porter and Wyman, *ibid.*, **60**, 1083 (1938).

[3] Langmuir, *ibid.*, **60**, 1190 (1938)

[4] Du Bridge, *Rev. Sci. Instruments*, **4**, 532 (1933).

[5] *I. e.*, the voltage of the metal plate coated with film on the right minus that of the plate on the left. This convention is used throughout in expressing the voltage of such combinations

varied from +5.4 to +4.0 over a period of three hours, showing some tendency to fall, but rising each time the benzene was renewed close to the initial value. The sign of the voltage agrees with the orientation of the films. After the observation was over the potentials of the two films were measured in air and found to be 4.9 and 0.29. In this and all following cases we adopt the convention that the number in brackets following the word "film" refers to the original contact potentials of the film in air. Measurements of other pairs of films all gave the same results, *e. g.*

X film (3.10 v.)/C_6H_6/X film (0.18 v.)

Voltage varied between +2.7 and +1.3 over a period of about fifty-two minutes, showing some tendency to drop but returning close to the original value when the benzene was renewed. After the measurements the potential of the left-hand X film in air was about 2.70.

When chloroform is substituted for benzene, neutralization is complete as in the case of water and aqueous solutions. For example the voltage from left to right of the combination

X film (4.9 v.)/$CHCl_3$/Y film (0.29 v.)

was −0.14. The potentials of the films in air after the measurements were 1.8 and 0.29. The same type of neutralization is produced by mixtures of chloroform and benzene containing about 60% or more by weight of chloroform but not by those containing less, as may be seen by the following three examples:

(1) X film (2.8)/C_6H_6 + $CHCl_3$ (25%)/X film (0.34)
Voltage +2.3 − +2.2 over a period of twenty-five minutes
Potentials of films after measurements 2.5 and 0.35

(2) X film (2.6)/C_6H_6 + $CHCl_3$ (50%)/X film (0.35)
Voltage +2.1 − +1.0 over a period of forty-five minutes
Potentials of films after measurements 1.7 and 0.16

(3) X film (1.9)/C_6H_6 + $CHCl_3$ (59%)/Y film (0.22)
Voltage fell quickly from 0.73 and reached a value of 0.01 in twenty-five minutes
Potentials of films after measurements 1.0 and 0.20

Other observations were made by placing small drops of mercury on films and making contact with them by means of a fine platinum wire. The voltages of the combination

Film/Hg/Pt

are always small and independent of the potentials of the films, as may be seen by the following examples, in which the different values of the voltage belong to different parts of the film

X film (2.6)/Hg/Pt, voltage +0.25, +0.15, +0.13, +0.19
Y film (−0.20)/Hg/Pt voltage 0, +0.20, 0

Contact with mercury has little or no effect on the subsequent potential of the films. This point was tested by dipping films into a beaker of mercury the surface of which had been scraped clean. After an X film having an initial potential of 3.0–3.2 v. was dipped repeatedly its potential was found to be 3.4–3.7 v. A color comparison showed that none of the film had been removed. In another case several layers were found to have been removed by continued dipping but there was no significant change in the potential. The same result is obtained when Y films are dipped in mercury. On the other hand, it may be seen from the data given above that prolonged contact with chloroform reduced the potentials of X films considerably. Contact with benzene, however, reduces the potentials only slightly.

If warm moist air is blown over the films so as to produce water condensation on the surface while the contact potentials are being measured there is no appreciable change, although, as we have pointed out, immersion in water leads to neutralization of the potential.

We have referred to the fact that when X and Y films are made electrodes in a glow discharge, they develop very large contact potentials. These are positive or negative according to the direction of the discharge. In the case of Y films these "discharge potentials" are abolished by dipping the films into water and aqueous substrates; in the case of X films a residual potential, amounting to several volts or more, always remains after dipping and seems to have the same degree of permanence as the native potentials of X films. Like the spontaneous potentials, these potentials are neutralized while the films are under water. Dipping into benzene wholly fails to reduce such "discharge potentials" in the case of both X and Y films. The same is true of dipping into mercury, although when several of the outermost layers are removed there is some reduction in the "discharge potentials," *e. g.*, in one case when 4 layers were removed from an X film a reduction from +13 to +7.4 v.; in another when several layers were removed from a Y film a reduction from about +15 to +4 or 5 v. The same results are obtained when the potentials are negative. Such removal of layers generally occurs the first time a slide is dipped; if subsequently a new "discharge potential" is impressed on the film and it is dipped in mercury no film is removed and there is no reduction of potential. When Y films are dipped in chloroform the "discharge potentials" are at once reduced to zero, although no film is removed. On the other hand "discharge potentials" of X films are completely unaffected by dipping in chloroform. Nevertheless, measurements of the voltages of combinations like those discussed above show that while X and Y films are in contact with mercury and chloroform the "discharge potentials" are always neutralized.

III. Effect of Applied Voltages

In this section we shall present a detailed investigation of the effects of applying a voltage between the plate and the liquid subphase while films are being built. Under the conditions of our experiments such voltages give rise to currents of the order of several milliamperes which may be read easily by placing a milliameter in series with the voltage source. In accordance with Langmuir's hypothesis such currents might be expected to have a marked effect on potentials by modifying the density of the surface charge. Langmuir has referred to observations suggesting this.[6] In any case, quite apart from the concept of surface charge and its relation to the current flowing, simply on the basis of Langmuir's general analysis of the electrostatic forces acting during the formation of films, it would be expected that applied voltages would alter the contact angles and the upper limiting potentials of the films, and perhaps also the slope of the potential–thickness curves throughout the whole process.

Since it is well known that metallic ions even at very low concentrations have marked effects on the properties of built-up stearate films,[7] an attempt was made to eliminate as far as was conveniently possible all sources of contamination of the solutions by traces of metallic ions. For this reason glass trays and glass barriers were substituted for the usual metal trays and barriers. Water for making up solutions was redistilled through a Pyrex glass still. In the earlier experiments the films were built on stainless steel slides, but in the greater part of the work a platinum slide was substituted to avoid complications due to possible electrolytic effects under the influence of applied voltages. Contact with the solution was made with a platinum wire. The source of voltage applied between the slide and solution was either a storage battery or dry cells.

To prevent large changes in *p*H, especially when working in the alkaline range, the solutions were buffered with borates.[8] The following solutions were used:

(1) 1.33×10^{-3} *M* H_3BO_3; 1.33×10^{-3} *M* NaOH; 0.12×10^{-3} *M* Ca $(Ac)_2{\cdot}2H_2O$; *p*H = 10.9; for X layers

(2) 1.87×10^{-3} *M* H_3BO_3; 0.93×10^{-3} *M* NaOH; 0.4×10^{-3} HCl; 0.12×10^{-3} *M* $Ca(Ac)_2{\cdot}2H_2O$; *p*H = 8.6; for X layers

(3) Same as (2) but with the addition of 2.0×10^{-6} *M* $CuCl_2{\cdot}2H_2O$, for Y layers

(4) 1.33×10^{-3} *M* H_3BO_3; 0.67×10^{-3} *M* NaOH; 0.67×10^{-3} *M* HCl; 0.12×10^{-3} *M* $Ca(Ac){\cdot}2H_2O$; and with or without 2.0×10^{-6} *M* $CuCl_2{\cdot}2H_2O$; *p*H = 7.4–7.7; for Y layers

(5) 1.33×10^{-3} *M* H_3BO_3; 0.67×10^{-4} *M* NaOH; 0.67×10^{-3} *M* HCl; 0.36×10^{-4} *M* $BaCl_2{\cdot}2H_2O$; 2.0×10^{-6} $CuCl_2{\cdot}2H_2O$; *p*H = 7.4; for Y layers

During the deposition of X layers, unless otherwise indicated, the slides were kept submerged in the solution for ten seconds on each dip. This procedure usually favors the deposition of more uniform X layers than can be obtained by more rapid dipping. Castor oil was used to keep the monolayer under constant compression. The experiments were conducted at room temperature, which varied between 19–24°.

A. Effects on X and Y Films Deposited on Stainless Steel.—If stainless steel slides are used for deposition of the film with an applied voltage, reproducible results can be obtained only for a certain length of time which seems to depend to some extent on the magnitude as well as on the polarity of the voltage. Invariably, however, in time the slide begins to show signs of electrolytic action such as small pits and there may even be an evolution of gas while the slide is submerged with an applied voltage in the course of depositing films. This occurs most rapidly when the voltage is high—22 v. was the highest voltage used in the work—and when the slide is attached to the positive pole of the battery. A slide affected in this manner is useless for further work without repolishing. The potentials of X films deposited on such slides fail to rise in the usual way with increase in number of layers, perhaps due to metallic ions escaping from the steel and becoming incorporated in the stearate films. It was pos-

[8] Sørensen's borate buffers given by W. Mansfield Clark in "The Determination of Hydrogen Ions," Williams and Wilkins Co., Baltimore, Md., 3d edition, 1928.

sible, however, by using new steel slides for only one or two films and working at relatively low voltages to obtain very consistent results.

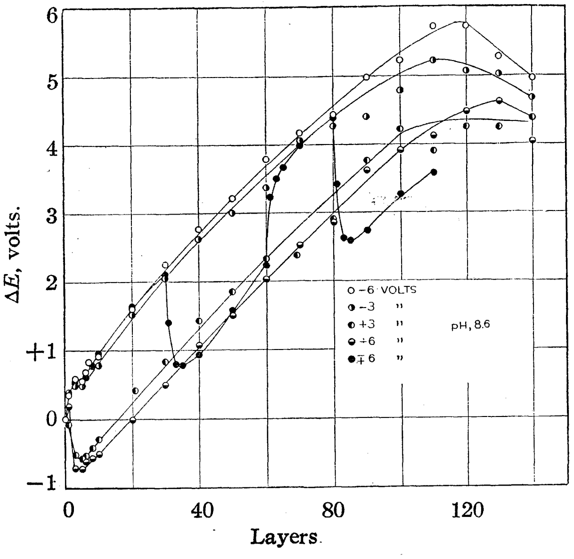

Fig. 1.

Figure 1 shows the change of contact potential with increase in number of layers for X films formed from solution (2), *p*H 8.6, on stainless steel at four different applied voltages, +3, +6, −3, −6 v. It should be noted that in all cases discussed in this paper we call the applied voltage positive when the positive pole of the battery is attached to the slide. The most striking characteristic of these curves is that from layer 5 to layer 90 they are parallel, *i. e.*, have equal slopes. Between 0 and 5 layers, however, the curves obtained with positive and negative applied voltages behave quite differently. The potentials of films made with positive voltages drop sharply, *e. g.*, to −0.6 v. for a voltage of +3, and to −0.7 v. for a voltage of +6. On the other hand, the potentials of films made with negative voltages rise, *e. g.*, to +0.5 for a voltage of +3 v. and to +0.5 for a voltage of +6. This initial behavior gives rise to the separation of the two parallel sets of curves.

The potential curve for a film formed without an applied voltage is not shown in this figure, but a typical curve lies between the positive and negative curves, although not necessarily parallel to them, usually more nearly coinciding at the start with the negative voltage curves and as the number of layers increases crossing over to the positive voltage curves. The curve for ∓6 v. in the figure was obtained by changing the direction of the applied voltage at 30, 60 and 80 layers. From 0–30 layers, with −6 v. applied, the curve is coincident with the −6 v. curve. On reversing the polarity the potential drops rapidly to the +6 v. level and becomes approximately coincident with the +6 v. curve. On changing back to −6 v. the potential rises steeply and this time coincides with the −3 v. curve. On reversing the polarity once more at 80 layers the curve drops below the +6 v. curve but becomes parallel with it at a lower potential level. Similar results have been obtained on substrates containing carbonates instead of borates.

In Fig. 2 are plotted the potential changes due to the X layers alone of the first four curves of Fig. 1, the contribution to the potential of the first five Y layers being in each case eliminated by subtracting from the actual potential the potential observed after the deposition of the last Y layer. The resulting curves are all the same within the experimental variation.

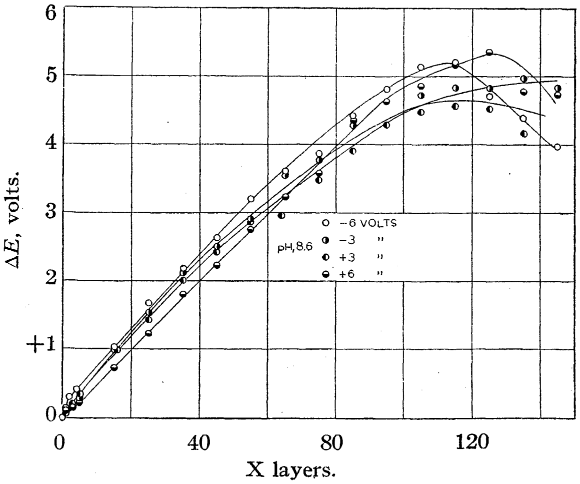

Fig. 2.

The effect of an applied voltage on Y films formed from solution (5), *p*H 7.4, is shown in Fig. 3.

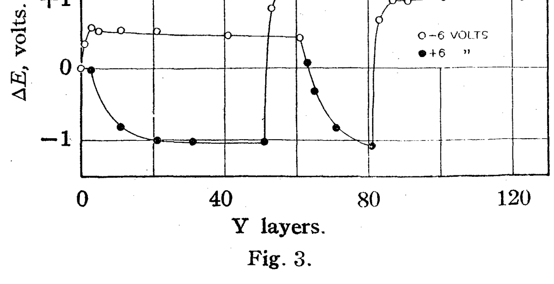

Fig. 3.

With −6 v. the potential rises to a maximum of +0.6 v. at three layers and declines from then on slightly as the thickness of the film increases to 61 layers. At this point the voltage is reversed and the potential drops rapidly to −1.1 v. at 81 layers. Return to the original voltage causes a sudden rise in potential to an approximately constant value of +1.0 v. from 87–123 layers. If we start with +6 v. the sequence is reversed as may be seen from the figure.

The separation of the two curves in Fig. 3 before reversing the polarity of the applied voltage amounts to 1.5 v., which is approximately the magnitude of the separation of the +6 and −6 v. curves for X films in Fig. 1. In both the curves of Fig. 3 there is an over-compensation when the polarity of the applied voltage is changed from +6 to −6 v. This may be a phenomenon similar to the over-compensation observed in Fig. 1 after the last change in polarity from −6 to +6 v. in the ∓6 volt curve.

B. X and Y Films Deposited on Platinum.—Essentially the same results are obtained with a platinum slide. However, in this case it is possible to work with higher applied voltages. In Fig. 4 potential curves are given for two X films deposited on platinum from solution (2), *p*H 8.6.

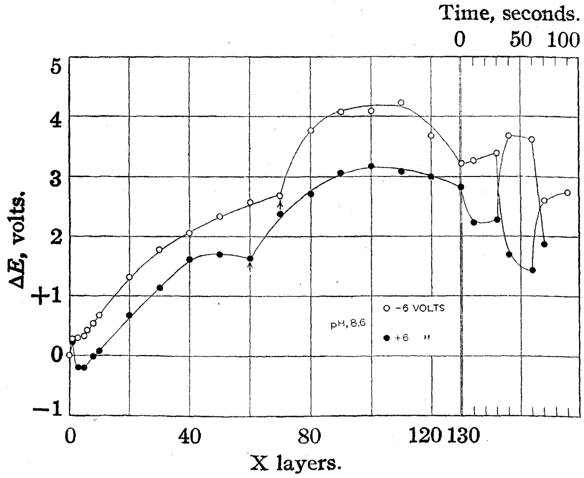

Fig. 4.

The first four layers after the initial layer are Y layers. The curves for +6 and −6 v. are very nearly linear and parallel between 5 and 40 layers. At thicknesses greater than 40 layers the curves cease to be linear but have the same general configuration. The two arrows in the figure indicate points after which a fresh monomolecular layer was spread on the substrate in the tray used for building the films. The increase of slope following renewal of the monomolecular layer in the tray is like what is always observed when there are traces of contaminating ions in the subphase. Apparently such ions slowly diffuse into the surface layer and impair its ability to form X films of high potential.

Figure 5 shows potential–layer curves for four films deposited on platinum from solution (1) at *p*H 10.9 with applied voltages of +6, −6, +22 and −22 v. The curves are in every way very similar to those in Fig. 4 at *p*H 8.6.

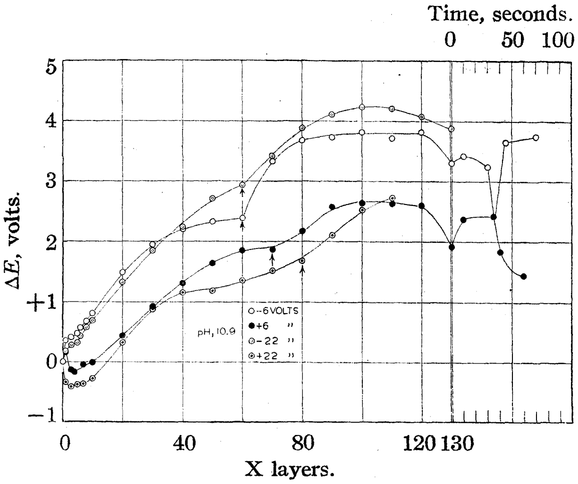

Fig. 5.

In Fig. 6 the six lower curves show the potential change due to the first 55 X layers of the films represented in Figs. 4 and 5. The point for the last Y layer in each case is taken as the origin. The six curves all fall together and the slopes are all the same, within the random variation among the films. This is like the situation shown in Fig. 2 for films on steel slides. In both cases the average slope is 58 mv. per X layer. Thus the increase of potential due to the addition of each successive X layer, at least up to a total of 55 layers, is independent of the metal on which the films are deposited, the *p*H of the substrate, and the sign and magnitude of the applied voltage.

As we have already pointed out, reversal of the applied voltage during the deposition of X or Y layers causes a sudden shift of contact potential from a value on the characteristic potential layer curve for the original voltage to a value on the curve for the reversed voltage. This shift, however, does not depend on the deposition of layers, but can be brought about equally well by reversing the applied voltage and dipping the slide into the substrate through a clean surface free of the monolayer. A few seconds in the liquid with reversed voltage is sufficient to establish the new value. The potential can be changed back and forth from one curve to the other many times in this manner, just as when layers are being deposited. If the applied voltage is not reversed there is practically no change in contact potential when the slide is submerged in the substrate, as the first two points indicate. At the right-hand sides of Figs. 4 and 5 are given what we will call potential–time curves illustrating this phenomenon. In these curves "time" refers to the total length of time that the slides were submerged with the applied voltage.

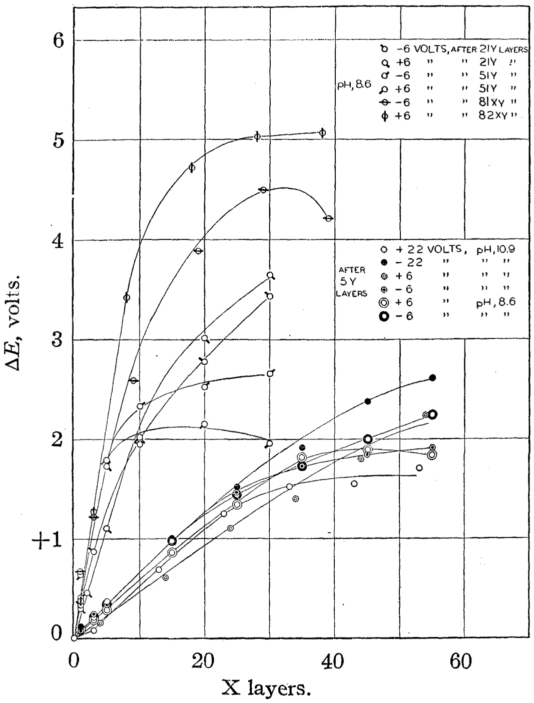

Fig. 6.

Potential–layer curves for Y films on platinum with applied voltages of +6 and −6 v. are shown in Fig. 7. Two different solutions were used: solution (3), *p*H 8.6, with copper; solution (4), *p*H 7.7, without copper. The small initial differences between the two pairs of curves from solutions (3) and (4) are due probably to the difference in *p*H rather than the copper content of the solution, for curves similar to the pair without copper at *p*H 7.7 are obtained at the same *p*H with copper. Comparison of these results with those for steel slides given in Fig. 3 shows that the nature of the underlying metal has only a slight effect on the shapes of potential curves of Y films, the curves for steel becoming horizontal, those for platinum continuing to rise or fall slightly. It is significant that the separation of the two Y film curves at 5 layers for applied voltages of +6 and −6 is about 0.6–0.7 v., which is also the separation of the parallel portions of the curves for X films on platinum obtained with the same applied voltages, shown in Figs. 4 and 5.

Potential–time curves for Y films submerged with an applied voltage are given at the right-hand side of Fig. 7. These are in general similar to those in Figs. 4 and 5 for X layers, which we have already described. The bracketed points are identical, the origin of the time curve having been displaced to the right merely for convenience in plotting.

It may be recalled that during the first dip of a chemically clean slide into a substrate covered with a monolayer, only a single layer is deposited on the slide under all conditions. This layer is formed when the slide is withdrawn from the liquid and seems to be different from either an X or a Y layer. Germer and Storks[9] have shown that the polar groups of this layer are attached to the metal surface of the slide. The effect of an applied voltage on the potential associated with such layers is somewhat different from that observed in the case of X and Y films. If the applied voltage is between +6 and −6 v., the initial layer always causes an increase in the contact potential but by a somewhat smaller amount for positive than for negative voltages. We have

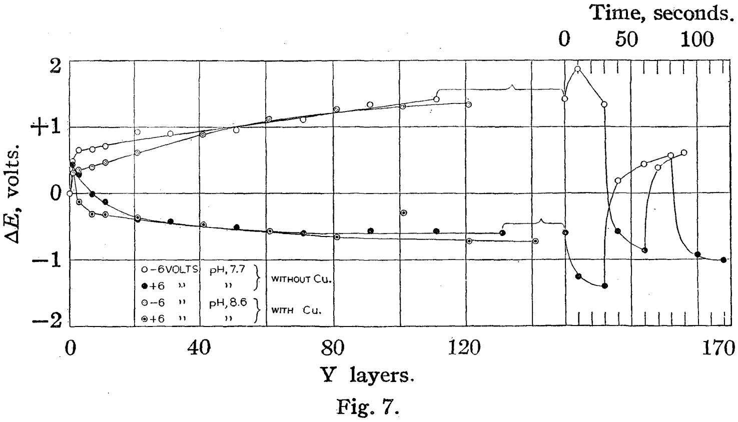

Fig. 7.

---

(9) Germer and Storks, *Proc. Natl. Acad. Sci.*, **23**, 390 (1937).

not investigated applied voltages between +6 and +22 v. but at +22 v. the initial layer produced a decrease in contact potential. These effects are apparent in certain of the figures already presented. Presumably there is some critical positive voltage, for any given set of conditions of substrate and temperature, at which the initial layer produces no change in contact potential.

C. Composite Films Deposited on Platinum.—It will be recalled that the addition of X layers to a Y film causes a steep rise of potential to values characteristic of a pure X film of the same total thickness, that the addition of Y layers to an X film causes a sudden drop of potential to the Y film level and that by alternating blocks of X and Y layers it is possible to shift the potential back and forth between the curves for pure X and Y films. The question arises as to the effect of an applied voltage on these phenomena.

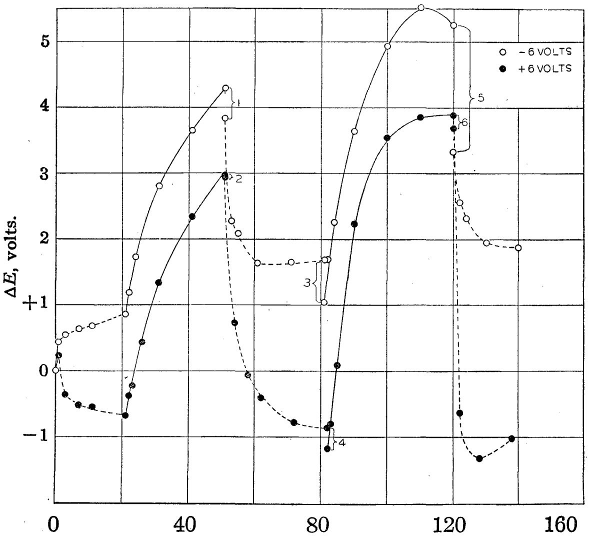

Fig. 8.—- - - - Y layers; ——— X layers.

Two sets of results bearing on this question are given in Figs. 8 and 9. The X layers were obtained from solution (2); the Y layers from solution (4), with copper. Two curves are shown in each figure, one for +6 v. and one for −6 v. In each case Y layers were deposited first and the potential curves obtained were in every way similar to those already described. In the experiment shown in Fig. 8 after 21 Y layers had been laid down X layers were deposited. During this process the potentials rose steeply, the curves for +6 and −6 v. being very nearly parallel. After a total of 51 layers, Y layers were again deposited and the potentials dropped sharply to approximately the values for pure Y films of the same total thickness formed with the corresponding applied voltages. At a total of 81 to 82 layers X layers were added once more. This time the potential rose considerably more steeply and to a higher value than before, after 21 Y layers. Finally, after a total of 120 layers, one more block of Y layers was deposited with much the same results as before. In the experiment shown in Fig. 9, 51 Y layers were deposited before the addition of X layers. The X layers then produced a steeper rise of potential than the first block of X layers at +6 or −6 v. in Fig. 8.

From these results it appears that with an applied voltage the alternation of blocks of X and Y layers is accompanied by a shift of potential back and forth between the curves for pure X and Y films obtained with that voltage. The situation is like that observed in the absence of such a voltage. The rate of increase of potential when X layers are deposited on underlying Y layers is greater the greater the total thickness of the film but it does not depend on the applied voltage. This point is shown by the upper group of curves in Fig. 6. These curves are obtained by plotting the potential against the number of layers for each block of X layers in the experiments shown in Figs. 8 and 9. In each case the origin is the point corresponding to the last preceding Y layer. The curves for a block of X layers added to a Y film of 21 layers are the same for applied voltages of +6 and −6 v., and have an initial slope of 240 mv. per layer. Those for a block of X layers

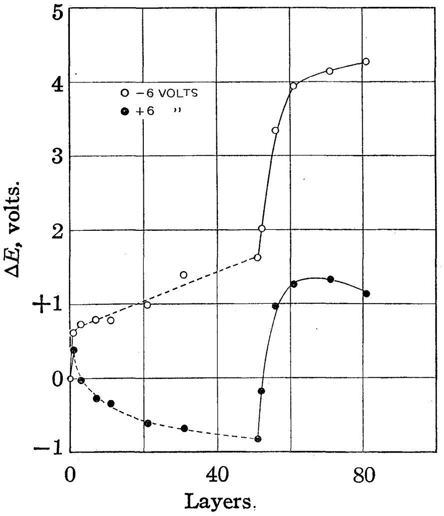

Fig. 9.—- - - - Y layers; ——— X layers.

added to a Y film of 51 layers at +6 and −6 v. have a slope of 360 mv. per layer; those for a block of X layers added to a film of 81 or 82 total layers at +6 and −6 v., a slope of about 430 mv. per layer or greater.

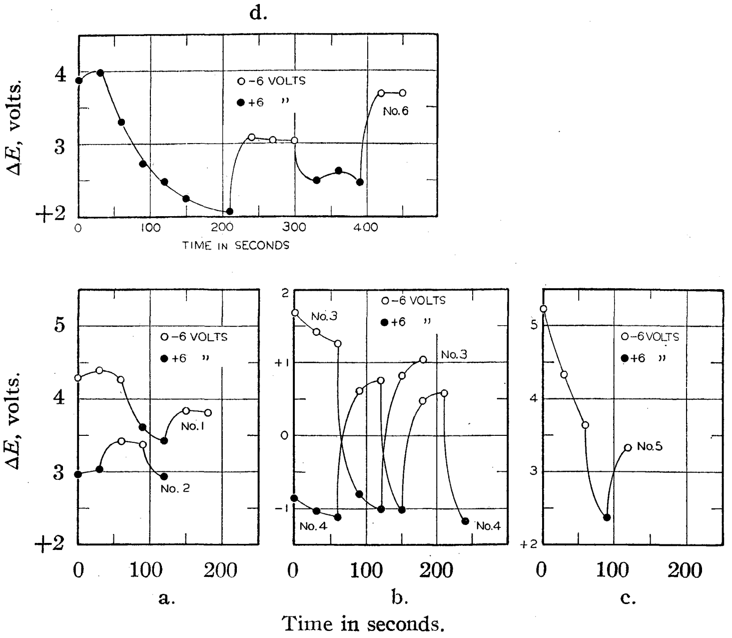

Fig. 10.

The treatment of the films represented in Fig. 8 between the numbered, bracketed points involved submerging them in the substrates with an applied voltage without the deposition of layers. During this treatment the behavior of these composite films is much like pure X or Y films. A complex film always resembles a film made up entirely of the kind of layer last deposited, as shown by Fig. 10.

The composition of the substrates used had no detectable influence in these phenomena.

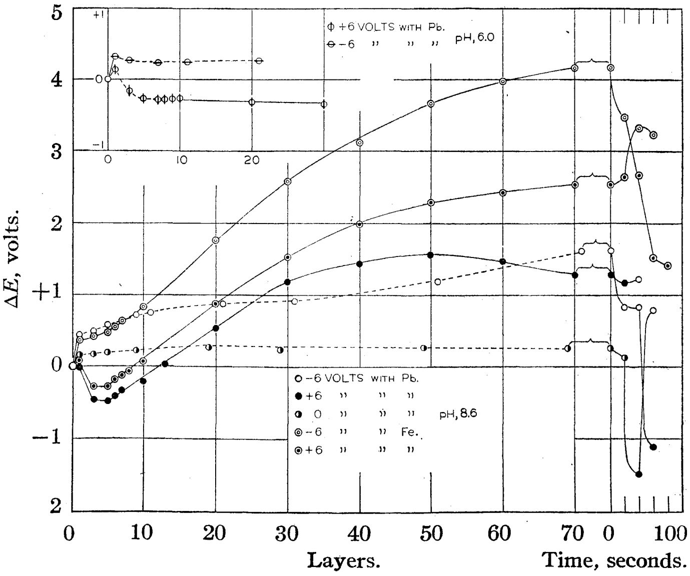

Fig. 11.—- - - - Y layers; ——— X layers.

IV. X and Y Films Deposited from Substrates Containing Iron and Lead

In the last section we described phenomena observed with films deposited on stainless steel and on platinum. Although the major effects were the same for both kinds of film, nevertheless there were certain minor differences: the potentials of simple X films on steel rose more nearly linearly and attained higher values than the potentials of X films on platinum (*cf.* Figs. 2 and 6); the potentials of Y films on steel quickly attained a constant value under the influence of an applied voltage, whereas the potentials of Y films on platinum continued to rise or fall, depending on the direction of the voltage, as the films increased in thickness. Since it is known that the properties of films are greatly affected by certain ions, even at very small concentrations, it seemed possible that these differences were due to the influence of ferric ions arising from the steel slides. In order to test this possibility, X films were deposited on platinum from solution (2) which had been made 1.4 × 10^{-5} molar in ferric chloride. The potential–layer curves of these films, which are given in Fig. 11, are quite similar to those of X films deposited on platinum from solution (2) without iron, except for a somewhat greater slope, the initial slope of these calcium–ferric stearate films being about 80 mv. per layer. Also the potential–time curves when these films are submerged in the subphase with an applied voltage are like those of films without iron. It appears then that no considerable effects are produced by the presence of ferric ions in the concentration we have used, and there must therefore be some other basis for the differences in behavior between films deposited on steel and on platinum.

On the other hand, the properties of films are greatly altered by small concentrations of lead. Langmuir[3] has reported that in the presence of lead acetate X films may be formed at *p*H 6, and that the potentials of such films are like those of Y films. On this basis he has suggested that the *p*H of the subphase is the primary factor which determines film potentials. Other observations of our own show certain curious effects of lead at other values of *p*H and with an applied voltage.

It will be recalled that films deposited from solution (2), *p*H 8.6, are always X films regardless of the applied voltage. However, when this solution was made 2×10^{-6} molar in lead acetate the films deposited on platinum were Y films with applied voltages of 0 and -6 v. and X films with a voltage of $+6$ v. The potential–layer curves of these films are given in Fig. 11. The initial slope of the X film curve (after the deposition of the last underlying Y layer) is about 80 mv. per layer, but the curve flattens out before reaching the higher values characteristic of X films without lead. The two Y film curves are much like those of other Y films formed with the same applied voltages without lead. The potential–time curves of these films, giving the effect of an applied voltage on films submerged without deposition of layers, are those characteristic of the respective types of film, X or Y.

In the insert in Fig. 11 are given the potential–layer curves for two films formed on platinum from a pure sodium acetate buffer of *p*H 6.0 containing lead acetate, 2×10^{-5} molar, with applied voltages of $+6$ and -6 v. Just as at *p*H 8.6, the film obtained with the positive voltage was an X film, the other a Y film. As in the case of the X film reported for *p*H 6 by Langmuir, the potential of this X film failed to rise above the characteristic Y level. It was noted while this film was being deposited that the contact angle as the slide was withdrawn from the liquid was considerably less than 90°, somewhat approaching the angle for a Y film. This accords with the observation based on many cases that large contact angles are associated with high contact potentials; for example, if under conditions otherwise favorable for the production of high potentials in X films, the slide is dipped too rapidly, the contact angle is small and the film fails to develop a high potential.

Curiously enough, when films are formed on stainless steel under these same conditions, *i. e.*, with a sodium acetate buffer of *p*H 5.9–6.0 and a concentration of lead acetate 2×10^{-5} molar, X layers are deposited at both $+6$ and -6 v. The potential of the film formed with the positive voltage becomes constant, after a few layers, at -0.5 v.; that of the film formed with the negative voltage, constant at $+0.4$ v. These potentials are the same as those of Y films obtained with the same applied voltages in the absence of lead.

The question arises whether these X films of low potential are in other respects like X or Y films. In one respect they show a striking difference from any other films, X or Y which we have studied. All other films when made electrodes in a glow discharge or subjected to X-ray treatment develop very large contact potentials, generally exceeding any values developed spontaneously by X films in the course of their formation. These low potential X films containing lead entirely fail to develop high potentials under such treatment. Two such X films of 35 layers, one formed with a positive voltage and having an initial potential of about -0.5 v., the other formed with a negative voltage and having an initial potential of about $+0.4$ v., gave, respectively, potentials of only -0.35 and -0.04 v. after the usual treatment with X-rays. When similar films were subjected to a rectified glow discharge the potentials failed to change by more than a small fraction of a volt, regardless of the direction of the discharge. There appears to be some curious feature in the structure of these lead containing X films which prevents the development of high potentials. Whether or not this may be related to the resistance of the films we will consider later.

V. Potentials Observed during the Early Stages of the Formation of X Films

It already has been observed,[2] when measurements are made after each dip during the early stages of building an X film without an applied voltage, that the potential increases in a stepwise manner, and that the contact angle alternates between 90° and values less than 90°. This effect we have attributed to the condition at the outer surface of the films where at the end of every other dip there must be an unpaired layer, presumably with its polar surface inward. As a result of the succeeding dip each such unpaired layer receives a partner, and we have suggested that during this dip it turns over so that its polar surface comes to face that of the partner, which is inward, an interpretation which accords with the X-ray spacing of the metallic ions, and the hydrophobic character of X films.

This stepwise increase of potential, which appears so significant in relation to events at the surface of the film, becomes blurred and lost as the thickness of the films increases beyond about 15 layers in the case of films formed without an applied voltage, perhaps in consequence of different areas of the same film falling out of step. When, however, the phenomenon is investigated in the case of X films formed with applied voltages, it shows up much more clearly and persists much longer. Certainly it remains undiminished up to thicknesses of 26 layers, which is as far as we have carried the measurements. The applied voltages seem to have a steadying effect on the films.

Two films were studied in this connection, both deposited on platinum from solution (2), *p*H 8.6, one with an applied voltage of +6, the other with −6 v. The results are shown in Fig. 12. X layers were formed after the fifth layer. As a result of the behavior at the addition of the seventh layer the two curves fall out of step. Corresponding to the stepwise increase of potential there was observed initially an alternation of contact angle. The rise of potential occurred with an angle of 90°. During the addition of alternate layers, when the potential failed to rise, or dropped, the angle was always less than 90°. After about 20 layers, this alternation of contact angle disappeared and the angle was always close to 90°, although the stepwise increase of potential continued undiminished.

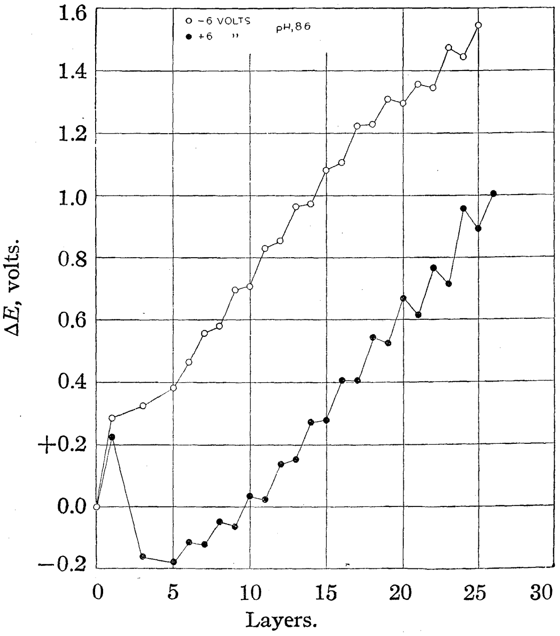

Fig. 12.

The parallel course of the two curves, after X layers begin to be formed, is very striking. It is also striking that the applied voltage has very little effect on the potential of the initial layer, and the separation of the curves for +6 and −6 v. is realized during the deposition of the two pairs of succeeding Y layers.

VI. Impedance of Films and Related Phenomena

We have referred in passing to the possibility of the resistance being different for different types of films. For example, this would be a possible reason for the fact that the large potentials produced by the X-ray treatment or a glow discharge, provided they are due to internal charges in the film, are abolished by dipping the films into aqueous solutions in the case of Y films but not in the case of X films. Again the fact that the lead films deposited at *p*H 6 never develop high potentials might be laid to a relatively low resistance. On the other hand, from attempts to measure voltages of circuits involving films in contact with conducting liquids (section II) it is evident that the d. c. resistance of all types of films must be very high. These considerations point to the importance of direct evidence on the resistance of the films, and in this section we discuss measurements bearing on this question.

An initial attempt was made to measure the impedance of the films by placing a small drop of mercury on the film, with which contact was made with a platinum wire. The binding post of the slide and the platinum wire were connected to the terminals for the unknown on an a. c. bridge and measurements attempted at 800 cycles. The results were not very satisfactory, but it was at once apparent that with high signal voltages the resistance of the films was very low, less than 1 ohm, whereas with signals of 1 or 2 v. the resistance was of the order of megohms. Evidently, the higher signals exceeded the breakdown voltages of the films.

Much more satisfactory measurements were obtained at radio frequencies with a General Radio Co. radio frequency bridge, by using as before the device of placing a small drop of mercury on the surface of the film. Two sets of measurements were made, one at a frequency of 1 megacycle (λ = 300 m.), the other at a frequency of 0.244 megacycle (λ = 1230 m.). The strength of the signal did not exceed a fraction of a volt. At the higher frequency the bridge was balanced by a condenser and power factor dial; at the lower frequency by a condenser and a series resistance. The capacity settings were very sharp; the power factor or resistance settings less so, particularly with the thicker films. A number of different mercury drops were used, but all the results given below were obtained with 3 different drops, all of very nearly the same size, 1.5–1.8 mm. in diameter. The same drop could be rolled from one place to another on a given film or from one film to another. There was considerable variation in the results obtained on the same film with different drops, or with the same drop in different places, due apparently to differences in the size of the drops and in the exact area of contact of a given drop with a film in different places. This variability was much greater for the power factor and resistance settings than for the condenser settings. Results on X and Y films deposited on stainless steel slides are given in Tables I and II. These are expressed in terms of parallel capacity, C_p, and resistance, r_p. Bracketed results were obtained with the same drop. The Y films were copper–barium stearate films formed at *p*H 7.4; the X films, of which the first four layers after the initial layer were Y layers, were calcium stearate films formed at *p*H 9.

It is evident from the data in these two tables that there is no significant difference between X and Y films in respect to either capacity or resistance. Other measurements on X films of low potential deposited from a sodium acetate buffer of *p*H 6, 2 × 10^{-5} molar in lead, gave substantially the same results. In both types of film the capacity decreases with thickness, as would be expected, but the capacity multiplied by the number of layers is the same, within the experimental variation, for all the films and at both frequencies, as shown by the fourth column. Since

$$C_p = A\epsilon/4\pi nt \qquad (1)$$

in which ϵ denotes dielectric constant, n number of layers, t the thickness of a layer and A the area of the drop in contact with the film, and since t is the same for X and Y films, this result implies that the dielectric constant is also approximately the same and approximately independent of frequency. The known size of the drops agrees with a value of the dielectric constant of approximately 2.5, or a value close to that obtained for stearate in the bulk phase. Thus on the basis of t = 24 Å. and ϵ = 2.5 the average value of n C_p = 14,500 gives for the radius of the area of contact of the drop with the film a value of 0.72 mm. The over-all diameter of the drops, which should be somewhat more than twice this value, was 1.5–1.8 mm., as well as could be estimated. This estimate of the dielectric constant is of some interest in relation to the question of possible water of hydration in the films.

The fifth columns of both tables give average values of the resistance per layer. Although these values probably do not differ significantly between X and Y films, they show a definite increase with the thickness of the films. Moreover, the values obtained at 1 megacycle are definitely less than those at the lower frequency. It may be noted that a value of 20,000 ohms per layer corresponds to a specific resistance of about 2 × 10^9 ohms, having regard to the size of the drops and the thickness of the layers. The resistance of the films measured at both frequencies is far less than would be judged from the experience of measuring the electromotive force of circuits involving films covered with mercury (section II). Evidently there is a phenomenon of power absorption in the films, increasing with frequency over the range studied.

In view of this, and also to explore the question of the breakdown of the films under high voltages, various d. c. measurements were undertaken. X and Y films of different numbers of layers were covered with a drop of mercury and subjected to a variable measured voltage in series with a galvanometer, which, with the shunt turned on full, gave a deflection of 1 mm. for a current of 4.37 × 10^{-9} ampere. The readings of the galvanometer were followed as the voltage was increased. With films of about 30 layers and thicker there was no observable deflection of the galvanometer until a certain critical breakdown voltage was reached. To determine values of this voltage it was unnecessary to make use of the galvanometer. As soon as it was reached the relatively low resistance voltmeter placed in parallel with the film was automatically shorted and the needle immediately fell to zero. With thinner films there were appreciable currents almost from the start. Values of the breakdown voltage for various X and Y films are given in Table III.

TABLE III

X Films[a] (Ca Stearate, *p*H 9)

Layers	11	15	23	39	71	135
Voltage	0.5	0.5	2.0	9, 10	27, 34	60, 90
Voltage per layer	0.05	0.03	0.09	0.2	0.4	~0.5

Y Films (Cu–Ba Stearate, *p*H 7.4)

Layers	7	17	35	71
Voltage	0.1	0.6	11	29
Voltage per layer	0.01	0.03	0.3	0.4

[a] The first six layers after the initial layer were Y layers.

Apparently the breakdown voltage per layer rises sharply at a thickness of about 20 layers. It may be pointed out that a value of 1 v. per layer corresponds to a field of about five million volts per centimeter. Below the breakdown voltage the resistance of the films is very high. In the thicker films where there is no observable galvanometer deflection up to the breakdown voltage (0.4 v. per layer) the resistance between the drop and the plate must be at least 10^8 ohms per layer, corresponding to a specific resistance of the order of 10^{13} ohms. In thinner films, where there is a deflection of a fraction of a mm. with fields as low as 10^{-2} v. per layer, the resistance cannot be more than about 10^7 ohms per layer. This is suggestive of the bridge measurements, in which the resistances per layer, though all of a different order of magnitude, are found to be less for the thinner films.

In view of these values of the breakdown voltage and the very high d. c. resistances observed below these voltages, it would appear hard to explain the magnitude of the current (of the order of a milliampere or two) observed when films are submerged in aqueous liquids with an applied voltage. The answer to this paradox is found in observations like those we have just described but with a drop of tap water substituted for the mercury drop. In this case, much as in the case of the mercury drop, there is no deflection of the galvanometer until a certain "breakdown" voltage is reached; at this point a current begins to flow which soon shoots up and rises almost vertically as the voltage is further increased. There is, however, the striking difference between these and the results obtained with mercury, that the critical voltage at which the current suddenly rises is very nearly independent of the thickness of the films: for the thin films it is higher, for thick films lower, than with mercury. The behavior of X and Y films[10] is shown in Fig. 13; they are not very different. For both, however, there is a difference in the voltage–current curves depending on the direction of the voltage. When the positive pole of the battery is connected with the slide the curve shoots up more steeply than in the opposite case, in which, though the curve begins to rise at about the same voltage, it does so more slowly until it passes over a kind of shoulder. It seems likely that this difference is due to an electrical asymmetry in the film, probably asso-

---

(10) Y films containing lead were not significantly different from Cu–Ba stearate Y films.

ciated with the initial layer (see for example Fig. 9). Below these breakdown voltages, the d. c. resistance of the films covered with water is, so far as we can say, as great as that of films covered with mercury. There is another contrast between the results obtained with water and mercury. With mercury drops the film seems to be ruptured permanently when the breakdown voltage is exceeded, and the resistance remains low. With water drops this is not the case, and subsequent curves obtained with the same drop in the same place on the film are about the same as the initial curve.

This very striking difference between the results obtained with films covered with water and with mercury may be due to a difference in the affinities of the two liquids for the surface, although neither water nor mercury wets the surface. It is suggestive to recall in this connection that Y films which have acquired large contact potentials as a result of a glow discharge completely lose these potentials as a result of being dipped in water, whereas the potentials remain unaffected or are only partially abolished when the films are dipped in mercury, even though several layers may be removed by the process. It is as if the water were able to penetrate the films.

VII. Discussion

In view of the spacing of the metallic ions revealed by the X-ray studies of Holley and Bernstein,[11] it is clear that the basic structure of X and Y films is the same: the layers, apart from the first layer, occur in pairs, with the polar surfaces together. On the other hand, there must be some structural differences to account for the very different properties and behavior of the two kinds of film. As a result of the great effects often produced by very small changes in the character of the substrate it seems likely that these differences are closely connected with the ionic composition of the films. If we accept the surface electrification hypothesis it would be such differences which determine whether or not the films acquire a charge when withdrawn from the substrate rather than the fact that the layers are deposited singly or in pairs. This accords with the fact that lead X films formed at *p*H 6 do not develop high potentials although the layers are deposited only one at each dip. Evidently, however, it is not the character of the whole film, but only that of the outermost layer or two which is the determining factor, since when one or two X layers are deposited on a Y film it develops the potential characteristic of an X film of the same total thickness and conversely when one or two Y layers are deposited on an X film. Moreover, when layers are successively removed from composite films the films appear to retrace their past history in respect to potential. We have seen that the characteristic potentials of all films disappear while the films are in contact with various polar liquids, but redevelop when the films are withdrawn from the liquids. Evidently the original surface charge is restored by the work of separation from the liquid, and the sign and magnitude of the charge depend on the character of the surface of the film rather than on the nature of the liquid, *e. g.*, whether chloroform, water or mercury.

On the other hand, certain other phenomena clearly depend not on the nature of the surface layer but upon that of the whole film, for example, the optical thickness of the films, the temperatures at which they soften and the change of optical thickness which accompanies softening. In all these respects X and Y films differ, and the experiments show that X augmented Y films and Y depressed X films behave like simple Y and X films, respectively.

It seems probable that, unlike the "natural" potentials of the films, potentials produced by the X-ray treatment or a glow discharge are due to the development of an internal charge in the body of the films as a result of the penetration of ions into the films. Otherwise it is hard to understand how these potentials, whether positive or negative, can persist as they do after X or Y films are dipped into mercury and several layers are removed. Even on the basis of this view, however, certain points remain obscure. Why are these potentials, whether positive or negative, abolished in the case of Y, but not of X, films as a result of dipping the films into water and chloroform? By what mechanism are they neutralized while the films are in contact with polar liquids, supposing that the internal charge is not removed? These phenomena, together with the curious behavior of the lead films, which fail to develop large potentials under any conditions, remain a difficult problem.

Consider now the experiments on the effect of a voltage applied between the slide and the liquid subphase while films are being deposited. The

---

(11) Holley and Bernstein, *Phys. Rev.*, **52**, 525 (1937).

data show clearly that for all types of film an applied voltage does not affect the shape of the potential–layer curves (except for the first three layers of simple X and Y films, as in Fig. 12), but simply serves to displace the curves by a constant amount up or down depending on its direction. The absolute magnitude of the shift is nearly if not quite independent of the magnitude of the applied voltage, as well as of the type of film. From this it appears, in terms of the surface charge hypothesis, that when the films, of whatever type, are withdrawn from the liquid they acquire the same charge as in the absence of the applied voltage, but that in addition to this there is superposed an effect due to the voltage. This effect might be interpreted as due either to a polarization, possibly involving a reorientation of an underlying layer, or to the accumulation of a subsidiary charge on the surface of the film. In accordance with the latter interpretation we may think of the film as a condenser of capacity given by equation (1). Then, under the influence of the applied voltage V_f effective across the film, the film will accumulate a charge per unit area given by

$$\sigma' = \epsilon\, V/4\pi nt$$

This charge, over and above the charge σ acquired by the film independently of the applied voltage at the time it is withdrawn from the liquid, would account for the displacement of the potential–layer curve by an amount V, without its being otherwise altered. But on either interpretation it is the charge σ which determines the character of the potential–layer curves, and it follows, somewhat unexpectedly, that σ is wholly unaffected by the applied voltage.

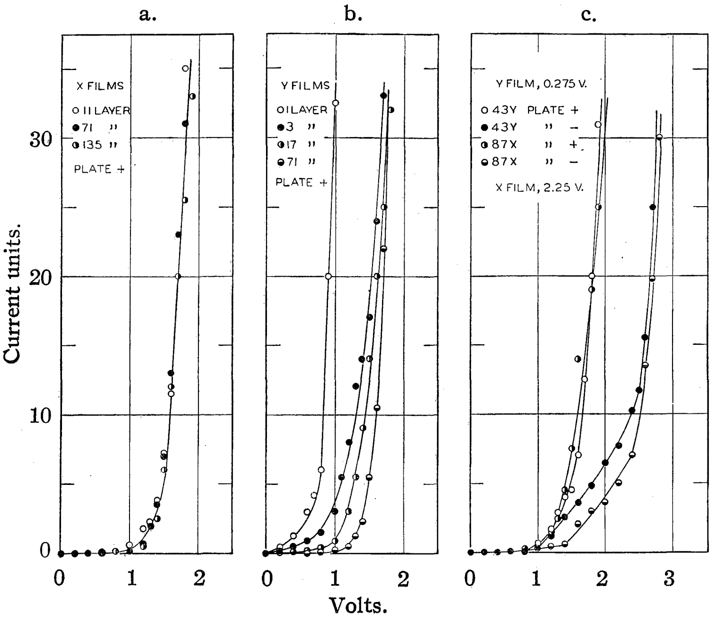

Fig. 13.—Voltage–current curves of X and Y films in contact with water.

It now remains to consider why the up or down displacement of the curves is independent of the magnitude of the applied voltage. An explanation of this is to be found in the results represented in Fig. 13. Evidently when a voltage V is applied between a point in the liquid and the submerged metal slide a voltage V_f at once begins to build up across the film. However, it may be seen from Fig. 13 that before V_f attains the value V (if V be sufficiently high) the critical point will be reached when the resistance of the film suddenly drops, and a current begins to flow. Equilibrium is then established when the current reaches such a value that the resulting voltage drop in the liquid is equal to $V - V_f$. Since after the attainment of the critical voltage, the current through the film rises sharply (see Fig. 13) it is evident that V_f should be very nearly independent of V, as it is found to be. This explanation has nothing to do with the nature of the reversible "breakdown" associated with the sudden rise of current in the film in contact with the liquid when the applied voltage reaches a certain value, but depends simply on the fact that such a process occurs.

Summary

Voltage measurements of circuits involving X and Y films in contact with polar liquids indicate that the potentials of the films are neutralized by contact with the liquids, although they reappear after the films are separated from the liquids. Similar measurements of films in contact with benzene show that in this case the potentials are not neutralized.

Contact potentials induced in X and Y films by exposure to a glow discharge are not abolished as a result of dipping the films in mercury even when several layers of the film are removed, but are abolished in the case of Y films by contact with water and chloroform.

The effect of applying an arbitrary voltage between the slide and the liquid while films are being

built is to displace the potential–layer curves up or down without altering their shape subsequent to the first three layers. The absolute magnitude of the displacement is independent of the type of film and of the magnitude of the applied voltage but the direction of displacement, up or down, depends upon the direction of the voltage. Similar shifts of potential are produced when films are immersed in the liquids under the influence of an applied voltage without the deposition of layers.

X or Y films containing lead fail to develop large contact potentials under all conditions and show certain unusual properties.

Impedance measurements at frequencies of 1 and 0.244 megacycles show no significant difference between X and Y films. They indicate a dielectric constant of about 2.5 and give evidence of power absorption. Breakdown voltages of X and Y films are the same. Breakdown voltages of films in contact with mercury increase with the thickness of the films, and correspond to fields of the order of 10^6 v./cm. Apparent breakdown voltages of films in contact with water are nearly independent of thickness and depend on the direction in which the voltage is applied. The specific d. c. resistance of both X and Y films is of the order of 10^{13} ohms.

The Volumetric Oxidation of Iodide and Bromide by Periodic Acid[1]

BY HOBART H. WILLARD AND LUCIEN H. GREATHOUSE

Periodic acid and periodates of the alkalies are powerful oxidizing agents in dilute aqueous solution and usually stable enough for use in volumetric analysis.

Reactions of periodates as oxidizing agents have been investigated from an early date.[2] The reaction between periodate and iodide with excess of the former

$$KI + 3KIO_4 = 4KIO_3$$

is of particular interest.[3]

The excess of periodate may be determined accurately in the presence of iodate by titrating with standard arsenite the iodine liberated from iodide in neutral solution, thus

$$KIO_4 + 2KI + 4H_3BO_3 = KIO_3 + I_2 + K_2B_4O_7 + 6H_2O$$

This principle was first stated by Péchard[4a] but the method was developed by Müller and his associates.[4b] For this purpose the solution is buffered preferably with boric acid–borax mixture.

Titrations based on these reactions have been used recently to identify polyhydric alcohols.[5]

Periodates Suitable as Reagents

Potassium Periodates.—The metaperiodate, KIO_4, commercially available, contained 79.51% of I_2O_7 compared with the theoretical value of 79.52% and was free from iodate by test with silver nitrate.[2c,6] It may be used as a primary standard for iodimetry.

The solubility of potassium metaperiodate in water was found to be as follows, in grams per 100 ml. of the saturated solutions

0°	25°	35°	45°	55°	65°
0.1546	0.5112	0.785	1.190	1.75	2.51

The specific gravity at 25° of the solution saturated at 25° was 1.00125. If the solubility at 25° as determined by Hill[7] is recalculated to grams per 100 ml. a value of 0.5106 is obtained.

The metaperiodate decomposes in solution with a strong odor of ozone. Dipotassium paraperiodate, $K_2H_3IO_6$, is much more soluble than the meta salt and more stable in solution and hence better suited for standard solutions.

Sodium Periodates.—The paraperiodates precipitated by the reaction of chlorine on iodate in alkaline solution vary in composition between $Na_3H_2IO_6$ and $Na_2H_3IO_6$.[7]

The precipitate is very insoluble in excess of sodium hydroxide. The metaperiodate, $NaIO_4$, is readily soluble in water and is therefore more useful as a reagent. Analysis of a sample prepared in this work gave 85.61% of I_2O_7 as compared with the theoretical value of 85.59%. It is prepared by dissolving the paraperiodate in dilute nitric acid and recrystallizing.

Standard Solutions.—Standard arsenite was prepared in the usual way from very pure arsenious oxide and brought to a *p*H of approximately 7 by buffering with sodium bicarbonate saturated with carbon dioxide.

Standard tenth normal potassium paraperiodate was prepared by dissolving the meta salt in hot water and adding a 10% excess of potassium hydroxide.

The rates of decomposition of metaperiodate and paraperiodate in 0.05 *M* solution at about 30° are shown in Fig. 1. The sodium salt was used to obtain a metaperiodate solution of this strength. Although the paraperiodate solution gave a faint odor of ozone its loss in strength shown in Fig. 1 was probably due also to a slow precipitation by impurities extracted from the glass container by the alkaline solution.

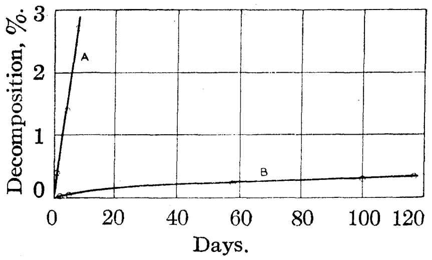

Fig. 1.—Decomposition of 0.05 *M* periodate solutions at 30°: A, sodium metaperiodate; B, dipotassium paraperiodate.

Standard solutions of periodic acid or of sodium metaperiodate acidified with one equivalent of sulfuric acid were found exceptionally stable. One such solution changed less than 0.1% after standing four months in the light and then two years in the dark. These acid solutions were not used because the reagents required were not commercially available at the time.

Determination of Iodide

If a neutral solution of iodide is oxidized to iodate by the addition of an excess of periodate, the latter can then be determined by titration with arsenite as already described. Since iodine is first liberated and subsequently oxidized the reaction must be carried out in a closed vessel.

Standard potassium iodide solution was prepared from a pure salt which had been recrystallized until free from chloride, bromide, and iodate. It was kept in an atmosphere of hydrogen and was standardized gravimetrically by precipitation with silver nitrate, with the following results:

Grams of iodine *in vacuo*, per gram of solution in air, 0.0125961 0.0125965 0.0125966 Av. 0.0125964

Influence of Temperature on the Reaction.—Experiments were made at 25, 35, 45 and 55°, following the reaction of 0.0025 mole of potassium iodide with 0.0075 mole of potassium paraperiodate in a volume of 250 ml. The standard periodate and iodide solutions were brought separately to the selected temperature, then mixed and diluted to volume quickly in a volumetric flask immersed in a thermostat at the same temperature. At suitable intervals 25-ml. samples were withdrawn, treated with borax and boric acid, then with an excess of potassium iodide solution, and titrated with 0.1 *N* arsenious acid. This titration gave residual periodate plus the oxidizing equivalent of such iodine as had been liberated but not yet oxidized to iodate. A second experiment was made at 25° but diluted to 500 ml. and 50-ml. samples withdrawn.

The results plotted in Fig. 2 indicated that at higher temperatures and with an excess of periodate the reaction would be rapid.

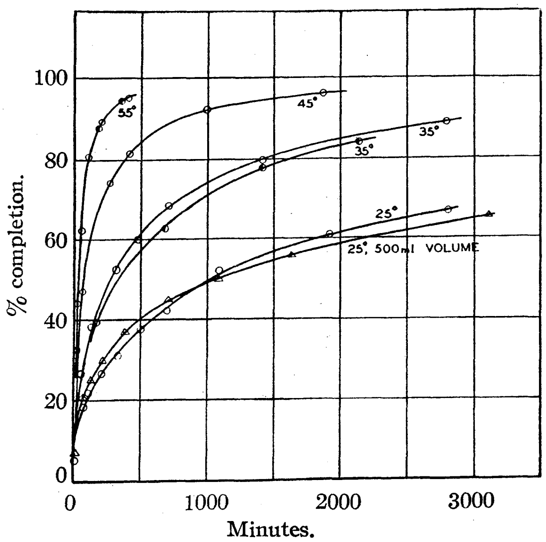

Fig. 2.—Effect of temperature on the reaction $3K_2H_3IO_6 + KI = 4KIO_3 + 3KOH + 3H_2O$: ◐, duplicate experiment; △, dilution experiment at 25°.

Determination of Iodide Alone.—One general procedure was used. Fifty milliliters of 0.1 *N* paraperiodate was introduced into a glass-stoppered 250-ml. Erlenmeyer flask. A flat-ended glass vial, containing 3 to 8 ml. of iodide solution, was lowered into the flask and placed upright on the bottom. Thus the two solutions were kept separate until the whole system was heated to the selected temperature. No other water was added except where noted. The flask was then stoppered and tilted to upset the vial and mix the solutions. After periods as noted in the tables, the reaction mixtures were cooled and excess periodate titrated.

In determinations 1 to 7 of Table I the oxidation was conducted at 70 to 80° and was complete in thirty-five to forty minutes when a small excess of periodate was used. In determinations 8 to 22 the reaction was conducted at 96 to 98° which reduced this period to about twenty minutes. After the iodine liberated at first had disappeared, the solution was neutralized with an excess of boric acid, the flask being opened and closed quickly.

In the determinations shown in Table I the factors of time, temperature and excess of periodate were varied to determine the limits within which the reaction would be

TABLE I

DETERMINATION OF IODIDE

No.	Iodine as KI taken, g.	Excess 0.1 N $K_2H_3IO_6$, ml.	Volume during oxidation, ml.	Time heated, min.	Error, mg. of iodine
1	0.0727	14.30	60	10	−0.2
2	.0767	12.41	60	7	.0

19	.0923	6.33	250	8	−1.1
20	.0704	16.65	250	5	0.0
21	.0760	14.00	250	5	− .6
22	.0831	10.63	250	5	−1.7

complete. In determinations 13 to 22 the volume was increased and the time allowed for reaction progressively decreased as the excess periodate varied, until in determinations 19, 21 and 22 the reaction was incomplete.

Determination of Iodide in Presence of Bromide.—When bromide was also present, slight liberation of bromine occurred which did not affect the accuracy of the iodine determination if no bromine was lost.

The presence of bromide accelerated the reaction so that the addition of boric acid could be omitted. This avoided the procedure of opening the flask during the reaction, which would have permitted loss of bromine. In Table II, in determinations 1 and 2, 50 ml. of 0.1 N $K_2H_3IO_6$ was used but in the others, 25 ml. of 0.1 N $K_2H_3IO_6$ and 75 ml. of water were added.

TABLE II

DETERMINATION OF IODIDE IN PRESENCE OF BROMIDE

No.	Iodine taken, g.	KBr, g.	Excess $K_2H_3IO_6$, ml.	Time heated, minutes	Error, mg.
1	0.0982	0.6	1.88	15	0.0
2	.0965	.6	3.13	10	− .1
3	.0380	5.0	6.25	3	.0
4	.0382	5.0	6.15	3	+ .1
5	.0386	5.0	5.95	3	.0
6	.0415	5.0	4.69	3	− .1

The determination of small percentages of iodide in mixtures with bromides is rapid and accurate.

Recommended procedure: Measure into an Erlenmeyer flask with a ground-glass stopper standard 0.1 N paraperiodate in 10 to 25% excess over that required to oxidize the iodide in the sample to iodate. Dissolve the sample in 5–10 ml. of water in a small vial with a flat end, and set this upright within the flask. Place the flask in a steam-bath, heat to 97–98°, stopper it and upset the vial to mix the solutions.

After the disappearance of iodine, which should occur in less than five minutes, continue heating for ten minutes, then loosen the stopper, cool, and add an excess of powdered boric acid. If the iodine color reappears, replace the stopper, and return to the steam-bath for ten minutes. Any iodine color persisting either before or after the boric acid addition indicates insufficient periodate, in which case the determination will not be accurate.

When bromide is present, the reaction is faster. The addition of boric acid during the reaction is not required, and should be delayed until the solution, after reacting for fifteen minutes, has been cooled. With higher bromide concentrations, a faint bromine color may appear slowly, differing, however, from the iodine color which appears at once when oxidation is incomplete. After completion of oxidation, cool, add an excess of boric acid, then an excess of 5% potassium iodide solution, about 1 ml. for each milliliter of unreacted 0.1 N periodate being sufficient to prevent volatilization of iodine. Titrate the iodine liberated with standard arsenite. Each milliliter of 0.1 N periodate is equivalent to 0.0021153 g. of iodine.

Determination of Bromide

Periodic acid oxidizes bromide in acid solution to bromine. The reaction is complete if the bromine is removed by bubbling air through the solution. The excess periodate may then be titrated to determine bromide.

A standard solution by weight was prepared from potassium bromide purified for atomic weight work. It was standardized by precipitation as silver bromide with the following results:

Grams of bromine *in vacuo*, per gram of solution in air
0.0157740 0.0157731 0.0157770 0.0157730 Av. 0.0157743

Either the standard paraperiodate solution, as in the iodine determination, or the acidified sodium periodate solution described earlier, may be used. There are also required a 5 N sulfuric acid solution, which must be free of reducing reagents, a starch iodide indicator, and Schiff fuchsine indicator for bromine as described by Guareschi.[8]

The reaction was conducted in an Erlenmeyer flask with a ground-glass stopper, through which passed one tube connected to an aspirator and another down into the flask so that air could be drawn through the reaction mixture from several fine openings. A U-tube containing the indicator solution was connected in the suction line. The fuchsine indicator must be used instead of starch iodide if chlorine is present.

Recommended Procedure.—If iodide or other constituents oxidizable by periodate in neutral solution are present, first determine the amount of the standard reagent required for this on a separate aliquot of the solution to be analyzed. To another aliquot, placed in the reaction flask, add this amount of standard periodate, plus a volume of 10 to 35% in excess of that required for oxidation of the bromide. If much iodide is present, keep the two solutions separate until

---

(8) Guareschi, *Z. anal. Chem.*, **52**, 451 (1913).

heated, then mix and oxidize as described before, which usually requires ten to fifteen minutes. Dilute to 100 ml. and acidify with 20 ml. of 5 *N* sulfuric acid in excess of that equivalent to the combined base in the bromide plus that in the standard periodate used. Heat and draw air through the solution until the bromine color disappears, then place the indicator solution in the U tube and repeat until no test for bromine is obtained. Cool, neutralize with 20 ml. of 5 *N* sodium carbonate, buffer the solution and titrate the excess of periodate.

TABLE III

DETERMINATION OF BROMIDE

No.	Bromine taken, g.	0.2 *M* KCl, ml.	Excess 0.1 *N* $K_2H_3IO_6$, ml.	5 *N* H_2SO_4, ml.	Time of heating, min.	Error bromine, mg.
1	0.3599		4.56	25	45	−0.1
2	.3600		4.54	20	55	.0
3	.3607		4.45	20	65	+ .1
4	.3401		7.48	10	90	− .6
5	.3038		11.86	10	95	+ .2
6	.2560		17.84	10	80	+ .3
7	.2001		24.84	10	55	+ .3
8[a]	.2211		22.25	18.5	150	.0
9	.3633	5	4.42	10	100	− .5
10	.3632	5	4.35	10	105	− .1
11	.3638	5	4.30	10	120	.0
12	.3621	10	4.33	10	120	+1.2
13	.3617	25	4.15	10	120	+3.1

[a] Reaction volume was 100 ml. except 300 ml. in No. 8.

Each milliliter of 0.1 *N* periodate is equivalent to 0.00792 g. of bromine.

Any considerable amount of chloride interferes but, as shown in the results of Table III, by using low acidity and a prolonged bubbling, separation from a millimole or less of chloride may be effected.

Summary

1. Potassium metaperiodate, KIO_4, can be purified readily so as to have the theoretical composition and may be used as a primary standard in iodimetry.

2. Dipotassium paraperiodate in a slightly alkaline solution, and sodium metaperiodate acidified with sulfuric acid are both stable volumetric solutions, the latter showing remarkable permanency. Metaperiodates in neutral solution decompose with noticeable rapidity.

3. Iodide may be determined in the presence of bromide, chloride, and other substances not oxidized by neutral periodate solution by oxidation to iodate with standard periodate, and titration of the excess of the latter with arsenious acid. Conditions required for a rapid reaction are shown.

4. Bromide may be determined in presence of small amounts of chloride by oxidation to bromine with standard periodate in slightly acid solution, expulsion of the bromine, and titration of the excess periodate.

The Electron Diffraction Investigation of the Molecular Structures of Hydrogen Disulfide, Dimethyl Disulfide and Sulfur Dichloride

BY D. P. STEVENSON AND J. Y. BEACH[1]

We have investigated the structure of the gas molecules of hydrogen disulfide, dimethyl disulfide and sulfur dichloride by the electron diffraction method. The apparatus has been described elsewhere.[2] The electron wave length was 0.0590 Å., determined from transmission pictures of gold foil (*a* = 4.070 Å.). The distance from the gas nozzle to the photographic plate was 12.19 cm. The photographs were interpreted by the visual method.[3] The radial distribution method[4] and a modification[5] of the radial distribution method also were used.

Hydrogen Disulfide.—The hydrogen disulfide was prepared according to Vanino.[6] The compound was clear and colorless. The photographs were taken within an hour after the compound was made. After standing for several days at room temperature the hydrogen disulfide turned yellow. A few semiquantitative measurements of the vapor

pressure agreed with the values reported by Butler and Maass.[7] This eliminated H_2S as a possible impurity. The only other possible impurity, hydrogen trisulfide, melts at −52°. As the melting point of our preparations was less than −80° (the melting point of hydrogen disulfide is −89°),[6] not much hydrogen trisulfide could have been present. The photographs were taken with the sample at about 33°. Even if some hydrogen trisulfide had been present in our sample, because of its low vapor pressure the amount of it in the vapor phase would have been small as compared with the amount of hydrogen disulfide.

The photographs of hydrogen disulfide show six evenly spaced maxima and minima. The intensities of the maxima drop off uniformly from the first to the sixth. The observed values of s [$s_{\text{obsd.}} = (4\pi \sin \Theta/2)/\lambda$] for the maxima and minima and the visually estimated intensities of the maxima are tabulated in Table I.

Results: S–S = 2.04 Å.
H–S = 1.33 Å. (assumed)
H–S–S = 95° (assumed)

The radial distribution function obtained by treating these data by the ordinary distribution method[4] is shown in Fig. 1, curve A. The modified radial distribution function[5] is shown in Fig. 1, curve B. The ordinary radial distribution function shows a peak at 2.04 Å. representing the sulfur–sulfur distance. The modified radial distribution function shows a sulfur–sulfur peak at 2.06 Å. and a small peak at 1.36 Å., at about the expected hydrogen–sulfur distance. Knowing the sulfur–sulfur distance to be about 2.05 Å., we assume 1.33/2.08 for the ratio of the hydrogen–sulfur distance to the sulfur–sulfur distance in calculating the theoretical curve. 2.08 Å. is the radius table[8] value for the sulfur–sulfur single bond distance. The H–S–S angle was assumed to be 95°. The theoretical curve is shown in Fig. 2, curve A. The effect of the hydrogen–sulfur terms on the theoretical intensity curve is negligible. Accordingly no attempt was made to locate the hydrogen atoms. Quantitative comparison of the photographs with the theoretical intensity curve is made in Table I. The sulfur–sulfur distance is 2.04 Å. Averaging the three sulfur distances, 2.04, 2.06 and 2.04 Å., obtained from the radial distribution functions and the visual method gives a final value of 2.05 ± 0.02 Å. for the sulfur–sulfur distance in hydrogen disulfide.

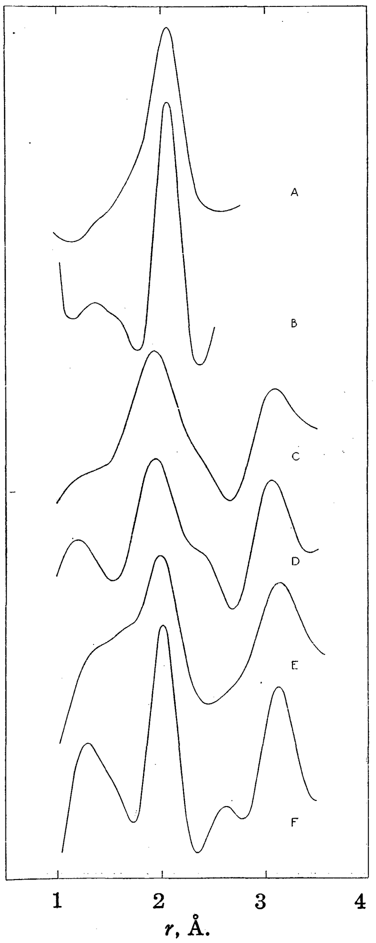

Fig. 1.—Radial distribution functions: Curve A, ordinary for H_2S_2; Curve B, modified for H_2S_2; Curve C, ordinary for $(CH_3)_2S_2$; Curve D, modified for $(CH_3)_2S_2$; Curve E, ordinary for SCl_2; Curve F, modified for SCl_2.

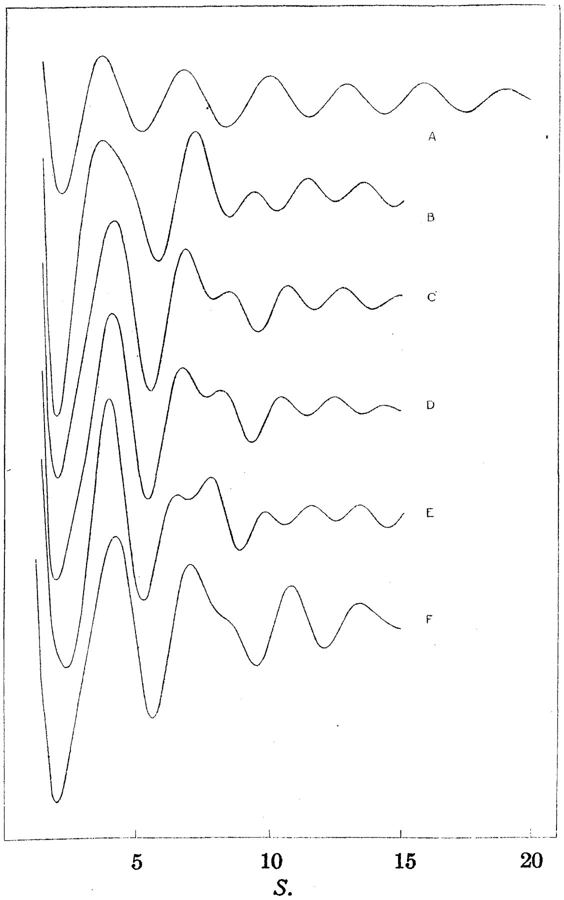

Fig. 2.—Theoretical intensity curves for H_2S_2 and $(CH_3)_2S_2$: Curve A, H_2S_2; Curve B, $[(CH_3)_2S_2]$, $\rho = 2.08/1.81$, $\alpha = 95°$; Curve C, $\rho = 2.08/1.81$, $\alpha = 105°$; Curve D, $\rho = 2.08/1.81$, $\alpha = 110°$; Curve E, $\rho = 2.08/1.81$, $\alpha = 120°$; Curve F, $\rho = 2.00/1.81$, $\alpha = 105°$.

Dimethyl Disulfide.—The method of Price and Twiss[9] for preparing disulfides was modified slightly according to the suggestions of Westlake.[10] In order to obtain the dimethyl disulfide one mole of methyl iodide and one mole of sodium thiosulfate were refluxed for an hour in an equal volume mixture of methyl alcohol and water. After cooling, potassium triiodide solution was added slowly with shaking until a faint iodine color remained for three minutes after addition. (Heat was applied near the end of the reaction in order to increase the rate.) Sodium sulfite was added to remove the excess iodine and the dimethyl disulfide was distilled out of the mixture along with water, methyl alcohol and some methyl sulfide. The dimethyl disulfide was salted out of the distillate, and distilled twice at atmospheric pressure. The boiling point (uncorr.) was 109°. Although the freshly distilled product was colorless, it developed a yellow color upon standing for a few hours, apparently losing dimethyl sulfide. The photographs were taken with the sample at 70° immediately after pumping off at room temperature any dimethyl sulfide which had formed after the distillation.

The photographs show five measurable maxima. The first two maxima are of roughly equal intensity. The third appears as a shelf on the second maximum. The fourth and fifth maxima are well defined but less intense than the first two maxima. The fourth is stronger than the fifth. The observed values of s are given in Table II, along with the intensities. The ordinary and modified radial distribution functions are shown in Fig. 1, curves C and D, respectively. Both radial distribution curves have maxima at 1.94 ± 0.01 Å. This is intermediate between a carbon–sulfur distance of 1.81 Å. and a sulfur–sulfur distance of about 2.06 Å. The two distances are not resolved. The peak at 3.08 Å. is due to the long carbon–sulfur distance. The sulfur–sulfur distance is more important in the scattering formula than the two equal carbon–sulfur distances so the peak at 1.94 Å. should be somewhat nearer the sulfur–sulfur distance than the carbon–sulfur distance. The carbon–sulfur single bond distance from the radius table[8] is 1.81 Å. The sulfur–sulfur distance then is about 2.05 Å. Later in the paper, in discussing hydrogen disulfide, we show that a sulfur–sulfur distance of about 2.05 Å. in a disulfide precludes the possibility that the molecule is pyramidal. We shall now proceed to determine more accurately the bond distances and angles of the chain molecule. The theo-

(10) Westlake, private communication.

retical intensity curve for the *trans* configuration of the molecule is indistinguishable from the theoretical intensity curve for the same molecule with free internal rotation. No attempt was made, therefore, to determine the freedom of rotation by electron diffraction, and all theoretical intensity curves were calculated for *trans* molecules. Assuming a ratio $\rho = 2.08/1.81$ for the ratio of the sulfur–sulfur to the carbon–sulfur distance we have calculated intensity curves for values of the C–S–S angle, α, equal to 95, 100, 105, 110 and 120°. These curves are shown in Fig. 2. When α is less than 105° the calculated curves are unsatisfactory in that the third maximum is not high enough on the second maximum. When ρ is greater than 105° the third maximum is too high. When ρ is decreased to 2.00/1.81 the third maximum drops in intensity. The curve for $\rho = 2.00/1.81$, $\alpha = 105$ is shown in Fig. 2. Quantitative comparison of photographs with the curve calculated for $\rho = 2.08/1.81$, $\alpha = 105°$ is given in Table II. Because there are two parameters ρ and α as well as the internal rotation and absolute size of the molecule a slightly greater probable error than usual is placed on the results. The final results obtained from the visual method and the radial distribution method are: S–S = 2.04 ± 0.03 Å., C–S = 1.78 ± 0.03 Å., C–S–S = 107 ± 3°.

Sulfur Dichloride.—The sulfur dichloride was prepared by passing excess chlorine into sulfur monochloride in the presence of a small quantity of iodine. The resulting mixture was fractionally distilled through a 30-inch (76-cm.) column. The fraction boiling between 59 and 60° was collected and again distilled immediately before the pictures were taken. Pictures were taken of a sample which boiled between 59 and 59.5° (uncorr.). The pictures were taken with the sample at about 15° within half an hour after the final distillation. Any chlorine which might have been formed after distillation by the slow reaction

$$2SCl = Cl_2 + S_2Cl_2$$

was pumped off a few seconds before the exposures were made.

The photographs show six fairly evenly spaced maxima, the intensities of which decrease uniformly from the first to the sixth. The fourth maximum is rather broad. The s values of the maxima and minima and the visually estimated intensities of the maxima are tabulated in Table III. The ordinary radial distribution function has maxima at 1.98 and 3.13 Å. The modified radial distribution function has maxima at 2.01 and 3.12 Å. The first peak at 2.00 Å. represents the sulfur–chlorine distance. The second peak is the chlorine–chlorine distance. These distances lead to a Cl–S–Cl angle of 103°. The theoretical intensity curves are shown in Fig. 3. There is only one shape parameter, the Cl–S–Cl angle. When the angle is equal to 100° or less the fourth maximum is too sharp on the theoretically calculated curves. When the angle is 110° the third maximum on the calculated curve is too high. The 120° curve is unsatisfactory because the fourth maximum is too sharp. Quantitative comparison of the photographs with the 102° 30′ and the 105° calculated curves is made in Table III. The final results are: S–Cl = 2.00 ± 0.02 Å. and Cl–S–Cl = 103 ± 2°.

Discussion.—The electron diffraction data on hydrogen disulfide do not show directly whether the two hydrogen atoms are on the same or different sulfur atoms. However, from the sulfur–sulfur distance it is possible to give the answer to this question. If the hydrogen atoms are on adjacent sulfur atoms the sulfur–sulfur bond is a single bond and would be expected to have the single-bond interatomic distance. The sulfur–sulfur single-bond distance has been observed in rhombic sulfur[11] to be 2.12 Å. Pauling and Huggins[12] from a study of interatomic distances decide that the most probable sulfur–sulfur single bond distance is 2.08 Å. If the two hydrogen atoms are on the same sulfur atom the sulfur–

[11] Warren and Burwell, *J. Chem. Phys.*, **3**, 6 (1935).

[12] Pauling and Huggins, *Z. Krist.*, **87A**, 205 (1934).

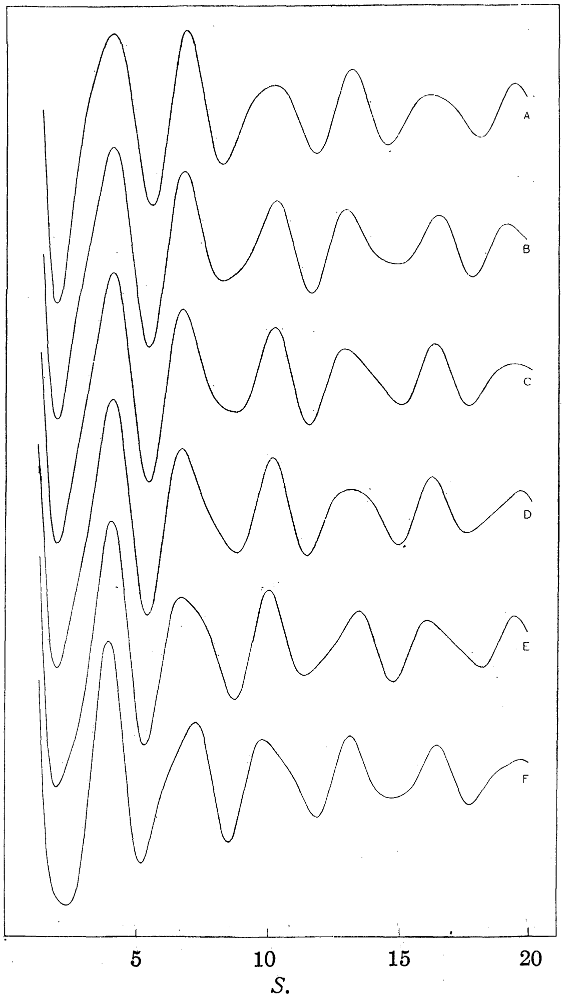

Fig. 3.—Theoretical intensity curves for SCl_2: Curve A, $\alpha = 95°$; Curve B, $\alpha = 100°$; Curve C, $\alpha = 102° 30'$; Curve D, $\alpha = 105°$; Curve E, $\alpha = 110°$; Curve F, $\alpha = 120°$.

sulfur bond will be a semipolar or dative bond. The interatomic distance for this type of bond has been observed in the case of several phosphates[13] and sulfates[14] to be about the double bond value. Electron diffraction work on $PSCl_3$,[2] $POCl_3$,[15] etc., has shown the interatomic distance for semipolar double bonds to be about the double bond value. The cause for this has been discussed.[2] The double bond sulfur–sulfur distance is 1.90 Å.[8]

The observed distance in hydrogen disulfide is 2.05 ± 0.02 Å. This is practically identical with the single bond distance, 2.08 Å. We conclude, therefore, that the hydrogen disulfide molecule is a chain molecule, the two hydrogens being on adjacent sulfur atoms. Butler and Maass[7] from a study of the refractivity and parachor of hydrogen sulfide and hydrogen disulfide have reached the same conclusion.

In treating the electron diffraction data for dimethyl disulfide we did not calculate theoretical intensity curves for pyramidal models (both methyl groups on the same sulfur atom) because of the radial distribution function. If the molecule were pyramidal the first peak on the radial distribution function would have been at about 1.86 Å. instead of at 1.94 Å., because of the shorter sulfur–sulfur distance for the pyramidal model. Accordingly theoretical intensity curves were only calculated for chain models. The sulfur bond angle of 107° in dimethyl disulfide is about the same as the angle observed for sulfur[11] (105°). The carbon–sulfur distance (1.78 ± 0.03 Å.) is equal to the radius table value (1.81) for the carbon–sulfur single bond within the experimental error. Brockway and Jenkins[16] have found 1.82 ± 0.03 Å. for the carbon–sulfur distance in dimethyl sulfide. The sulfur–chlorine distance in sulfur dichloride (2.00 + 0.02 Å.) seems slightly less than the radius table value (2.03 Å.). This effect for similar compounds has been discussed.[16]

Summary

The molecular structures of hydrogen disulfide, dimethyl disulfide and sulfur dichloride have been investigated by the method of electron diffraction. Hydrogen disulfide and dimethyl disulfide are chain molecules. In hydrogen disulfide the S–S distance is 2.05 ± 0.02 Å. In dimethyl disulfide the S–S distance is 2.04 ± 0.03 Å., the C–S distance is 1.78 ± 0.03 Å. and the C–S–S angle is 107 ± 3°. Sulfur dichloride is a bent molecule. The S–Cl distance is 2.00 ± 0.02 Å., the Cl–S–Cl angle is 103 ± 3°.

The Conductivities of Electrolytes in Anhydrous Acetic Acid*

BY BRUCE V. WEIDNER,[1] A. WITT HUTCHISON AND G. C. CHANDLEE

The recent contributions of Kraus, Fuoss and co-workers[2] on "The Properties of Electrolytic Solutions" have furnished the first satisfactory explanation of the unusual conductance phenomena exhibited by solutions of electrolytes in solvents with low dielectric constants. Since considerable interest has been shown in recent years in the properties of solutions in anhydrous acetic acid, which has a low dielectric constant,[3] $\epsilon = 6.25$, it was thought that additional studies[4] of conductivities in this solvent might prove of value especially in view of the above contributions.

In the present investigation conductance data have been obtained for solutions of certain quaternary ammonium salts, the chlorides and nitrates of the alkali metals and sodium acetate.

Experimental

The bridge assembly, thermostat and cells, as well as the method of purification of the solvent, were described previously.[4b] The specific conductivity of the acid used in the preparation of the solutions varied from 0.37 to 0.70 × 10^{-8} mho at 25°. Recently acid with a specific conductivity as low as 0.18 × 10^{-8} mho was obtained in quantity in this way.

Lithium chloride was prepared by the method of Richards and Willard.[5]

The chlorides of sodium, potassium and ammonium and the nitrates of lithium, sodium, potassium and cesium were purified by three recrystallizations of C. P. reagents from conductivity water and dried in an oven at 120° for three days.

Sodium acetate was prepared by the method of Davidson and McAllister.[6]

The quaternary ammonium compounds[7] were prepared by passing the corresponding halide into an alcoholic solution of trimethylamine. The second crop of crystals obtained from these solutions was then twice recrystallized from pure methyl alcohol and heated to constant weight at 120°.

The stronger solutions were made by adding weighed amounts of the dry salt to a known weight of pure acetic acid. The solutions of low concentration were obtained by dilution.

Discussion of Results

The experimental results are given in Tables I to XII. The concentrations are expressed in moles per liter. In calculating the equivalent conductances no solvent correction was applied.[8] The specific conductivity of the solvent is that measured at the completion of each dilution run. The starred values are for *k*-solvent varying between 0.40 and 0.70 × 10^{-8} mho. In each case at least two different samples of the solution were measured. In addition, duplicate dilution runs were made for several of the electrolytes. These results were in very good agreement with the data listed here but were omitted in order to conserve space.

A comparison with the results of Kolthoff and Willman[4a] is possible in the case of the sodium acetate and lithium chloride solutions. The data for sodium acetate are in satisfactory agreement but those obtained for lithium chloride in the present work are definitely higher. These differences might be due to a difference in the method of the preparation of the salt. Two separate preparations of lithium chloride were studied in the present work and the data obtained were in excellent agreement.

An examination of curves in which values of Λ were plotted against $\sqrt{c}$ indicated them to be of the type previously described[8] for solutions in solvents of low dielectric constants. In the dilute range the slope of such curves is chiefly determined by the ion pair equilibrium.[9] In the more concentrated solutions the effect of triple ion formation[10] is evident. The data for tetramethyl-

[7] All the quaternary ammonium compounds were very kindly prepared by Mr. J. H. Jones of this Laboratory.

[8] Application of a solvent conductance correction showed a curvature in the log Λ *vs.* log *c* plots which seemed anomalous and also gave somewhat less satisfactory agreement with what might be expected from Walden's rule. Furthermore, some uncertainty exists regarding the nature of the solvent conductance. In view of these considerations it seemed best not to make a correction.

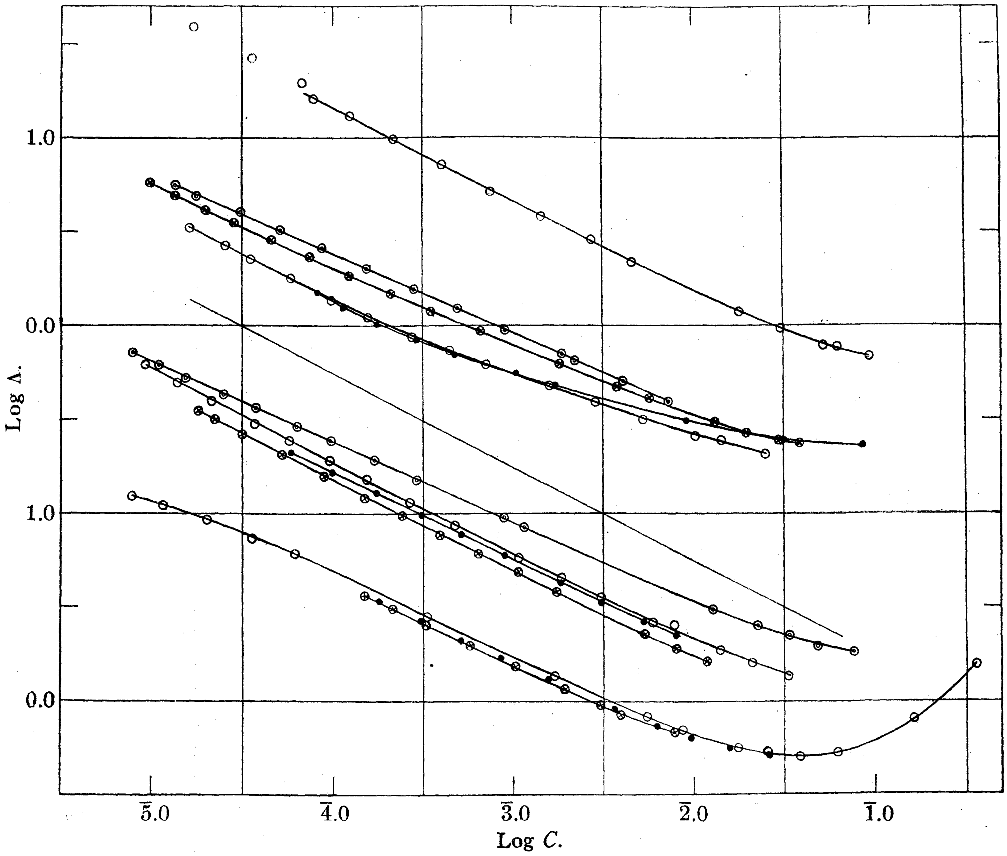

Fig. 1.—The ordinates have unit value. In plotting, the second and third groups of curves and the upper simple curve have been displaced by 1, 2 and 3 units, respectively. The straight line has a slope of $-1/2$. In the first group: ○, tetramethylammonium chloride; ⊗, tetramethylammonium bromide; and ●, trimethyl-*n*-butylammonium bromide. The second group are for the chlorides: ⊙, lithium; ○, potassium; ⊗, sodium; and ●, ammonium. The third group are nitrates: ⊙, cesium; ⊗, potassium; ●, lithium; and ○, sodium. The top curve is for sodium acetate.

ammonium chloride solutions show a distinct minimum due to this effect while in the case of the other substances investigated it is apparent that, though not reached, a minimum is being approached. More concentrated solutions were not investigated because of solubility limitations in the case of several of the materials used. Plots of log Λ against log *C*, Fig. 1, gave nearly straight lines indicative of small values for the ion pair dissociation constant.[9,11]

The limiting equivalent conductances and the ion pair dissociation constants for several of the salts were evaluated by the methods of Kraus and Fuoss.[2] Unfortunately these calculations must be based on the data obtained in the more dilute solutions where considerable uncertainty exists regarding the influence of the solvent conductances in the case of acetic acid. Because of this difficulty the numerical values obtained are of doubtful significance. The results, however, were in reasonable accord with the general predictions of the theory.

We wish to acknowledge the kindness of Professor C. A. Kraus in discussing with us certain points in regard to the interpretation of these data.

Summary

The specific conductances of a number of uni-univalent electrolytes have been determined in dilute solutions in acetic acid with a specific conductivity varying from 0.37 to 0.70 × 10^{-8} mho at 25°.

5,5-Crotyl Alkyl Barbituric Acids[1]

BY WILBUR J. DORAN AND H. A. SHONLE

A recent report from this Laboratory described a series of barbituric acids containing the unsaturated 2-methylallyl.[2] Since some of these derivatives produced an anesthesia of brief duration, we believed that the isomeric 5,5-crotyl alkyl and 5,5-(1-methylallyl) alkyl barbituric acids might also be of short duration.

Crotyl substituted barbituric acids described in the literature are 5,5-dicrotyl,[3] 5,5-crotyl allyl[4] and, since the preparation of the barbituric acids herein described was completed, 5,5-crotyl isopropyl[5] and 5,5-crotyl isobutyl barbituric acids.[5]

A representative group of 5,5-crotyl alkyl barbituric acids, prepared by treating the sodium salts of 5-monoalkyl barbituric acids with crotyl bromide, is described in this paper. The treatment of 5-monoethyl barbituric acid with crotyl bromide gave two 5,5-crotyl ethyl barbituric acids, which we believe to be the *cis* and *trans* isomers. Our crotyl isopropyl and crotyl isobutyl barbituric acids differ in melting points from those described in the I. G. Farbenindustrie patent.[5] These may also be cases of *cis* and *trans* isomers.

A barbituric acid containing the isomeric 1-methylallyl group in the 5-position, and a 2-crotyl thiobarbituric acid were included in this study.

Pharmacological results, in Table I, give the minimum anesthetic dose (M. A. D.), the minimum lethal dose (M. L. D.) and the average duration of anesthesia determined by the intraperitoneal administration of dilute solutions of the sodium salts of the barbituric acids in white rats. With few exceptions the 5,5-crotyl alkyl barbituric acids produce an anesthesia of shorter duration than the isomeric 2-methylallyl barbituric acids. 5,5-(1-Methylallyl) ethyl barbituric acid has a duration of anesthesia twice as long as that of the isomeric *cis*- and *trans*-crotyl ethyl barbituric acids, while 5-*n*-butyl 2-crotyl thiobarbituric acid produced only convulsant effect.

Experimental

The crotyl alkyl barbituric acids were prepared either by condensing the crotyl alkyl ethyl malonate with urea, or by condensing crotyl bromide with the alkyl barbituric acid, using the usual procedure for the introduction of the allyl group.

Since the action of phosphorus tribromide on crotyl alcohol produces an equilibrium mixture of crotyl and 1-methylallyl bromide (consisting of 87% of the primary isomer), it is necessary to separate these isomers by distillation procedures just prior to use.[6] Instead of using vacuum, we used atmospheric pressure for the fractionation of the crotyl bromide from this isomeric mixture. Fractionating 222 g. through a 30-cm. Widmer column during a period of two hours, we obtained as a final fraction 31.5 g. boiling at 106–108° (uncorr.) and possessing $n^{25}\text{D}$ 1.47936. It was therefore almost pure crotyl bromide.

FRACTIONATION OF 222 G. OF AN ISOMERIC MIXTURE OF CROTYL BROMIDE

Fraction	B. p., °C. (uncorr.)	Wt., g.	$n^{25}\text{D}$	% crotyl bromide
1	98–100	8.8	1.46228	11.0

3	101–103	30.0	1.47218	61.5
4	103–105	33.8	1.47479	75.0
5	105–103	41.6	1.47677	86.5
6	105–106	36.3	1.47872	96.0
7	106–108	31.5	1.47936	99.5
8 Residue		10.0		
		217.3		

1-Methylallyl bromide was obtained from the equilibrium mixture of crotyl and 1-methylallyl bromides by slow fractionation through a long column at atmospheric pressure.[6] The fraction boiling at 88–90° which was used contained less than 10% of the primary bromide.

To dilute alcoholic solutions of the sodium salts of the various pure monosubstituted barbituric acids, were added molecular proportions of the freshly distilled crotyl bromide. In some instances a small amount of a copper salt was added. The reaction was completed usually after several hours of warming. The crude 5,5-crotyl alkyl barbituric acids which separated at the end of the reaction, after the alcohol solvent was removed under vacuum, were dissolved in chloroform and were freed from unreacted 5-mono alkyl barbituric acids by extracting with dilute sodium bicarbonate solution. The disubstituted barbituric acids were freed from chloroform and then recrystallized from dilute alcohol until a constant melting point was obtained.

In the case of 5,5-crotyl ethyl barbituric acid two fractions were obtained on recrystallizing from dilute alcohol, each of which had a constant melting point. The final purification of the lower melting isomer was effected by

Ethyl 1-methylallyl barbituric acid had a M. A. D. of 125 mg./kg. and a M. L. D. of 175 mg./kg. The average duration of M. A. D. was seven hundred and twenty minutes.

[a] Anschütz thermometer used. [b] British Patent 475,948 gives a melting point of 137–138° for 1-methylethyl crotyl barbituric acid and 115° for 2-methylpropyl crotyl barbituric acid. [c] Also obtained in a hydrated form melting at 88–90°, calcd. for $C_{13}H_{20}N_2O_3 \cdot H_2O$: N, 10.37%; found: N, 10.58 and 10.65%.

recrystallization from hot water. That these are isomeric crotyl ethyl barbituric acids and not a mixture of crotyl ethyl and 1-methylallyl ethyl barbituric acids was proved by the catalytic hydrogenation of each isomer. Using Adams platinum catalyst, each isomer, after reduction, gave butyl ethyl barbituric acids which had identical melting points, and which showed no depression in melting point when mixed with each other or when mixed with a known sample of *n*-butyl ethyl barbituric acid. From this it is evident that they were isomeric crotyl ethyl barbituric acids, presumably of the *cis–trans* type. Some evidences of similar isomers were obtained with some of the other barbituric acids, but the amounts were so small that products of constant melting point were not obtained.

1-Methylallyl bromide, obtained as described above, was added immediately to a solution of a molecular amount of sodium ethylate and ethyl ethylmalonate in absolute alcohol. The solution was kept cold during the addition. It was then stoppered and allowed to come to room temperature and to stand at room temperature for two days. It was desired to avoid the use of heat during this reaction, because of the rapid isomerization rate of 1-methylallyl bromide. The crude 1-methylallyl ethyl ethyl malonate was freed from alcohol and sodium bromide, dried, and fractionated under vacuum. Two fractions were obtained, the first being 1-methylallyl ethyl ethyl malonate, boiling at about 104–108° (uncorr.) at 6 mm. and possessing $n^{25}\mathrm{D}$ 1.4333, and the second, crotyl ethyl ethyl malonate, boiling at 114–118° (uncorr.) at 6 mm. and possessing $n^{25}\mathrm{D}$ 1.4390. The identification of these malonic esters was established from the structures of the barbituric acids obtained by condensing the esters in the usual manner with urea in the presence of sodium ethylate.

The lower boiling ester gave a barbituric acid which melted at 146.5–148.0°. The anal. calcd. for $C_{10}H_{14}O_3N_2$: N, 13.34; found: N, 13.36 and 13.16. When it was reduced catalytically using Adams catalyst, a reduced barbituric acid was obtained which after crystallization melted at 165.5–166.0°. Since there was no depression of the melting point when mixed with a known sample of 5,5-secondary butyl ethyl barbituric acid, it was evident that we originally had 5,5-(1-methylallyl) ethyl barbituric acid. Crystals of the two forms of crotyl ethyl barbituric acid melting at 107° and 118–119° were obtained when the higher boiling ester fraction was condensed with urea.

5,5-Crotyl *n*-propyl, 5,5-crotyl 1-methylethyl, 5,5-crotyl *n*-butyl, 5,5-crotyl 1-methylpropyl, 5,5-crotyl 2-methylpropyl, 5,5-crotyl 1-methylbutyl, and 5,5-crotyl 3-methylbutyl barbituric acids were prepared by treating freshly fractionated crotyl bromide with the sodium salt of the appropriate monosubstituted barbituric acid.

5,5-Crotyl 1-methylbutyl barbituric acid was also prepared from urea and crotyl 1-methylbutyl ethyl malonate, which was prepared by condensing crotyl bromide with 1-methylbutyl ethylmalonate in the presence of sodium ethylate. Crotyl 1-methylbutyl ethyl malonate boiled at 140–145° (uncorr.) at 10 mm. and possessed $n^{25}\mathrm{D}$ 1.4450.

A solution of the sodium salt of 5-*n*-butyl thiobarbituric acid was treated with crotyl bromide with the expectation of obtaining 5,5-*n*-butyl crotyl thiobarbituric acid. After several hours of refluxing, part of the alcohol was taken off under vacuum and the reaction product filtered off and washed with sodium bicarbonate solution. The resulting disubstituted thiobarbituric acid was purified by several recrystallizations from dilute alcohol and had a melting point of 238–239°. The anal. calcd. for $C_{12}H_{18}N_2O_2S$: N, 11.02; found: N, 11.09 and 11.14.

Since the injection of a sodium salt of this thiobarbituric acid produced only convulsions, the possibility of substitution on an atom other than the methylene carbon had to be considered.

A portion of the *n*-butyl crotyl thiobarbituric acid was refluxed for about twenty hours in dilute alcoholic hydrochloric acid solution. The alcohol was evaporated off and the residue filtered off and recrystallized from dilute alcohol. A product melting at 203–205° (uncorr.) was obtained. When it was mixed with 5-*n*-butyl barbituric acid (m. p. 204–207°, uncorr.) there was no depression of the melting point. From these facts, it was evident that the crotyl group was attached to the sulfur and that the disubstituted thiobarbituric acid melting at 238–239° was 5-*n*-butyl 2-crotyl thiobarbituric acid.

The reaction of crotyl bromide with 5-*n*-butyl thiobarbituric acid is therefore different from its reaction with 5-*n*-butyl barbituric acid.

A similar reaction had been reported previously for alkyl, allyl and benzyl halides and 5-methyl thiobarbituric acid.[7]

Table I covers some of the physical properties of the

crotyl alkyl barbituric acids described and includes a brief summary of their pharmacological response.

Summary

Crotyl ethyl, crotyl 1-methylbutyl and 1-methylallyl ethyl ethyl malonates have been prepared and characterized. A series of eight crotyl alkyl barbituric acids has been prepared, and some of their physical and pharmacological properties are described. Also 5,5-(1-methylallyl) ethyl barbituric acid and 5-*n*-butyl-2-crotyl thiobarbituric acids have been prepared and pharmacologically studied.

The presence of *cis–trans* isomers has been observed in 5,5-crotyl alkyl barbituric acids.

The Preparation of Acetylenic Carbinols[1]

BY KENNETH N. CAMPBELL, BARBARA K. CAMPBELL AND LAWRENCE T. EBY

Acetylenic alcohols have been prepared, in general, through the Grignard reaction[2] or by condensing an acetylene with an aldehyde or ketone in an anhydrous solvent such as ether. In some cases the latter reaction has been carried out using the sodium derivative of the acetylene,[3] in others the sodium enolate of the carbonyl compounds has been used,[4] while in still other cases use has been made of condensing agents such as sodamide,[5a] potassium *t*-butylate[5b] and potassium hydroxide.[5c] None of these methods is entirely satisfactory.

Since large amounts of acetylenic alcohols were needed for other work, we investigated the preparation of these alcohols from sodium acetylide and a carbonyl compound, using liquid ammonia as a solvent. Such a method would have considerable advantages over the older methods in simplicity and ease of manipulation. At the time this work was started, there was but one reference in the literature to the use of liquid ammonia as a solvent for the reaction.[6] Later, McGrew and Adams[7] reported the preparation of ethynylethylcarbinol by a method similar to ours, and a recent series of patents[8] describes the preparation of some acetylenic carbinols in liquid ammonia solution.

We have shown that sodium acetylide in liquid ammonia will condense with many aldehydes and ketones to give the corresponding carbinols in good yields (see Table I) and the method is a general one. Comparatively small amounts of the glycols, formed by the condensation of two molecules of the carbonyl compound with one of acetylene, were obtained. The yield of the acetylenic carbinols can be increased, and that of the glycol decreased, by passing acetylene gas into the mixture during the entire course of the reaction. The reaction has been extended successfully to include the sodium derivatives of monoalkyl acetylenes. Several of the carbinols prepared in this work have not been described before. These include: 1-phenyl-3-propyn-1-ol, 3-methyl-4-nonyn-3-ol, 4-methyl-5-decyn-4-ol, 4-nonyn-3-ol and 4-methyl-5-undecyn-4-ol.

In the case of methylethylethynylcarbinol, this method of preparation was compared with others. The liquid ammonia method was found to be the most satisfactory, as it gave better yields and was carried out more easily. Although a direct comparison of methods was not carried out in other cases, the short time required, and the ease of manipulation, in the liquid ammonia method would seem to make it preferable even if, in certain cases, other methods gave better yields.

The condensation of sodium acetylide with a carbonyl compound does not seem to involve an enol form of the latter, since benzophenone and benzaldehyde will undergo the reaction. The following mechanism is suggested to explain the glycol formation, and the effect of excess acetylene gas.

$$HC\equiv CNa + R\text{—}\underset{\underset{O}{\|}}{C}\text{—}R' \longrightarrow$$

The preparation of the chloride from methylethylethynylcarbinol was investigated in some detail. Gaseous hydrogen chloride at 0° reacted only slightly with the alcohol, and little or no chloride was formed. Phosphorus trichloride in pyridine gave the chloride in fair yields, but the purification was difficult. Concentrated aqueous hydrochloric acid reacted with the carbinol at room temperature to give the chloride in about 40% yields, and purification was fairly simple. A more detailed study of the preparation and reactions of such acetylenic halides is in progress.

Experimental

Preparation of Alkylethynylcarbinols.—One mole of sodium acetylide was prepared[9] by adding 23 g. of sodium to about 1 liter of liquid ammonia, contained in a 2-liter, 3-necked round-bottomed flask fitted with a mechanical stirrer, while a rapid stream of dry acetylene was passing through the solvent. The acetylene was then shut off, and one mole of the aldehyde or ketone was added dropwise, with stirring, over a period of one hour. Stirring was continued for about three hours longer, with addition of liquid ammonia from time to time to keep the liquid level at about 1 liter. If acetylene gas is passed through the reaction mixture for the entire time, the yield of carbinol is in some cases, at least, higher and less glycol is formed. The reaction mixture may be hydrolyzed immediately, but generally the liquid ammonia was allowed to evaporate (overnight) and the resulting solid was hydrolyzed with ice and water. The hydrolysis mixture was made slightly acid, with cooling, with 50% sulfuric acid, the organic layer dissolved in ether, if viscous, washed with brine and dried over magnesium sulfate. The original aqueous layer and the wash water were extracted with ether in the case of the lower, water-soluble carbinols, and the extract added to the main product. The residue remaining after evaporation of the ether was distilled under reduced pressure through a small Vigreux column. In nearly all cases some high-boiling glycol was obtained after the carbinol had distilled over.

Preparation of Alkylalkynylcarbinols.—A liquid ammonia solution of sodamide was prepared[10] from 23 g. of sodium, 0.5 g. of ferric nitrate and 1.5 liters of liquid ammonia. To this was added 1.1 moles of alkylacetylene, dropwise, with stirring, in the course of fifteen minutes, and the mixture was stirred for an additional thirty minutes. Then 1 mole of aldehyde or ketone was added dropwise over a period of one hour. Stirring was continued for three hours and the mixture was allowed to stand overnight to evaporate the ammonia. The residue was hydrolyzed with ice and water and made slightly acid with 50% sulfuric acid. The organic layer was washed with water, dried over magnesium sulfate and distilled under reduced pressure through a small Vigreux column.

Preparation of Methylethylethynylcarbinol by Other Methods. Grignard Method.—An acetylenic Grignard reagent was prepared by treating ethylmagnesium bromide (made from 34 g. of magnesium and 166 g. of ethyl bromide) with a current of dry acetylene gas for several hours. The Grignard reagent was then cooled in an ice-bath, and a solution of 72 g. of methyl ethyl ketone in an equal volume of dry ether added over a period of three hours. The mixture was hydrolyzed and worked up in the usual way. There was obtained a 6% yield of carbinol, and a 65% yield of glycol.

Potassium *t*-Butylate Method.—The procedure of Gould and Thompson[5b] was followed. Considerable difficulty was found in purifying the product, as the *t*-butyl alcohol and the carbinol tended to distill together. A 40% yield of pure carbinol was obtained.

Sodium *t*-Butylate as Condensing Agent.—Sodium *t*-butylate was prepared by adding 23 g. of sodium to a liquid ammonia solution of 150 g. of *t*-butyl alcohol. The liquid ammonia was removed by allowing the mixture to stand overnight, and then heating it for two to three hours on a water-bath to drive off excess *t*-butyl alcohol and residual ammonia. The rest of the procedure was similar to that used with potassium *t*-butylate. A 53% yield of carbinol was obtained.

Conversion of Methylethylethynylcarbinol to the Chloride.—When 50 g. of the carbinol (b. p. 78° under 150 mm., $n^{20}\mathrm{D}$ 1.4310) was saturated at 0° with dry hydrogen chloride, the product shaken with anhydrous potassium carbonate and distilled from fresh carbonate, no halogen-containing compound was obtained, and 26 g. of the carbinol, b. p. 74–78° under 150 mm., $n^{20}\mathrm{D}$ 1.4330, was recovered.

The general procedure of Juvala[11] was tried. A mixture of 60 g. of carbinol and 11 g. of pyridine was added dropwise, with stirring, at 0°, to 33 g. of phosphorus trichloride. The liquid layer was decanted, the solid residue washed with a little dry ether and the liquid and ether combined and stored over anhydrous potassium carbonate. The material was distilled under reduced pressure through a small helix-packed column from fresh carbonate to give 20 g. of an impure chloride, b. p. 50–57° (135 mm.), $n^{20}\mathrm{D}$ 1.4330–1.4386, $d^{20}{}_4$ 0.9175.

Forty grams of the carbinol was shaken for a few minutes with 200 cc. of concentrated hydrochloric acid. The layers were separated, and the organic layer was stored in a refrigerator over anhydrous potassium carbonate. The light yellow liquid was distilled through a small helix-packed column from fresh carbonate to give 30 g. of material of b. p. 51–60° (137 mm.), $n^{20}\mathrm{D}$ 1.4328–1.4390. Refractionation of this material yielded 20 g. of chloride of b. p. 51–52° (135 mm.), $n^{20}\mathrm{D}$ 1.4328–1.4331, $d^{20}{}_4$ 0.9140, *MR*D obsd. 33.13, *MR*D calcd. 32.71.

Anal. Calcd. for C_6H_9Cl: Cl, 30.41. Found: Cl, 30.36.

[a] Acetylene gas was passed through the mixture during the entire reaction. Mr. Froning has obtained 60% yields of dimethylethynylcarbinol and 15% yields of the glycol by this method, on 5-mole runs. See J. F. Froning, Master's Dissertation, University of Notre Dame, 1938. [b] Other workers have obtained poor yields from acetophenone. See Carothers and Coffman, THIS JOURNAL, **54**, 4071 (1932).

Summary

1. A general method has been described for the preparation of acetylenic carbinols from the sodium salt of acetylene or a monoalkylacetylene, and an aldehyde or ketone, in liquid ammonia solution.
2. Several new acetylenic carbinols have been prepared and characterized.
3. The preparation of the chloride from methylethylethynylcarbinol has been described.

Relation of Refractive Index to Density in Dental Hard Tissues[1]

BY RICHARD S. MANLY[2]

In certain biological mixtures and in many mineral series, the refractive index has become valuable because it is linearly related to the density. Since in previous work[3] a number of density fractions of pure enamel and dentine had been prepared, the mean refractive indices were determined to discover any similar relations in these tissues.

The reported values for the refractive indices of enamel are in good agreement. Von Ebner[4] and Hoppe[5] report a figure of 1.627 for the ordinary ray and the former, 1.6234 for the extraordinary ray. Taylor and Sheard[6] and Eisenberg[7] noted that the refractive index of enamel prisms ranges between 1.612 and 1.625. Wishart in 1933 (personal communication) examined a few specimens of enamel and found the refractive index to be less than 1.625, usually near 1.618, but appearing to vary somewhat from that number. For two samples of normal dentine Taylor and Sheard[6] found a refractive index of 1.577 ± 0.003. No values for the refractive index of cementum have been reported.

Experimental

A "mean refractive index" was estimated by the following interpolation procedure. A few milligrams of the 60-mesh enamel or dentine powder was stirred into a drop of liquid of known refractive index and placed on a constant temperature stage under a microscope. A "sodium" filter (Eastman Kodak Co. filters nos. 64 and 73) was used over the light source. Determination of the mean refractive index, *i. e.*, the refractive index at which half the particles were higher and half lower than the liquid, was made by interpolation from the counts obtained with 3 or 4 different liquids.

[7] Eisenberg, *Am. Dental Surg.*, **50**, 225 (1930).

The counting method employed was the Becke line test.[8,9] One hundred particles were counted for each sample in various liquids. For refractive index standards, mixtures of α-chloronaphthalene ($n^{25}\text{D}$ 1.63) and liquid petrolatum ($n^{25}\text{D}$ 1.475) were prepared whose indices ranged from 1.530 to 1.630 in steps of 0.005. Calibration was made at 25 ± 0.1° with an Abbe refractometer.

Discussion

In enamel a proportionality exists between the mean density and refractive index as shown in Fig. 1. The equation is $d = 7.69\ n - 9.494 \pm 0.001$. The probable error of n is ± 0.001, which is within the variations due to birefringence.[10] Inasmuch as mineral apatites usually have refractive indices of about 1.634, the upper limit of enamel is of interest: only 0.09% of the original enamel exhibited a refractive index greater than 1.6293.

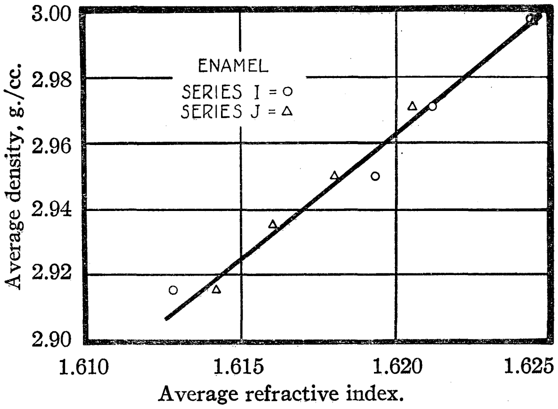

Fig. 1.—Enamel refractive index is proportional to the density.

In dentine the relation between refractive index and density is shown by the straight line in Fig. 2. The slope, 8.6, is somewhat steeper than that of enamel and the line lies 0.45 g. per cc. below the enamel curve when the latter is extrapolated to a density of 2.7. This fact suggested that the dentinal tubules were filled with air during the density and refractive index determinations. From the usual equation relating refractive index and density of a mixture[11] the volume per cent. of air, apatite, and protein in one dentine fraction (n, 1.5495; d, 2.135) was calculated. Values for density and refractive index of air, apatite and protein were taken from the literature. The calculated air space of 9 volume per cent. compares favorably with Feiler's estimation[12] of 12 to 24% tubule space. The calculated inorganic percentage was 75.0, in fair agreement with the value 78.4%, found by analysis.

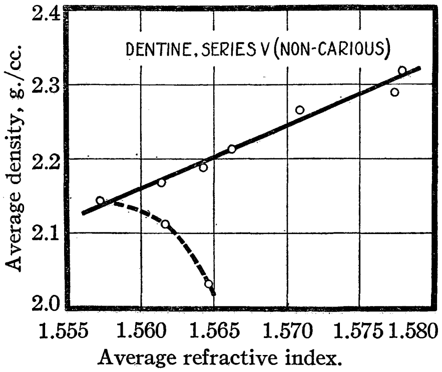

Fig. 2.—Refractive index–density relations for dentine. The two points on the dotted line are cementum.

Pulverized secondary cementum was found to have a refractive index range of 1.560 to 1.570. The two points on the dotted line of Fig. 2 are cementum, since they fall within this range and have the correct density[3] for cementum.

On vacuum drying for seven hours at 110°, an average decrease of 0.0018 was found in refractive index on six fractions of enamel. With dentine the decrease was much greater, 0.02–0.03, and the linear relationship with the original, oven-dry density was abolished. Cementum, on the other hand, behaved like enamel since the refractive index of the *oven-dry* material was decreased by only 0.001 on vacuum drying while the refractive index of *air-dry* cementum actually increased with the same treatment. As a tentative explanation for these differences in behavior, it may be assumed that neither capillary formation nor shrinkage is possible in the highly consolidated enamel, the former occurs chiefly in dentine and the latter in cementum.

A difference has been observed in the refractive index behavior of the inorganic salts of enamel and dentine. When ashed by glycol procedure[13] the refractive index of the inorganic material of dentine was 1.591–1.605, of enamel, 1.614. Heating the dentine ash or the unashed dentine for five hours at 900° raised the refractive index to 1.641–1.644, showing an essential change in structure. Enamel became opaque after five hours at

900°, making refractive index determinations impossible.

Acknowledgment.—The author is glad to acknowledge the enthusiastic counsel of Dr. Harold C. Hodge throughout the course of the work.

Summary

1. The mean refractive indices of powdered enamel and dentine samples, with differing and known density limits, were determined by the Becke line procedure.

2. The refractive indices of dried enamel lie between 1.612 and 1.630 and are proportional to the density.

3. The refractive indices of dried dentine lie between 1.555 and 1.580 and are roughly proportional to the density when the fractions are dried under the same conditions for both determinations. Vacuum drying brought about a marked lowering of refractive index.

4. Secondary cementum exhibited a refractive index of 1.560–1.570 which was little affected by vacuum drying.

The Crystal Structure of Ammonium Cadmium Chloride, NH_4CdCl_3

BY HENRI BRASSEUR[1] AND LINUS PAULING

In crystalline cadmium chloride, $CdCl_2$, there are octahedral groups $CdCl_6$ condensed into layers, each chlorine atom being adjacent to three cadmium atoms.[2] Tetrahedral coördination is shown by cadmium[3] with cyanide groups in $K_2Cd(CN)_4$, and with sulfur, selenium and tellurium atoms in the sphalerite and wurtzite type crystals CdS, CdSe and CdTe, and might well occur with chlorine also. There are accordingly two types of reasonable structures for complexes with the composition $(CdCl_3)_x$, the first involving octahedra with shared corners, as for example in the cubic crystal $KMgF_3$, and the second involving rings or chains of tetrahedra, as in the metasilicates. We have determined completely the structure of the orthorhombic crystal NH_4CdCl_3, and have found it to be based on octahedral coördination about the cadmium atoms, the $CdCl_6$ octahedra being polymerized into infinite double rutile strings which extend parallel to the *c*-axis of the crystal.

Experimental Methods and Results

The crystals of NH_4CdCl_3 used in this investigation were obtained by evaporation of an aqueous solution containing equimolar amounts of NH_4Cl and $CdCl_2$. The transparent white needles used for the x-ray photographs were about 0.1 sq. mm. in cross section and 3 to 10 mm. in length. In addition to single crystals many twins were obtained; the nature of the twinning was not studied.

Crystallographic study[4] has shown the crystals to be orthorhombic, with axial ratios 0.6059:1:0.7992 and density 2.93. X-ray photographs prepared with 15° oscillation about the directions [100], [010], and [001], with use of CuKα radiation filtered through nickel, gave the following dimensions for the unit cell

$$a_0 = 8.96 \pm 0.02 \text{ Å.}$$
$$b_0 = 14.87 \pm 0.03 \text{ Å.}$$
$$c_0 = 3.97 \pm 0.01 \text{ Å.}$$

These lead to the axial ratios 0.603:1:0.267, in good agreement with the crystallographic values, after dividing the crystallographic *c*-axis by three. All indices used in this paper refer to the X-ray axes a_0, b_0, c_0 given above.

The observed reflections show the lattice to be simple. The absence of prism reflections $\{h0l\}$ with h odd and $\{0kl\}$ with $k + l$ odd provides strong evidence that the space group is $D_{2h}^{16}-Pnam$ or its subgroup $C_{2v}^{9}-Pna$. In the absence of any observed deviation from holohedral habit of the crystals, we have assumed the space group to be D_{2h}^{16}; this assumption is given later justification by the derivation of a satisfactory atomic arrangement based on the holohedral space group.

The Atomic Arrangement

The sets of equivalent positions provided by $D_{2h}^{16}-Pnam$ are

8d: $xyz,\ \tfrac{1}{2}+x\ \tfrac{1}{2}-y\ z,\ \tfrac{1}{2}-x\ \tfrac{1}{2}+y\ \tfrac{1}{2}+z,\ \overline{xy}\ \tfrac{1}{2}+z,\ \overline{xyz},\ \tfrac{1}{2}-x\ \tfrac{1}{2}+y\ \bar{z},\ \tfrac{1}{2}+x,\ \tfrac{1}{2}-y\ \tfrac{1}{2}-z,\ xy\ \tfrac{1}{2}-z$

The unit cell contains 4 NH_4CdCl_3, the number of molecules calculated from the cell dimensions and density being 3.99. The possibility that 8 Cl occupy the positions 8d is ruled out by the small value 3.97 Å. of c_0, since the distance $c_0/2 = 1.99$ Å. between non-bonded chlorine atoms is very much less than that found in any crystal. It was noted, moreover, that the intensities of the X-ray reflections indicate strongly that all of the atoms are in planes $c_0/2$ apart. An arrangement of this type leads to the same structure factor for all the reflections ($hk0$), ($hk2$), ($hk4$), etc., and also for all the reflections ($hk1$), ($hk3$), etc.; and it was observed that on oscillation photographs the intensities of the reflections with $l = 2$ and $l = 4$ reproduce those with $l = 0$, but somewhat diminished because of the larger scattering angles, and that similarly the intensities of the reflections with $l = 3$ reproduce those with $l = 1$.

This observation requires that all of the atoms occupy the positions 4c, forming layers at $z = {}^1/_4$ and $z = {}^3/_4$. (Layers at $z = 0$ and $z = {}^1/_2$ are ruled out by the fact that positions 4a and 4b could accommodate only two of the five atoms in the molecule.)

There are ten parameters to be evaluated in the determination of the atomic arrangement: x_{NH_4}, y_{NH_4}, x_{Cd}, y_{Cd}, x_I, y_I, x_{II}, y_{II}, x_{III} and y_{III} (the subscripts I, II and III referring to the three non-equivalent sets of chlorine atoms). As the first step in this process sections of the three-dimensional Patterson-Fourier diagram[5] were made for the levels $z = 0$ and $z = {}^1/_2$, as recommended by Harker,[6] with use of the general equation

$$P(x,y,z) = \Sigma_h \Sigma_k \Sigma_l \mid F_{hkl} \mid^2 \cos 2\pi(hx + ky + lz) \quad (1)$$

The calculations could be based on the observed values of intensities of planes ($hk0$) and ($hk1$) alone, because of the intensity regularities, mentioned above, which result from the special values ${}^1/_4$ and ${}^3/_4$ for the z coördinates of all the atoms. The function f^2/Z^2 (f being the atomic scattering power and Z the atomic number) in its dependence on $\sin \theta/\lambda$ has nearly the same values for the atoms Cd, Cl, and N. An averaged function for these atoms was plotted, and summed over l for series of reflections (hkl), with l either even or odd, in order to obtain the factors with which the intensities for reflections ($hk0$) and ($hk1$) were multiplied to give the sums over l in Equation 1. The remaining double summations for $z = 0$ and $z = {}^1/_2$ were then carried out with the aid of the Beevers–Lipson strips,[7] all of the data of Table I being used. The values of $\mid F \mid$ given in the table were obtained from visually estimated intensity values by correction for the Lorentz and polarization factors, the temperature factor being ignored. Contour diagrams representing the results of the calculations are shown as Figs. 1 and 2.

products of the scattering powers of the atoms. The principal peaks expected are those for Cd–Cd and Cd–Cl. At $z = 0$ the Cd–Cd peak should occur for the two atoms at x_{Cd}, y_{Cd} $^1/_4$ and $^1/_2$ +

$x_{Cd}\ ^1/_2 - y_{Cd}\ ^1/_4$; that is, at the point $^1/_2\ ^1/_2 - 2y_{Cd}$. The most pronounced peak in Fig. 1 is in fact at $^1/_2$, 0.385, corresponding to $y_{Cd} = 0.0575$. The most pronounced peak of Fig. 2, at 0.1667, $^1/_2$, similarly corresponds to $^1/_2 - 2x_{Cd}\ ^1/_2$, and leads to the value $x_{Cd} = 0.1667$. Another Cd–Cd peak, at $2x_{Cd}2y_{Cd}$, also appears on this diagram in the position required by these parameter values.

These values of x_{Cd} and y_{Cd} can be combined with the coördinates of the remaining peaks to obtain values for the coördinates for chlorine atoms. Thus for the level $z = 0$ Cd–Cl or Cd–N peaks are expected at $x_{Cd} - x, y_{Cd} - y$; $^1/_2 + x_{Cd} - x$, $^1/_2 - y_{Cd} - y$; etc. The parameter values obtained in this way are

$$\begin{aligned} x_{I} &= 0.305 & y_{I} &= 0.219 \\ x_{II} &= .164 & y_{II} &= .505 \\ x_{III} &= .025 & y_{III} &= .893 \end{aligned}$$

In addition the ammonium ions can be assigned the parameter values $x_{NH_4} = 0.43$, $y_{NH_4} = 0.82$, inasmuch as these positions are the only ones compatible with a minimum NH_4–Cl distance of about 3.1 Å. These parameter values lead to a structure which is stereochemically satisfactory, as described below.

In order to obtain more accurate values of the parameters a section at $z = {}^1/_4$ of a three-dimensional Bragg–Fourier calculation was carried out, with use as the signs of the F's of those given by the approximate parameter values. The summation over l for the series

$$D(x,y,z) = \Sigma_h\, \Sigma_k\, \Sigma_l\, F_{hkl} \cos 2\pi(hx + ky + lz) \qquad (2)$$

was made in a way similar to that for the Patterson diagrams, namely, by summing the quantity f/Z for series of reflections (hkl) with l even or odd to obtain factors for F_{hk0} and F_{hk1}.

The Bragg–Fourier diagram at $z = {}^1/_4$, shown as Fig. 3, has a very high peak for the cadmium atom, three peaks for the three chlorine atoms, and a small peak for the ammonium ion, in positions corresponding to the following parameter values, which differ by only small amounts from the initial values:

$$\begin{aligned} x_{Cd} &= 0.165 & y_{Cd} &= 0.054 \\ x_{I} &= .284 & y_{I} &= .215 \\ x_{II} &= .167 & y_{II} &= .496 \\ x_{III} &= .026 & y_{III} &= .898 \\ x_{NH_4} &= .43 & y_{NH_4} &= .82 \end{aligned}$$

The agreement between observed and calculated amplitudes of reflection is seen from Table I to be satisfactory. Screening-constant atomic scattering factors[8] were used in the calculation of the F values.

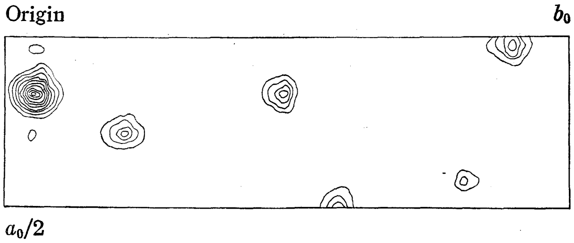

Fig. 3.—Bragg–Fourier diagram for the section $z = {}^1/_4$. The four peaks in the upper part of the diagram represent, from left to right, the atoms Cd, Cl_I, Cl_{II}, and Cl_{III}, and the two peaks below represent Cl_{II} (in part) and NH_4.

Description of the Structure

The structure found for NH_4CdCl_3 is shown in Fig. 4. Each cadmium atom is surrounded by six chlorine atoms, which form a nearly regular octahedron. The Cd–Cl distances have the values 2.60 (2), 2.62, 2.64, and 2.72 (2) Å., the average of these, 2.65 Å., being almost identical with the Cd–Cl distance in $CdCl_2$, 2.66 Å. The variation about the average is probably not real, but the result of small errors in the parameter values. The Cl–Cl distances along octahedral edges have the values 3.53 (2), 3.68 (2), 3.69 (2), 3.73 (2), 3.80 (2), and 3.97 (2) Å. Each octahedron shares two opposed edges with other octahedra to form octahedral strings parallel to the c-axis, as in the rutile structure. These rutile

TABLE II

INTERATOMIC DISTANCES IN NH_4CdCl_3

Atom	Neighbors	Distance Å.	Atom	Neighbors	Distance Å.
Cd	2 Cl_{II}	2.60	Cl_{II}	2 Cd	2.60
	1 Cl_I	2.62		2 NH_4	3.40
	1 Cl_{III}	2.64		1 NH_4	3.47
	2 Cl_{III}	2.72		1 Cl_{III}	3.53
				2 Cl_{II}	3.62

	1 Cl_{III}	3.34		2 Cl_{III}	3.80
	2 Cl_{II}	3.40		2 Cl_{II}	3.97
	1 Cl_{II}	3.47		1 Cl_I	4.30
	1 Cl_{III}	3.82		1 Cl_I	4.64
Cl_I	1 Cd	2.62	Cl_{III}	1 Cd	2.64
	4 NH_4	3.27		2 Cd	2.72
	2 Cl_{II}	3.73		1 NH_4	3.34
	2 Cl_{III}	3.76		1 NH_4	3.82
	2 Cl_{III}	3.80		1 Cl_{II}	3.53
	2 Cl_I	3.97		2 Cl_{III}	3.68
	1 Cl_{II}	4.30		2 Cl_{II}	3.69
	2 Cl_I	4.59		2 Cl_I	3.76
	1 Cl_{II}	4.64		2 Cl_I	3.80
				2 Cl_{III}	3.97

---

[8] L. Pauling and J. Sherman, *Z. Krist.*, **81**, 1 (1932).

strings are further condensed in pairs, each octahedron sharing two edges with octahedra of the adjacent string. The four shared edges are, as usual for partially ionic crystals, somewhat shorter than the unshared edges.

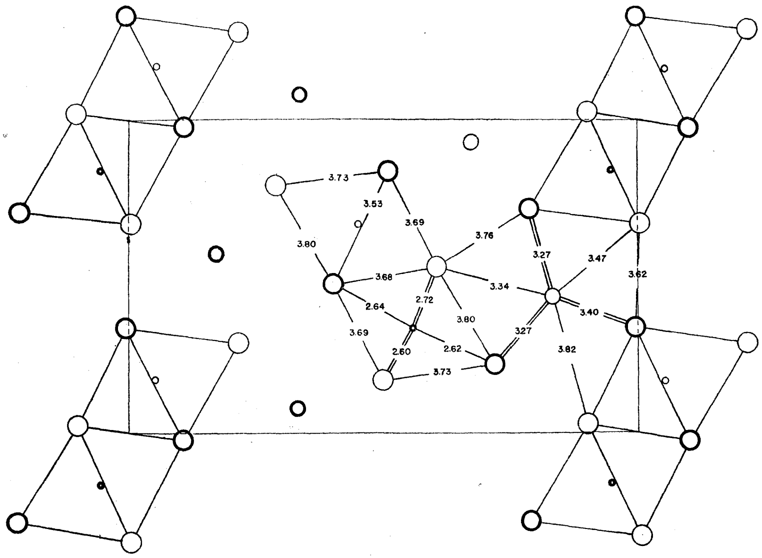

Fig. 4.—The structure of NH_4CdCl_3, projected on the plane (001). Light circles represent atoms at $z = {}^1/_4$ and heavy circles those at $z = {}^3/_4$. Cadmium and chlorine atoms are shown as small and large circles, and ammonium ions as circles of intermediate size.

Each ammonium ion is in contact with nine chlorine atoms, at about 3.27 (2), 3.27 (2), 3.34, 3.40 (2), 3.47, and 3.82 Å. The average of these distances, excluding the largest, is 3.31 Å., which is nearly the same as in NH_4Cl (NH_4–Cl = 3.27 Å. for the high temperature form, with the sodium chloride structure, and 3.34 Å. for the low temperature form, with the cesium chloride structure). The nine chlorine atoms are arranged in the most compact configuration possible for coördination number nine—a triangle of three in the equator, and smaller triangles above and below rotated through 60°. The Cl–Cl distances along the edges of this polyhedron have the values 3.62 (2), 3.69 (2), 3.73 (2), 3.76 (4), 3.80 (2), 4.30 (2), 4.59 (2), and 4.64 (2) Å.

Cleavage along planes of the zone [001] might be expected for the crystal; no cleavage has been reported, however, nor did we observe any in experiments with our small crystals.

The chlorine atoms form bonds to the following numbers:

Cl_I: 1 with Cd, 4 with NH_4
Cl_{II}: 2 with Cd, 3 with NH_4
Cl_{III}: 3 with Cd, 2 with NH_4

These have the total strengths 7/9, 1, and 11/9, respectively; there is, accordingly, some discrepancy with the electrostatic valence rule.[9] It is interesting that the substance crystallizes with this structure rather than a structure such as that of $KMgF_3$, in which the halogen atoms are equivalent, each being common to two octahedra.

The arrangement of the chlorine atoms is compact; as shown in Table II, each chlorine atom has eleven or twelve chlorine atoms as neighbors, at distances between 3.53 and 4.64 Å.

The authors are indebted to the Belgian-American Foundation for the grant of a Fellowship to one of them, permitting this investigation to be carried out.

Summary

A complete structure determination has been made of the orthorhombic crystal NH_4CdCl_3. The unit of structure has the dimensions a_0 = 8.96 ± 0.02 Å., b_0 = 14.87 ± 0.03 Å., c_0 = 3.97 ± 0.01 Å., and contains 4 NH_4CdCl_3. The atomic positions are $xy\ 1/4,\ \frac{1}{2}+x\ \frac{1}{2}-y\ 1/4,\ \frac{1}{2}-x\ \frac{1}{2}+y\ 3/4,\ \overline{xy}\ 3/4$ of the space group $D_{2h}^{16} - Pnam$, with the following parameter values x, y: Cd, 0.165, 0.054; Cl_I, 0.284, 0.215; Cl_{II}, 0.167, 0.496; Cl_{III}, 0.026, 0.898; NH_4, 0.43, 0.82.

The $CdCl_3$ complexes occur in the crystal as infinite polymers, in the form of double rutile strings of $CdCl_6$ octahedra parallel to the c-axis. These complexes are held together by ammonium ions, each of which has nine chlorine atoms coördinated about it. Interatomic distances in the crystal (Table II) are closely related to those in $CdCl_2$ and NH_4Cl.

The Inversion of Sucrose

BY PAUL M. LEININGER[1] AND MARTIN KILPATRICK

In a paper on electrolyte effects in reactions between a non-electrolyte and the hydrogen ion[2] two typical examples were given, representative of electrolyte effects in (1) reactions showing specific catalysis by the hydrogen ion, and (2) reactions showing acid catalysis in the general sense. This classification has been clarified by experiments in solutions of heavy water,[3] and by Pedersen's analysis of prototropic reactions.[4]

From an examination of the electrolyte effects it appeared that the inversion of sucrose and the hydrolysis of the acetals should be considered purely as catalysis by the hydrogen ion. Evidence of catalytic effects of acid molecules has been advanced by Hammett and Paul,[5] and by Gross, Steiner and Suess.[6] Experiments on the inversion of sucrose in acetate–acetic acid buffer solutions have shown, however, there is no detectable catalytic effect of the molecules of such a weak acid as acetic.[7]

If we are dealing with a case of specific hydrogen-ion catalysis, we can for aqueous solutions postulate the equilibrium

$$S + H_3O^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \left\{ S{\cdot}H_3O \right\}^+ \xrightarrow{k_2} \text{Products} \quad (1)$$

where $k_2 \ll k_{-1}$ and the equilibrium concentration is maintained at all times. The velocity constant is given by

$$k = \frac{k_1}{k_{-1}} k_2 = Kk_2 \quad (2)$$

Now K will vary with the electrolyte concentration, and the resulting change in the concentration of the collision complex will cause a change in the measured velocity constant k. These changes have been observed for the hydrolysis of the acetals and for the inversion of sucrose, but even in dilute solution they seem larger than one would expect, by analogy, from an examination of the change, with electrolyte concentration, of the dissociation constant of anilinium or *o*-chloroanilinium ion.[8,9]

Pedersen determined these two equilibrium constants over a convenient range of temperature, and found no great change in the heat of dissociation (ΔH) with temperature, in contrast to the marked variation of the heat of dissociation with temperature for uncharged acids. By analogy it might be expected that for reactions between a non-electrolyte and an ion, as represented by equation (1), there would be little change with temperature in E_A, the heat of activation computed from the integrated form of the Arrhenius equation

$$E_A = \frac{2.303\, RT_1T_2}{T_1 - T_2} \log \frac{k_{T_1}}{k_{T_2}} \quad (3)$$

where k_{T_1} and k_{T_2} are the velocity constants at temperatures T_1 and T_2, respectively. This seems to be the case for the hydrolysis of diethyl acetal.[2]

An examination of the extensive literature on sucrose inversion (on which some excellent experimental work has been done) yields a number of surprises. For example, in a recent number of THIS JOURNAL we have "The activation energy of 25.7 ± 0.05 kcal. found in the present work on sucrose is in good agreement with 25.83 and 25.8 kcal. obtained by others."[10] The statement ±0.05 kcal. seems hardly justified, since calculation of E_A by equation (3) over the three temperature intervals shows a variation of approximately ±1000 cal. In the same number a communication on the present study[11] calls attention to the fact that the energy of activation varies both with temperature and with concentration of hydrochloric acid. The effect of temperature was reported by Moelwyn-Hughes,[12] who showed that some of the earlier work also revealed a decrease in the activation energy with rise in temperature. The effect of electrolyte concentration on E_A calculated by a method similar to equation (3) has been independently reported by Duboux,[13]

but Duboux seems unaware of the decrease in energy of activation with increasing temperature reported by Moelwyn-Hughes. Quite recently Pearce and Thomas[14] determined the velocity constants for the inversion of sucrose in 1 molal hydrochloric acid solution in the presence of various salts, and concluded that the heat of activation was practically constant and independent of the nature of the salt. Finally, an examination of the data in the literature indicates that the velocity constant and the energy of activation are also dependent on the initial sucrose concentration.

The present paper includes a report of the work with 0.0584 molar sucrose solutions over the temperature range 0–40°, and with concentrations of hydrochloric acid up to four molar. The results obtained indicate that the literature on the sucrose inversion presents a more understandable picture when one considers the variables, electrolyte and sugar concentration, as well as temperature and concentration of catalyst.

Experimental Part

Sucrose.—Merck best reagent sucrose was used. Several duplicate runs were made with Pfanstiehl special sucrose, but no difference in velocity was observed.

Hydrochloric Acid.—Baker C. P. analyzed hydrochloric acid was used. Here again the same results were obtained with solutions prepared from constant-boiling hydrochloric acid.

Sodium Chloride.—Kahlbaum "zur Analyse mit Garantieschein" grade of sodium chloride was used.

Dilatometers.—At 0° the dilatometer used was that described by Kilpatrick,[15] except for runs lasting over two days, where sealed dilatometers were used. At all other temperatures the dilatometers used were similar to those described by Brönsted, Kilpatrick and Kilpatrick.[16]

Thermostats.—Water-baths regulated to ±0.005° were electrically heated and controlled by relay circuits of radio tube type similar to the one described by Beaver and Beaver.[17] For the experiments at 0°, ice-packed Dewar flasks, kept in a refrigerator room, served as thermostats.

Determination of Temperature.—Temperatures were determined by means of a platinum resistance thermometer, calibrated by the Bureau of Standards, and used in conjunction with a Mueller bridge. Temperature regulation was better than ±0.005° at all temperatures with the possible exception of −0.01° for the long time runs. Although the individual temperatures are given only to one hundredth of a degree, the temperature interval was measured to one thousandth of a degree. The maximum possible error in the temperature interval was 0.01°.

Determination of Concentrations.—The sucrose concentration was known to 0.05%. The hydrochloric acid concentration was obtained by titration of the reacted mixture. The molarity of the hydrochloric acid was thus determined directly for each solution at the temperature at which the experiment had been carried out. The concentration of hydrochloric acid was known to 0.1%. The validity of the method was established by making a duplicate run with a hydrochloric acid solution made up by weight from constant-boiling acid.

Determination of Rate.—Solutions of sucrose and hydrochloric acid were brought to the temperature of the thermostat. A volume of the sucrose solution sufficient to make the resulting mixture 0.0584 molar with respect to sucrose was then added to the hydrochloric acid which had already been placed in the mixing vessel of the dilatometer. After thoroughly mixing, the solution was sealed off and the rate of contraction noted. At the higher temperatures it was necessary to evacuate the solutions before mixing in order to prevent formation of air bubbles during the course of the run. The reader is referred to an earlier paper[15] for the technique employed at 0°. In the case of the acid–salt mixtures, the sucrose was added to a hydrochloric acid solution in which a definite amount of sodium chloride had been dissolved. The velocity constants were evaluated by Guggenheim's method.[18]

Results

The reaction was of the first order over the entire range of temperature and concentration investigated. Scatchard,[19] and Reed and Theriault,[20] analyzing the data of Pennycuick,[21] arrived at similar conclusions.

In Table I are given the values of the observed velocity constant k (the number of moles of sucrose reacting per mole of sucrose per minute) obtained at −0.01°. In this table are also given the values of $k_{H_3O^+} = k/C_{H_3O^+}$ experimentally determined (column 3), and computed as will be described later (column 4).

TABLE I

ELECTROLYTE EFFECT AT −0.01°

HCl (moles/liter)	10^3k, min.$^{-1}$	$10^4k_{H_3O^+}{}^4$ obsd.	$10^4k_{H_3O^+}$, calcd.

the experiments marked with an "*a*" in the table; in all cases the addition of the salt caused an increase in $k_{H_3O^+}$, but in no case was the increase as large as that corresponding to the addition of an equal amount of acid.

TABLE II

SUMMARY OF $k_{H_3O^+}$ VALUES

Temp., °C.	No. of expts.	HCl (moles/liter)	$10^3 k_{H_3O^+}$
10.00	1	1.124	1.305
10.00	2	2.141	2.178
10.00	2	2.997	3.365
10.00	2	3.905	5.350
10.00	2	4.592	7.767

[a] Solution 1.003 molar with respect to added sodium chloride.

[b] Sucrose concentration reduced to 0.0146 molar.

Where more than one experiment was carried out at a given temperature and acid concentration, the average deviation of $k_{H_3O^+}$ from the mean was computed; the average of the average deviations for these experiments is 0.3%.

In Fig. 1, log $k_{H_3O^+}$ for a given concentration of hydrochloric acid is plotted against the reciprocal of the absolute temperature; the curves reading from top to bottom represent acid concentration of 4.592, 2.999, 2.140, 0.9528 and 0.4767 molar. In addition to our own results, we have plotted results obtained by other workers, as stated in the legend below the figure.

Hitchcock and Dougan[22] also used the dilatometric method to study the rate of inversion of sucrose; for solutions containing two grams of sucrose in 100 cc. of solution, their value of $k_{H_3O^+}$ at 25° differs by only 0.4% from ours at an acid concentration of one molar, but at half molar the difference is 1.9%.

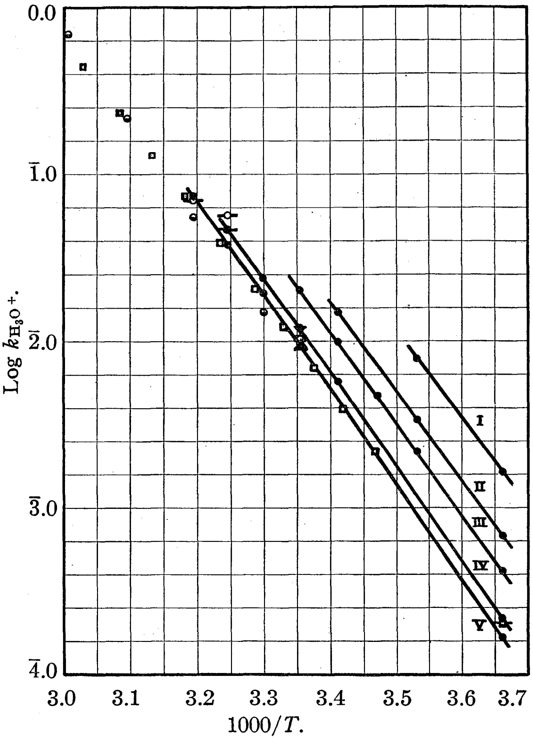

Fig. 1.—Variation of log $k_{H_3O^+}$ with 1000/*T*. Our data sucrose 2 g. per 100 cc. and: I, HCl 4.592 molar; II, HCl 2.999 molar; III, HCl 2.140 molar; IV, HCl 0.9528 molar; V, HCl 0.4767 molar. □, Moelwyn-Hughes,[12] 5% sucrose, HCl 0.19 molar. ◒, Heidt and Purves,[10] 0.01 molar sucrose, HCl 0.00965 molar. -□-, Duboux,[13] sucrose 11.42 g. per 100 cc., HCl 0.4767 molar. ▽, Sturtevant,[23] sucrose 0.1082 molar, HCl 0.5310 molar; sucrose 0.1152 molar, HCl 0.9059 molar. △, Hitchcock and Dougan,[22] sucrose 2 g. per 100 cc., HCl 0.486 molar; sucrose 10 g. per 100 cc., HCl 0.486 molar. -○-, Pennycuick,[21] sucrose 0.5 molar, HCl 0.507 molar and sucrose 0.5 molar, HCl 0.905 molar (at 35°); sucrose 0.5 molar, HCl 0.02 molar (at 40°).

Tables I and II and Fig. 1 show that at any temperature $k_{H_3O^+}$ is a function of the concentration of hydrochloric acid, increasing with increase in the concentration of acid. At a given temperature, over the range of concentration investi-

---

[22] Hitchcock and Dougan, *J. Phys. Chem.*, **39**, 1177 (1935).

gated, the effect may be expressed by the equation

$$\log k_{H_3O^+} = \log k^\circ_{H_3O^+} + \beta C \qquad (4)$$

where $k_{H_3O^+}$ represents the velocity constant for molar hydrogen ion in a solution C molar in hydrochloric acid. Figure 2 shows the applicability of equation (4) to our data at −0.01°.

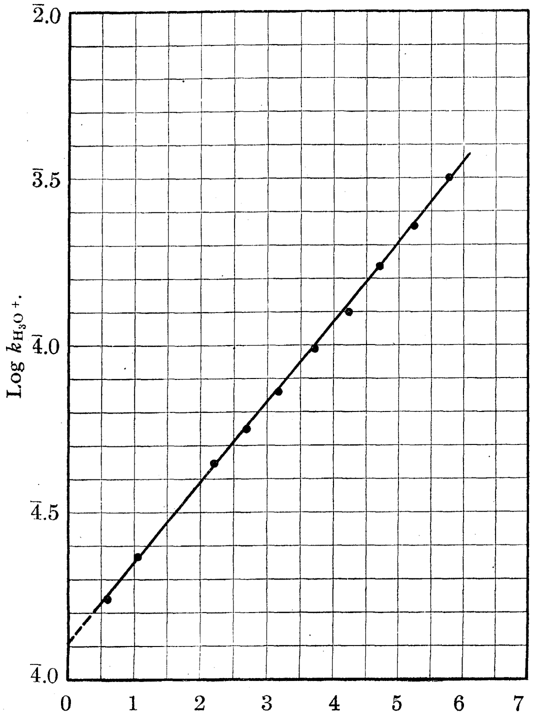

Fig. 2.—Electrolyte effect at −0.01°.

By the method of least squares we obtained the equation

$$\log k_{H_3O^+} = \bar{4}.1057 + 0.2394\ C \text{ (at } -0.01^\circ) \qquad (4a)$$

valid at −0.01°. The values of $k_{H_3O^+}$ (calcd.) given in the fourth column of Table I were computed by equation (4a); the average deviation from the observed value is 2.0%.

Using the polarimetric method, Duboux[13] recently has measured the rate of inversion of sucrose at 0° over a wide range of concentration of hydrochloric acid. His solutions contained 11.42 g. of sucrose in 100 cc. of solution, as compared to our 2.00 g. Upon recomputing his values on the basis of molarity, and applying to the recomputed values the method of least squares, we obtained

$$\log k_{H_3O^+} = \bar{4}.1898 + 0.2392\ C \text{ (Duboux, } 0^\circ) \qquad (4a')$$

The agreement between the two values of β is excellent. The difference in the value of the intercept can be attributed to the difference in the sucrose concentration. That increase in concentration of sucrose causes an increase in $k_{H_3O^+}$ may also be seen in Table II. For a solution 0.95 M in hydrochloric acid, and containing 2 g. of sucrose per 100 cc., $k_{H_3O^+}$ (observed) is 46.68 × 10^{-3} at 35°, while for a solution containing 0.5 g. per 100 cc., $k_{H_3O^+}$ (observed) is 44.00 × 10^{-3}.

The following equations, analogous to (4a), express the effect of acid concentration upon $k_{H_3O^+}$ at the other temperatures investigated.

$$\log k_{H_3O^+} = \bar{4}.8660 + 0.2230\ C \text{ (at 10.00°)} \qquad (4b)$$
$$\log k_{H_3O^+} = \bar{3}.2198 + .2116\ C \text{ (at 15.00°)} \qquad (4c)$$
$$\log k_{H_3O^+} = \bar{3}.5587 + .2045\ C \text{ (at 20.00°)} \qquad (4d)$$
$$\log k_{H_3O^+} = \bar{3}.8793 + .1992\ C \text{ (at 25.00°)} \qquad (4e)$$
$$\log k_{H_3O^+} = \bar{2}.1932 + .1922\ C \text{ (at 30.00°)} \qquad (4f)$$
$$\log k_{H_3O^+} = \bar{2}.4902 + .1846\ C \text{ (at 35.00°)} \qquad (4g)$$
$$\log k_{H_3O^+} = \bar{2}.7857 + .1806\ C \text{ (at 40.00°)} \qquad (4h)$$

These equations were derived from the data given in Table II; they represent the lines obtained by plotting log $k_{H_3O^+}$ against the acid concentration, at the temperature in question.

It was hoped that a quantitative expression for the effect of sucrose concentration upon $k_{H_3O^+}$ might also be formulated from the existing data. While this has not proved possible, there is considerable experimental evidence of the existence of the effect. In addition to the evidence already cited, we mention the following. Hitchcock and Dougan,[22] using the dilatometric method at 25°, noted that at constant acid concentration an increase in the concentration of sucrose caused an increase in $k_{H_3O^+}$. The same thing is shown by a comparison of $k_{H_3O^+}$ obtained by Sturtevant[23] at 25°, using the calorimetric method, with $k_{H_3O^+}$ computed from our equation (4e); by a comparison of the values of $k_{H_3O^+}$ obtained by Heidt and Purves[10] at 30 and 40°, using the copper reduction method, with values computed from our equations (4f) and (4h); by a comparison of the values of $k_{H_3O^+}$ of Pennycuick[21] at 35 and 40°, obtained by the polarimetric method, with values computed from our equations (4g) and (4h); and by a comparison of the values of $k_{H_3O^+}$ of Moelwyn-Hughes,[12] obtained polarimetrically at 15.45 and 19.40°, with our values, after making a correction for the difference in temperature. From all the work examined, with the sole exception of that of Pearce and Thomas,[14] the same conclusion was drawn.

In Table III is given the Arrhenius energy of activation, E_A, computed by means of equation

(23) Sturtevant, This Journal, **59**, 1528 (1937).

TABLE III

ELECTROLYTE EFFECT ON ENERGY OF ACTIVATION

Temp. range, °C.	HCl (moles/liter)	k_{T_2}/k_{T_1}	E_A, cal.
−0.01 to 10.00	1.124	5.506	26,180
− .01 to 10.00	2.141	5.246	25,440
− .01 to 10.00	2.997	5.055	24,870

30.00 to 40.00	.4744	3.852	25,440
30.00 to 40.00	.6524	3.834	25,350

[a] Solution 1.003 molar with respect to sodium chloride.

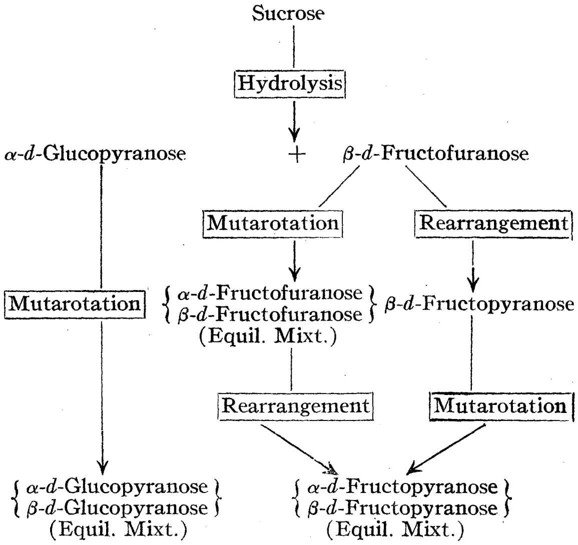
[b] In ref. 11, 4.842 given for hydrochloric acid molarity should be 4.592.

(3) from the values of $k_{H_3O^+}$ listed in Table II, and from values calculated by equation (4a). At this point it is desirable to discuss the probable accuracy of the determination of E_A. For the temperature interval 20 to 30°, errors of 0.3% in the values of $k_{H_3O^+}$, in opposite directions, would result in an error of 104 cal. in E_A at 25°. Errors of 0.1% in the values of the acid concentration, taken in opposite directions, would affect E_A to the extent of 33 cal. Since the effects of possible errors in temperature, time and concentration of sucrose are negligible, the maximum error in E_A determined from velocity constants at temperatures other than −0.01° may be taken as ±150 cal. In similar fashion, a possible error of 2.0% in $k_{H_3O^+}$ at −0.01° yields ±400 cal. for E_A at 5°, and ±250 cal. at 10°.

The two values marked with an "*a*" in the last column of Table III show a diminution of E_A in the presence of sodium chloride; the effect is, however, less than that of an equal amount of acid. Duboux[13] has made similar observations. On the other hand, Pearce and Thomas[14] report no appreciable effect of salt upon E_A. An examination of the results of these authors, however, reveals a distinct trend in the values of E_A in the solutions of barium chloride, which leads us to the conclusion that E_A does decrease with increasing electrolyte concentration.

In view of the change in E_A with electrolyte concentration and temperature reported in Table III, it seems advisable to consider the possibility of reactions other than hydrolysis affecting the measured rate and to reconsider the validity of the dilatometric method.

The following scheme represents the probable reactions involved.



The mutarotation of α-*d*-glucopyranose is approximately fifty times faster than the observed rate under our experimental conditions.[24-26] The mutarotation of β-*d*-fructopyranose is faster than that of α-*d*-glucopyranose.[25,27,28] No rate data are available for hydrochloric acid solutions on the other processes indicated. For enzymes, however, the rate of change of β-*d*-fructofuranose to equilibrium fructose has been shown to be three times faster than the mutarotation of β-*d*-fructopyranose.[29] The possibility of acid decomposition of the equilibrium mixtures of glucose and fructose is ruled out. For the conditions investigated the acid decomposition of the fructose equilibrium mixture is four powers of ten slower

than the observed rate.[30] The glucose portion of invert sugar is less readily attacked by acids than the fructose.[31] Although complete rate data are not available for all processes, the fact that the reaction was of the first order in all experiments indicates that the measured reaction is simple and free from complications.

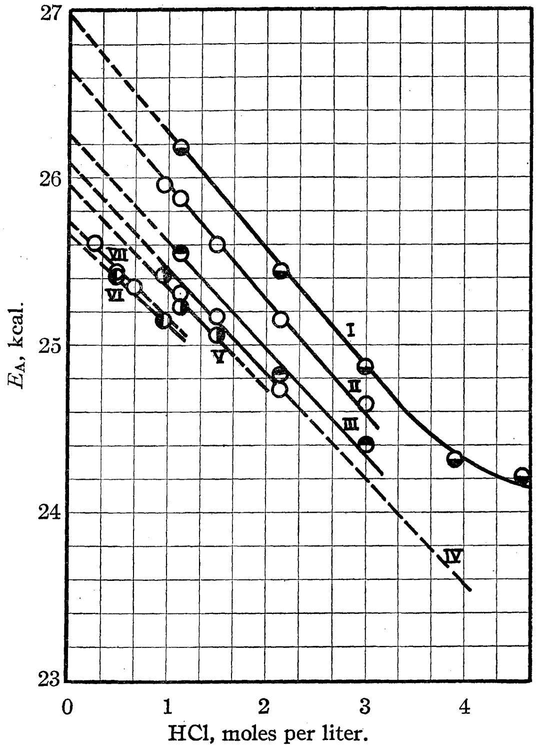

Fig. 3.—Electrolyte effect on energy of activation: I, −0.01 to 10.00°; II, −0.01 to 20.00°; III, 10.00 to 20.00°; IV, 15.00 to 25.00°; V, 20.00 to 30.00°; VI, 25.00 to 35.00°; VII, 30.00 to 40.00°.

In regard to the dilatometric method the volume change for the mutarotation of *α-d*-glucopyranose is approximately 3% of the measured change and in the opposite direction.[26,32] For *β-d*-fructopyranose the volume change is also an expansion amounting to 23% of the measured volume change.[27] Since these processes are rapid the volume change may still be proportional to the percentage of sucrose reacted. The validity of the dilatometric method rests upon the comparison of this method with the polarimetric method[22] and the fact that the dilatometric, polarimetric, calorimetric[23] and copper reduction methods[10] all yield first order constants which are in good agreement when electrolyte and sucrose effects are taken into consideration. Finally, a comparison of the electrolyte effect of hydrochloric acid at 0° (see Table I and equation 4a) obtained by the dilatometric method is in excellent agreement with results obtained by the polarimetric method (see equation 4a′).[13]

In Fig. 3 the value of E_A at the mid-point of the temperature interval is plotted against the concentration of hydrochloric acid. Reading from the top down, the curves represent the effect of acid concentration upon E_A at temperatures of 5, 10, 15, 20, 25, 35 and 30°, respectively. It is evident that E_A decreases with rise in temperature up to 30°, and that E_A decreases with increase in acid concentration. For concentrations not greater than four molar, E_A appears to be a linear function of the acid concentration; at the higher temperatures, however, E_A could not be determined over a wide range of concentration.

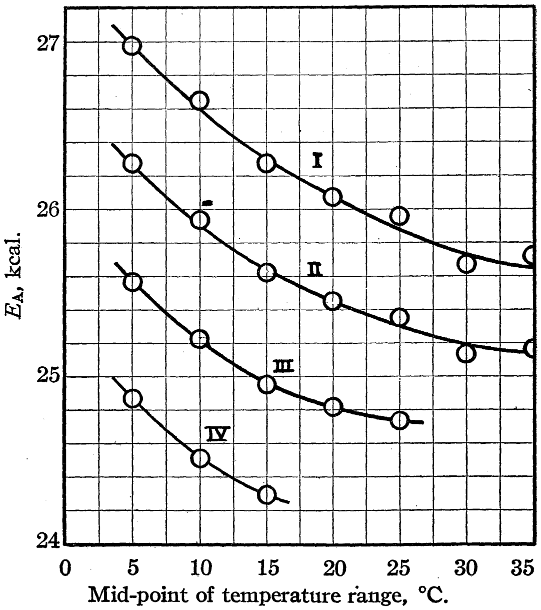

Fig. 4.—Effect of temperature on energy of activation: I, 0 molar HCl; II, 1 molar HCl; III, 2 molar HCl; IV, 3 molar HCl.

Figure 4 and Table IV illustrate the variation of E_A with temperature. The four curves represent E_A at acid concentrations of 0, 1, 2 and 3 molar, respectively, as read off from the lines in Fig. 3.

The graphically determined values of E_A at zero acid concentration were confirmed by computation, by means of equation 3, from the intercepts of equations (4a), (4b), etc. The figure

TABLE IV

TEMPERATURE EFFECT ON THE ENERGY OF ACTIVATION

Temp. range, °C.	E_A, cal. 0 molar HCl	1 molar HCl	2 molar HCl	3 molar HCl
−0.01 to 10.00	26,980	26,280	25,570	24,870
− .01 to 20.00	26,650	25,940	25,230	24,510
10.00 to 20.00	26,280	25,620	24,950	24,290
15.00 to 25.00	26,080	25,450	24,820	...
20.00 to 30.00	25,960	25,350	24,740	...
25.00 to 35.00	25,670	25,130	...	...
30.00 to 40.00	25,720	25,160	...	...

shows E_A to decrease with increase in temperature, the rate of change, $\Delta E_A/\Delta T$, being approximately −70 cal. per degree at 10° and smaller at higher temperatures.

It already has been mentioned that a decrease in E_A with increase in temperature was observed previously by Moelwyn-Hughes.[12] His values of E_A are consistently lower than ours for the same temperature and concentration of hydrochloric acid, as may be seen in Fig. 1. Using 5% sucrose solutions, Moelwyn-Hughes found $\Delta E_A/\Delta T$ to be −94 cal. per degree at 33.6°, which is much larger than the rate of change observed by us at this temperature. The early work of Urech,[33] cited by Moelwyn-Hughes in support of his statement of change of E_A with temperature, does not appear to be sufficiently accurate for the purpose in hand. In his analysis of Urech's data, Moelwyn-Hughes averaged values of E_A obtained at different acid concentrations, which is unjustifiable in view of the effect of acid concentration upon E_A. The data of Spohr,[34] also cited by Moelwyn-Hughes, are not convincing proof of the effect of temperature on E_A. Spohr's value of E_A at 32.5° for 0.250 *N* hydrobromic acid is in good agreement with our value for hydrochloric acid. Computation of E_A from the data of Heidt and Purves[10] for the temperature intervals 30–40, 40–50, and 50–59.7° fails to show a consistent effect of temperature.

In addition to the effects upon E_A of temperature, and of concentration of electrolyte, there is probably a slight effect of the sucrose concentration. At a given acid concentration our value of E_A at the mid-point of the 0–25° interval is consistently higher than that of Duboux.[13] The difference between the two values varies from 200 to 900 cal. Duboux's solutions contained 11.42 g. of sucrose per 100 cc., ours, 2 g.

In order to facilitate comparison with data in the literature, we have in Table V given *B* as computed from the equation

$$\log_e k_{H_3O^+} = B - \frac{E_A}{RT} \qquad (5)$$

where $k_{H_3O^+}$ is expressed in sec.$^{-1}$, the values of $k_{H_3O^+}$ employed were obtained from equations (4a), (4b), etc., and E_A was taken from Figure 4.

TABLE V

VARIATION OF *B* WITH TEMPERATURE AND ACID CONCENTRATION

Midpoint of temp. range, °C.	*B* 0 molar HCl	1 molar HCl	2 molar HCl	3 molar HCl
10.00	36.00	35.25	34.56	33.80
15.00	35.45	34.79	34.08	33.40
20.00	35.07	34.44	33.85	...
25.00	34.72	34.20	33.69	...
30.00	34.47	34.02	...	...
35.00	34.33	33.91	...	...

From Table V it appears that *B* decreases both with increase in temperature and with increase in acid concentration. The effect of temperature decreases markedly at the higher temperatures, as does the effect of temperature upon E_A.

Discussion

Inspection of Tables IV and V indicates that the activation energy is the quantity of first importance in the problem, and that the change in activation energy with concentration is the more important effect. From the point of view of the transition state theory,[35–37] the activation energy can be set equal to the increase in heat content, ΔH, for the reaction

$$S + H_3O^+ \longrightarrow \text{Critical complex} \qquad (6)$$

The change in ΔH with change in concentration can then be found by considering the heats of transfer in the following cycle

$$\begin{tikzcd}
\text{Concentration HCl } C_2 & S \arrow[d, "\Delta H_1"] & + & H_3O^+ \arrow[r, "\Delta H''"] \arrow[d, "\Delta H_2"] & X \arrow[d, "\Delta H_3"] \\
\text{Concentration HCl } C_1 & S & + & H_3O^+ \arrow[r, "\Delta H'"] & X
\end{tikzcd} \qquad (7)$$

where $\Delta H'' - \Delta H' = \Delta H_1 + \Delta H_2 - \Delta H_3$

The heat of transfer (ΔH_1) of a mole of sucrose from a solution of concentration $\overline{C}$ in sucrose and C_2 in hydrochloric acid, to a solution $\overline{C}$ in sucrose and C_1 in hydrochloric acid may be considered small in comparison to ΔH_2 and is neglected in

this calculation. The heat of dilution of H_3O^+ from C_2 to C_1 can be computed from the heat of dilution of hydrochloric acid and potassium chloride on the assumption that the heat of dilution of the chloride ion in hydrochloric acid solutions may be taken as one-half the heat of dilution of potassium chloride for the same change in concentration.

Table VI gives the approximate changes in ΔH_2 per mole at 18°, calculated from the data given by Bichowsky and Rossini.[38]

TABLE VI

COMPARISON OF ΔH_2 AND ΔE_A

C_2 Moles per liter	C_1	Calories per mole ΔH_2	ΔE_A, 20°	ΔE_A, 5°
4	3	300	610[a]	550[a]
3	2	300	620[a]	700
2	1	300	630	710
1	0	500	630	700

[a] Read from Fig. 4.

The value for the heat of transfer (ΔH_3) of a mole of the activated complex between solutions of different hydrochloric acid concentration is dependent on the structure assigned to the activated complex. If we assume that the hydrogen ion makes contact at the oxygen atom joining the two lactone rings of the sucrose molecule,[14] we would have an ion which might be expected to have a heat of dilution intermediate between those of sucrose and hydrogen ion. This would mean that the maximum value of $\Delta H'' - \Delta H'$ would be equal to ΔH_2. The change in E_A for the various intervals compared in Table VI should not exceed the values given for ΔH_2. E_A shows the expected decrease with increasing concentration, but the observed values of ΔE_A are consistently larger than ΔH_2. The heat of dilution of the hydrogen ion is greater at lower temperatures and the values of ΔE_A at 5° show an increase over ΔE_A at 20° except at four molar.

In regard to the effect of sucrose concentration on E_A, calculation of ΔH_1 for solutions of sucrose[39,40] up to 0.5 molar indicates that E_A should decrease by approximately 100 cal. in going from 0.05 to 0.5 molar. Here again the observed effect seems larger than the calculated, though in the right direction.

From these calculations it seems that the change in the energy of activation with electrolyte concentration is understandable on the basis of the transition state theory. The fact that the magnitude of the effect as calculated from the theory is not in agreement with the experimentally determined values may be due to our neglect of the heat of transfer of sucrose (ΔH_1) from one concentration of hydrochloric acid to another. In addition our values for ΔH_2 are based on heats of dilution for aqueous solutions which did not contain sucrose.

A similar picture will result if we do not consider the critical complex at the top of the energy barrier, but consider a preëquilibrium between a collision complex and the reactants, the assumption being made that equilibrium is maintained between the collision complex and the reactants at all times. From equation 2 we have

$$\begin{tikzcd}[column sep=small, row sep=small] \ln k = & \ln K \arrow[d, equal] & + & \ln k_2 \arrow[d, equal] & & \\ & \frac{\Delta S}{R} \arrow[d, dash] & & b \arrow[d, dash] & \cong & \frac{\Delta S^*}{R} \\ & \frac{\Delta H}{RT} & & \frac{\epsilon_A}{RT} & & \end{tikzcd} \qquad (8)$$

where K is the equilibrium constant, ΔH the difference in heat content between the collision complex and reactants, ΔS is the entropy difference, b is a constant, and ϵ_A the activation energy for the unimolecular decomposition of the collision complex. The constant b will include the entropy of activation of the transition state theory.

From the above we have

$$\ln k = \ln C + \frac{\Delta S + \Delta S^*}{R} - \frac{\Delta H + \epsilon_A}{RT} \qquad (9)$$

C being a constant.

At a concentration of acid C_1 we have

$$k_1 = Ce^{(\Delta S_1 + \Delta S_1^*)/R}\, e^{-(\Delta H' + \epsilon_A')/RT} \qquad (10)$$

and at C_2

$$k_2 = Ce^{(\Delta S_2 + \Delta S_2^*)/R}\, e^{-(\Delta H'' + \epsilon_A'')/RT} \qquad (11)$$

The change in the measured energy of activation with change in acid concentration will be

$$(\Delta H'' + \epsilon_A'') - (\Delta H' + \epsilon_A')$$

and our approximate calculations are valid if we assume $\epsilon_A'' = \epsilon_A'$. ϵ_A need not be considered as the true energy of activation, but can be related to it by the equation $\epsilon_1 = \epsilon_A + SRT$ where S is the number of degrees of freedom.

Any attempt at an explanation of the change in B which is associated with the changes in $\Delta S + \Delta S^*$ seems unprofitable until we are able to know something of the order of magnitude of the equilibrium constant K.

Experimental studies on various acetals[41] indicate that E_A does not show any great change with temperature or with concentration of electrolytes, but the reactions are too sensitive to hydrogen ion to allow investigation over any wide range of concentration of acid. We plan to extend this study to a reaction of a less complicated substrate than sucrose, which can be studied over a similar range of hydrochloric acid concentration and temperature.

Summary

1. The velocity constant $k_{H_3O^+}$ for the inversion of sucrose has been measured from 0 to 40° over a wide range of hydrochloric acid concentration.
2. Equations for the effect of the electrolyte, hydrochloric acid, on $k_{H_3O^+}$ are given at 5° intervals between 10 and 40° and at $-0.01°$. The effect of electrolyte decreases with increasing temperature.
3. It has been shown that $k_{H_3O^+}$ increases with increasing sucrose concentration.
4. The energy of activation calculated from the Arrhenius equation shows that E_A and B decrease with increasing concentration of hydrochloric acid. This appears to be a general electrolyte effect.
5. The energy of activation also decreases with increasing sucrose concentration.
6. The decrease in E_A and B with increasing temperature has been confirmed.
7. An explanation of these results has been attempted on the basis of the transition state theory and the consideration of a preëquilibrium between reactants and the collision complex.

The Action of *t*-Butylmagnesium Chloride with Acetyl Chloride

BY FRANK C. WHITMORE AND W. R. WHEELER

Researches in this Laboratory have shown that ketones of the type $RCOCR_3$ may be obtained by the action of tertiary alkylmagnesium halides and an acid halide.[1] In the present study *t*-butylmagnesium chloride was added to an excess of acetyl chloride in ether solution to determine the by-products.

Pinacolone, the normal product, was obtained in but 17% yield. $(CH_3)_3CMgCl + CH_3COCl \rightarrow (CH_3)_3CCOCH_3 + MgCl_2$. Other products were pinacolyl acetate, ethyl acetate, mesityl oxide, isobutylene, isobutane, carbon monoxide and hexamethylethane.

Pinacolyl alcohol, the product from the reducing action of the Grignard reagent on the ketone, appeared as its acetate in 8% yield.

Ethyl acetate, present to the extent of 9%, based on the acid chloride, was probably formed by interaction of acetyl chloride with the solvent ether rather than by direct reduction of the acid chloride to the primary alcohol.[2] This is confirmed by the formation of only 6.6% of isobutylene. Also, results from this Laboratory[3] have shown that ethyl esters are formed in the reaction of *n*-propyl, *n*-butyl and *n*-amyl Grignard reagents with *t*-butylacetyl chloride, in which cases formation of ethyl alcohol by reduction is excluded. Since acid halides are known to cleave ethers in the presence of anhydrous zinc chloride,[4] an experiment was undertaken which demonstrated that the anhydrous magnesium chloride, formed during the course of the reaction, may act in the same way as zinc chloride.

Several modes of formation are possible for the mesityl oxide, which occurred in 6.6% yield. Karasev[5] observed that *t*-butylmagnesium chloride reacts with ethyl acetate to produce acetone and its condensation products, mesityl oxide and phorone. Kondakow[6] prepared mesityl oxide from isobutylene and acetyl chloride in the presence of anhydrous zinc chloride. Recalling the similarity of zinc and magnesium chlorides in promoting the cleavage of ethers, the latter formation is also possible. In that case the small yield of isobutylene would be explained. Further studies on the mechanism of the forma-

tion of ethyl acetate and of mesityl oxide are in progress.

The trace of hexamethylethane found is the coupling product ordinarily formed in the preparation of the Grignard reagent. A small amount of carbon monoxide was also produced; its formation has been noticed previously in analogous reactions.[7]

The evolution of so large an amount of isobutane as 23.6% was unexpected, and would seem to indicate that both pinacolone and mesityl oxide, totalling 24%, had reacted with the Grignard reagent to form isobutane and the —OMgCl compounds of their enol forms.

Experimental

Preparation of Materials.—The *t*-butylmagnesium chloride was prepared in the usual manner[1] from pure *t*-butyl chloride. The reagent evolved no gas when refluxed in a dry, nitrogen-filled fractionating column.

The acetyl chloride was obtained from Eastman practical grade by careful distillation from dimethylaniline in a 1.5 × 65 cm. fractionating column packed with 3.5 mm. glass helices (Column I).

Reaction of *t*-Butylmagnesium Chloride with Acetyl Chloride.—In a three-liter three-necked flask fitted with a dropping funnel, stirrer and condenser were placed 253 g. (3.2 moles) of acetyl chloride and 640 cc. of dry ether. To this was added, over a twelve-hour period, 2.46 moles of the clear, filtered Grignard reagent in 1010 cc. of solution. A yellow precipitate formed; gas was evolved and collected in carboys filled with salt solution and protected by calcium chloride tubes to prevent the diffusion of water vapor back into the reaction flask. When the addition was complete, the flask was immersed in a salt–ice bath and about one liter of water added with stirring, causing the mixture to become warm and evolve a small amount of gas. The ether layer was separated and the water extracted with three 300-cc. portions of ether. The combined extracts were dried over anhydrous magnesium sulfate and distilled in column I. Some gas was evolved on warming, which was combined with the other gases. Distillation at 742–746 mm. gave the following fractions: nos. 1–7, ether; 8–10, 10.1 g., b. p. 36–61.5°, $n^{20}\text{D}$ 1.3752–1.3868; 11–12, 18.6, 61.5–75.5°, 1.3815–1.3770; 13–14, 7.7, 75.5–85°, 1.3780–1.3827; 15–17, 15.2, 85–104.5°, 1.3920–1.3976; 18–21, 31.3, 104.5–109°, 1.3965–1.3943; 22–23, 15.9, 109–114°, 1.3952–1.3821; 24–26, 34.6, 114–122.5°, 1.3764–1.3852. The remainder of the distillation was carried out at 51 mm. pressure: 27–29, 15.9, 55–60°, 1.4210–1.4157; 30–33, 29.1, 60–64°, 1.4085–1.4040; residue, 46.3 g.

Identification of Products.—No. 9.—Identification of this material was not entirely satisfactory. It contained halogen, and its b. p. 45–50° and $n^{20}\text{D}$ 1.3831 indicate that it was probably impure *t*-butyl chloride, b. p. 50°, $n^{20}\text{D}$ 1.3850.

13.—The b. p. and $n^{20}\text{D}$ corresponded to ethyl acetate. Hydrolysis gave acetic acid, identified by Duclaux numbers, and ethyl alcohol, 3,5-dinitrobenzoate, m. p. 91°.

14–16.—Repeated refraction of these cuts through a 0.55 × 43 cm. helix-packed column (column E) resulted only in the separation of ethyl acetate and pinacolone, and a small amount of hexamethylethane, boiling *ca.* 100°, m. p. 90–94° (sealed tube), insoluble in 93% sulfuric acid.

19.—Identified as pinacolone, 2,4-dinitrophenylhydrazone, m. p. 124.5°.

21–23.—These cuts, washed free of acetic acid using sodium bicarbonate, yielded only pinacolone on redistillation in column E.

25.—The b. p., $n^{20}\text{D}$ and neutral equivalent corresponded to acetic acid.

27–29.—Redistillation through column E gave a fraction of b. p. 128° and $n^{20}\text{D}$ 1.4377 which was identified as mesityl oxide, 2,4-dinitrophenylhydrazone, m. p. 199–200°. Semicarbazide reacted with it to form a solid, m. p. 130.5°, described as one of the possible products.[8]

32–33.—The b. p. and $n^{20}\text{D}$ correspond to pinacolyl acetate. Hydrolysis gave an acid identified as acetic by its Duclaux numbers, and an alcohol boiling at 128°, phenylurethan m. p. 76°, corresponding to pinacolyl alcohol.

Residue.—The material could not be distilled without decomposition even at 5 mm. pressure. Decolorization in acetone solution yielded a reddish oil which could not be crystallized from the usual solvents. It was not investigated further.

Analysis of Gaseous Products.—Analysis was accomplished with the aid of a 0.55 × 36 cm. low temperature column, packed with a single nichrome spiral and the conventional Orsat apparatus. The following products were indicated: isobutane, 33.8 g.; isobutylene, 9.2 g.; carbon monoxide, 0.2 g.

Reaction of Acetyl Chloride with Ether.—One mole of redistilled acetyl chloride, 200 cc. of ether and 120 g. (1.26 moles) of anhydrous magnesium chloride, prepared by the method of Vanino[9] were stirred and refluxed for one hundred hours. The mixture became pasty but no gas was evolved. Water was added to remove the magnesium chloride, the ether layer washed again with a small amount of water and dried over magnesium sulfate. Distillation in a 0.9 × 45 cm. helix-packed column gave about 60 g. of material boiling at 22–31°, indicating that some ethyl chloride was present in ether solution, and four fractions, totaling 8.9 g., boiling 65–83°, $n^{20}\text{D}$ 1.3712–1.3735, which proved to be mainly ethyl acetate; yield 8–10%.

Summary

1. Products formed in the reaction of *t*-butylmagnesium chloride with excess acetyl chloride are isobutane, isobutylene, carbon monoxide, ethyl acetate, pinacolone, pinacolyl acetate and mesityl oxide.

2. Acetyl chloride has been shown to react with diethyl ether in the presence of anhydrous magnesium chloride to form ethyl acetate.

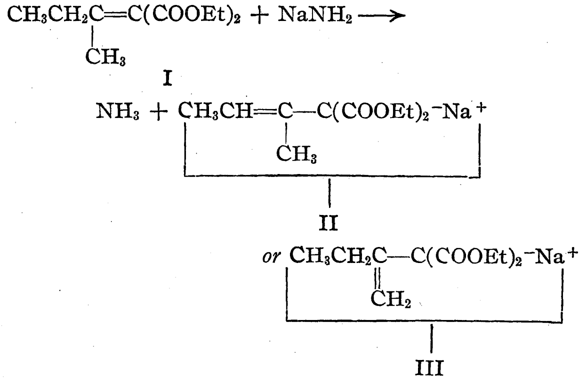
The Introduction of Substituted Vinyl Groups. II. (1-Methylpropenyl)-alkylmalonic Esters

BY ARTHUR C. COPE AND EVELYN M. HANCOCK

The preceding paper of this series described a practical indirect method for preparing isopropenylalkylmalonic esters.[1] This communication presents a similar method by means of which 1-methylpropenyl (or symmetrical dimethylvinyl) alkylmalonic esters can be prepared.

The starting point in the syntheses is ethyl (1-methyl-propylidene)-malonate, I, which was obtained by condensing methyl ethyl ketone with malonic ester. On treatment with sodamide, the alkylidene ester gives a sodium derivative, which could be either II or III, since the hydrogen which is lost as ammonia in the reaction might come from either the methylene or the methyl group of I.



$$CH_3CH_2\underset{CH_3}{\underset{|}{C}}{=}C(COOEt)_2 + NaNH_2 \longrightarrow$$

I

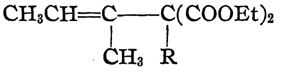
$$NH_3 + \left[CH_3CH{=}\underset{CH_3}{\underset{|}{C}}{-}C(COOEt)_2^{-}Na^{+}\right]$$

II

$$or\ \left[CH_3CH_2\underset{CH_2}{\underset{\|}{C}}{-}C(COOEt)_2^{-}Na^{+}\right]$$

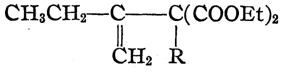
III

The sodium enolate was alkylated with several alkyl halides and dialkyl sulfates. The alkylated esters, which were obtained in good yields, must be either symmetrical dimethylvinyl derivatives, (IV, derived from II), 1-ethylvinyl derivatives (V, derived from III) or mixtures of the two structural types. Formula IV, in addition, permits the existence of two geometric isomers.



$$CH_3CH{=}\underset{CH_3}{\underset{|}{C}}{-}\underset{R}{\underset{|}{C}}(COOEt)_2$$

IV



$$CH_3CH_2{-}\underset{CH_2}{\underset{\|}{C}}{-}\underset{R}{\underset{|}{C}}(COOEt)_2$$

V

The structures of the alkylated esters described in Table I, with the exception of the allyl derivative, were determined by ozonization. Decomposition of the ozonides gave acetaldehyde in quantity and only traces of formaldehyde. The products are, therefore, 1-methylpropenyl esters (formula IV), containing small amounts of the isomeric 1-ethylvinyl substituted esters (formula V).

Two of the esters boiled over three and five degree ranges, respectively, even after careful refractionation. Since the esters were analytically pure, and the structural isomers (V) appear to be present in quite small quantities, the boiling points suggest the presence of both of the possible geometric isomers.

Experimental Part

Ethyl (1-Methylpropylidene)-malonate

Methyl ethyl ketone condenses with malonic ester more slowly and less completely than does acetone under similar conditions.[1] The yield of condensation product does not exceed 20%, although a large proportion of the unreacted malonic ester is recovered.

A mixture of 1 kg. (6.25 moles) of ethyl malonate, 670 g. (9.3 moles) of methyl ethyl ketone, 800 g. of acetic anhydride and 120 g. of zinc chloride was heated under reflux in an oil-bath at 110° for sixty hours. The mixture was cooled, diluted with 800 cc. of benzene and washed with five 500-cc. portions of water. The water washings were extracted with benzene and the product distilled in the same manner as ethyl isopropylidene-malonate.[1] The recovery of ethyl malonate, b. p. 98–100° (22 mm.), plus a small intermediate fraction, was 700 g. (70%), while the yield of condensation product, b. p. 134–136° (22 mm.) was 255 g. (19%). A similar preparation was heated for five days at 100°, after which another 120-g. portion of zinc chloride was added and the mixture heated for seven more days at 100°. The recovery of ethyl malonate plus the intermediate fraction was 612 g. (61%), and the yield of ethyl (1-methylpropylidene)-malonate, b. p. 119–120° (9 mm.), was 260 g. (19%); n^{25}_{D} 1.4479, d^{25}_{25} 1.0108; M_D calcd. 55.85, observed 56.86, exaltation +1.01. *Anal.* Calcd. for $C_{11}H_{18}O_4$: C, 61.64; H, 8.47. Found: C, 61.91; H, 8.49. Duplicate quantitative reductions of 3-g. samples with palladinized charcoal catalyst in ethyl alcohol solution at room temperature and atmospheric pressure were complete in one hour and required 100.2 and 99.5% of the theoretical quantity of hydrogen, respectively. The reduction product was identified as ethyl *s*-butylmalonate by saponification to *s*-butylmalonic acid, m. p. 78–79°,[2] and by conversion to *s*-butyl malonamide with concd. aqueous ammonia;[3] m. p. and mixed m. p. with a known sample 232–233° (uncorr.).

Alkylation of Ethyl (1-Methylpropylidene)-malonate. A. Sodamide Procedure.—The ester was alkylated by a procedure similar to the one used with ethyl isopropylidene-malonate,[1] except that equivalent quantities of ester and

sodamide were used, rather than an excess of the latter. The properties of five alkyl (1-methylpropenyl)-malonic esters, purified by shaking with concd. ammonia and redistilling through a Widmer column, together with data concerning the preparations, are recorded in Table I.

B. Sodium Ethoxide Procedure.—The ethyl (1-methylpropylidene)-malonate may be alkylated in alcoholic solution, but the yields are poor due to alcoholysis. For example, the following results were obtained in the preparation of ethyl (1-methylpropenyl)-butylmalonate. A solution of 5.75 g. (0.25 mole) of sodium in 200 cc. of absolute alcohol was prepared in a 500-cc. three-necked flask and cooled to −5°. Ethyl (1-methylpropylidene)-malonate, 54 g. (0.25 mole), was added dropwise and the solution stirred for twenty minutes at −5°. Butyl iodide, 56 g. (0.3 mole), was added and the solution quickly heated to boiling. After one and three-quarters hours of refluxing the practically neutral solution was cooled and diluted with water. The ester was extracted with benzene and distilled in vacuum. The yield of crude ester was 61 g., but after shaking with concd. ammonia for two days and redistilling, the yield of pure ester was only 21 g. (31%).

Structures of the Alkylated Esters.—The methyl and ethyl substituted esters (Table I) were reduced quantitatively with palladinized charcoal catalyst, as described above. They required 101 and 99% of the theoretical quantity of hydrogen, respectively, or within experimental error of one mole. The ozonizations were carried out as follows. Solutions of the esters (0.01 mole) in 12 cc. of pentane at −10 to −15° were treated with a rapid stream of ozonized oxygen for one and one-half hours. The solvent was removed in vacuum and the ozonide decomposed with zinc dust and water in the presence of hydroquinone and silver.[4] The mixture was steam distilled rapidly until about 75 cc. had collected. This distillate was transferred to a Claisen flask, and the most volatile portion removed by distilling a volume of 2 cc. into an ice-cooled receiver. Both the original distillate and the residue after redistillation gave positive red and blue ring tests for formaldehyde with resorcinol and gallic acid.[5] The somewhat less sensitive test with resorcinol and sodium hydroxide[6] was negative in each case. The amounts of formaldehyde formed were therefore very small. Further evidence of this fact was obtained by treating the residue from the final distillation with 2,4-dinitrophenylhydrazine reagent. Only traces of an aldehyde were present. The 2 cc. of distillate, however, on treatment with 2,4-dinitrophenylhydrazine and hydrochloric acid in absolute alcohol, gave the 2,4-dinitrophenylhydrazone of acetaldehyde in quantity, m. p. and mixed m. p. 166–168° (corr.).[7] The corresponding derivative of formaldehyde melts at 166° (corr.) but mixtures of the formaldehyde and acetaldehyde derivatives melt 20 to 30° lower.

Similar distillates from the decomposition of the ozonide of a known ester which yields formaldehyde, ethyl isopropenylethylmalonate, gave strong tests for formaldehyde by all of the above methods.

Summary

A method is described by means of which 1-methylpropenyl (or symmetrical dimethylvinyl)-alkylmalonic esters may be prepared from ethyl (1-methylpropylidene)-malonate. The latter ester gives a sodium derivative with sodamide, losing hydrogen from the methylene of the ethyl group rather than from the methyl group. Subsequent alkylation produces the substituted vinyl alkyl malonic esters, $CH_3CH{=}C(CH_3)C(R)(COOEt)_2$.

The Introduction of Substituted Vinyl Groups. III. (Dialkylvinyl)-alkylcyanoacetic Esters

BY ARTHUR C. COPE AND EVELYN M. HANCOCK

Indirect methods similar to those previously described for introducing isopropenyl and 1-methylpropenyl groups into malonic ester[1] are not equally practical for synthesizing higher (1-alkylvinyl)-alkylmalonic esters. Such syntheses would require as intermediates higher 1-alkylalkylidenemalonic esters, $RCH_2C(R')=C(COOEt)_2$. Esters of the latter type are difficult to prepare because ketones higher in molecular weight than methyl ethyl ketone do not condense easily with malonic ester. Higher ketones do condense readily with cyanoacetic ester to give excellent yields of alkylidene cyanoacetic esters.[2] This paper reports an investigation of the alkylation of these cyanoacetic ester derivatives.

Aralkylidene cyanoacetic esters, which are activated by an aryl group in addition to the nitrile and ester groups, have been alkylated previously.[3] However, an attempt to alkylate an alkylidene derivative not similarly activated by an aryl group, ethyl isopropylidenecyanoacetate, was reported to be unsuccessful.[4] We have found that alkylidenecyanoacetic esters can be alkylated, and that (dialkylvinyl)-alkylcyanoacetic esters are produced in good yields if the conditions of synthesis minimize destruction of the products by alcoholysis.

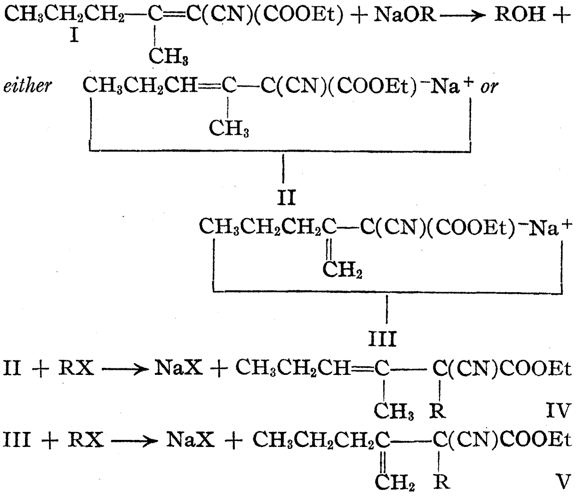
Sodium derivatives can be prepared from the alkylidenecyanoacetic esters by reaction with sodamide, metallic sodium, or sodium alkoxides. Sodamide is the reagent of choice in the malonic ester series,[1] but it produces both cleavage and polymerization of the cyanoacetic esters. The use of powdered sodium in inert solvents causes partial reduction of the unsaturated esters, and partially reduced products are formed when the enolates are alkylated. Sodium alkoxides react with the alkylidene esters to give good yields of the sodium derivatives, which can be alkylated satisfactorily in alcohol solution under proper conditions.

The (dialkylvinyl)-alkylcyanoacetic esters which are produced in the alkylations undergo alcoholysis even more readily than do the corresponding malonic esters, so that the success of their synthesis in alcohol solution is rather surprising. The alkylations of the cyanoacetic esters proceed very rapidly, however, so that the products are in contact with the alcohol and sodium alkoxide for only a short time, and there is little opportunity for alcoholysis.

Yields in the alkylation reactions are poorest in methyl alcohol solution, better in ethyl alcohol, and highest in isopropyl alcohol. This is the order of decreasing effectiveness of the three alcohols in producing alcoholysis in ester–alcohol interchange reactions.[5]

As would be expected, the rapid alkylations obtained with the most active alkylating agents give highest yields. The syntheses of 1-ethylpropenyl and 1-propyl-1-butenyl substituted esters, containing the groups $CH_3CH=C(C_2H_5)$- and $CH_3CH_2CH=C(C_3H_7)$-, gave excellent yields. The yields of 1-methyl-1-alkenyl substituted esters, containing $RCH=C(CH_3)$- groups, were lower regardless of the size of the group R. This is attributed to the hindrance to alcoholysis afforded by the presence of a group larger than methyl in the 1-position of the alkenyl residue in the former esters.

Alkylidenecyanoacetic esters prepared from unsymmetrical ketones can lead to two structural types, as the following equations with the methyl propyl ketone condensation product illustrate.



$$\underset{\text{I}}{CH_3CH_2CH_2{-}\underset{\displaystyle CH_3}{\underset{|}{C}}{=}C(CN)(COOEt)} + NaOR \longrightarrow ROH +$$

$$\textit{either}\quad CH_3CH_2CH{=}\underset{\displaystyle CH_3}{\underset{|}{C}}{-}C(CN)(COOEt)^-Na^+ \quad \textit{or}$$

$$\text{II}$$

$$CH_3CH_2CH_2\underset{\displaystyle CH_2}{\underset{\|}{C}}{-}C(CN)(COOEt)^-Na^+$$

$$\text{III}$$

$$\text{II} + RX \longrightarrow NaX + CH_3CH_2CH{=}\underset{\displaystyle CH_3}{\underset{|}{C}}{-}\underset{\displaystyle R}{\underset{|}{C}}(CN)COOEt \qquad \text{IV}$$

$$\text{III} + RX \longrightarrow NaX + CH_3CH_2CH_2\underset{\displaystyle CH_2}{\underset{\|}{C}}{-}\underset{\displaystyle R}{\underset{|}{C}}(CN)COOEt \qquad \text{V}$$

Ozonization of the alkylation products gave propionaldehyde but only traces of formaldehyde, so that formula IV is correct rather than V. The alkylation products of alkylidenecyanoacetic esters derived from four other methyl ketones were ozonized, and the higher aldehydes to be expected on cleavage of molecules having the structures indicated in Table I were formed, while only traces of formaldehyde were produced. Consequently, in this series as well as in the malonic ester series,[1b] the formation of a sodium derivative involves the loss of hydrogen from the methylene of an alkyl group higher than methyl, rather than from the methyl group.

When the various alkylated esters were purified by distillation alone, they were found to contain the corresponding alkylidene esters as impurities. Alkylidenecyanoacetic esters form sodium bisulfite addition compounds,[6] so that it was possible to remove any unalkylated ester present by shaking the crude product with 20% sodium bisulfite solution. Addition of an excess of sodium carbonate solution to the sodium bisulfite extract liberates the alkylidenecyanoacetic esters, which can be recovered in this manner.

Experimental Part

Both methyl and ethyl alkylidenecyanoacetates were alkylated in methyl, ethyl and isopropyl alcohols. Analytically pure esters result only when the alkyl of the ester is the same as that of the alcohol used as a solvent, for otherwise ester interchange results during the alkylation, and mixed esters are produced. Although the mixed esters do not have constant boiling points, they are perfectly satisfactory for use as intermediates in syntheses in which the alkyl of the ester group is removed. The yields of methyl esters obtained in methyl alcohol were poor, and they were prepared in this manner only to obtain pure samples for analyses and physical constants. Methyl esters alkylated in ethyl alcohol usually gave as good yields as did the ethyl esters, however, and both classes gave highest yields when alkylated in isopropyl alcohol.

An additional advantage of using isopropyl alcohol as a solvent is the fact that it permits the use of dialkyl sulfates, particularly diethyl sulfate, as alkylating agents. The dialkyl sulfates are poorly adapted to alkylating esters in ethyl alcohol solution, because of the rapid side reaction which occurs with the alcohol. The hydrogen of the hydroxyl group in isopropyl alcohol is less reactive, so that the competing reaction of the alcohol with the dialkyl sulfate is diminished, and the ester alkylation becomes the principal reaction.

Alkylations in Alcohol Solution.—The ethylation of ethyl (1-methylbutylidene)-cyanoacetate (I) in isopropyl alcohol will be described as a typical example. A solution of 13.8 g. (0.6 mole) of sodium in 600 cc. of dry isopropyl alcohol was prepared in a one-liter three-necked flask. The solution was cooled to 60°, at which temperature sodium isopropoxide started to crystallize out. Ethyl (1-methylbutylidene)-cyanoacetate, 108.6 g. (0.6 mole), was added during four minutes, with stirring. The mixture was cooled in ice during the addition, and the solution was at 25° when the addition was completed. Diethyl sulfate, 94 g. (0.61 mole), was added in one portion and the solution quickly heated to the boiling point. The reaction was vigorous, and after one-half to one hour of refluxing, the solution was neutral to litmus. The mixture was cooled in ice, diluted with 1400 cc. of water, and the ester layer separated. The water layer was extracted four times with benzene, and the combined ester and benzene extracts washed twice with water. Distillation from a modified Claisen flask gave 118 g. of crude ester, b. p. 125–140° (16 mm.). After shaking the crude product for twelve hours with 200 cc. of 20% sodium bisulfite solution and redistilling through a Widmer column, the yield of a mixture of the ethyl and isopropyl esters of ethyl (1-methyl-1-butenyl)-cyanoacetic acid, b. p. 129–133° (14 mm.) was 100 g. (80%, calculated as the ethyl ester). Other alkylations in isopropyl alcohol were performed in a similar manner. When the less active alkyl halides are used in these alkylations, it is not essential to cool the solutions before adding the halides. With the dialkyl sulfates, the reactions are too vigorous unless this precaution is taken. Alkylations in methyl and ethyl alcohols were performed using 700 cc. of the anhydrous alcohols per mole of sodium, and cooling the sodium alkoxide solutions to −5° during the addition of the alkylidene esters. After the esters were added, the solutions were stirred for twenty minutes at −5 to −10° before adding the alkylating agent. The mixtures were then heated rapidly to the boiling point, and the reactions were usually vigorous. Small aliquot portions of those reaction mixtures which did not become neutral were titrated from time to time with standard acid, and refluxed until the alkalinity became constant. The properties of various (dialkylvinyl)-alkylcyanoacetic esters and data concerning the preparations are recorded in Table I.

Sodamide in Inert Solvents.—A sodium derivative was prepared from methyl (1-methylhexylidene)-cyanoacetate by adding 0.5 mole of the ester to an equivalent quantity of sodamide in liquid ammonia solution. On replacing the ammonia with toluene containing a small amount of ether, according to the procedure used in other alkylations with sodamide,[1] a very insoluble sodium derivative was precipitated. Diethyl sulfate was added and the mixture refluxed until it became neutral (two hours), after which the ester was washed and distilled. The low boiling portion of the distillate contained methyl amyl ketone, a cleavage product of the alkylidene ester. The crude ester fraction weighed 21 g., and a large tarry residue remained. The impure product was shaken with sodium bisulfite solution and redistilled. The yield of pure methyl (1-methyl-1-hexenyl)-cyanoacetate, identical with the product described in Table I, was only 14 g. (13%).

Sodium in Inert Solvents.—Powdered sodium was used in several cases for preparing sodium derivatives of the alkylidenecyanoacetic esters. For example, 0.25 mole of methyl (1-propylbutylidene)-cyanoacetate was treated

[a] We are indebted to Mr. C. S. Miller for semi-micro Kjeldahl analyses. [b] Dimethyl sulfate gave a 65% yield. [c] Diethyl sulfate gave a 45% yield, ethyl bromide 41%. [d] Using diethyl sulfate. [e] Using propyl bromide. [f] 55% with isopropyl bromide. [g] Using allyl chloride. [h] Yield in ethyl alcohol 83%, calculated as the methyl ester. [i] Yield in ethyl alcohol 77%. [j] Yield in ethyl alcohol 58%. [k] Yield in ethyl alcohol 93%. [l] Ozonized by the procedure described in the Experimental Part.

with 0.25 mole of powdered sodium under 250 cc. of dry ether. The sodium had all dissolved after three hours of refluxing, and the soluble sodium derivative was alkylated with diethyl sulfate approximately as in the similar alkylation of ethyl isopropylidenemalonate.[1a] A 58% yield of methyl (1-propyl-1-butenyl)-ethylcyanoacetate was obtained, b. p. 117–119° (4 mm.); n^{25}_D 1.4489, d^{25}_{25} 0.9482. This ester gave satisfactory nitrogen analyses (calcd. for $C_{13}H_{21}O_2N$: N, 6.28; found: N, 6.38), but the low index of refraction, compared with that of the pure ester prepared in methyl alcohol and described in Table I, indicates the presence of the corresponding reduced ester as an impurity.

Ozonizations.—The esters indicated by footnote *l* in Table I were ozonized by the procedure described previously.[1b] The aldehydes formed on decomposition of the ozonides were converted to the 2,4-dinitrophenylhydrazones as before, and color tests for formaldehyde were made. In each case, a trace of formaldehyde was present, as indicated by positive ring tests with both gallic acid and resorcinol, but in no case was there enough to give the moderately sensitive resorcinol test with sodium hydroxide. As in the previous work, the most volatile portion of each of the distillates was treated with 2,4-dinitrophenylhydrazine and hydrochloric acid in alcohol solution. The derivatives formed were nearly pure as precipitated, and one recrystallization brought them to constant melting point in each case. The respective 1-alkyl-alkenyl esters gave the following aldehydes, as shown by the melting points of their 2,4-dinitrophenylhydrazones and mixed melting points with known samples. The 1-methylpropenyl ester gave acetaldehyde, m. p. and mixed m. p. of the derivative 163–165°. The 1-methyl-1-butenyl esters gave propionaldehyde, m. p. and mixed m. p. of the derivative 153–154°. The 1-methyl-1-pentenyl esters gave butyraldehyde, m. p. and mixed m. p. of the derivative 121–122°. The 1,3-dimethyl-1-butenyl ester gave isobutyraldehyde, m. p. and mixed m. p. of the derivative 181–182°. The 1-methyl-1-hexenyl ester gave valeraldehyde, m. p. and mixed m. p. of the derivative 108–109°.[7] (These melting points are uncorrected.)

Summary

Alkylidenecyanoacetic esters derived from both symmetrical and unsymmetrical ketones give sodium derivatives when treated with sodium alkoxides in alcohol solution. Alkylation of these sodium derivatives with alkyl halides and dialkyl sulfates produces (dialkylvinyl)-alkylcyanoacetic esters, RCH=C(R′)C(R″)(CN)COOR‴. In the formation of a sodium derivative from five alkylidenecyanoacetic esters derived from a series of methyl ketones, hydrogen is lost from the methylene of an alkyl group higher than methyl, rather than from the methyl group. Yields in the alkylation reactions are highest when sodium isopropoxide and isopropyl alcohol are employed, presumably because of the relatively slow alcoholysis of the products in this solvent.

---

[7] The valeraldehyde derivatives had a higher melting point than the one previously recorded. All others are in agreement with those reported by Campbell, *Analyst*, **61**, 391 (1936).

BRYN MAWR, PENNA. RECEIVED SEPTEMBER 26, 1938

[CONTRIBUTION FROM THE WILLIAM H. CHANDLER CHEMISTRY LABORATORY, LEHIGH UNIVERSITY]

The Action of Bromine on Nitrothiophene

BY V. S. BABASINIAN

The literature has very little to reveal regarding the behavior of nitrothiophene toward bromine. Casual references to the changes involved merely imply that the halogen attacks the nitro group with avidity, converting the compound to tetrabromothiophene.[1] The reaction was studied more closely in this Laboratory. It was found that in direct contact with the theoretical amount of bromine, nitrothiophene yields mainly tetrabromothiophene, but the product invariably is contaminated with the unattacked nitro compound. On the other hand, when the amount of bromine is reduced to the required minimum for the replacement of a single hydrogen in the thiophene nucleus, brominated intermediates appear in the product along with tetrabromothiophene. The reaction is likewise modified if brominations are effected in neutral or alkaline aqueous suspensions, or in ordinary organic solvents. Small-scale experiments performed under these conditions[2] give every indication that in the direct bromination of nitrothiophene the nitro group offers a degree of resistance to replacement by bromine, permitting the formation of a number of substituted derivatives, and under proper control the reaction pursues a course that can be followed with reasonable certainty.

The author proposes to show that with bromine vapor at room temperature, nitrothiophene

---

[1] (a) Meyer, "Die Thiophengruppe," Braunschweig, 1888, p. 102; (b) Steinkopf and co-workers, *Ann.*, **512**, 137 (1934).

[2] The author desires to record his gratitude to Messrs. John B. Fishel and Horace F. Ether who performed the preliminary experiments. The analytical data for tetrabromothiophene, given later, were secured by Mr. Ether.

yields four compounds in quantities ample for conclusive identification, and the presence of a fifth derivative of thiophene may be demonstrated by qualitative tests. In the following list the approximate yield of each crude product from 50 g. of nitrothiophene is indicated. The melting points are those of the purified compounds.

—Thiophene	2-Bromo-5-nitro-	2,3-Dibromo-5-nitro-	2,5-Dibromo-3-nitro-	Tetrabromo-
Formula				Yield, g.	8.5	6.0	0.8[3]	10.0
M. p., °C.	47–48	75.5–76	61	116–117

In the reaction product a fifth derivative of thiophene was isolated in extremely small quantities. Its composition as 2,3,5-tribromothiophene,  is provisionally inferred from a superficial examination of physical properties.

Discussion of Results

The results attained in this bromination justify the assumption that in bromonitrothiophene the substituents occupy positions 2 and 5. They also elucidate the course of the reaction, and offer criteria for the evaluation of the relative stability of intermediates.

The Structure of Bromonitrothiophene.—There are two factors that are likely to control the course of the reaction between bromine and nitrothiophene: namely, (a) the alpha orienting effect of sulfur, and (b) the meta orienting effect of the nitro group. Under the predominating influence of (a) or (b) one would expect the formation of either 2-bromo-5-nitrothiophene or 3-bromo-5-nitrothiophene. If both factors were effective the two isomers might appear as a mixture. It is quite significant that in this reaction approximately 9 g. of an homogeneous bromonitrothiophene was isolated. More important is the fact that the compound produced was in every detail identical with the bromonitrothiophene prepared from 2-bromothiophene by nitration.[4] The formation of the same bromonitrothiophene, whether one brominates *2-nitrothiophene* or nitrates *2-bromothiophene*, points to the conclusion that the product is 2-bromo-5-nitrothiophene.[5] There is no valid reason to doubt the meta orienting capacity of the nitro group. And if under the influence of this factor 3-bromo-5-nitrothiophene was also produced in any quantity, it quickly changed to 2,3-dibromo-5-nitrothiophene because of the available alpha position which an additional bromine could readily occupy.

The Course of the Reaction and Relative Stability.—In the brominated product 2,3-*dibromo-5-nitrothiophene* is also present in moderate quantities. It is natural to assume that this compound was formed by the further bromination of 2-bromo-5-nitrothiophene. Had the reaction followed a normal course, a large percentage of the latter would have produced the former. When the yields of the two products are compared, it will be seen that the amount of 2-bromo-5-nitrothiophene is much larger than that of 2,3-dibromo-5-nitrothiophene. This means that the 2-bromo compound is more resistant to the action of the halogen than the 2,3-dibromo derivative. As the latter accumulates in the reaction product, it is attacked by bromine and ultimately changed to tetrabromothiophene.[6]

From the results it is also possible to determine with reasonable assurance the relative stability of the nitro group toward bromine in these two compounds. That in 2-bromo-5-nitrothiophene this group is not vulnerable may be inferred from the complete absence of 2,5-dibromothiophene in the reaction product. 2,3-Dibromo-5-nitrothiophene shows an altogether different behavior. Had the nitro group been firmly held by the nucleus, further bromination would have resulted in the formation of 2,3,4-tribromo-5-nitrothiophene; but not a trace of this product could be isolated in these experiments. Moreover, if any importance could be attached to evidence gleaned from tests of purely qualitative

---

(3) This product could originate only from β-nitrothiophene. Steinkopf and Höpner were able to prove that ordinary nitrothiophene contains about 97.5% of the alpha compound and 2.5% of the beta isomer [*Ann.*, **501**, 176, 182–183 (1933)]. In the course of the present study a partial separation of the two isomers was made by the repeated crystallization of ordinary nitrothiophene from petroleum ether. In one of the bromination experiments a sample of ordinary nitrothiophene was used which had not been separated into the two isomers. Omission of this procedure resulted in a marked increase in the yield of 2,5-dibromo-3-nitrothiophene.

(4) Babasinian, THIS JOURNAL, **57**, 1763 (1935). Compare also ref. 1b, p. 161. The compound produced in this way was provisionally described as 2-bromo-5-nitrothiophene, but no evidence was offered in support of this structure.

(5) *Cf.* von Schweinitz, *Ber.*, **19**, 640, 648 (1886).

(6) 2,5-Dibromo-3-nitrothiophene is not expected to manifest this behavior. Steinkopf and co-workers[1b] (pp. 137 and 161) had pointed out that, unlike 2,3-dibromo-5-nitrothiophene, this compound remains quite stable in an excess of bromine.

nature, 2,3,5-tribromothiophene was formed, at any rate, in detectable quantities. The appearance of this compound and the complete absence of 2,3,4-tribromo-5-nitrothiophene led to the inference that in 2,3-dibromo-5-nitrothiophene the nitro group is too weakly held by the nucleus to resist replacement by the halogen. In consequence, the loosely held group leaves the nucleus to favor the formation of tetrabromothiophene.

Experimental

Fifty grams of nitrothiophene, prepared in the usual way,[7] was spread in a crystallizing dish and supported over 27 cc. of bromine in a covered desiccator. The reaction was allowed to proceed at room temperature for thirty days. In twelve hours over one-half of the bromine had been absorbed and the solid had completely liquefied into a dark red oil. In the following twenty-four hours the oil had in part changed to fine crystals. The final product was a mixture consisting of light red crystals and a yellow oil. Bromine was more rapidly absorbed during the last few days of the allotted period than at the beginning.

Tetrabromothiophene in the Oily Mixture.—The reaction product was chilled and filtered under suction. The precipitate was washed with water, dried, and refluxed with several portions of petroleum ether. The solvent extracted a small quantity of nitrothiophene. The undissolved white residue weighed about 9 g. It was crystallized from hot alcohol and melted at 116–117°.

Anal. Calcd. for C_4Br_4S: S, 8.00; Br, 79.97. Found: S, 7.86; Br, 80.23.

The oily filtrate was neutralized with dilute sodium carbonate, washed with water, and steam-distilled.[8] The distillate was collected in four fractions: Fraction I contained a white solid and an almost colorless oil; II was uniformly oily; III was also uniformly oily; IV distilled slowly as a pure white solid.

Each of the first three fractions was dissolved in ether and dried with calcium chloride. Fraction IV was filtered and dried. Ether was removed from the first three fractions and the oily residues were examined.

2-Bromo-5-nitrothiophene in Fractions I and II.—Fraction I was cooled in ice for a long time and filtered under suction. The crystalline precipitate was brownish-white, yield 7.5 g. It was dissolved in boiling petroleum ether and decolorized with darco. Upon cooling the filtrate yielded snow-white needles which acquired a faint yellow color in air. The recrystallized product melted at 47–48°. The mixed melting point with a pure sample of 2-bromo-5-nitrothiophene was 46–47°.

Anal. Calcd. for $C_4H_2S(NO_2)Br$: S, 15.41; Br, 38.42. Found: S, 15.36; Br, 38.26.

Fraction II was cooled in a freezing mixture and filtered. The solid proved to be 2-bromo-5-nitrothiophene.

2,3-Dibromo-5-nitrothiophene in Fraction III.—Fraction III was cooled and filtered. The precipitate yielded 3.5 g. of bright yellow crystals which melted at 74–75°. A petroleum ether solution, after treatment with darco, yielded white crystals which acquired a faint yellow coating when exposed to air. The compound is moderately volatile with steam. The distilled solid is pure white, while the clear aqueous residue in the distillation flask retains the faint yellow color. After recrystallization from petroleum ether the steam-distilled solid remained almost white in a brown desiccator for several weeks. It melted at 75.5–76°.[9]

Anal. Calcd. for $C_4HS(NO_2)Br_2$: S, 11.17; Br, 55.70. Found: S, 11.04; Br, 55.80.

Fraction IV Yields Tetrabromothiophene, 2,3-Dibromo-5-nitrothiophene, and a Trace of Lower-melting Crystals.—The solid obtained as Fraction IV weighed 9.5 g. It was crystallized from a large volume of methanol. The nitrogen-free crystals melting at 113–114° proved to be tetrabromothiophene. After concentration the alcoholic filtrate yielded 2.5 g. of 2,3-dibromo-5-nitrothiophene. Upon further concentration the mother liquor was found to contain a trace of a white solid which melted at 62–67°.

The isolation of compounds in the oily filtrates was accomplished by distillation *in vacuo* at constant pressure. Serious decomposition could be reduced to a negligible minimum if the process was carried out slowly, below 130°.

Oily filtrates from Fractions I, II and III were distilled under a pressure of 5 mm. and collected at the following temperature ranges: A, at or below 105° (trace of solid or oil); B, at 109–110° (mainly solid); C, at 112–115° (oil); D, at 118–123° (mainly solid); E, at 123–128° (solid and oil). Distillates containing mixtures of oil and solid were cooled and filtered. The precipitate was freed from impurities by the usual methods. Oils, or oily filtrates, were dissolved in solvents and cooled; when the solution failed to form crystals, the solvent was evaporated and the oil was refractionated. Purified products could be obtained only in small quantities. When melting points and qualitative tests furnished fair indications of identity with previously analyzed compounds, results were checked by determinations of mixed melting points.

Distillate A was composed mainly of unattacked *nitrothiophene.*

Distillate B yielded *2-bromo-5-nitrothiophene.*

Distillate C produced a compound melting at 28–32° in quantities too small for complete purification. This is probably *2,3,5-tribromothiophene*[1a] (p. 79).

Distillate D contained almost exclusively *2,3-dibromo-5-nitrothiophene.*

Distillate E was found to be a mixture of *tetrabromothiophene, 2,3-dibromo-5-nitrothiophene,* and *2,5-dibromo-3-nitrothiophene.* For the isolation of these compounds the distillate was cooled and filtered. The solid was dissolved in methanol and purified with darco. From the clear solution bright yellow crystals of 2,3-dibromo-5-nitrothiophene were obtained.

The oily filtrate was dissolved in boiling alcohol. Upon

(7) Babasinian, THIS JOURNAL, **50**, 2749 (1928).

(8) A dark brown semi-solid remained in the distillation flask. Weight, after drying, about 10 g. Insoluble in most ordinary solvents. Boiling acetone removed from it a dark red heavy oil leaving an insoluble brown powder which burned very slowly over a direct flame. The oil and the brown powder were not examined further.

(9) There can be no doubt that the white product, showing this melting point, is 2,3-dibromo-5-nitrothiophene. Steinkopf and coworkers describe it as a bright yellow solid and give its melting point as 75° (ref. 1b, p. 156).

cooling crystals were obtained which had the characteristics of tetrabromothiophene. The mother liquor was carefully concentrated. When cooled in a freezing mixture, white, shiny crystals were formed which melted at 55–65°; weight less than 1 g. It was recrystallized from petroleum ether, then distilled with steam and the solid distillate was again crystallized from the same solvent. The final product melted at 61°. Analysis showed that the compound was 2,5-dibromo-3-nitrothiophene.[10]

Anal. Calcd. for $C_4HS(NO_2)Br_2$: S, 11.17; Br, 55.70. Found: S, 10.90; Br, 56.16.

Summary

In the vapor phase and at room temperature a limited quantity of bromine converts ordinary nitrothiophene into 2-bromo-5-nitrothiophene, 2,3-dibromo-5-nitrothiophene, 2,5-dibromo-3-nitrothiophene and tetrabromothiophene.

Qualitative tests also indicate the formation in traces of one other brominated derivative of thiophene.

The reaction confirms the heretofore assumed structural formula of bromonitrothiophene.

The reaction leads to the inference that in 2-nitrothiophene the nitro group resists replacement by bromine during the entry of the first atom of halogen into the thiophene nucleus; but this group is considerably loosened after the entry of the second bromine atom.

BETHLEHEM, PENNA. RECEIVED SEPTEMBER 12, 1938

Ternary Systems. V. Phthalic Acid, Magnesium Phthalate and Water. VI. Magnesium Phthalate, Lithium Phthalate and Water

BY STERLING B. SMITH AND EDWARD C. ELY[1]

Introduction

A number of phase rule studies of ternary systems involving phthalates and acid phthalates, particularly of the alkalies, have been made in this Laboratory. It is for the purpose of gaining further information regarding the solubilities of these salts that this investigation has been undertaken.

Experimental Part

Materials and Methods.—The phthalic acid used was prepared by crystallizing from aqueous solution sublimed phthalic anhydride obtained from the Eastman Kodak Company.

Magnesium phthalate was prepared by adding to an aqueous solution of phthalic acid an excess of magnesium carbonate, A. R. The solution was boiled to drive off carbon dioxide and filtered hot to remove the insoluble magnesium carbonate. The filtrate was evaporated to a small volume and allowed to stand several days while the magnesium phthalate crystallized out. The salt was filtered on a Büchner funnel and allowed to dry in the air. The composition of this salt was found by analysis to be $2MgC_8H_4O_4 \cdot 11H_2O$. Air dried samples heated to constant weight in an electric oven at 120° lost weight corresponding to 34.72, 34.60, 34.58, 34.45, 34.27 and 34.23% of water. The theoretical value for the per cent. of water in $2MgC_8H_4O_4 \cdot 11H_2O$ is 34.47%.

Lithium phthalate, $2Li_2C_8H_4O_4 \cdot 3H_2O$, was prepared as described in a previous publication.[2]

Magnesium acid phthalate, while not a component of either of these systems, appears as one of the solid phases and is used in the preparation of mixtures for analysis. It was prepared by adding slightly more than one-half the equivalent weight of magnesium carbonate to an aqueous solution containing the equivalent weight of phthalic acid, boiling off the carbon dioxide and evaporating to crystallization.

Solubilities were determined by analyzing solutions obtained by rotating mixtures of the three components in an electrically controlled thermostat for a minimum of twenty-four hours. In making up the mixtures, as far as possible the salts were used which exist as solid phases after equilibrium has been reached. At 0° the temperature was maintained constant by the use of ice and a small amount of salt. Temperature variations were within ±0.1°. When equilibrium was attained, the mixtures were allowed to settle and samples for analysis removed from the clear supernatant liquid by means of a pipet. When necessary to ensure a clear solution, a small plug of cotton or glass wool was inserted in a short piece of rubber tubing and slipped over the end of the pipet. Due to the viscosity of many of these solutions, density determinations were not attempted.

The composition of the solid phases was determined by the analysis of wet residues according to Schreinemakers.[3]

In the system phthalic acid, magnesium phthalate and water, phthalic acid was determined by titration with standard alkali. Magnesium phthalate was determined by precipitation of the magnesium as magnesium am-

[3] Schreinemakers, *Z. physik. Chem.*, **11**, 76 (1893).

monium phosphate followed by ignition to the pyrophosphate. Water was determined by difference.

In the system magnesium phthalate, lithium phthalate and water, water was determined as loss in weight when a sample was heated to constant weight in a platinum dish in an electric oven at 180°. Magnesium phthalate was determined in the same sample by the pyrophosphate method and lithium phthalate determined by difference. Solutions saturated with both lithium phthalate and magnesium phthalate were so viscous and so dense that a week was required for the solid phase to settle. Even then these solutions were slightly turbid after passing through glass wool. No improvement was found after centrifuging. Solubility determinations, therefore, in this system near its univariant point may be off as much as 0.5%.

Experimental Results.—Isotherms at 0, 25 and 50° have been completed for the system phthalic acid, magnesium phthalate and water. Compound formation takes place at all three temperatures. The solubility isotherms, therefore, consist of three intersecting curves representing isothermally univariant equilibrium between the solutions and one solid phase, and two isothermally invariant points where two solid phases are in equilibrium with the solution.

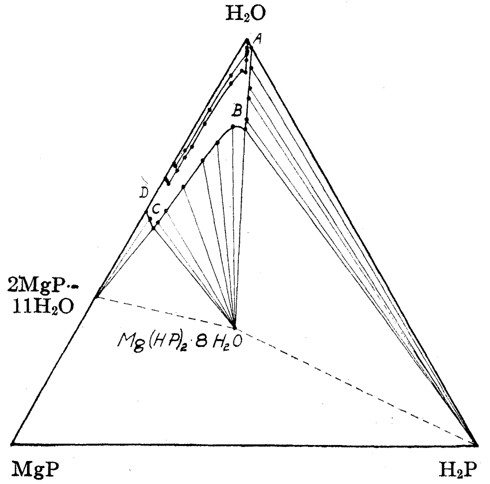

Fig. 1.—Temperatures, 0, 25, 50°.

One isotherm at 25° has been completed for the system magnesium phthalate, lithium phthalate and water. A second isotherm at 50° was undertaken but due to the extreme viscosity of the solutions at the higher concentrations, no conclusive results were obtained near the invariant point and further experiments abandoned. The 25° isotherm shows no evidence of compound formation. The isotherm consists of two intersecting curves representing isothermally univariant equilibrium between the solutions and one solid phase, and one isothermally invariant point at which the solution is in equilibrium with two solid phases. The portion of the 50° isotherm which is reported is similar. It is possible that compound formation or solid solution may occur in that region where unsatisfactory non-reproducible results were obtained.

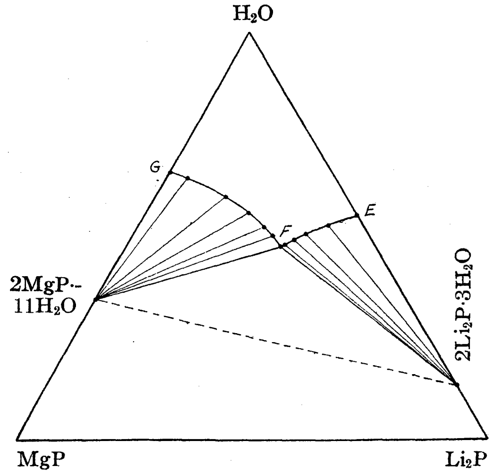

Fig. 2.—Temperature, 25°.

Experimental results are given in Tables I and II. The symbol "P" is used here as in previous work to designate the phthalate radical, $C_8H_4O_4$.

The Acid Salt.—The composition of the acid salt, $Mg(HP)_2 \cdot 8H_2O$, was determined by the extrapolation of tie lines which intersect at a point in the isotherms representing a composition which agrees very closely with this. The algebraic extrapolation of the tie lines as shown by Hill and Ricci[4] gives values for the composition which agree closely with the theoretical value of 28.91% water. The maximum deviation in this case was 0.90% with an average deviation of 0.10%. When samples of the hydrated acid salt were dried in an electric oven for twenty-four hours at 110°, percentages of water were found ranging from 28.71 to 29.12. Analyses of the hydrated acid salt for magnesium phthalate and phthalic acid gave an average value for water by difference of 29.08%. The octahydrate was kept in a desiccator over anhydrous magnesium acid phthalate for a prolonged period without loss in weight, giving no evidence of a lower hydrate.

The acid salt, $Mg(HP)_2 \cdot 8H_2O$, is congruently soluble only at 50°, for the three temperatures studied.

Summary

1. The solubility relations in the ternary system phthalic acid, magnesium phthalate and water at 0, 25 and 50° have been determined.

2. Compound formation has been found to take place in this system at all of these temperatures.

3. The composition of this compound has been shown to be $MgC_8H_4O_4 \cdot H_2C_8H_4O_4 \cdot 8H_2O$.

4. This acid salt is crystallizable from aqueous solution at temperatures of 50° and above.

5. When crystallized from water solution at room temperature, magnesium phthalate has the formula, $2MgC_8H_4O_4 \cdot 11H_2O$.

6. An isotherm showing the solubility relations in the ternary system magnesium phthalate, lithium phthalate and water at 25° has been completed. A 50° isotherm is incomplete.

7. No evidence of double salt formation in this system has been established.

Heats of Adsorption of Gases on Chromic Oxide at Low Temperatures*

BY RALPH A. BEEBE AND DENNIS A. DOWDEN

As a result of numerous researches on the adsorption of gases on catalytically active solid surfaces, van der Waals and activated adsorptions have become clearly recognized as separate and distinct types. In many instances it has been shown that a gas may be held in both states of adsorption upon the same solid surface. Frequently the two types occur in more or less well separated temperature ranges, the activated type being characteristic of the higher temperature. In certain cases, however, the critical increment of the activated adsorption is sufficiently low so that the temperature range of this process overlaps that of the low temperature van der Waals adsorption.

In the present investigation heats of adsorption, in the low temperature region, have been measured calorimetrically using the six gases, argon, hydrogen, deuterium, carbon monoxide, nitrogen, and oxygen on a reduced chromic oxide surface. The order of magnitude of the heats indicates that all these gases, with the single exception of argon, are in part held in a state of activated adsorption as well as in the van der Waals state even at the low temperature of −183°. Moreover, in the experiments with carbon monoxide, nitrogen, and oxygen, the complex form of the time–temperature curves on a partially covered surface has led us to the conclusion that the adsorbed gas changes over on the surface from an initial van der Waals state to a final state of activated adsorption.

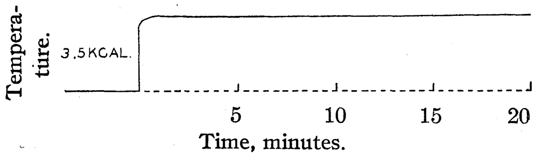

Fig. 1.—Time–temperature curve for argon at −183°.

The catalytic activity of chromic oxide at −183° for the reaction $H_2 + D_2 \rightleftarrows 2HD$[1] leads to the conclusion that the adsorption of hydrogen and of deuterium on that adsorbent is, in part at least, of the activated form. Special interest is therefore attached to the heats of adsorption of the hydrogen isotopes which give independent evidence for the activated adsorption of these gases at −183°. The present work confirms the results of a previous investigation by Beebe and Orfield[2] using hydrogen alone.

Experimental

Apparatus.—A detailed description of the vacuum jacketed calorimeter used in this work has been given in an earlier publication. The calorimeter, which had a total heat capacity of 4.839 cal. at −183° and contained 11.95 g. of chromic oxide, was used without any dismantling or alteration after the heat measurements with hydrogen previously described.[2] The thermocouple wires were led into the calorimeter by means of tungsten bridges sealed through the Pyrex glass. The whole calorimeter vessel including the tungsten bridges was immersed in a suitable bath for constant temperature. For the temperatures −183, −195, and 0°, respectively, baths of liquid oxygen, liquid nitrogen, and an ice–water mixture were used. In the experiments designated in Table II for hydrogen and deuterium, and in all the other work except the first carbon monoxide series, a small quantity (about 0.2 cc.) of helium was admitted to the inside of the calorimeter. This produced a residual pressure of approximately 0.1 mm., and served to improve the conditions for effective heat distribution.

Especially in the hydrogen and deuterium measurements, very careful attention was given to experimental details such as the temperature and duration of outgassing, and the protection of the external leads of the thermocouple from chance fluctuations in room temperature. As a result, it was possible to read the differential heats with greater precision than in the earlier work, and the results were remarkably reproducible in successive series of measurements for all corresponding increments of gas added to the surface.

In Fig. 1 is given a typical time–temperature curve for argon at −183°. The rapid rise to maximum temperature following the admission of the gas, and the almost negligible rate of cooling after the temperature rise, both indicate that the calorimetric conditions were very satisfactory, and the temperature recorded by the thermocouple was truly the average temperature of the whole metal calorimeter with negligible heat lag due to poor thermal distribution. This type of curve, which was obtained under all conditions in the measurements with argon as well as with the isotopes of hydrogen,[3] will be referred to as a *normal* time–temperature curve in comparison to curves of *abnormal* type resulting from the more complex nature of the adsorption processes in the cases of the other gases studied at −183°.

[1] Gould, Bleakney and Taylor, *J. Chem. Phys.*, **2**, 362 (1934).

[2] Beebe and Orfield, THIS JOURNAL, **59**, 1627 (1937).

[3] Owing to a misunderstanding, the time–temperature curve in Fig. 2 of the paper by Beebe and Orfield was inverted when printed. The downward break in the curve as printed actually represents a rise in temperature.

Because of the much greater rate of heat loss from the metal calorimeter by radiation at the higher temperature, the rate of cooling after the liberation of the heat of adsorption was very much more rapid at 0° than at −183°. However, owing to the rapid rate of adsorption and consequent quick rise to maximum temperature, the heat at 0° could be determined from the time–temperature curves with a fair degree of accuracy. It is noteworthy, however, that this calorimetric method is more satisfactory at the lower temperature.

Materials.—The hydrogen was prepared from electrolytic tank hydrogen by first passing over hot copper and then through a trap filled with glass wool and immersed in liquid air.

Deuterium was produced by electrolysis of 99% deuterium oxide with careful provision for the exclusion of gaseous impurities during the electrolysis and the transfer of the gas.

The method of preparation of carbon monoxide has been described previously.[4] Analysis showed that it contained at least 98% of carbon monoxide and no oxygen.

Pure oxygen was obtained by heating potassium permanganate crystals *in vacuo*.

The nitrogen was obtained from tank nitrogen by mixing with 5% of electrolytic hydrogen, passing the mixed gases over a mixture of copper and copper oxide granules at 400°, and removing the water vapor by means of a calcium chloride tube and liquid air trap.

The argon gas purchased from the Air Reduction Sales Company was spectroscopically pure.

The chromic oxide was the same "unglowed" sample used in the earlier experiments.[2] Following each series of heat measurements, the surface was outgassed for three hours at 400°, except in the case of oxygen. For the removal of the latter gas, the final three-hour period of outgassing was preceded by a one-hour period of reduction in a hydrogen atmosphere. During this reduction the hydrogen was removed and replaced several times to eliminate the water vapor produced.

Results

The Adsorption Isotherms at −183°.—In Fig. 2 are plotted the isotherms from data obtained in the course of the heat measurements at −183°. Hydrogen, deuterium, and carbon monoxide were adsorbed instantaneously (in less than two minutes) with no residual pressure up to 20, 28, and 120 cc., respectively. Argon, nitrogen, and oxygen produced small residual pressures even for the initial increments of gas admitted. In no case was the amount of gas, unadsorbed after two minutes, more than 4% of the total increment admitted. In all cases in which there was residual unadsorbed gas the pressure underwent a slow decrease which was usually complete in twenty minutes. The pressures plotted in Fig. 2 were read twenty minutes after admission of the gas increments. The amount of gas adsorbed in the interval between two and twenty minutes after admission was never more than 2% of the total increment adsorbed, and in most cases much less than that. It was therefore disregarded and the amount of gas adsorbed after two minutes was used in the calculation of the differential heats.

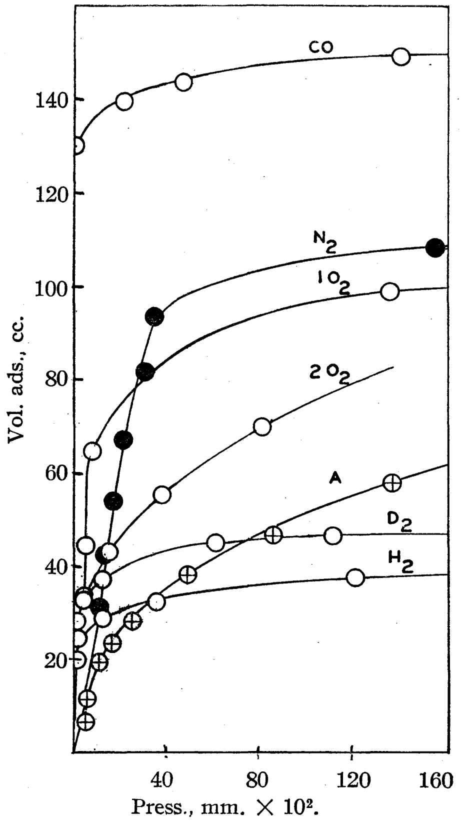

Fig. 2.—Adsorption isotherms on 11.95 g. of Cr_2O_3 at −183°.

With the exception of oxygen, the isotherms were remarkably reproducible. The curves shown in Fig. 2 for carbon monoxide and nitrogen are composites of four series with the former and two with the latter. Only one series was measured with argon. The isotherms for hydrogen and deuterium in Fig. 2 represent data from four series with deuterium and three with hydrogen. These measurements with the hydrogen isotopes were performed before any of the other gases were admitted to the chromic oxide surface. The order of experiments was D_2, D_2, H_2, D_2, H_2, H_2, D_2. For simplicity, only a few representative points have been plotted, but for the scale used, other points not plotted would fall on the isothermal lines without any apparent deviation. It is therefore definitely established that deu-

terium is more firmly held than hydrogen on a chromic oxide surface at −183°.

Analysis showed that the adsorbed carbon monoxide could be removed unchanged by evacuation at 400°, the desorbed gas containing no carbon dioxide. No attempt was made to analyze the other gases after desorption but the reproducibility of the isotherms as well as the differential heat curves, for all the gases studied with the exception of oxygen, provide strong evidence that the three-hour evacuation at 400° was sufficient to remove the adsorbed gases completely without changing the state of the chromic oxide surface. The adsorbed film of oxygen could be removed only as water vapor after reduction in hydrogen. This treatment resulted in a change in the activity of the surface as shown by the failure of the isotherms and heat curves to coincide in the successive series of measurement for oxygen. No experiments with oxygen were attempted until all the other work had been completed. Hence only in the case of the first oxygen series was the surface the same as that employed for the other gases.

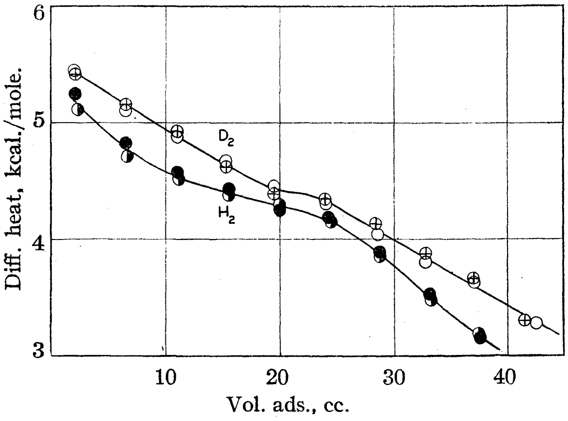

Fig. 3.—Series 1, H_2 ●; Series 2, H_2 ◑; Series 1, D_2 ⊕; Series 2, D_2 ○.

The Heats of Adsorption at −183°, Argon, Hydrogen, and Deuterium.—The results for the single series of differential heat measurements with argon are given in the lower curve in Fig. 8. Because of the magnitude of the differential heats which fall between 4.2 and 2.7 kcal./mole and because of the normal form of the time–temperature curves (Fig. 1) it is concluded that the process for argon at −183° is a simple van der Waals adsorption.

In all, four series of differential heat measurements were made with deuterium and three with hydrogen. The results of two series with each isotope are shown in Fig. 3. Details for typical series are also given in Table I. It is apparent that the heats are definitely higher with the heavier isotope for all corresponding portions of the chromic oxide surface.

The integral heats, obtained by a process of summation of the differential heats for the increments comprising the first 37.2 cc. of each isotope adsorbed, are listed in Table II (Series 1–7). The integral heats evolved when 37.2 cc. of gas was admitted at one time were also measured in one experiment for each hydrogen isotope. The results are given in Table II (Series 8 and 9). It is interesting that the values obtained by direct admission of the whole 37.2 cc. are higher than those found by a summation of the differential heats. We believe that this difference is a real one and not due to experimental error. A similar discrepancy has been observed by Magnus and his co-workers[5] in the case of sulfur dioxide on charcoal, and these authors have suggested an explanation based on the assumption of slow establishment of equilibrium in the crevices of the adsorbent. It is probable that a similar

explanation is applicable in the present instance, In any case, it appears to be established that for the interval 0 to 37.2 cc. adsorbed, the integral heat of adsorption of deuterium exceeded that of hydrogen by approximately 0.35 kcal. per mole.

The Heats of Adsorption at −183°, Carbon Monoxide, Nitrogen, and Oxygen.—Unlike the gases already discussed, carbon monoxide, nitrogen, and oxygen failed to produce normal time–temperature curves under all conditions. This anomalous behavior is illustrated in the case of carbon monoxide by the curves in Fig. 4. Curves I, II, and III are the time–temperature curves obtained with approximately equal increments of about 4.5 cc. of the gas on a surface to which had been added already 0, 55, and 112 cc., respectively, *i. e.*, these curves were obtained from measurements on a bare surface, a partly covered surface, and a nearly saturated surface.

A normal type of curve was obtained when no carbon monoxide was previously adsorbed (Curve I); however, with successive increments of the gas the rise to maximum temperature became less and less sharp, and then began to divide into a rapid and a slow stage (Curve II) until finally the slow stage had assumed such a low rate that it could scarcely be detected in the twenty-minute period of observation (Curve III). Except when the experiments were interrupted overnight (see below), all the other time–temperature curves observed in the series of measurements fitted in form to their intermediate positions in the series. In all the carbon monoxide increments up to 120 cc. adsorbed, *all the gas disappeared from the gas phase within one minute after admission.*

From these observations we are forced to conclude that the adsorption of carbon monoxide on chromic oxide at −183° consists of two distinct and separate processes which we shall call Process A and Process B. Process A is rapid for all states of the surface and gives a heat of approximately 4 kcal.; Process B is rapid for a bare surface but becomes progressively slower for successive increments until it is too slow to observe. Process B yields an additional heat of about 8 kcal., bringing the total heat up to 12 kcal. For reasons given later under Discussion we believe Process A is a van der Waals adsorption, and that the final result of Process B is a state of activated adsorption. If this is true, the heat values 4 and 12 kcal. represent differential heats of van der Waals and of activated adsorption, respectively, and have therefore been so designated in Fig. 5. Furthermore, because of the slow evolution of heat long after all the gas had disappeared from the gas phase, it seems probable that the gas, initially adsorbed by van der Waals forces, subsequently underwent a change into the activated state without leaving the surface.

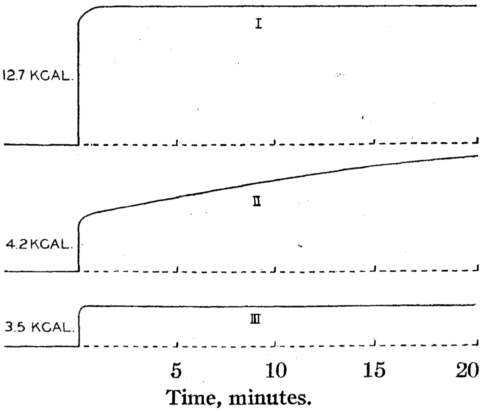

Fig. 4.—Time–temperature curves for CO at −183°.

The data listed in Fig. 5[6] indicate that there is a decrease in the differential heats of activated adsorption with increasing surface covered suggesting a variation in surface activity.[7] However, we do not feel certain that this has been demonstrated conclusively because of the difficulty in estimating the total heat rise, especially in the region 30–80 cc. adsorbed.

The heat experiments with nitrogen and oxygen produced the same division into Processes A and B. As in the case of carbon monoxide, the heat of Process A was about 4 kcal. for both these gases. The heats of activated adsorption were, however, about 8 kcal. for nitrogen and 20–27

(6) From the experimental observations on a relatively bare surface, it is possible to estimate the differential heats of the activated adsorption only. On a nearly covered surface where Process A occurs exclusively, only van der Waals heats are measured. On partially covered surfaces (Curve II, Fig. 4), however, it is possible to determine both the heat of van der Waals absorption from the initial rapid heat evolution, and the heat of activated adsorption from the total heat evolved. For this reason heat data for both types of adsorption are given for the region 40–80 cc. adsorbed. The heat of activated adsorption could be determined with fair accuracy for the initial increments up to a total of 30 cc. Beyond that point it became increasingly difficult to estimate the total heat evolution because of the decreasing rate of Process B with each successive increment. Beginning at about 40 cc. adsorption, it was possible to estimate the initial sharp rise due to van der Waals adsorption. Beyond 55 cc. the results could be determined more accurately because Process A was more sharply differentiated for the later increments.

(7) It is possible that the activated adsorption of carbon monoxide, oxygen, and nitrogen is non-selective as it has been shown to be with hydrogen (see below). In that case, the true differential heats would decrease more rapidly with successive increments than in the experimental values given in Fig. 5.

kcal. for oxygen. Typical time–temperature curves are given in Figs. 6 and 7 for initial, intermediate, and final increments of each gas. The differential heats for both activated and van der Waals adsorption are shown in Figs. 8 and 9.

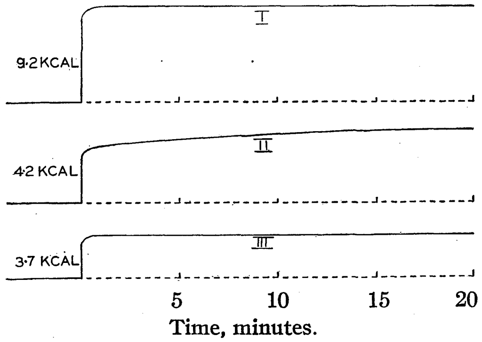

Fig. 6.—Time–temperature curves for nitrogen at −183°.

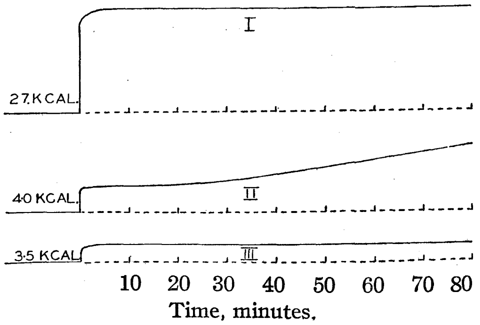

Fig. 7.—Time–temperature curves for oxygen at −183°.

Owing to the change in activity of the chromic oxide surface in the three oxygen experiments, the differential heat values were not reproducible. Series 1, 2, and 3 produced initial heats of 27, 21, and 25.5 kcal., respectively. It is noteworthy that the same order of activity for the three series is indicated by the adsorption isotherms from Series 1 and 2 in Fig. 2. Unfortunately, Series 3 was not carried far enough to determine the position of the isotherm.

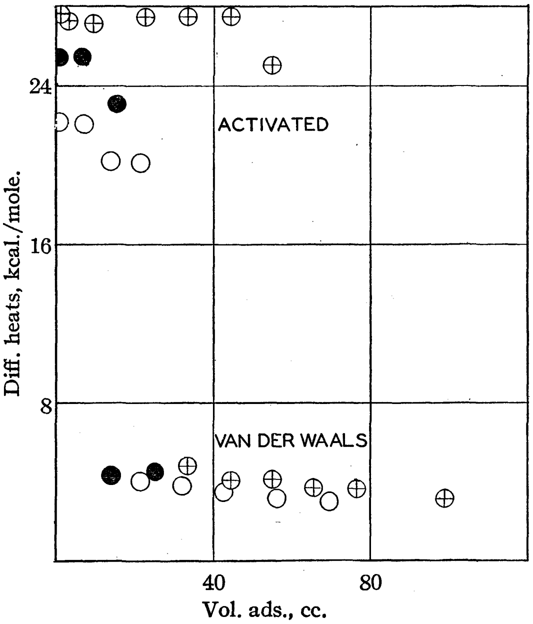

Fig. 9.—O_2 on Cr_2O_3 at −183°: Series 1 ⊕; Series 2 ○; Series 3 ●.

Following several of the series of heat measurements, the chromic oxide surface was outgassed for one hour at −183°. The differential heats were measured for increments subsequently added to the surface. As might have been expected, the form of the time–temperature curves and the magnitude of the heats both indicated van der Waals adsorption exclusively. The data for two such experiments with carbon monoxide and one with nitrogen are given in Figs. 5 and 8. A similar result was obtained in previous work in this Laboratory with carbon monoxide on copper at −183°.[8] These experiments demonstrate the reversibility of the van der Waals process at −183°, as well as the irreversible nature of the activated adsorption.

Carbon Monoxide on an Oxygen Covered Surface, and Oxygen on a Carbon Monoxide Covered Surface at −183°.—An investigation was made of the heat liberated by the addition of carbon monoxide to an oxygen covered surface at −183°.[9] Following oxygen Series 3 at −183°, the unadsorbed oxygen and presumably most of the van der Waals adsorbed oxygen were removed by evacuation for one hour at the same temperature. It is estimated that 25 cc. of activated adsorbed oxygen remained. The differential heats for carbon monoxide on this surface were then determined. The time–temperature curves for intermediate increments in the series had the abnormal form observed with carbon monoxide on an initially bare surface, indicating the presence of the rapid Process A, van der Waals adsorption, followed by a slow Process B, activated adsorption. The results of this experiment are given in Table III.

Another series of heat measurements was conducted for oxygen on a carbon monoxide covered surface at −183°. In this experiment the surface was prepared by adding carbon monoxide at −183° until there was a residual pressure, and then outgassing for one hour at that temperature, leaving a surface film of approximately 100 cc. of carbon monoxide adsorbed in the activated state. The differential heats then obtained upon admission of successive increments of oxygen are given in Table III. The time–temperature curves were normal, giving no evidence for a slow process. The magnitude of the heats indicates an activated adsorption for the initial increments with a van der Waals adsorption of the final increment added.

A comparison of our data in Table III, with the results of the experiments with a single gas on an initially bare surface, reveals the following facts: (1) the presence of 25 cc. of adsorbed oxygen reduces the volume of carbon monoxide adsorbed in the activated state from 113 to 40 cc. (at 1 mm. residual pressure) but causes no great change in the heat of activated adsorption which is approximately 12 kcal. whether the surface was initially bare or oxygen-covered; (2) 100 cc. of adsorbed carbon monoxide brings about a very great decrease in the volume of oxygen adsorbed in the activated form from 25 to 4 cc.; moreover, the heat of the activated adsorption of oxygen is reduced from 25 kcal. on the initially bare surface to 13 kcal. on the carbon monoxide covered surface.

The complexity of the experimental conditions especially when two gases are present simultaneously on the chromic oxide surface which itself contains two different kinds of atoms makes an explanation of the above observations rather precarious. An explanation appears to be possible if we assume that: (1) the activated adsorption of oxygen occurs on the surface chromium atoms only; (2) the activated adsorption of the carbon monoxide occurs chiefly on the oxygen atoms of the chromic oxide but to some extent on the most active chromium atoms. However, we prefer not to present such an explanation until further experimental results are available.

Heat of Adsorption of Carbon Monoxide at −195°; the Energy of Activation of Process B.—In order to find the temperature coefficient of the rate of Process B, heat measurements were made in one series for carbon monoxide at −195°. The results were analogous to those at −183°

---

[8] Beebe, Low and Goldwasser, THIS JOURNAL, 58, 2196 (1936).

[9] Because it was impossible to reproduce exactly the state of activity of the surface after oxygen was once admitted, it is important to know the order in which the experiments were conducted. After the oxygen measurements were begun, the order of experiments was, oxygen Series 1 and 2 at −183°, oxygen Series 3 and carbon monoxide on an oxygen covered surface at −183°, oxygen on a carbon monoxide covered surface at −183°, and oxygen on a plain surface at 0°.

except that Process B was slower for corresponding surface covered. As a result it was possible to differentiate Processes A and B earlier in the series (20 cc. adsorbed). Process B persisted further in the series making it possible to estimate the heats of activated adsorption up to 112 cc. adsorbed. The differential heats are given in Fig. 5. This persistence of Process B at −195° for larger amounts adsorbed than at −183° was possibly due to the higher total adsorptive capacity of the chromic oxide at the lower temperature. The adsorptive capacity beyond 112 cc. was not determined because the supply of liquid nitrogen ran out at that point.

From the rates of heat evolution at −195 and −183°, it was possible to estimate the rates of Process B at those two temperatures. From these data the energy of activation of the process was calculated. For surfaces on which the amounts already adsorbed before admission of the increment were 40, 50, 60, and 70 cc., respectively, the corresponding activation energies were 180, 300, 420, and 690 cal.

Heats of Adsorption at 0°.—The adsorption of argon and of the isotopes of hydrogen was negligibly small at 0° in the low pressure range studied, and the adsorptive capacity of the chromic oxide for carbon monoxide, oxygen, and nitrogen was much less at 0 than at −183°. The differential heats were determined for each of the latter three gases. The results for carbon monoxide and oxygen are given in Table IV. Only two increments of nitrogen of 1.88 cc. each were adsorbed. These had residual pressures of 1 and 1.7 mm., respectively, and each produced heats of 18.1 kcal.

At 0° the time–temperature curves were normal in type with all three gases giving no evidence for the two Processes A and B found at −183°. It is probable that van der Waals adsorption (Process A) was absent, and that the rate of the activated adsorption (Process B), which was slow after the initial increments at −183°, was too rapid to observe on any part of the surface at the higher temperature.

Discussion

Hydrogen and Deuterium at −183°.—The most important conclusion to be drawn from the work on the hydrogen isotopes is that the heats are altogether too high to be accounted for by van der Waals forces alone, and the process must be in large part of the activated type. The significance of the heat measurements, in connection with the catalytic activity of chromic oxide at −183° observed by Gould, Bleakney, and Taylor,[1] has been discussed in detail by Beebe and Orfield.[2] The discussion given by them for hydrogen may be applied equally well to the present data with deuterium.

According to Urey and his co-workers,[10] the heats of vaporization of hydrogen and deuterium are, respectively, 183 and 276 cal. per mole. We find the higher heat of adsorption for the heavier isotope. It should not be inferred from this, however, that only van der Waals forces are in operation at −183°.

In a study of the dissociation pressures of potassium deuteride and hydride in the temperature range 270 to 360°, Sollers and Crenshaw[11] have found that potassium holds hydrogen more strongly than deuterium, but a detailed study of their data leads them to suggest that at low temperatures the hydride may have the higher dissociation pressure. This would be in accordance with the results of the present investigation on chromic oxide shown in Fig. 2, and exactly the reverse of the case of hydrogen and deuterium adsorption on copper previously studied in this Laboratory.[12]

---

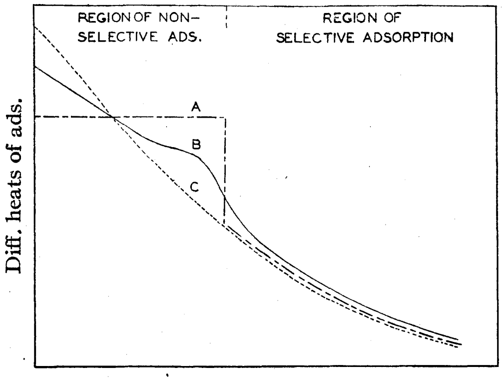
The difference in the shapes of the two differential heat curves in Fig. 3 seemed at first perplexing, but can be explained, we believe, in the following manner. It has been demonstrated[13] that the adsorption of the initial increments of hydrogen on chromic oxide at −183° is non-selective,[14,15] occurring on those portions of the surface with which it first comes in contact.[2] If this non-selectivity of the process were complete the heat values would be constant for the whole region studied because they would really represent integral heats of adsorption for successive layers.[4] If, on the other hand, the adsorption were non-selective for a part of the surface but selective for the remainder, then a discontinuous curve like Curve A in Fig. 10 would be expected provided the true distribution of energies on the surface is represented by Curve C. It is easy to see that the experimentally determined curve for hydrogen is of the form of Curve B which lies between Curves A and C. It is further noteworthy that the region of non-selective adsorption cannot go much beyond 20 cc. adsorbed because from here on there is a residual gas pressure, as shown in Table I, indicating equilibrium conditions under which non-selective adsorption would be impossible.

The fact that the horizontal step in the heat curves, which is so definite for hydrogen, is almost absent in the deuterium data, suggests that the phenomenon of non-selective adsorption is much less marked for the heavier isotope. Now non-selective adsorption occurs when the rate of adsorption is great compared to the rate of diffusion of the gas; this causes the gas to be adsorbed on those successive layers of the adsorbent with which it first comes in contact. The slower rate of diffusion of deuterium should give more time for the non-selective process to occur. Since, however, it is the hydrogen adsorption which is the more non-selective of the two, it seems evident that the rate of adsorption of the lighter isotope must be the greater by a ratio considerably more than enough to compensate for the $\sqrt{2}$ diffusion factor. Of course the rates cannot be compared by direct measurement because the adsorption of either isotope is complete in less than one minute after admission to the adsorbent surface.

Pace and Taylor[16] found no difference for hydrogen and deuterium in the rates of the activated adsorption process on chromic oxide at 218° and one atmosphere pressure. It is not surprising that the present investigation, carried out at −183° and very low pressures, should yield results which differ from those of the above authors. Moreover, because of the very low value of T used in the exponential $e^{-E/RT}$, a small difference in the activation energies for the two isotopes would be sufficient to account for a relatively large difference in the rates of adsorption.



Volume adsorbed.

Fig. 10.

Carbon Monoxide, Nitrogen, and Oxygen at −183°.—Evidence has been presented under Results to show that on a partially covered surface at −183° the adsorption of carbon monoxide, nitrogen, and oxygen consists of two processes which have been called Process A and Process B. Analysis of the experimental data shows that Process A is rapid under all conditions and is nonspecific in nature, yielding a heat of about 4 kcal. regardless of the nature of the gas adsorbed[17] or of the state of the adsorbing surface. We believe that these observations justify the assumption that Process A is a van der Waals adsorption exclusively. Process B differs from Process A in two important respects: (1) the heats of adsorption are much higher than in Process A and are specific to the gas used and to the condition of the chromic oxide surface; and (2) the rate of adsorption varies greatly as a function of the amount of gas already on the surface. The first of the above characteristics of Process B eliminates the possibility that it is a van der Waals process,[18] and

---

(13) This was done with a calorimeter similar to that described by Beebe [*Trans. Faraday Soc.*, **28**, 761 (1932)]. Using this instrument at −183°, it was found that the form of the time–temperature curve obtained upon admission of hydrogen was greatly influenced by the position of the thermocouple. This was interpreted to indicate non-selective adsorption by the same reasoning as that used by Beebe in the case of carbon monoxide on copper at 0°.

(14) Russell and Ghering, THIS JOURNAL, **57**, 2544 (1935).

(15) This phenomenon has been called "non-uniform" in previous publications from this Laboratory. We believe, however, that the term "non-selective" used by Russell and Ghering, describes the process more accurately; we shall therefore use it in the future.

(16) Pace and Taylor, *J. Chem. Phys.*, **2**, 578 (1934).

(17) The three gases carbon monoxide, nitrogen, and oxygen and in addition argon have boiling points which all fall within the twelve-degree range from −183 to −195° and as a consequence we should expect them to have approximately the same heats of vaporization. It is therefore not surprising that the heats of van der Waals adsorption which result from changes of a physical nature are found experimentally to be nearly the same for all four gases.

(18) Barrer, *Proc. Roy. Soc.* (London), **161A**, 476 (1937), has calculated from the isotherms at low temperatures the heats of adsorption of nitrogen, argon, and hydrogen on graphite and has suggested that the higher values obtained for the initial increments of gas adsorbed may be attributed to the van der Waals adsorption of the molecules in cracks sufficiently narrow to permit both walls to influence the adsorption. For crevices with plane and nearly parallel sides, the heat of adsorption would be approximately double the value for a plane surface. Moreover, the calculations of DeBoer and Custers, *Z. physik. Chem.*, **25B**, 225 (1934), showed, for adsorption in hemispherical pockets, tubes, and cells, maximum energies of four, six, and eight times, respectively, the energies on a plane surface. The high initial heats of 8 kcal. observed by us in the case of nitrogen conceivably might be explained on the basis of the calculations of DeBoer and Custers. However, the higher heats of 12 and 27 kcal. with carbon monoxide and oxygen could scarcely be

we must conclude that the final result of Process B is a state of activated adsorption.[19]

From the experimental evidence, however, it is difficult to decide with certainty whether the rate controlling factor in Process B is one of activated adsorption or of activated surface diffusion. As we shall see, the choice between these alternatives depends upon the accessibility of the adsorbing surfaces to the incoming gas. We shall use the case of carbon monoxide in this discussion, although it also applies to nitrogen and oxygen.

We have already assumed that the chromic oxide surface is capable of both van der Waals and activated adsorption. Let us make certain further assumptions:

1. The van der Waals adsorption requires zero activation energy, and it is easy for a van der Waals adsorbed molecule to be desorbed and begin a surface migration.
2. The activated adsorption requires a small finite activation energy which increases with successive increments from an initial negligibly small value to a relatively large value as the surface becomes more completely covered.[20] Desorption occurs with great difficulty for molecules held on the surface in the activated state.
3. All the surface, whether internal or external, is easily accessible either by direct gaseous diffusion or by a very rapid surface migration of the van der Waals adsorbed carbon monoxide to the internal part of the surface.

On the basis of these assumptions the time required for the activated adsorption would be the rate controlling factor. The adsorption of the first carbon monoxide increment admitted to a bare chromic oxide surface would be in part van der Waals and in part activated depending upon whether the chance collisions of the carbon monoxide molecules with the surface brought them first into contact with points of low or high surface energy. But the molecules held by van der Waals forces would soon move to adjacent active points, with the net effect that the gas would disappear immediately from the gas phase and the time–temperature curve would show a quick rise in temperature giving a heat of 12 kcal. (Curve I, Fig. 4). After the initial increments had been added, the most active surface points would become covered so that there would be none left capable of immediate activated adsorption. As a result, the next increment added would be first adsorbed by van der Waals forces but these adsorbed molecules would then migrate rapidly on the surface to points capable of activated adsorption but requiring a finite activation energy so that this activated process would be slower. The time–temperature curve (Curve II, Fig. 4) would then be divided, with a quick rise corresponding to a rapid van der Waals adsorption of 4 kcal. of heat and the slow rise due to Process B, the activated adsorption, producing a heat of about 12 kcal. This activated adsorption process would of course become progressively slower as the degree of activity of remaining uncovered surface points became less and less. Finally, when all points capable of activated adsorption were covered, the slow Process B would be eliminated and only van der Waals adsorption would occur on the remaining surface, resulting in the normal type of curve (Curve III, Fig. 4) with a heat of 4 kcal. On the basis of this theory the experimentally determined activation energies for Process B, which ranged from 180 to 690 cal. for the interval 40–70 cc., would be the energies of activation of the activated adsorption.

On the other hand, we may arrive at an alternative explanation of Process B by changing assumptions 2 and 3 above as follows:

2. The activated adsorption requires a negligibly small activation energy on all parts of the surface, adsorption occurring immediately once a gas molecule comes into contact with an active surface point.
3. Only the external part of the surface is readily accessible to the gas,[21] a finite time being

---

accounted for in that way. In addition to this the large variation in the heats of Process B with the three gases makes it very probable that it is not a van der Waals process.

(19) The absence of any slow Process B at −183° in the curves for hydrogen and deuterium seems, at first, to be anomalous, especially when we consider that there is evidence that the adsorption of these gases is activated in part at least. If we assume, however, that the activated adsorption for the isotopes of hydrogen requires an even smaller energy of activation than does that for carbon monoxide, nitrogen, or oxygen, we may predict that, at an even lower temperature, the rate of Process B might be sufficiently slow to differentiate it from Process A.

(20) The decreasing differential heats with successive increments (Fig. 5) indicate variable surface activity. At −183°, even small differences in the activity of the surface points, and consequently in the activation energies required for adsorption, would suffice to account for relatively large differences in the rates of adsorption on different portions of the surface. This is true because of the small value of T used in the exponential $e^{-E/RT}$.

(21) During the preparation of the adsorbent, the removal of water molecules from the hydrated chromic oxide gel must have produced a relatively large percentage of internal surface on the walls of cracks or capillaries penetrating the granules. The point at issue is whether these cracks or capillaries are of sufficient width so that the carbon monoxide molecules can reach their walls with ease or whether a considerable length of time might be required. In other words, is the internal surface "internal" to a carbon monoxide molecule?

required for the surface migration of carbon monoxide molecules, initially adsorbed on the external surface, down the faces of the cracks or capillaries into the internal surface of the chromic oxide.

We may then explain the time–temperature curves for partially covered surfaces (Curve II, Fig. 4) as indicating an initial van der Waals adsorption on the easily accessible external surface followed by a slow surface migration to the points located in the internal surface which are capable of activated adsorption. The decreasing rate of Process B with successive increments of gas added to the surface would then be attributed to the increasing periods of time required for the surface diffusion of the adsorbed molecules into the more and more difficultly accessible areas of the internal surface. In other words, the rate controlling factor would be an activated diffusion, and the experimental values 180 to 690 cal. would be the activation energies for this diffusion process.[22]

It is of course possible that both activated adsorption and activated diffusion have some influence on the rate of the slow process observed. Regardless of the mechanism,[23] the important point, which must be emphasized, is that we have definite evidence that there are two distinct types of adsorption on the same partially covered chromic oxide surface at −183°, and that the gas initially held by van der Waals forces changed over, *on the surface,* into the activated state.

The Effect of Temperature on the Adsorption.—In comparing the results at −183° with those at 0° using carbon monoxide, nitrogen, and oxygen, respectively, on the chromic oxide, it is apparent that the amount of each of these gases adsorbed is considerably less at the higher temperature. This is not surprising in the case of the carbon monoxide and that of the nitrogen because the adsorption of these gases is a reversible process, a large fraction of the gas adsorbed at −183° being desorbed when the temperature is raised to 0°. This would mean simply that certain surface points capable of holding carbon monoxide or nitrogen at −183° are no longer able to do so at 0°. The adsorption of oxygen, on the other hand, is irreversible, and oxygen once adsorbed in the activated state is removable only by reduction in a hydrogen atmosphere at about 400°. It is not easy to see, therefore, why the volume adsorbed at 0° should not be at least as great as that adsorbed at −183°. We suggest the possibility that pairs of oxygen atoms may be held in an activated state on each chromium atom of the surface at −183° but that single atoms of the oxygen are held on each chromium atom at 0°. This postulated difference in the nature of the adsorption complexes at the two temperatures would also account for the observed change in the heat of adsorption from 25 kcal. at −183° to 50 kcal. at 0°.[24] The marked difference in the heats of adsorption of nitrogen at the two temperatures seems to indicate that, with this gas also, there must be a great difference in the nature of the binding forces in operation at the two temperatures. In contrast with the data for oxygen and nitrogen, the heats of activated adsorption of carbon monoxide are very nearly the same at −183 and 0°, indicating that there is little difference in the nature of the binding at the two temperatures.

Anomalous Effect Caused by Interruption of a Series of Heat Measurements.—In the measurements with carbon monoxide at −183° the successive increments usually were admitted at intervals of approximately one hour. When the series was interrupted overnight, say for a period of fifteen hours, with the surface partially covered, the first time–temperature curve recorded the next morning was always anomalous in two respects: (1) the slow Process B was almost completely absent; and (2) the heat of the rapid Process A was measurably higher (about 0.2 kcal.) than that for the preceding increment, or of the next increment following after a one-hour period. In other words, when the adsorption had been carried to the stage at which the next time–temperature curve would be like Curve II in Fig. 4 if the series were not interrupted, the curve actually obtained after an overnight interruption was more nearly of the form of Curve III, Fig. 4, and the heat of Process A was 4.4 instead of 4.2 kcal. The second time–temperature curve recorded in the morning was free from these anomalous characteristics, giving a heat of 4.2 kcal. for Process A and having the slow rise in temperature indicating the recurrence of Process B. This anomalous behavior was always observed whenever a carbon monoxide series in the intermediate stage was interrupted overnight.

---

[22] Lennard-Jones [*Trans. Faraday Soc.,* **28,** 333 (1932)] has calculated an activation energy of this order of magnitude for the surface diffusion of argon on potassium chloride at −183°.

[23] In this discussion we have assumed that the van der Waals and activated adsorption occur exclusively on different surface points. It is possible, however, that the *same* points may be capable of both types of adsorption, and this possibility already has been suggested by Lennard-Jones.[22] On the latter assumption, Process B might represent the change of a molecule, held to a given point by van der Waals forces, over into the activated state on the *same* point. There is nothing in our observations to justify the elimination of this possibility which would, of course, be unfavorable to the theory of activated diffusion as the rate controlling factor in Process B.

[24] This high heat of reaction at 0° is of the same order of magnitude as the heat of the stoichiometric reaction between oxygen and chromic oxide to form chromium trioxide (36.2 kcal. per mole of oxygen). It seems probable, therefore, that the surface reaction is somewhat similar to the stoichiometric one in this case.

The same was always true for the oxygen and nitrogen adsorption experiments.

We believe this anomaly can be explained as follows. Suppose there are surface points on which the carbon monoxide molecules are held by forces of the van der Waals type, but with a binding energy slightly greater than the average van der Waals binding, and suppose that as a result of this greater binding force a considerable time is required for the desorption of molecules from these points, which we shall call X-points. These X-points would become covered in the early increments and owing to the greater difficulty of desorption they would then remain covered during the admission of later increments at the stage represented by Curve II, Fig. 4, so long as the series of measurements was continued without interruption. On the other hand, upon standing overnight, the X-points would be left vacant by the slow process of desorption, the desorbed molecules being subsequently adsorbed on points capable of activated adsorption. The first increment admitted in the morning would then be adsorbed on the X-points, with a heat of 4.4 kcal., which is 0.2 kcal. in excess of the normal 4.2 kcal. Moreover, because of the difficulty of desorption from the X-points, Process B, resulting from a shift over to the state of activated adsorption, would be practically eliminated. However, for the next increment following after the normal one-hour interval, with the X-points covered, the normal heat of 4.2 kcal. would be obtained and the normal rate of Process B would be observed.

Conclusion.—We wish to emphasize the novel application of the calorimetric method in the present investigation. Using charcoal at 20° as an adsorbent, Lendle[25] has measured the heat evolved during the slow activated adsorption on charcoal of oxygen *from the gas phase*, a process which could also be followed by observing the slow disappearance of unadsorbed gas. Barry and Barrett[26] have made a similar calorimetric study in the case of the adsorption of water vapor on gold. In the experiments with carbon monoxide on chromic oxide at $-183°$, there was no residual unadsorbed gas after the first minute, and the slow evolution of heat could be attributed only to a change *on the surface* from the van der Waals to the activated state.[27] Because all the gas disappeared almost instantaneously, the calorimetric method offered the only means of observing the presence of the slow process. It will be interesting to find out how general is this activated adsorption via an initial van der Waals process. Calorimetric work at $-183°$ now in progress in this Laboratory shows that the adsorption of oxygen on iron synthetic ammonia catalyst follows the same complex mechanism, the time–temperature curves being of the same general form as Curve II, Fig. 7. The details of this work will be published at a later date.

Summary

1. The heats of adsorption of argon, hydrogen, deuterium, carbon monoxide, nitrogen, and oxygen, on reduced chromic oxide, have been determined calorimetrically in the low temperature region.

2. The magnitude of the heats indicates that all these gases except argon are adsorbed in part in the activated state even at $-183°$.

3. The form of the time–temperature curves on a partially covered surface at $-183°$ indicates that with carbon monoxide, nitrogen, and oxygen the adsorption is complex, the gases initially adsorbed in the van der Waals state undergoing a slow change on the surface over into a state of activated adsorption.

4. From the heat measurements with carbon monoxide at -183 and $-195°$ the activation energy of the above slow surface change has been estimated at 180 to 690 cal./mole. It is suggested that the rate controlling process in this slow change may be (1) a slow activated adsorption, or (2) a slow surface diffusion.

5. The effects of carbon monoxide on the heat of oxygen adsorption and of oxygen on the heat of carbon monoxide adsorption have been investigated experimentally.

6. The heats of adsorption of carbon monoxide, nitrogen, and oxygen have been measured at 0° as well as at $-183°$, and the results at the two temperatures have been compared.

Acid Amides as Hypnotics. I. Acylureas[1]

BY F. F. BLICKE AND A. P. CENTOLELLA[2]

The introduction of an acyl group such as diethylbromoacetyl or allylisopropylacetyl into urea converts the latter into an excellent hypnotic. Publications which illustrate the manner in which hypnotic activity varies with the nature of the acyl group are very few in number.

[a] The compounds were recrystallized in the following manner: compounds 8, 14, 18, 20, 21 and 22 from petroleum ether (90–100°); compound 7 from alcohol; compounds 3, 4, 11 and 16 from dilute alcohol; compounds 2, 5, 6, 9 and 12 from acetone; compound 13 from 50% acetone; compounds 10, 17 and 19 from a mixture of one part acetone and two parts petroleum ether; compounds 15 and 23 from a mixture of one part acetone and nine parts petroleum ether.

In this paper we have described a number of disubstituted acetylureas, $R_2CH\text{-}CO\text{-}NH\text{-}CO\text{-}NH_2$ (Table II), which were examined pharmacologically by Mr. J. W. Nelson and Dr. G. F.

---

[1] This paper represents part of a dissertation submitted to the Horace H. Rackham School of Graduate Studies by A. P. Centolella in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the University of Michigan.

[2] The Upjohn Company Fellow.

Cartland in The Upjohn Company Laboratories.[3] It was quite surprising to find that none of these ureas were effective to any great degree when injected intraperitoneally into white rats although, in a second paper, it will be shown that some of the corresponding acetamides are strong hypnotics.

The ureas were obtained by the following general method: conversion of malonic ester into the required disubstituted derivative, $R_2C(CO-OC_2H_5)_2$, hydrolysis of the ester, elimination of carbon dioxide with the formation of a disubstituted acetic acid, $R_2CH—COOH$, preparation of the corresponding acetyl chloride and treatment of the latter with urea or methylurea.[4]

The new intermediates are described in Table I.

Experimental Part

The procedures are illustrated in the case of allyl-β-phenylethylacetylurea.

To sodium ethylate, prepared from 1000 cc. of absolute alcohol and 46 g. of sodium, there was added, slowly, 320 g. of malonic ester. After one hour the mixture was stirred and refluxed and 370 g. of β-phenylethyl bromide added during the course of two hours. The mixture was stirred and refluxed for two hours longer, most of the alcohol removed by distillation and 500 cc. of water added to the cold residue. The ester layer was separated and the aqueous layer extracted six times with 75-cc. portions of ether; yield of β-phenylethylmalonic ester 424 g. or 80% of the calcd. amount; b. p. 182–185° (12 mm.).[5]

In a manner similar to that described above, allyl-β-phenylethylmalonic ester was prepared from sodium ethylate, obtained from 300 cc. of alcohol and 13.8 g. of sodium, 159 g. of β-phenylethylmalonic ester and 73.2 g. of allyl bromide; yield 159 g. or 88% of the calcd. amount.

A mixture of 80 g. of potassium hydroxide, 250 cc. of 70% alcohol and 101 g. of the disubstituted malonic ester was refluxed for twenty-four hours, most of the alcohol removed, 250 cc. of water added and then about 140 cc. of hydrochloric acid added to the cold mixture. The crude acid separated from the acidic mixture as an oil but soon solidified; yield 78 g. or 94% of the calcd. amount.

Fifteen grams of the allyl-β-phenylethylmalonic acid was heated in an oil-bath at 180° until most of the carbon dioxide had been evolved and then heated at 150–160° for six hours; yield 10.7 g. or 86% of the calcd. amount.

A mixture of 28 g. of the acetic acid and 45 g. of commercial thionyl chloride was heated for two hours on a steam-bath after the initial vigorous reaction had subsided and the excess thionyl chloride then removed; the yield of acid chloride was 21 g. or 70% of the calcd. amount.

Nine grams of allyl-β-phenylethylacetyl chloride and 9.6 g. of dry urea were heated in an oil-bath at 125°. As soon as the material had melted the temperature was dropped to 110–115°. After six hours the product was cooled and rubbed in a mortar with enough 10% sodium carbonate solution to keep the mixture alkaline. The solid material was filtered, washed with water and recrystallized; yield 8.9 g. or 90% of the calcd. amount.

Summary

A number of new disubstituted malonic esters, malonic acids, acetic acids, acetyl chlorides and acetylureas have been described.

No strong hypnotics were found among the disubstituted acetylureas, $R_2CH—CO—NH—CO—NH_2$, studied.

Acid Amides as Hypnotics. II. Acetamides[1]

BY F. F. BLICKE AND A. P. CENTOLELLA[2]

It has been known for a long time that certain representatives of three types of acid amides—substituted acetamides, acylureas and cyclic amides such as substituted barbituric acids and hydantoins—exhibit strong hypnotic activity.

During late years, due to the popularity of barbituric acid compounds, the study of the acetamide type has been neglected except for the publications of Volwiler and Tabern[3] and of Junkmann.[4]

Most of the acetamides, described hitherto as compounds which possess hypnotic action, are trisubstituted derivatives such as diethylallylacetamide. Since, in general, trisubstituted acetamides are more difficult to obtain than the disubstituted compounds we have prepared a considerable number of the latter in order to determine their activity as hypnotics.

In Table I of this paper there have been described di-*n*-alkyl- and *n*-alkyl-β-cyclohexylethylacetamides and, in some instances, corresponding N-alkyl and N-hydroxyalkyl derivatives. The evaluation of all of our compounds, from the pharmacological standpoint, has been carried out by Mr. J. W. Nelson and Dr. G. F. Cartland in The Upjohn Company Laboratories and the data obtained will be published by them in another journal. However, it may be stated that the following amides in Table I have been shown to be very effective hypnotics when injected intraperitoneally into white rats: diethylthio-, ethylbutyl-, N-methylethylbutyl-, ethylamyl-, ethylhexyl- and N-β-hydroxyethylethyl-β′-cyclohexylethylacetamide.

Especially interesting is the relatively high activity of diethylthioacetamide; in fact, it is the strongest hypnotic in the group (Table I) and is approximately five times as potent as diethylacetamide. However, the therapeutic index (minimum lethal dose/minimum hypnotic dose) of both diethylthioacetamide and diethylacetamide is low, 1.2 in each instance.

The disubstituted acetamides, described in Table II, are of three types. In type I, one substituent is represented by the β-phenylethyl group, the other, R, by ethyl, propyl, isopropyl, allyl, butyl, isobutyl, β-cyclohexylethyl or β-phenylethyl. In this group the ethyl, propyl, isopropyl, allyl and isobutyl compounds are strong hypnotics.

[a] Levy [*Compt. rend.*, **194**, 175 (1932)] found 104° but did not record an analysis.

troduced into the amide group; R′ = methyl, ethyl, butyl or β-hydroxyethyl. Three compounds in this series proved to be strong hypnotics: N-ethylethyl-β-phenylethylacetamide, N-ethylpropyl-β-phenylethylacetamide and N-β-hydroxyethylpropyl-β′-phenylethylacetamide.

Six compounds of the general formula III were prepared in which $x = 1, 2, 3, 4, 5$ and 6. Two of these compounds are strong hypnotics, namely, ethyl-β-phenylethylacetamide and ethyl-ε-phenylamylacetamide.

Experimental Part

The amides were obtained by interaction of the disubstituted acetyl chloride with ammonia or the required amine. The new acid chlorides and their general method of preparation were described previously.[5]

Allyl-β-phenylethylacetamide was obtained in 87% yield when 4.5 g. of allyl-β-phenylethylacetyl chloride was added slowly, with vigorous stirring, to 20 cc. of ammonia water which was cooled with ice.

To prepare N,N′-bis-(diethylacetyl)-ethylenediamine 20 cc. of a 66% aqueous solution of ethylenediamine was stirred, cooled and 2.6 g. of diethylacetyl chloride added dropwise. The precipitate was filtered, washed with water, dried and recrystallized four times from petroleum ether; yield 2.4 g. or 95% of the calcd. amount.

No attempt was made to discover a satisfactory procedure for the preparation of diethylthioacetamide. However, sufficient material for our purpose was obtained when 22 g. of phosphorus pentasulfide and 23 g. of diethylacetamide were mixed intimately, 175 cc. of benzene added and the mixture refluxed for five minutes. The warm benzene was decanted from the pasty residue and the latter extracted with three 25-cc. portions of hot benzene. The solvent was removed from the combined benzene solutions and the gummy, yellow residue recrystallized from petroleum ether (90–100°).

Summary

A number of new dialkyl-, alkyl-β-cyclohexylethyl- and alkyl-β-phenylethylacetamides have been described. In some instances N-alkyl derivatives were prepared.

Some of the amides have been found to be strong hypnotics.

Sterols. XLVII.* The Reduction Products of Estrone

BY RUSSELL E. MARKER AND EWALD ROHRMANN

In paper XLII[1] of this series the isolation and properties of two isomeric estranediols from human non-pregnancy urine were described. These diols were designated tentatively as diol-A, melting at 242° and diol-B, melting at 204°. Oxidation of these diols yielded different diketones, indicating that the two diols must differ at least in regard to the configuration at C_5 or C_{10}. It is not surprising that one of these diols isolated from the non-pregnancy urine was identical with an estranediol first obtained by Dirscherl[2] by the catalytic hydrogenation of estrone.

By the catalytic hydrogenation of estrone in an acid medium Dirscherl obtained two estranediols, one melting at 206° and the other at 155°. In addition to these he obtained two monohydroxy estrane compounds which apparently were formed by the elimination of the hydroxyl group at C_3. In his work no attempt to establish the configuration of the hydroxyl groups was made.

In an attempt to obtain more information concerning the configuration of the estranediols we have carried out the hydrogenation of α-estradiol in acid medium. This reaction yielded a diol melting at 204° which was found to be identical with the diol obtained by Dirscherl from the catalytic hydrogenation of estrone. This diol must therefore possess the α-configuration at C_{17}. In addition to this diol a compound of the composition $C_{18}H_{30}O_2 \cdot C_{18}H_{30}O$ melting at 175° was obtained. This substance appears to be a molecular compound. Upon oxidation with chromic acid at room temperature, it yielded a diketone melting at 170° which was identical with the diketone obtained by the oxidation of α-estranediol.

The α-estradiol used in the hydrogenation experiment was prepared in good yield by the aluminum isopropylate reduction of estrone. The compound was separated from the β-estradiol by means of its insoluble digitonide.[3]

In the catalytic hydrogenation of estrone and α-estradiol we have obtained no positive evidence of the formation of the estranediol melting at 242° obtained from human non-pregnancy urine.[1] This fact suggests that whereas catalytic hydrogenation of estrone produces compounds having the same configuration at C_5 and C_{10}, the reductive processes taking place in the body during the utilization of estrone may result in the formation of estranediols differing in their configurations at these asymmetric centers.

Experimental Part

Reduction of Estrone with Aluminum Isopropylate.—A mixture of 1 g. of estrone, 70 cc. of dry isopropyl alcohol and 1 g. of aluminum isopropylate was refluxed on a steam-bath for five hours. Approximately 50 cc. of the mixture was then slowly distilled off over a period of five hours. One gram of potassium hydroxide in 30 cc. of hot methanol was then added to the hot residue and the mixture allowed to stand for thirty minutes. The mixture was then poured into water and acidified with hydrochloric acid. The acidic mixture was extracted with ether and the ether extract was washed with water. The ether was removed, the crystalline residue dissolved in 15 cc. of hot 80% alcohol, and a boiling solution of 2 g. of digitonin in 80 cc. of 95% alcohol and 20 cc. of water was added. The resulting solution was cooled and allowed to stand for six hours. The white crystals of the digitonide which separated were filtered and washed with a little 95% alcohol. The dried crystalline digitonide weighed 1.5 g.

The digitonide was dissolved in 15 cc. of hot pyridine and the resulting solution heated on the steam-bath for twenty-five minutes. The hot solution was then poured into 200 cc. of ether and 15 cc. of methanol and the white precipitate was filtered and washed with ether. The filtrate was washed first with dilute hydrochloric acid and then with water. The ethereal solution was evaporated on the steam-bath and the crystalline residue after crystallization from acetone melted at 174°. This product gave no depression in melting point when mixed with an authentic sample of α-estradiol.

The filtrate from the digitonide separation was evaporated to a volume of 25 cc., 200 cc. of ether added, and the mixture thoroughly shaken. The mixture was filtered and the residue washed with ether containing 5% methanol. The filtrate was evaporated to dryness and the residue was crystallized from acetone to give β-estradiol melting at 215° (uncorr.).

Reduction of α-Estradiol.—To a solution of 1 g. of α-estradiol, m. p. 175°, dissolved in 100 cc. of absolute alcohol containing 1 cc. of concentrated hydrochloric acid, was added 500 mg. of platinum oxide catalyst. This was shaken with hydrogen at about five pounds (0.3 atm.) pressure and room temperature for five hours. The mixture was filtered and the filtrate poured into 300 cc. of water. The resulting mixture was extracted with ether and the ether extract washed first with sodium hydroxide

solution and then with water. The ether was evaporated and the residual alcohol removed by heating *in vacuo*. The sirupy residue was dissolved in acetone and allowed to crystallize at 0°. The white crystals which separated were recrystallized from acetone to give a product melting at 204°. This gave no depression in melting point with an authentic sample of estranediol obtained by the hydrogenation of estrone.

The filtrate remaining after removal of the high melting diol was evaporated to a volume of about 4 cc. and allowed to crystallize at 0°. The white crystals were recrystallized from acetone to give needles melting at 175°. This gave a depression of 18° when mixed with a sample of estranediol-3,17α.

Anal. Calcd. for $C_{18}H_{30}O_2 \cdot C_{18}H_{30}O$: C, 79.9; H, 11.2. Found: C, 79.8; H, 11.0.

To a solution of 50 mg. of the molecular compound, m. p. 175°, in 15 cc. of glacial acetic acid was added a solution of 200 mg. of chromic oxide in 10 cc. of glacial acetic acid and 2 cc. of water. The resulting solution was allowed to stand at room temperature for forty minutes. The mixture was then poured into 200 cc. of water and the resulting mixture extracted with ether. The ether extract was washed with sodium carbonate solution and finally with water. The ether was evaporated and the crystalline residue distilled in high vacuum, the fraction distilling at 130–160° being collected. This fraction was crystallized from aqueous methanol to give crystals melting at 170° which gave no depression in melting point when mixed with the diketone (m. p. 170°) obtained by the oxidation of estranediol-3,17α.

Anal. Calcd. for $C_{18}H_{26}O_2$: C, 78.8; H, 9.5. Found: C, 78.9; H, 9.9.

Summary

Estrone has been reduced with aluminum isopropylate to give α- and β-estradiols. α-Estradiol upon catalytic hydrogenation yielded estranediol-3,17α, and a molecular compound $C_{18}H_{30}O_2 \cdot C_{18}H_{30}O$. Oxidation of both compounds yielded estranedione.

Sterols. XLVIII.* Isolation of Androsterone and Pregnanol-3-α from Human Pregnancy Urine

BY RUSSELL E. MARKER AND ELMER J. LAWSON

Recently a new theory of the biogenesis of the steroidal hormones was proposed.[1] This theory assumes that the cortical hormones (C_{21} and C_{19}) and the sex hormones (C_{21}, C_{19} and C_{18}) arise, not from cholesterol, but from a precursor (I) which may be cortin itself, constructed possibly from sugar units, by reductive processes possibly involving ascorbic acid in the suprarenal glands. While dehydrative and hydrolytic processes are involved, there is no necessity in this theory to assume that any of the steroidal hormones are formed by oxidations. Examples of transformations of the type we postulated in the organism have been found recently. Steiger and Reichstein[2] have shown that their substance J, and a new stereoisomer, O, are not, as was thought at the time of the appearance of Paper XL,[1] 3,11,20-triols, but are instead 3,17,20-triols. When triol-J is heated with alcoholic sulfuric acid, dehydration occurs with the formation of *allo*-pregnanol-3β-one-20. This type of dehydration coupled with the reduction of the carbonyl grouping at C_{20} is supposed to account for the degradation of the dihydroxyacetone residue to give ultimately a $CH_3—\overset{|}{C}H—OH$ (α) residue at C_{17}. It should be noted that while dehydration may remove the hydroxyl group either at C_{17} or C_{21} to give after reduction $C_{17,20}$ or $C_{20,21}$ glycols, the formation of $C_{17,21}$ glycols is not possible, and these should not be found in urines or glandular extracts.

Again, recent work by Mason[3] has shown that Kendall's compound E (Reichstein's Fa, Wintersteiner's F) is converted by the action of calcium hydroxide into adrenosterone. This reaction is simply a hydrolytic process, constituting in fact the reversal of an ordinary aldol condensation. Thus it is not necessary to employ an oxidative mechanism to account for the formation of the C_{19} steroids from the C_{21} steroids. The possibility of the oxidation of steroids in the suprarenals is also very remote in view of the presence of the highly reducing ascorbic acid. Certainly, no oxidation vigorous enough to rupture ordinary —C—C— bonds or oxidize methylene groups is likely to occur, or need be postulated.

An essential feature of the theory is the as-

Fig. I

sumption that carbonyl groups adjacent to tertiary carbon atoms can be reduced to methylene groups *in vivo* as well as *in vitro*. This type of reduction has been observed in the laboratory in the case of the reduction of 7-keto-cholesteryl chloride to α-cholestyl chloride[4] and in the case of the reduction of uranetrione[5] to pregnanediol and uranediol. It is further assumed that while this reaction involves no inversion of the tertiary hydrogen at C_{17}, the tertiary hydrogen atom at C_9 is inverted from the β- to the α-type. Evidence for the occurrence of this type of reduction can be adduced from the isolation from urines of uranediol[6] and uranolone[7] which contain no oxygen atoms at C_{20}, and from cortical extracts by Steiger and Reichstein[2] of the compounds J, O and K, which contain no oxygen atoms at C_{11}. There is no reasonable doubt that the parent structure of J, O and K is that of *allo*-pregnane since all these have been converted to androstanedione-3,17. The question of the configuration at C_9 of the parent ring system of the other cortical derivatives having oxygen atoms at C_{11} is, as both Steiger and Reichstein[8] and one of us[1] have indicated, not definitely settled. The attempted correlation of corticosterone and digoxigenin[9,9a] has not shed any further light on this problem; indeed the non-identity of the Δ^4,3,11-diketocholenic acids obtained might be used as an argument to indicate that cortical derivatives are of the *allo*-urane type.

Further support for our theory of the biogenesis of the steroidal hormones has now been found in the isolation of pregnanol-3-α and androsterone from human pregnancy urine.

We have reported previously the fractionation of semicarbazones of ketones from human pregnancy urine. At the time that work was carried out a semicarbazone fraction of intermediate solubility was obtained which was assumed to be impure *allo*-pregnanol-3α-one-20 semicarbazone. An investigation of this fraction, however, has shown it to be androsterone, as proved by mixed melting points and its conversion to androstanedione. We believe that the occurrence of androsterone in human pregnancy urine and of estrone in stallions' urine indicates that these hormones are derived ultimately from sources other than the gonads, namely, from the suprarenal steroids by degradations of the type we have discussed previously. Thus, androsterone (IV) could arise from adrenosterone (III) as indicated in Fig. 1. To conceive of the androsterone as being derived from progesterone would involve a side-chain oxidation of a type more vigorous than is likely to occur in the glands.

The isolation of pregnanol-3-α, which we have prepared from pregnanol-3α-one-20,[10] was accomplished by precipitating the 3-β-OH sterols with digitonin and fractionating the 3-α-OH sterols by means of chromatographic adsorption and high vacuum distillation. The pregnanol-3-α, after isolation as its acetate which is not very soluble in cold methanol, showed no depression in melting point with an authentic sample. With the exception of cholesterol and equistanol, this is the first mono-oxygenated steroid isolated from glandular extracts or urines.

[9] Steiger and Reichstein, *ibid.*, **21**, 828 (1938).

[9a] Since this paper was submitted for publication, Mason and Hoehn [THIS JOURNAL, **60**, 2824 (1938)] have shown that the diketocholenic acid derived from digoxigenin is Δ^4,3,12-diketocholenic acid.

[10] Marker and Lawson, *ibid.*, **60**, 2438 (1938).

It undoubtedly arises from progesterone by reductive processes such as we have discussed, and its presence in urines must be considered valuable evidence in support of the proposed theory.

Experimental Part

In the crystallization of the semicarbazones of the ketonic fraction of human pregnancy urine sterols, the more insoluble semicarbazone was that of *epi-allo*-pregnanolone. From the mother liquors of this was obtained the more soluble semicarbazone of *epi*-pregnanolone. A fraction of intermediate solubility between these two semicarbazones was crystallized from ethanol six times to a decomposition point of 255°. This semicarbazone became very insoluble as it became purer, thus resembling the semicarbazone of *epi-allo*-pregnanolone, and for that reason it was not further investigated until the present time. The yield was 1.5 g. from 150,000 liters of human pregnancy urine.

Androsterone from Human Pregnancy Urine.—To a solution of 500 mg. of the above semicarbazone in 25 cc. of ethanol was added a solution of 2.5 cc. of concd. sulfuric acid in 5 cc. of water, and the mixture was refluxed for one hour. Water was added and the mixture extracted with ether. The residue after evaporation of the ether was sublimed in a high vacuum at 135–150° and then crystallized from dilute methanol to give a product melting at 176°. It gave no depression in melting point when mixed with an authentic sample of androsterone, but depressed the melting point of *epi-allo*-pregnanolone to 140–145°.

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.6; H, 10.4; mol. wt., 290. Found: C, 78.8; H, 10.5; mol. wt. (Rast), 283.

Oxidation of Androsterone to Androstanedione.—Twenty milligrams of androsterone isolated from human pregnancy urine was dissolved in 5 cc. of acetic acid and a solution of 7 mg. of chromic oxide in 2 cc. of 90% acetic acid was added. After standing for one hour at room temperature, water was added and the product extracted with ether. After removal of the solvent the residue was sublimed in high vacuum at 120° and then crystallized from dilute methanol to give androstanedione, m. p. 128°, which did not depress in melting point when mixed with an authentic sample.

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.1; H, 9.8. Found: C, 79.0; H, 9.9.

Isolation of Pregnanol-3-α from Human Pregnancy Urine.—The sterol fraction from 40,000 liters of human pregnancy urine after hydrolysis by alkali, removal of the pregnanediol and *allo*-pregnanediol by crystallization from acetone, and the ketones by Girard's reagent, was dissolved in 500 cc. of ether. To this was added 5 liters of ligroin and the ether removed by distillation. The mixture was cooled and the ligroin layer decanted from the tar which separated. The tarry residue was dissolved in 2 liters of ethyl alcohol and 200 g. of digitonin in 8 liters of hot alcohol was added. It was allowed to stand overnight and the digitonide was filtered and washed well with cold alcohol. The filtrate was concentrated to about 500 cc. and 5 liters of ether was added. It was again filtered from digitonin and the filtrate was evaporated to dryness *in vacuo*. This treatment removed all sterols having hydroxyl groups of the beta configuration.

The residue was dissolved in 250 cc. of pyridine and 200 g. of succinic anhydride was added. After heating for one hour on a steam-bath, ice was added and the succinate extracted with a large volume of ether. The pyridine was removed by washing with dilute hydrochloric acid and the ethereal layer was then extracted with sodium carbonate solution and a 2% solution of sodium hydroxide. The aqueous layers were combined, acidified and then extracted with ether. The solvent was removed and the residue saponified by refluxing with alcoholic potassium hydroxide solution. This carbinol fraction was extracted with ether and the solvent evaporated to dryness. On standing for several months some crystalline material appeared. It was treated with sufficient ether (cold) to filter. Upon washing with cold ether 23 g. of crystalline substance was obtained. The filtrate gave no precipitate when treated with a solution of alcoholic digitonin. The solvent was removed from the filtrate and the residue (115 g.) was dissolved in 2 liters of dry benzene. It was treated chromatographically with 800 cc. of aluminum oxide in 24-mm. diameter tubes. The absorbed material was washed with one liter of dry benzene, then with 5 liters of dry ether. Evaporation of the ether wash gave 12 g. of residue, which was sublimed *in vacuo* and the fraction distilling up to 120° collected. Upon washing with acetone this sublimate crystallized. It was converted into its acetate by boiling for half an hour with acetic anhydride. The acetate was crystallized several times from methanol, but could not be completely purified. After hydrolysis with alcoholic potassium hydroxide the sterol was dissolved in benzene, passed through a tube of aluminum oxide and washed out by ether and acetone. The eliminated material was crystallized from dilute methanol to a constant melting point of 146°. The product when mixed with *epi*-pregnanol-3 gave no depression in melting point. The amount of purified product was 26 mg., although much larger amounts are present.

Anal. Calcd. for $C_{21}H_{36}O$: C, 82.8; H, 11.8. Found: C, 82.5; H, 11.6.

Work on the identification of the *epi*-sterols from the other fractions is in progress at present and will be reported in THIS JOURNAL when the chemical structure of the products has been ascertained.

We wish to thank Dr. Oliver Kamm and Parke, Davis and Co. for their generous help and assistance in various phases of this work.

Summary

The theory of the biogenesis of the steroidal hormones is discussed, and additional supporting evidence cited. The isolation of androsterone and pregnanol-3-α from human pregnancy urine is described.

Sterols. XLIX.* Isolation of Pregnanediols from Bull's Urine

BY RUSSELL E. MARKER, EUGENE L. WITTLE AND ELMER J. LAWSON

In a recent paper[1] from this Laboratory it was suggested that the parent male, female and cortical hormones arise from a common precursor, and that in the course of utilization of these hormones they are excreted as reduction products. For example, while the three isomeric pregnanediols, pregnanediol-3(α),20(α), *allo*-pregnanediol-3(α),-20(α) and *allo*-pregnanediol-3(β),20(α), which are the reduction products of progesterone, have been isolated from the urines of pregnant women, mares and cows,[2] they have been found to be absent or present only in traces in the urines of stallions[3] and non-pregnant women.[4] However, we have now found that bull's urine contains large amounts of the pregnanediols. The table below shows the approximate quantities of the pregnanediols present in various urines. Evidently bull's urine is the richest source of the pregnanediols yet investigated.

	Approximate quantities isolated, mg. per gallon of urine		
	Pregnanediol-3(α),-20(α)	*allo*-Pregnanediol-3(α),-20(α)	*allo*-Pregnanediol-3(β),-20(α)
Human pregnancy	50	25	6
Human non-pregnancy	8	4	.
Human male	.	.	.
Mare pregnancy	50	25	6
Cow pregnancy	25	15	3
Stallion	none	none	none
Bull	100	50	12

Thus there are now at least three instances of the apparently anomalous occurrence of steroids in urines, namely, the presence of estrone in stallion's urine,[5,6] of androsterone[7] in human pregnancy urine and of the pregnanediols in bull's urine. At present it seems that these results can best be explained by assuming, in accordance with the theory set forth recently,[1] that these compounds originate from cortical derivatives. In this connection it should be noted that cortical extracts have been found to have both estrogenic and progestational activity,[8,9] and recently Beall and Reichstein[10] have isolated progesterone and *allo*-pregnanol-3(β)-one-20 from this source. Also, Reichstein[11] recently has announced the isolation from cortical extracts of 21-hydroxyprogesterone. While it might be argued, since Reichstein's extracts are obtained from the suprarenals of both bulls and cows, that the progesterone he isolated was derived only from cows, the isolation of the pregnanediols from bull's urine nullifies this argument. Whether these pregnanediols come from the testes or the suprarenals is not yet known, but it is evident, since the bull has no ovaries, that progesterone is formed in other glands. If the pregnanediols from bull's urine are formed from cortical derivatives, it appears that either progesterone or Δ^4-pregnenol-20(α)-one-3 is an intermediate step in the reductive processes involved. Should the latter prove to be the case, it might suggest that Δ^4-pregnenol-20(α)-one-3 functions as a male hormone in the bull. There seems to be no doubt but that the occurrence of the pregnanediols is normal for the bull since the urine investigated was collected from sixteen bulls, and inordinately large amounts would have had to have been excreted if these steroids arose as the result of some disfunction in one of the bulls.

Besides the isomeric pregnanediols, a considerable amount of equistanol has also been found in bull's urine. Equistanol is present in the urines of mares, stallions, cows and bulls, but not in humans. On the other hand, human urine contains comparable amounts of cholesterol but only traces are present in the urines of mares, cows, bulls and stallions.

The mode of isolation of these steroids was essentially the same as that employed in other similar investigations reported from this Laboratory. The urine collected from sixteen mature bulls was hydrolyzed with hydrochloric acid, extracted with butanol and then hydrolyzed by alkali. It was filtered and extracted to yield an ether insoluble solid, and a sirupy concentrate. The former, after acetylation, yielded pregnanediol-3(α),20-

(α) diacetate, and a mother liquor which gave *allo*-pregnanediol-3(α),20(α) on hydrolysis. The sirupy concentrate after Girard's reagent and acid-succinate separations yielded a carbinol fraction which was treated with digitonin solution. The digitonide mixture gave, after decomposition, *allo*-pregnanediol-3(β),20(α), and β-equistanol. The results of our investigation of the other fractions obtained will be submitted soon for publication.

The authors wish to thank Dr. Oliver Kamm and Parke, Davis & Co. for their generous assistance in various phases of this work.

Experimental Part

The bull's urine used in this investigation was collected from 16 mature bulls. After hydrolyzing the urine by boiling with 10% hydrochloric acid for thirty minutes, a precipitate which formed was collected and the filtrate thoroughly extracted with butanol. The solvent was removed by vacuum distillation to a sirup and the latter dissolved in a large volume of ether and filtered from some solid material. The ether was evaporated to give 4500 cc. of sirup.[12]

The concentrate was dissolved in 10 liters of ether and shaken with sodium carbonate and sodium hydroxide solution to remove phenolic and acidic materials. The ether was evaporated and the residue steam distilled with an excess of aqueous potassium hydroxide (20 pounds (9.1 kg.) of potassium hydroxide per 1000 gallons (3800 liters) of urine extract) until no more volatile organic material came over. The mixture was cooled to room temperature, filtered and the residue washed well with water and ice cold ether. The filtrate was extracted well with ether and the solvent removed. The ether insoluble precipitate amounted to 175 mg. per gallon.

Pregnanediol-3(α),20(α) and *allo*-Pregnanediol-3(α), 20(α).—The precipitate obtained as described above was refluxed for one hour with 7 volumes of acetic anhydride, the solution cooled to 0°, and filtered. The crystalline acetate was recrystallized from methanol to give a pure product melting at 180°. The yield was 100 mg. per gallon. Mixed with pregnanediol-3(α),20(α)-diacetate, this acetate gave no depression in melting point.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.2; H, 10.0. Found: C, 73.9; H, 10.0.

Hydrolysis of this pregnanediol-3(α),20(α) diacetate with alcoholic potassium hydroxide gave pregnanediol-3(α),20(α) melting at 240°. It gave no depression in melting point when mixed with an authentic sample.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.6; H, 11.1.

The acetic anhydride mother liquors were evaporated to dryness and the residue hydrolyzed with alcoholic potassium hydroxide solution. Dilution of the solution with water gave a solid which was collected, washed well with water, and recrystallized from alcohol to a melting point of 243°. This was *allo*-pregnanediol-3(α),20(α) since it depressed to 215° with pregnanediol-3(α),20(α) but gave no depression with *allo*-pregnanediol-3(α),20(α). The yield was approximately 50 mg. per gallon of urine.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.5; H, 11.2.

The diacetate prepared in the usual manner was crystallized from methanol. It melted at 141° and did not depress with an authentic sample of *allo*-pregnanediol-3(α),-20(α) diacetate.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.2; H, 10.0. Found: C, 74.0; H, 9.9.

The β-Steroids in Bull Urine.—The ether washings of the crude pregnanediols and the ether extract of the aqueous filtrate were combined and evaporated to a sirup. The sirup was dried by distilling 1 liter of benzene from it. The tarry residue was dissolved in 1 liter of alcohol and refluxed thirty minutes with 30 g. of Girard's reagent. The solution was diluted with ether and ice, the layers separated, and the aqueous layer extracted with ether. The aqueous layer was acidified with hydrochloric acid and heated on a steam-bath. The ketonic oil was extracted with ether and set aside for an examination now in progress.

The ethereal extract from the Girard's separation was evaporated to a sirup which was dried as before by distilling benzene from it. The residue was heated for one hour with 300 cc. of pyridine and 240 g. of succinic anhydride and then poured on ice. Ether was added and the pyridine removed by shaking with hydrochloric acid. The acid succinate mixture was then removed from the ethereal solution by shaking with sodium carbonate solution. The ethereal solution which contained hydrocarbons was reserved for a separate investigation now in progress. The carbonate solution was acidified, extracted with ether and after removal of the ether, hydrolyzed with an excess of alcoholic potassium hydroxide. The carbinol mixture was extracted with ether, and the solvent removed. The residue was dissolved in hot alcohol and an excess of a hot 2% alcoholic digitonin solution (200 mg. of digitonin per gallon of urine) was added. After standing overnight the digitonide was filtered and washed with cold alcohol. The filtrate was evaporated to 200 cc. and 5 liters of ether added. The suspension was filtered to remove the digitonin and soluble digitonides. The digitonin–digitonide mixture was combined giving 245 mg. per gallon of urine. The filtrate which contained sterols of the *epi*-OH configuration was reserved for a separate investigation now in progress.

The digitonides were dried and heated with 5 volumes of pyridine on a steam-bath for one hour. This was poured into ether, filtered, and the digitonin washed well with ether. The ethereal filtrate was freed of pyridine by shaking with hydrochloric acid solution, the solvent removed, and the residue dissolved in a small amount of benzene. On standing overnight a crystalline crop deposited. This was collected and recrystallized from methanol and acetone to give *allo*-pregnanediol-3(β),-20(α), m. p. 215°. When mixed with *allo*-pregnanediol-3(β),20(α), it gave no depression in melting point. Mixed with uranediol it depressed the melting point to 185°.

---

[12] We wish to thank the Parke, Davis & Co. for performing the above collection, hydrolysis and extraction at their laboratories and supplying us with the ethereal concentrate.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.6; H, 11.2.

Upon refluxing with acetic anhydride it gave a diacetate melting at 168° which gave no depression in melting point when mixed with the diacetate of *allo*-pregnanediol-3(β),20(α). This compound was present in bull urine to the extent of 12 mg. per gallon.

The benzene was removed from the filtrate of the *allo*-pregnanediol-3(β),20(α) and the residue sublimed in high vacuum collecting a fraction distilling at 120–150°. This was crystallized from ethyl alcohol and methyl alcohol to a melting point of 137°. The product was saturated to bromine and when mixed with β-equistanol isolated from stallion, cow pregnancy, and mare pregnancy urine it gave no depression in melting point.

Upon refluxing with acetic anhydride it gave an acetate melting at 126° which did not depress the melting point of β-equistanol acetate. Equistanol was present in bull's urine to the extent of 8 mg. per gallon. As in the case of stallions, mares and cows pregnancy urine, the amount of cholesterol present was very small when compared to that in human urine. An investigation of the other steroid fractions will be reported in This Journal in the near future.

Summary

Pregnanediol-3(α),20(α), *allo*-pregnanediol-3(α),20(α), *allo*-pregnanediol-3(β),20(α) were isolated from bull's urine in quantities about twice or more than that of human pregnancy urine. Equistanol also was isolated but very little cholesterol was found.

β-Alkoxy Ethyl Esters of Chlorocarbonic and Carbamic Acids

By H. G. Ashburn, A. R. Collett and C. L. Lazzell

In order to study the relative narcotic powers of a series of carbamic acid esters containing an ethereal oxygen in the alcohol group, we have prepared a series of twelve esters of chlorocarbonic acid, ten of which are new, and from them their corresponding carbamic acid esters, eleven of which are new.

β-Alkoxyethanols.—The β-alkoxyethanols were prepared by treating ethylene oxide with the desired alcohol in the presence of a small amount of sulfuric acid as a catalyst,[1,2] except in the cases of the tertiary butoxy and tertiary amoxy ethanols for which aluminum fluosilicate was used as a catalyst.[3,4]

β-Alkoxyethyl Chlorocarbonates.—The chlorocarbonates were prepared by the action of phosgene upon the various β-alkoxyethanols.[5] A calculated excess of liquid phosgene was placed in a 500-cc. round-bottomed flask clamped in a freezing mixture. A reflux condenser, through which a freezing mixture was passed, was then attached. The alcohol was added drop by drop, the mixture being stirred mechanically, until all was added, and the reaction mixture allowed to come to room temperature gradually. The flask was opened and allowed to remain open for a day, at room temperature, in order to evaporate the excess phosgene. The mixture was poured into ice water, the ester separated and dried over anhydrous calcium chloride. It was then distilled *in vacuo* at 1–20 mm. pressure. The tertiary butoxy and tertiary amoxy chlorocarbonates could not be prepared by this reaction. *bis*-Ethylene chlorocarbonate was obtained in both cases.

The analyses were made in a few cases by digesting the sample with 10% sodium hydroxide, then titrating against standard silver nitrate, using potassium chromate as an indicator. In all cases the chlorocarbonates were converted into their respective carbamates and analyzed for nitrogen by the Kjeldahl method. Refractive indices were determined by means of an Abbe refractometer and surface tension values obtained by means of a du Nouy tensiometer at 25°. The Harkins correction for the ring method was applied. The yields are based upon the amount of the glycol ether used. Table I shows the boiling points, under reduced pressure, the refractive indices, surface tensions (corrected), yields, and the densities of the chlorocarbonates.

β-Alkoxyethyl Carbamates.—The carbamates were prepared from the corresponding chlorocarbonates by treating them with aqueous ammonia. The carbamates, with the exception of the β-methoxy, β-ethoxy- and β-isopropoxyethyl carbamates were purified by distillation *in vacuo*. These three were purified by crystallization from propylene chloride. The yield is based on the chlorocarbonate used. In Table II the yield, melting point or boiling point, and the analyses for the carbamates are given.

Narcotic Properties

Emerson and Abreu[6] have found that the β-ethoxyethyl carbamate is less active and less toxic than urethan. They also found that the propoxy and isopropoxy derivatives are roughly equivalent to urethan in narcotic activity and toxicity and

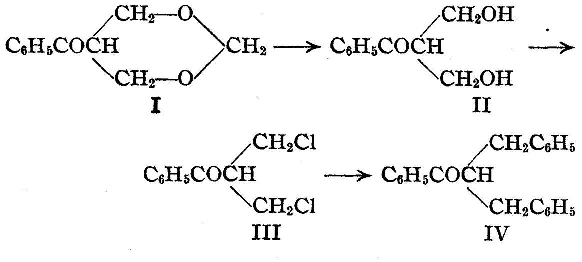
The Condensation of Paraformaldehyde with Aromatic Ketones

BY REYNOLD C. FUSON, W. E. ROSS AND C. H. MCKEEVER[1]

The condensation of simple aliphatic ketones has been studied thoroughly and can be caused to proceed in a controllable manner to give relatively simple products. With aromatic ketones, however, the reaction appears to take place only with difficulty. For example, the interaction of formaldehyde and acetophenone in the presence of various alkaline catalysts has been reported to give only complex products.[2] Using potassium carbonate as the catalyst Manta[3] converted propiophenone to a dimethylol derivative in which the carbonyl group had been reduced to a carbinol group. With isobutyrophenone Manta obtained a still more complex product. In Manta's experiments the reaction mixtures were heated.

We have found that simpler products are obtained if the reaction is carried out at room temperature and allowed to continue for a longer period. When acetophenone was treated with paraformaldehyde in methanol in the presence of potassium carbonate a high yield was obtained of a compound which proved to be the formal of the dimethylol derivative (I).

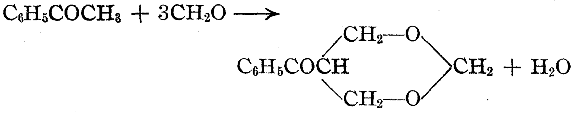
The structure of the formal was proved by the following transformations.



Treatment with concentrated hydrochloric acid converted it to the dichloro ketone (III) and formaldehyde. The latter was identified by formation of the β-naphthol derivative, di-β-naphtholmethane. The structure of the dichloro ketone was established by converting it into dibenzylacetophenone (IV) by the Friedel-Crafts method. An authentic specimen of this compound, made from acetophenone and benzyl chloride by the method of Nef,[4] proved to be identical.

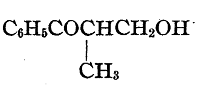
The formal was hydrolyzed by treatment with concentrated sulfuric acid but the dimethylol derivative (II) could not be isolated.

The foregoing facts indicate that the reaction between acetophenone and paraformaldehyde is represented by the equation

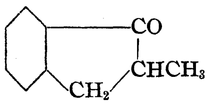


Although the ratio of aldehyde to ketone was varied considerably, the formal was always the chief product. This is remarkable because acetal formation generally does not take place in alkaline media. It is somewhat strange also that none of the early workers in the field have reported this reaction. However, the result is not entirely novel. In 1937, Gilbert, Morgan and Griffith[5] obtained a formal by treating methyl ethyl ketone with formaldehyde in the presence of sodium hydroxide.

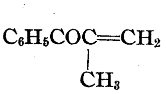
Propiophenone reacted slowly with paraformaldehyde to give β-benzoylpropyl alcohol (V) which shows no tendency to undergo spontaneous dehydration. For example, it forms the corresponding urethan when treated with phenyl isocyanate.



V



VI



VII

Dehydration was effected, however, by the action of concentrated sulfuric acid. The product proved to be α-methylhydrindone (VI) and not the expected isopropenyl ketone (VII). Bromine brought about substitution giving α-bromo-α-methylhydrindone. The melting point of this derivative corresponds with that given by Salway and Kipping[6] for α-bromo-α-methylhydrindone. Confirmatory evidence for the structure of the α-methylhydrindone was obtained by oxidation which converted it to *o*-phthalic acid.

This ring closure involves the cyclodehydration

of a 2-aroyl-1-alkanol and is a novel method of synthesis of 2-alkyl-1-indanones.

Experimental

The Action of Formaldehyde on Acetophenone.—A mixture of 45 g. of paraformaldehyde, 180 g. of acetophenone, 2 g. of potassium carbonate and 300 cc. of methyl alcohol was shaken for seven days at room temperature and poured into a liter of water. The mixture was acidified with hydrochloric acid and extracted with four 100-cc. portions of benzene. The combined benzene extracts were washed three times with water. The solvent was evaporated and the residue distilled under diminished pressure. Sixty-four grams of acetophenone was recovered. Eighty-five grams of the formal of 2-benzoyltrimethylene glycol was obtained; b. p. 124–126° (3 mm.). The residue remaining in the flask was a heavy viscous resin. The formal reduced Benedict's solution and gave a silver mirror with Tollens' reagent.

Anal. Calcd. for $C_{11}H_{12}O_3$: C, 68.71; H, 6.29. Found: C, 68.91; H, 6.5.

The Action of Hydrochloric Acid on the Formal.—Five grams of the formal was shaken with 50 cc. of concentrated hydrochloric acid at room temperature for twenty-four hours. The mixture was then allowed to stand until the oil had solidified completely. The solid was collected on a filter, the filtrate was diluted to 150 cc. and to it were added 7.5 g. of β-naphthol and 30 cc. of ethyl alcohol. The mixture was boiled for five minutes and allowed to cool. The crystals which formed weighed 6 g. After recrystallization from dilute ethyl alcohol the compound melted at 190–191°, with darkening at 180°. It was evidently di-β-naphtholmethane.

The yield of the solid chloro compound—1,3-dichloro-2-benzoylpropane—was 5 g.; m. p. 56–57°.

Anal. Calcd. for $C_{10}H_{10}OCl_2$: C, 55.3; H, 4.6; Cl, 32.67. Found: C, 55.73; H, 4.55; Cl, 32.97.

Condensation of 1,3-Dichloro-2-benzoylpropane with Benzene.—To a solution of 10 g. of the dichloride in 200 cc. of dry benzene was added all at once 8 g. of anhydrous aluminum chloride. The mixture was shaken overnight and decomposed with ice. The oily product obtained by benzene extraction solidified after several hours and was recrystallized from 80% ethyl alcohol; m. p. 78°. A mixed melting point determination showed the compound to be α,α-dibenzylacetophenone.

The Action of Sulfuric Acid on the Formal of 2-Benzoyltrimethylene Glycol.—Ten grams of the formal was poured into 50 cc. of concentrated sulfuric acid, with stirring. The mixture became warm and the odor of formaldehyde was discernible. After standing for ten minutes, it was poured into 500 cc. of water. By extracting this mixture with ether there was obtained a pungent lachrymatory oil. Distillation gave a small amount of yellow liquid; b. p. 101–105° (3 mm.). The residue set to a resin which was insoluble in alcohol and acetone. The distillate also resinified when allowed to stand.

The Reaction of Propiophenone with Formaldehyde.—A mixture of 40 g. of propiophenone, 9 g. of paraformaldehyde, 4 g. of potassium carbonate and 200 cc. of methyl alcohol was shaken at room temperature for four days. It was then poured into a liter of water. The resulting mixture was acidified with hydrochloric acid and extracted with three 60-cc. portions of benzene. The combined benzene extracts were washed three times with water and the solvent evaporated. By distillation of the residue there was obtained 32 g. of propiophenone and 8 g. of an oil boiling at 143–145° (5 mm.). The residue was negligible.

The 32 g. of recovered propiophenone was shaken for seven days with a mixture of 7.5 g. of paraformaldehyde, 2 g. of potassium carbonate and 100 cc. of methyl alcohol. From this run 16 g. of the oil was obtained. It was 2-benzoylpropyl alcohol.

Anal. Calcd. for $C_{10}H_{12}O_2$: C, 73.12; H, 7.37. Found: C, 73.31; H, 7.58.

The phenylurethan (from 80% methyl alcohol) melted at 86–87°.

Anal. Calcd. for $C_{17}H_{17}O_3N$: N, 4.94. Found: N, 5.2.

α-Methylhydrindone.—Ten grams of the keto alcohol was poured into 50 cc. of cold sulfuric acid, with stirring. The stirring was continued for two hours and the mixture was poured into 500 cc. of water. Extraction with ether gave 6 g. of α-methylhydrindone; b. p. 88–90° (3 mm.).

Anal. Calcd. for $C_{10}H_{10}O$: C, 82.15; H, 6.9. Found: C, 82.22; H, 7.2.

Oxidation with dilute nitric acid gave a high yield of *o*-phthalic acid.

α-Bromo-α-methylhydrindone.—To a solution of 1 cc. of the α-methylhydrindone in 10 cc. of carbon tetrachloride was added from a pipet a solution of bromine in carbon tetrachloride. The addition was continued until a slight color persisted. Approximately 11 cc. of a solution containing 0.05 g. of bromine per cubic centimeter was added. The reaction was accompanied by copious evolution of hydrogen bromide. The solvent was evaporated and the residual oil solidified after being allowed to stand for several days. The bromohydrindone crystallized from dilute alcohol in large, colorless plates; m. p. 72–73°.

Summary

The condensation of paraformaldehyde with acetophenone has been carried out in methanol with potassium carbonate as the catalyst. An excellent yield is obtained of the formal (I) of the dimethylol derivative.

Similar treatment of propiophenone gives the monomethylol derivative (V). When dehydrated this compound is transformed into α-methylhydrindone (VI).

The Effect of Acids on Carotenoids[1]

BY FORREST WARD QUACKENBUSH, HARRY STEENBOCK AND WILLIAM HAROLD PETERSON

The action of acids on carotenoids has become a matter of practical importance as well as scientific interest in recent years. The ensiling of legumes with mineral acids, *e. g.*, mixtures of hydrochloric–sulfuric (the A. I. V. process) and phosphoric, has produced a silage which often appears to have not only all the carotene of the green alfalfa but in some cases more carotene than is found in the original herbage.[2–4] Such results naturally have raised doubts regarding the validity of the data and have indicated the need of more information regarding the character of the pigments contained in the so-called carotene fraction.

The work described in this paper shows that several carotene-like pigments are produced by the action of acids on green forage, that these pigments have no vitamin A value, and that they may to some extent be secreted into milk.

Experimental

Effect of Mineral Acid on the Apparent Carotene Content of Alfalfa.—The samples (forage or silage) were extracted with hot alcohol, the extract was saponified with alcoholic potassium hydroxide, and the carotenoids were obtained by shaking with several portions of benzine (Skellysolve B, b. p. 65–75°). The united extracts were washed with water and the non-carotene pigments (xanthophyll, etc.) removed by extracting with an equal volume of 85% ethanol in four successive portions. The residual carotene and the extracted xanthophyll were determined spectrophotometrically. The results agreed satisfactorily with the values obtained by the method of Willstätter and Stoll.[5]

Typical analytical data (Table I) showed increases in the carotene values in alfalfa which had been treated with mineral acids. It was observed that while the carotenoid pigments from fresh green alfalfa separated sharply between benzine and 85% ethanol, those from acidified alfalfa did not. With fresh alfalfa the alcohol was practically colorless after three extractions of the benzine solution but with silage or acidified fresh alfalfa even the fourth extract was highly colored. Continued extraction did not result in a sharper separation, and the use of higher concentrations of alcohol gave only slightly better results. The immediate cause of these analytical difficulties became clear when the carotene fractions were subjected to chromatographic analysis.

TABLE I

INCREASE IN "CAROTENE" FRACTION FROM ALFALFA AFTER TREATMENT WITH MINERAL ACIDS

	Sample and treatment	Carotenoids (gamma/g. dry tissue) Carotene	Xanthophyll
1	Green alfalfa	126	225
2	A. I. V. silage from above alfalfa	184	190
3	Green alfalfa	193	368
4	Green alfalfa acidified before extraction	261	134
5	A. I. V. silage from above alfalfa	302	298

Chromatographic Separation of the Carotene-like Pigments.—In the first experiments magnesium oxide (Merck U. S. P. X, heavy) was used to make the chromatographic column. The benzine solution was evaporated to dryness in a vacuum and the residue taken up with a small volume of benzine. The concentrated solution was poured on the adsorbent and the column washed with benzine to a maximum separation of the bands.

Three sharp bands made their appearance from the carotene fraction of green alfalfa. These were identified by their relative positions in the chromatogram, by their spectral absorption, and by their phasic distribution between benzine and 85% ethanol as due to α-carotene, β-carotene and lutein, respectively. β-Carotene preponderated in quantity. Acidified forage gave a fourth band almost as wide as that of β-carotene. It occupied a position in the column so close to lutein that, even after long washing, the two almost merged. The upper portion of the new band was dull red and the lower portion yellow-orange. To effect their separation the column was removed, and divided; the pigments were eluted with ether, transferred to benzine, and readsorbed on fresh magnesium oxide. By repeating this fractionation several times, small quantities of red and yellow pigments, which appeared to be free from each other, were obtained. In benzine the yellow pigment exhibited sharp maximal spectral absorption at 448 and 477 mμ. The red pigment showed no distinct maxima, but a general absorption throughout the range between these two regions.

A search was made for a more satisfactory method for separating the pigments and calcium carbonate, magnesium carbonate and aluminum oxide were found to be better than magnesium oxide. Benzene, ether, and carbon disulfide gave no better results than benzine. However, good separation was obtained in a magnesium oxide column by washing with benzine containing a small quantity of absolute alcohol. The pigments in the carotene

fraction from silage separated into six major bands in addition to those of γ- and β-carotene. There were also some minor bands but these contained insufficient pigment for characterization. For convenience the six major bands were given the alphabetical designations, A to F.

The method finally adopted for separating the pigments was as follows. The benzine solution was forced into a uniformly packed column of magnesium oxide by means of air or nitrogen under a pressure of 1 to 1.5 atmospheres. The chromatogram was washed with benzine until the carotene bands had separated from the other pigments. Washing was then continued with a mixture of absolute ethanol (1% by volume) in benzine until bands A, B, and C had clearly separated and the carotene bands had passed out of the column. By increasing the alcohol to 2%, bands, D, E, and F were separated and bands, A, B, and C were eluted consecutively. Bands D, E, and F were eluted by increasing the concentration of alcohol, first to 3% and then to 5%. When the several eluates were collected and their extinction coefficients measured (475 mμ), it was found that less than 10% of the total pigment had been lost. A diagram of a typical chromatogram obtained with the carotene fraction from A. I. V. alfalfa silage is shown in Fig. 1.

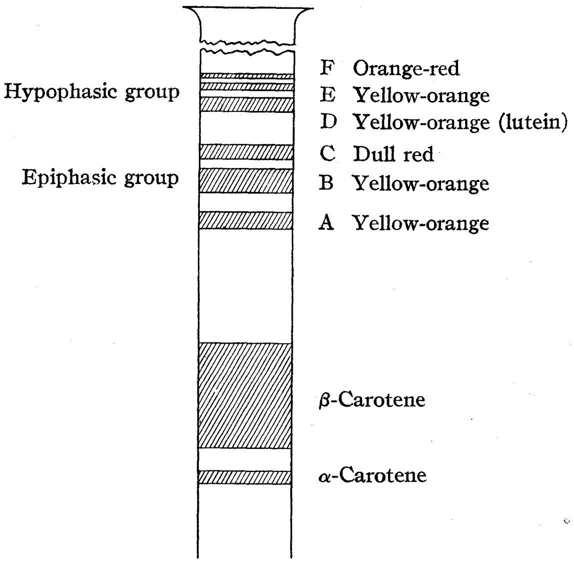

Fig. 1.—Diagram of a magnesium oxide chromatogram showing the chief carotenoid bands obtained from A. I. V. alfalfa silage.

Properties of the Pigments.—Besides occupying different positions in the chromatogram, the six pigments exhibited dissimilarities in color, spectral absorption, and phasic distribution. In the magnesium oxide column, pigments A, B, D, and E were a deep yellow, pigment C a dull brick-red, and pigment F an orange-red. In dilute benzene solution pigments A, B, D, and E were greenish-yellow and pigments C and F were reddish.

Pigments A, B, D, and E gave absorption bands which were essentially identical in form and in position of their maxima; all conformed to published data for lutein. Pigment C gave an abnormally wide absorption band which was highest in the region between 448 and 476 mμ (in benzine) but without any distinct maximum. On the other hand pigment F exhibited two distinct, though not sharp, maximal absorption bands. The absorption values of the pigments in three different solvents are given in Table II.

TABLE II

REGION OF MAXIMAL SPECTRAL ABSORPTION OF THE SIX PIGMENTS FROM ALFALFA SILAGE

Pigment	Solvent CS_2	$CHCl_3$	Benzine
A	475–476 506	457 486–487	447 477
B	475–476 506	457 486–487	447–448 477
C	480–504	457–486	448–476
D	475–476 506	456–457 486–487	447–448 477
E	476 506	457 487	447–448 476–477
F	477–484 502–509	457–464 486–491	449–453 478–481

The phasic distribution of the six pigments was especially significant. Pigments A, B, and C were distinctly epiphasic, while D, E, and F were hypophasic to the same degree. Their percentage distribution as shown in Table III was obtained by shaking the benzine solutions of the individual pigments, in similar concentrations (having equal extinction coefficients), with equal volumes of 85% ethanol.

TABLE III

PHASIC DISTRIBUTION OF THE PIGMENTS BETWEEN BENZINE AND 85% ETHANOL

(Expressed in per cent. of total)

	Isolated from silage		Obtained from lutein by acid treatment	
Pigment	Benzine	85% EtOH	Benzine	85% EtOH
A	81	19	79	21
B	84	16	79	21
C	81	19	^{a}	^{a}
D	22	78	21	79
E	23	77	22	78
F	22	78	..	..

[a] Only a trace; insufficient for measurements.

In the hope of obtaining the epiphasic pigments in crystalline condition, the carotene fraction from 10 kg. of acidified alfalfa was fractionated chromatographically. The resulting benzine–alcohol eluates of pigments A, B, and C were concentrated to small volumes and allowed to stand in a refrigerator for several weeks. Although these solutions were many times more concentrated than a saturated solution of β-carotene, the pigments failed to crystallize. Attempts to crystallize them from ethanol, benzene plus methanol, and carbon disulfide were likewise unsuccessful.

Origin of the Pigments.—The apparent increase in the carotene content of alfalfa silage prepared with mineral acids was accompanied by a decrease in xanthophyll (Table I). This suggested that the new pigments were formed from the xanthophyll pigments by the action of acids. When the crude xanthophyll fraction from untreated alfalfa was refluxed with acid as is done in extracting silage, the solution was almost completely decolorized. When an acidified solution of the crude xanthophyll, 0.1 *N* hydrochloric acid in 85% ethanol, was held at 45–50° overnight, its extinction coefficient decreased 25%. When this solution was made slightly alkaline with potassium hydroxide (in 85% ethanol) and shaken with benzine 65% of the pigment passed into the benzine phase. A control sample of crude xanthophyll lost none of its color when subjected to the same treatment except for the addition of acid, and only 17% of the pigment passed into the benzine phase.

To determine the effect of acid on lutein, pure lutein was prepared from fresh green alfalfa by two successive adsorptions on magnesium oxide from alcohol–benzine mixtures. The second eluate produced typical lutein crystals. When these were dissolved in 85% ethanol, the resulting solution showed a value $E^{1\ \mathrm{cm.}}_{475} = 4.0$. This is equivalent approximately to 0.20 mg. of lutein per cc. Ten-cc. portions of this solution were set aside at 45–50° in the dark, for fourteen hours, after the addition of various acids. The solutions were then made slightly alkaline with potassium hydroxide, and each was adjusted to a volume of 20 cc. with 85% ethanol, and shaken with 20 cc. of benzine. When equilibrium was attained, the percentage distribution between the two solvents was determined spectrophotometrically. That the stronger acids produced marked changes in the solubility of the pigment was shown by the values obtained for the benzine phase (Table IV). The values for the 85% ethanol phase represent the difference between these figures and 100.

TABLE IV

EFFECT OF VARIOUS ACIDS UPON LUTEIN

Sample	Normality and kind of acid	% of pigment remaining after treatment	% of remaining pigment found in the benzine phase	Chromatographic distribution of pigments after treatment (Total pigment remaining = 100% in each case)

[a] Pigments from bands D and E combined.

The chromatogram yielded not less than three and in some cases five well-defined bands which in their position and appearance resembled strikingly the bands obtained from silage. Treatment with acetic acid produced bands A, B, and D. All other acids produced one additional band, E, and in two cases a fifth band, C. Lutein subjected to all the manipulations except acidification retained its chromatographic behavior unchanged.

The individual pigments were collected quantitatively as they were eluted from the chromatogram. The extinction coefficient and solution volume were then measured for each fraction. From these data the percentage of each pigment in the sample was calculated (Table IV). Care was taken to maintain a fairly constant volume of eluate, and to make the spectrophotometric readings with solution depths which would give log I/I_0 values very close to 0.50. Close agreement was then obtained between the values for total pigment before and after separation.

The phasic distribution and spectral absorption of pigments A, B, D, and E obtained from lutein were found to be identical with those of the corresponding pigments found in silage (Tables II and III).

Pigment D proved to be residual lutein. When the various D-fractions from all of the samples were combined and analyzed chromatographically, the pigment remained almost quantitatively in a single band; other pigments appeared only in traces. When a sample of lutein was mixed with the purified pigment D, and a chromatogram prepared, again a single band appeared. However, when pure lutein was mixed with any of the other three purified pigments, *viz.*, A, B, and E, two bands appeared in the chromatogram. Analyzed separately each produced a single band.

From the various data which have been presented it is concluded that pigments A, B, and E are derived from lutein by the action of acids. The origin of pigments C and F has not as yet been clearly ascertained.

Occurrence and Distribution of the Acid-derived Pigments.—When it was found that the acid-derived pigments could be extracted from freshly acidified alfalfa, the question arose as to whether they were products of ensiling or artifacts formed during extraction under acid conditions. To determine this a sample of alfalfa silage was made slightly alkaline with potassium hydroxide before extraction and its carotenoids were compared with those extracted from silage in the usual way, *i. e.*, without alkalization. The epiphasic fractions from these two extracts were found to contain equal quantities of total pigment, and the chromatograms from both fractions contained the eight bands previously described (Fig. 1).

It is evident from the results presented in Table IV that mineral acids are more effective than lactic or acetic acid in converting lutein to pigments A and B. It might be predicted that a carotene fraction from silage produced by a natural lactic acid fermentation would contain a relatively higher percentage of true carotene than that from silage prepared with mineral acids. This was found to be the case (Table V). Only 57% of the pigment in the carotene fraction from the A. I. V. silage was found in the carotene

bands of the chromatogram as compared with 75% for the naturally fermented silage.

Since silages constitute a considerable part of the ration of the dairy cow, it is important to know whether the acid-derived pigments are present in butter fat produced on such rations. Four samples of butter fat which have been analyzed contained such pigments. Gillam and Heilbron[6] have reported that the chief carotenoids in butter fat are carotene, kryptoxanthin and lycopene. The presence of kryptoxanthin was confirmed, but lycopene was not detected in our samples.

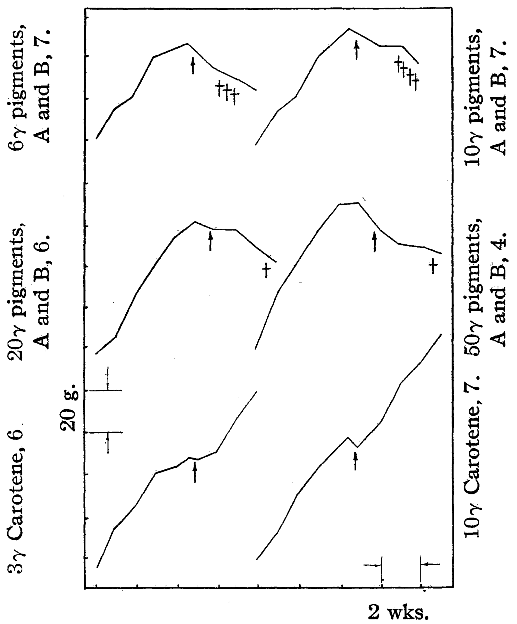

Fig. 2.—Growth curves of rats which received β-carotene and pigments A and B.

Biological Assay of the Epiphasic Pigments, A and B.—The epiphasic pigments, A and B, were tested for vitamin A activity before our technique for chromatographic fractionation had been fully developed. The tests were made on a mixture of the two pigments in which pigment A was present in somewhat larger amounts than pigment B. The assays were executed essentially according to the technique of Baumann and Steenbock.[7] The control rats were fed pure β-carotene separated chromatographically from extracts of fresh green alfalfa. To facilitate convenient dosage the pigments were incorporated in Wesson oil by evaporating their concentrated benzine solutions with the oil under reduced pressure. Resumption of growth, cure of ophthalmia, and the production of normal vaginal smears were employed as criteria of vitamin A activity. The β-carotene was fed at levels of 3 and 10 gamma daily. The mixture of pigments A and B was fed at levels equivalent to 6, 10, 20 and 50 gamma of β-carotene based on the extinction coefficients of their solutions. While the feeding experiments were in progress the oil solutions were checked for deterioration from time to time by spectrophotometric methods.

The data show clearly that the epiphasic pigments, A and B, could not function as precursors of vitamin A (Fig. 2). While the daily administration of 3 gamma of β-carotene restored growth and normal oestrus and cured the ophthalmia completely, even the highest dosage with pigments A and B, equivalent to 50 gamma of β-carotene, failed to restore even normal oestrus.

Discussion

When the separation of the non-carotene pigments into six distinct bands was first observed, its significance was viewed with some suspicion. It was well known that certain extraneous substances can affect the distribution of pigments in a chromatogram. Furthermore, it has been reported[8] that carotenes may undergo profound changes during chromatographic adsorption. However, the possibility that the pigments were of chromatographic origin is not supported by the experimental evidence. The non-carotene portion of the chromatogram from silage was unlike that from fresh alfalfa. When the chromatogram from alfalfa was washed with benzine–alcohol mixtures, bands A, B, and C failed to make their appearance; practically all of the pigment remained in band D. Also, after the initial separation, each of the new pigments gave a single characteristic band when chromatographed by itself. And, finally, besides differing in their chromatographic behavior, the individual pigments showed other differences in physical properties, *e. g.*, solubility and in some cases spectral absorption.

It is probable that Kuhn, *et al.*,[9] dealt with a mixture of pigments A, B, D, and E when they treated lutein with oxalic acid. The severity of their treatment was not markedly different from ours, for while they used a lower concentration of acid they employed a higher temperature. Although they did not differentiate their resultant pigment from lutein in its chromatographic behavior or spectral absorption, it was distinctly more epiphasic than lutein. We likewise did not succeed at once in separating our pigments from lutein chromatographically although we used a number of adsorbents and solvents. It was only later through a fortunate choice of mixtures of solvents that we were able to effect a good separation.

It is evident that the pigments derived from lutein are the chief cause of the abnormal caro-

tene values reported for A. I. V. silage. The extent to which the apparent carotene values differ from the true values is dependent on such factors as strength of acid used, lutein content of the forage, temperature of the silage and period of ensiling. While the usual method of analysis may give carotene figures that are nearly twice the true values for A. I. V. silage, too high results are also obtained in the analysis of silages made by normal fermentation processes. The need for a more reliable method of determining carotene in these silages is obvious.

Chromatographic data on butter indicate the presence of the same pigments as those found in silage. Although the amount of these new pigments has not been determined, their presence points to the need of more information regarding the value of acid-preserved silages for increasing the vitamin A potency of milk.

Summary

Five new carotenoids, designated as pigments A, B, C, E, and F, have been obtained from alfalfa silage and from acidified fresh alfalfa. They were not present in untreated forage. Dilute solutions of A, B, and E in benzine were greenish-yellow and those of C and F were reddish.

The pigments were partially fractionated by their phasic distribution between benzine and 85% ethanol; A, B, and C were epiphasic, E and F were hypophasic. Quantitative separation was effected by use of the magnesium oxide chromatogram and elution with benzine-alcohol mixtures. The bands of A, B, and C formed below that of lutein; those of E and F above it. The pigments were eluted from the column in the alphabetical order given by gradually increasing the percentage of alcohol in the solvent. Spectral absorption of the pigments was markedly less valuable for differentiation than chromatographic behavior. Absorption curves of A, B, and E were essentially the same as those of lutein; those of C and F showed no well-defined maxima.

A high order of solubility in the usual carotenoid solvents was shown by A, B, and C. Attempts to effect their crystallization were not successful.

A, B, and E were produced from lutein in large amounts by treatment with either 0.025 hydrochloric or sulfuric acid, and in smaller amounts with 0.025 *N* lactic and acetic acids. The stronger acids favored the production of B; weaker acids the production of A. The origin of C and F was not clearly established.

Inasmuch as the usual methods of carotene analysis fail to differentiate between carotene and pigments A, B, and C, values obtained by these methods on silages, especially those prepared with mineral acids, are obviously too high.

When fed to vitamin A deficient rats, A and B exhibited no biological activity. Both pigments were found in butters produced by cows on A. I. V. silage.

Researches on Pyrimidines. CLIX. Synthesis of 6-Benzyl- and 5-Benzyluracils[1]

BY TREAT B. JOHNSON AND JOSEPH C. AMBELANG[2]

One conclusion predictable from an examination of the skeleton structure of the pyrimidine cycle as represented by formula II, is the existence of two interdependent zones of chemical activity which envelop the pyrimidine molecule. Each of these zones is characterized by its encompassment of a specific organic structure. Zone "A" includes the unsaturated amidine portion of the pyrimidine cycle, while zone "B" incloses the cyclic allyl structure of the molecule. Any alteration or tautomeric change in the specific, unsaturated structure embraced by one zone necessarily leads to a corresponding change in the constitution of the grouping in the other, and also its chemical reactivity. In other words, we are dealing with a dual system of reactions in our study and development of pyrimidine chemistry and if tautomeric structures be accepted for these unsaturated cyclic groupings in the different zones, as theory provides, positions 1 and 3 included in zone "A" and positions 4 and 6 in zone "B," respectively, are identical.

(1) Constructed from a portion of a dissertation presented by Joseph C. Ambelang, in June, 1938, to the Graduate Faculty of Yale University in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

(2) Sterling Professorship of Chemistry Research Assistant 1938–1939.

These conclusions lead to the recognition of an unique symmetry of the pyrimidine cycle characterized by an axis of symmetry (x-x') passing through the two permanent numerical positions of the ring, namely, 2 and 5. It is an interesting fact that in the pyrimidine portion of the constitutional formula of the vitamin B_1 molecule (thiamine), this axis of symmetry (x-x') prevails, and constitutes a chain of four carbon atoms as represented in formula I. This chain includes the two permanent positions of the pyrimidine moiety (2 and 5).

$$C—\overset{2}{C}\cdots\cdots\cdots\cdots\overset{5}{C}—C$$

I

It might be predicted, therefore, on the basis of this knowledge and reasoning that the reactivity of a substituent grouping in position 5 of the pyrimidine ring would be dependent on, or influenced in some degree by, the character of the group or radical attached to the carbon in position 2. Such a postulation has already been supported by experimental data. In fact, we already have a knowledge of chemical reactions applicable to pyrimidine compounds, which are specific for the two zones of influence, "A" and "B," and permit us to confine our attack to either zone independently, without involving the grouping characteristic of the other. This dual system of reactions has also been revealed by researches on the chemistry of purines.[3]

In the light of our previous knowledge from researches in this Laboratory, and under guidance of the above speculations, it became of great interest to the authors to learn more about structural differences influencing the degree of reactivity of organic groupings functioning in the pyrimidine ring and occupying particularly positions 5 and 6 or 5 and 4 in zone "B" (formula II) of the pyrimidine molecule. It was, therefore, decided to incorporate a new series into our researches, and to synthesize first for study the two isomeric benzyluracils, namely, 6-benzyluracil and 5-benzyluracil as represented by formulas III and IV, respectively. Neither compound has been described previously in the literature. The methods of synthesis and a description of several intermediates and new derivatives are presented in the experimental part of this paper. In a future publication the authors will discuss some interesting results obtained by catalytic reduction of these two isomeric uracil derivatives III and IV.

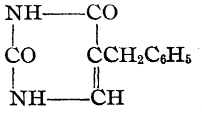
III



IV

Experimental Part

Preparation of 2-Thio-6-benzyluracil

$$\overline{NH—CS—NH—C(C_7H_7){=}CH—CO}$$

Method 1.—Ten grams (0.05 mole) of ethyl phenylacetylacetate (ethyl γ-phenylacetoacetate) was mixed intimately with 3.7 g. (0.05 mole) of thiourea and 10 drops of concentrated hydrochloric acid. After standing for one week in a stoppered flask, the suspension was transferred to an open dish and dried *in vacuo* over concentrated sulfuric acid. The desiccated product was then refluxed for two hours with 9 g. of potassium hydroxide in 33 g. of absolute alcohol and the solution finally concentrated at 100°, until encrustation appeared. On acidifying with hydrochloric acid this pyrimidine separated as an oil which soon solidified. It was purified by crystallization from 95% alcohol and melted at 222–223°. The yield was only 9% of the theoretical. This method of synthesis has been applied previously by Sonn and Litten[4] but with no mention of yields obtained. They assigned a melting point of 216–219° to the compound. No attempt was made by them to desulfurize the pyrimidine. This reaction very probably involves first the formation of the intermediate ureide $C_6H_5CH_2COCH_2CONHCSNH_2$, which is then closed up to the pyrimidine by the action of the alkali.

Method 2.—Thiourea (52 g.) and ethyl phenylacetylacetate (140 g.) were dissolved in a cooled solution of sodium ethylate (0.68 mole of sodium in 495 g. of absolute alcohol) and the mixture heated on a steam-bath for four hours. The excess of alcohol was then removed by evaporation and the residue dissolved in 125 cc. of water. Acidification of the cooled solution with hydrochloric acid led to the precipitation of the desired thiopyrimidine in a

(4) Sonn and Litten, *Ber.*, **66**, 1518 (1933).

yield of 37%. It was purified by crystallization from 95% alcohol and melted at 222–223°. This pyrimidine is soluble in aqueous ammonia and hot glacial acetic acid; moderately soluble in hot alcohol and acetone, slightly soluble in water and insoluble in benzene, ether, chloroform, and carbon bisulfide.

Anal. Calcd. for $C_{11}H_{10}ON_2S$: N, 12.84. Found: N, 12.85, 12.95.

$NH—C(SC_2H_5)=N—C(C_7H_7)=CH—CO$, **2-Ethyl-thio-6-benzyl-4-oxypyrimidine.**—A solution of 9 g. of pseudo-ethylisothiourea hydrobromide in 10 cc. of water was mixed with 10 g. of ethyl phenylacetylacetate, and to the mixture was added 5.5 g. of potassium hydroxide dissolved in 8 cc. of water. After standing at ordinary temperature overnight the solution was acidified with acetic acid when the above mercaptopyrimidine separated in a yield of 28%. It was purified by crystallization from methyl alcohol and melted at 128–129°. This compound is soluble in ethyl alcohol, glacial acetic acid, acetone, benzene, chloroform and boiling carbon bisulfide; moderately soluble in ether, and insoluble in aqueous ammonia.

Anal. Calcd. for $C_{13}H_{14}ON_2S$: N, 11.38. Found: N, 11.52, 11.56.

6-Benzyluracil, $NH—CO—NH—C(C_7H_7)=CH—CO$. —This pyrimidine is prepared easily as follows: (1) by digestion of 2-thio-6-benzyluracil with 10% chloroacetic acid; and (2) by hydrolysis of the corresponding 2-ethylthio derivative with hydrochloric acid. The pyrimidine was purified by crystallization from glacial acetic acid or 95% alcohol and melted at 261–262°. It is soluble in warm acetic acid and in aqueous ammonia; moderately soluble in acetone, hot alcohol; slightly soluble in hot water, and insoluble in ether, benzene, chloroform and carbon bisulfide.

Anal. Calcd. for $C_{11}H_{10}O_2N_2$: C, 65.32; H, 4.98; N, 13.86. Found: C, 65.16, 65.34; H, 4.98, 4.90; N, 13.80, 13.85.

$NH—CO—NH—C(C_7H_7)=CBr—CO$, **6-Benzyl-5-bromouracil.**—6-Benzyluracil is attacked by bromine in glacial acetic acid at 40–50° with substitution in the pyrimidine ring giving this monobromo substitution product. The compound was purified easily by crystallization from glacial acetic acid and melted at 230–232°. The pyrimidine is soluble in warm glacial acetic acid, acetone, and aqueous ammonia, and insoluble in water, ether, benzene, and chloroform.

Anal. Calcd. for $C_{11}H_9O_2N_2Br$: N, 9.97. Found: N, 9.97, 10.00.

That the bromine is substituted in the pyrimidine ring and not in the aromatic nucleus of the benzyl group substituted in position-6 was shown as follows: 1 g. of the bromopyrimidine was oxidized by refluxing it in hot water with barium permanganate (0.0059 mole) and barium hydroxide. After complete discoloration of the permanganate the alkaline solution was filtered, and then concentrated to a volume of 20 cc. and cooled. On acidifying with hydrochloric acid colorless benzoic acid deposited and melted, after crystallization from hot water, at 121–122°.

Chlorination of 6-Benzyluracil in Methyl Alcohol

$NH—CO—NH—C(OCH_3)(C_7H_7)—C(Cl_2)—CO$,[5] **Formation of 2,4-Diketo-6-benzyl-6-methoxy-5,5-dichlorohexahydropyrimidine.**—Chlorine gas was passed into an ice-cooled suspension of 0.5 g. of 6-benzyluracil in 30 cc. of methyl alcohol until the pyrimidine dissolved. The cold reaction mixture was then exposed to a blast of air to remove the alcohol and excess of chlorine and the residue allowed to dry. We obtained 0.6 g. of the above hexahydropyrimidine, which was purified by crystallization from methyl alcohol, or a mixture of chloroform and carbon tetrachloride. It melted at 157–159° with decomposition. This pyrimidine is soluble in glacial acetic acid, acetone, ether, and chloroform; and slightly soluble in warm benzene, hot water, and insoluble in petroleum ether.

Anal. Calcd. for $C_{12}H_{12}O_3N_2Cl_2$: N, 9.24. Found: N, 9.20, 9.17.

This pyrimidine is not changed by exposure to pyridine. Two grams was dissolved in 20 cc. of pyridine and the solution allowed to stand for one week. It had assumed a greenish fluorescence. After volatilizing the pyridine a sirup was obtained which deposited crystals on treatment with water. This solid was identified as the original hexahydropyrimidine, and after crystallization from dilute methyl alcohol melted at 160–162°.

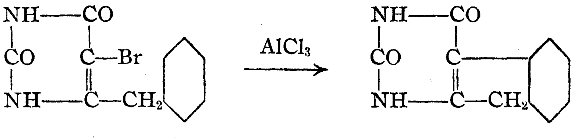
Anal. Calcd. for $C_{12}H_{12}O_3N_2Cl_2$: C, 47.54; H, 3.99; N, 9.24. Found: C 47.62; H, 3.64; N, 9.57.

$NH—CO—NH—C(C_7H_7)=C(Cl)—CO$, **Action of Hydrobromic Acid on the above Hexahydropyrimidine. Formation of 6-Benzyl-5-chlorouracil.**—This change is brought about by digesting the hexahydropyrimidine (1 g.) in glacial acetic acid (25 cc.) with constant boiling hydrobromic acid (2 cc.). After boiling for two hours the acid solution was poured into water when the above chlorouracil derivative separated. It was purified by crystallization from dilute acetic acid and melted at 266–267°.

Anal. Calcd. for $C_{11}H_9O_2N_2Cl$: N, 11.84. Found: N, 12.02.

This same chloropyrimidine is formed in poor yield by passing chlorine gas into a suspension of 6-benzyluracil in 10% acetic acid.

Attempted Cyclization of 6-Benzyl-5-bromouracil:



one and five-tenths grams of 6-benzyl-5-bromouracil and 1.5 g. of aluminum chloride were dissolved by stirring in 50 cc. of nitrobenzene. After standing for four hours at room temperature and two hours at 50° the solution was then poured into ice water. The nitrobenzene was removed by steam distillation and the insoluble residue left behind purified by crystallization from dilute acetic acid. We recovered 1.4 g. of the unaltered bromopyrimidine melting at 232–233°.

Preparation of $C_6H_5CH_2CH_2COOC_2H_5$, Ethyl Hydrocinnamate.—A quantitative yield of this ester was pre-

---

[5] See Johnson and Sprague, THIS JOURNAL, **60**, 1622 (1938).

pared for our research by reduction of ethyl cinnamate in the presence of Raney nickel catalyst.[6] Eighty grams of the cinnamic ester was diluted with ethyl alcohol to a volume of 100 cc., the mixture transferred to a copper liner of an autoclave, and after addition of 3 g. of the nickel catalyst was subjected to 120 atmospheres of hydrogen at room temperature. After twenty minutes of shaking the observed drop in pressure corresponded to the absorption of 0.5 mole of hydrogen. The purified ester boiled at 104–105° at 3 mm. and at 245° under atmospheric pressure.

Formation of the Sodium Salt of Ethyl-formyl 3-Phenylpropionate.[7]—A mixture of 178 g. (1 mole) of ethyl hydrocinnamate and 81 g. (1.1 mole) of ethyl formate was added slowly over a period of twenty hours to 23 g. of sodium wire suspended in 500 cc. of anhydrous ether. The excess of ether was then distilled off *in vacuo* at room temperature and the crude salt of the resulting formyl derivative used for the following reaction.

Formation of $\mathrm{NH{-}CS{-}NH{-}CH{=}C(C_7H_7){-}CO}$, **2-Thio-5-benzyluracil.**—The crude sodium salt from the preceding preparation and 50 g. of pulverized thiourea were added to 350 g. of absolute alcohol and the mixture then refluxed at 100° for four hours. The excess of alcohol was then evaporated, the crude reaction product dissolved in 500 cc. of cold water and the aqueous solution acidified with hydrochloric acid. Sixty-eight grams of the above pyrimidine separated. It was purified by crystallization from ethyl alcohol and melted at 210–211°. This pyrimidine is soluble in aqueous ammonia, glacial acetic acid, and acetone, moderately soluble in hot ethyl alcohol; slightly soluble in hot water and insoluble in ether, chloroform and benzene.

Anal. Calcd. for $C_{11}H_{10}ON_2S$: N, 12.84. Found: N, 12.83, 12.76.

5-Benzyluracil, $\mathrm{NH{-}CO{-}NH{-}CH{-}C(C_7H_7){-}CO_2}$.—This pyrimidine is formed by digesting the above 2-thiopyrimidine with 10% chloroacetic acid. It was purified by crystallization from glacial acetic acid and melted at 294–295°. The pyrimidine is soluble in aqueous ammonia, slightly soluble in dioxane, acetone, ethyl alcohol and hot water, and insoluble in chloroform, ether and benzene.

Anal. Calcd. for $C_{11}H_{10}O_2N_2$: C, 65.32, H, 4.98; N, 13.86. Found: C, 65.18, 65.61; H, 4.90, 4.95; N, 13.77, 13.82.

$\mathrm{NH{-}CO{-}NH{-}CH(OCH)_3{-}C(Cl)(C_7H_7){-}CO}$, **2,4-Diketo-6-methoxy-5-benzyl-5-chlorohexahydropyrimidine.**—Chlorine gas was bubbled into an ice-cooled suspension of 5-benzyluracil (1 g.) in methyl alcohol (50 cc.) until the pyrimidine practically dissolved. The alcohol solution was then exposed to a blast of air to remove the excess of solvent and chlorine gas when we obtained 1 g. of this hexahydropyrimidine. It was purified by crystallization from methyl alcohol. This pyrimidine showed a characteristic double melting point, melting first at 217–218°, then solidifying and melting finally at 232–234°. It was soluble in acetone and glacial acetic acid, and insoluble in ether and benzene.

Anal. Calcd. for $C_{12}H_{13}O_3N_2Cl$: N, 10.34. Found: N, 10.59, 10.70.

When this pyrimidine was digested with hydrobromic acid in glacial acetic acid it was converted into 5-benzyluracil melting at 292–294°.

Summary

1. 2-Thio-6-benzyluracil and 2-thio-5-benzyluracil have been synthesized.

2. These two isomeric pyrimidines are desulfurized by digestion with chloroacetic acid giving smoothly 6-benzyluracil and 5-benzyluracil.

3. 6-Benzyluracil is attacked by bromine in glacial acetic acid solution with formation of the corresponding 5-bromo derivative.

4. Both 6-benzyl- and 5-benzyluracil are attacked normally by chlorine in wood alcohol giving hexahydropyrimidines. The chlorination is confined entirely to zone "B" of the pyrimidine molecule.

Colloid Chemistry of Leaf and Flower Pigments. II. Qualitative Analysis of Leaf Pigments[1]

BY WILDER D. BANCROFT AND JOHN E. RUTZLER, JR.

In spite of all the work that has been done on plant pigments, nobody seems to have worked out any quick and easy method of identifying qualitatively the types of pigments occurring in leaves and flowers. The late Mrs. Onslow[2] says that no such thing is possible.

Even if Mrs. Onslow's pessimistic view were right—which we do not admit—we believe that a poor system of qualitative analysis would be better than none at all. Our experience convinces us that such a system will bring to light many interesting facts that have been overlooked in the past. Nobody knew, for instance, that leuco-anthocyanins are present in the leaves of the sugar maple in July but not in May. A careful study of this system will show whether flavone-like substances are or are not the precursors of leuco-anthocyanins in this plant. We[3] have been using our system of qualitative analysis successfully in determining the precursors of anthocyanins in specific cases.

It is for these and other reasons that we are presenting a preliminary system of qualitative analysis of leaf pigments. We do not know the limits of accuracy and there are cases in which the proposed scheme does not function well owing to excessive adsorption. It has worked well for us so far, and we are presenting it for consideration and criticism. Most of the data were available in the literature and we have merely arranged and checked them. We have been using the method for over three years and have found it helpful.

Unless otherwise stated all leaves are used fresh and are shredded by hand, although the scheme of analysis also works when dry leaves are employed. Such terms as carotenes, xanthophylls, flavones, anthocyanins, anthocyanidins and leuco-anthocyanins, are used generically and refer to any or all of the pigments grouped under any one head and not necessarily to any single pigment. It would probably be wiser to extract in some cases in an oxygen-free atmosphere and in the dark, but these precautions were not taken and may be considered as future refinements, which may be of importance when studying the flavones and leuco-anthocyanins.

Recommended Method of Qualitative Analysis

1. **Tests for flavones, leuco-anthocyanins, anthocyanins and anthocyanidins** are made by treating the shredded leaves with a 2–10% solution of formic acid, extracting by heating in boiling water if no pink or red color appears in the cold extract after from six to twenty-four hours. The solution may be colorless, pale yellow, red or pink. If colorless or pale yellow, no anthocyanins or anthocyanidins are present. Addition of aqueous ammonia or aqueous caustic soda causes a marked deepening of the yellow color if flavones are present. If the stronger formic acid causes a visible decomposition of the chlorophyll, this must be taken into account.

In a few cases with yellow autumn leaves, notably with those of the dogwood before it turns pink, the formic acid solution is yellow and the color does not deepen appreciably on adding ammonia. If enough ether is added to make a second liquid layer, the yellow goes to a considerable extent, sometimes completely, into the ether layer. This means that flavones are present at most in small amounts. The yellow color is due chiefly to what Tswett[4] calls "water-soluble yellow pigments of unknown constitution." Since the organic chemists have not yet determined how many of these there are or what their special properties are, it is impossible at present to differentiate them.

A pink or red color in the formic acid solution denotes anthocyanins, anthocyanidins or both, either accompanied or unaccompanied by flavones. If the solution is colorless with cold extraction and pink, red or brownish-red when extracted hot, practically all of the pink or red pigment was present in the leaf as leuco-anthocyanins. In such a case it is more satisfactory to heat the shredded leaves on the water-bath in a 5–10% sulfuric acid solution. With a strong acid, hydrolysis takes place rapidly and it is only necessary to heat for fifteen minutes to an hour to get a good test. In cases of doubt it is desirable to add butyl alcohol to the cooled solution. The red pigment concentrates in the butyl alcohol layer and becomes conspicuous.

To determine the presence of anthocyanins and anthocyanidins in the pink formic acid solution, add isoamyl alcohol to the pink solution and dilute gradually with water. If the isoamyl alcohol extracts practically all the pink color from dilute acid solution, the pigments are anthocyanidins and not anthocyanins. This case occurs rarely except when one has broken down a leuco-anthocyanin. If the isoamyl alcohol extracts practically no pink color, the pigments are anthocyanins. If both layers become pink, continued extraction with isoamyl alcohol may be done until one or the other of the layers becomes practically colorless. Willstätter and Everest[5] recommend

washing the amyl alcohol layer with dilute sulfuric acid.

To determine flavones in the presence of anthocyanins, shake the pink formic acid solution with ether. Remove the practically colorless ether layer and add aqueous ammonia or caustic soda to it. A yellow color in the water layer denotes the presence of flavones. Anthocyanidins do not interfere with this test, and leuco-anthocyanins do not go into the ether layer. If the ether layer is yellow and the color goes only partly into the water layer on adding aqueous ammonia or caustic soda, Tswett's "water-soluble yellow pigments of unknown constitution" must be present along with flavones.

If the amyl alcohol test for anthocyanidins is negative, the amyl alcohol layer may be removed and tested for flavones with aqueous ammonia or aqueous caustic soda. Anthocyanidins interfere with this test.

Anthocyanins are glycosides and anthocyanidins are the corresponding sugar-free pigments. So far as we now know, anthocyanidins occur only very rarely as such in plants. A test for them is desirable, partly because it is not uncommon for chemists accidentally to convert anthocyanins into anthocyanidins in the laboratory, and partly because anthocyanidins may occur more often than we now realize in autumn leaves whose red color is due to decomposition of leuco-anthocyanins.

2. **Tests for carotenes and xanthophylls** can be made more rapidly if the leaves are air-dried or vacuum-dried. It is safer, but not necessary, to use the leaves that have been extracted with the formic acid solution, because that eliminates any possible confusion over flavones and water-soluble yellows. Treat air-dried leaves with a low-boiling petroleum ether or with a so-called heptane, 90–100°. A little chlorophyll dissolves, so a greenish-yellow denotes presence of carotenes or xanthophylls or both. The green can be removed, if desired, by letting the solution stand in contact with aqueous hydrochloric acid. Add 90–95% methyl alcohol to the petroleum ether or heptane solution. Xanthophylls go into the methyl alcohol layer and carotenes stay in the upper layer. If both are present, the extraction should be continued until one or the other layer becomes practically colorless.

3. **Tests for chlorophyll** in red, yellow and brown leaves can be made by treating them, after or before extraction with formic acid and with heptane, with a methyl alcohol solution or with a 50–50 mixture of methyl and isoamyl alcohols. A green color, which disappears on adding aqueous hydrochloric acid, denotes presence of chlorophyll. The disappearance of the chlorophyll is a time reaction and does not occur instantaneously. Since chlorophyll goes readily into benzene and anthocyanin does not, the two can be separated qualitatively by shaking with benzene.

Simplified Method of Analysis

A quicker, simpler and less accurate method of qualitative analysis is to extract the leaves with methyl alcohol which takes out practically everything. Make up an ether–water system such that the two liquid layers are about equal in volume. Add some of the methyl alcohol extract. A green color in the ether layer denotes chlorophyll. This green will disappear gradually on adding hydrochloric acid, more slowly after adding ammonia. It is safer not to draw final conclusions in regard to yellow pigments until the chlorophyll has disappeared pretty completely. To the ether–water mixture containing some of the methyl alcohol extract, add aqueous hydrochloric acid solution. A pink color in the water layer indicates anthocyanins or anthocyanidins. Remove the ether layer and add aqueous ammonia to it. A yellow color in the water layer shows the presence of flavones. A yellow color exclusively or chiefly in the ether layer indicates the so-called water-soluble yellow pigments.

Remove the ether layer, add "heptane" to it and evaporate off the ether. Add 90–95% methyl alcohol. A yellow color in the heptane denotes carotenes and a yellow color in the water layer shows xanthophylls, subject always to possible errors due to the presence of water-soluble yellow pigments.

Positive results by this method are reliable. Negative results should be checked if there is any reason to doubt them. Methyl alcohol usually will extract anthocyanins readily, but we have seen a red cactus blossom which was scarcely touched by methyl alcohol and gave up its pigment readily to a formic acid solution. Acetic acid has very little effect on the flavones in the jonquil. Since methyl alcohol increases the mutual solubility of ether and water, a large amount of methyl alcohol may introduce complications, while smaller amounts of methyl alcohol may mean correspondingly smaller amounts of pigment to be tested.

Discussion

Both these methods work with from a fraction of a leaf upward. Any group of pigments that cannot be determined in an extract from six leaves can be ignored for all ordinary purposes, though there may be especial reasons for determining such pigments as flavins. For substances like these, special methods must be and have been developed.

By using an approximately constant weight of leaves in approximately the same state of dryness and a constant amount of solution, the methods can be made semi-precise. It was possible to show one year that leuco-anthocyanins were present in the leaves of the sugar maple in Ithaca in July and not in the leaves of the Norway maple. It was also shown that the green leaves of the copper beech, which had been red earlier in the season, contained relatively large amounts of leuco-anthocyanins in July, small amounts early in September and an almost negligible amount toward the end of September. A more exhaustive study of this system ought to give some definite information as to the precursors of leuco-anthocyanins. We do not know now whether flavones are or are not possible precursors of the leuco-anthocyanins and we do not know anything about the reds that appear in young leaves in tropical forests.

Summary

It is possible to identify many leaf and flower pigments by suitable treatment with methyl alcohol, butyl alcohol, amyl alcohol and ether in acid and alkaline solutions.

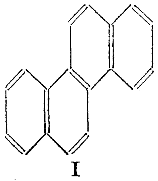
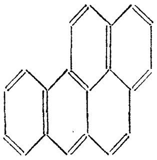
A New Synthesis of Chrysene Derivatives

By Melvin S. Newman

The desirability of preparing methyl derivatives of all of the five polycyclic aromatic hydrocarbons of the formula $C_{18}H_{12}$ has been pointed out previously.[1] Of these, derivatives of 1,2-benzanthracene have received the greatest attention. With the recent synthesis of 8-methyl-1,2-benzanthracene[2] all of the monomethyl derivatives of 1,2-benzanthracene have been made available for the study of the effect of structure on cancer-producing activity.[3] Of the other members of this class of hydrocarbons chrysene, I, offered a most promising field for research not only because of the similarity of its carbon skeleton to that of the steroids but also because the active carcinogenic agent in coal tar, 3,4-benzpyrene, II,[4] may be considered as a chrysene substituted in positions 4 and 5.



I



II

Of the known methods for the synthesis of chrysene and its derivatives[5] none seemed adequate for the preparation of various methyl- and dimethylchrysenes desired for biological testing. The work herein reported was undertaken in an effort to find a general method suitable for the preparation of variously substituted derivatives of chrysene.

The successful synthesis proceeds from benzalacetophenone by well-known reactions to α,γ-diphenylbutyric acid.

$$C_6H_5COCH{=}CHC_6H_5 + HCN \longrightarrow$$
$$C_6H_5COCH_2CH(CN)C_6H_5 \xrightarrow[H_2SO_4]{CH_3OH}$$
$$C_6H_5COCH_2CH(COOCH_3)C_6H_5 \xrightarrow{H_2O}$$
$$C_6H_5COCH_2CH(COOH)C_6H_5 \xrightarrow[HCl]{Zn—Hg}$$
$$C_6H_5CH_2CH_2CH(COOH)C_6H_5$$

The acid chloride of α,γ-diphenylbutyric acid was cyclized in benzene solution by aluminum chloride to 1-keto-2-phenyl-1,2,3,4-tetrahydronaphthalene III (87% yield) and the remaining steps in the synthesis are indicated below. This part of the synthesis consists essentially of an extension of the phenanthrene synthesis of Cook.[6]

Although one might expect the ketone III to be somewhat hindered, the Reformatsky reaction proceeded vigorously and the yield of the acid IV varied from 60 to 68%. The double bond is placed in the ring instead of the alternate position of conjugation with the carboxyl group because of the failure to isolate III from the products of ozonization. Surprisingly, low pressure catalytic reduction of this acid, its sodium salt, or its methyl ester using palladium or platinum catalysts failed almost completely. Invariably the acid was recovered for the most part unchanged. Reduction in excellent yield was finally effected by the action of 2% sodium amalgam on an aqueous alcoholic solution of the sodium salt, *using acid which had been recovered from unsuccessful attempts at catalytic hydrogenation.* When freshly prepared pure acid was used, *no reduction took place.* While an exhaustive search into the reason for this phenomenon was not made, the effect was noted in several different runs. If an alcoholic solution of the pure acid were shaken with Adams platinum catalyst and hydrogen and then recovered, this acid could be reduced by sodium amalgam. It may be that

some colloidal platinum is the cause of the results noted for in a patent[8] it is claimed that spongy metals or alloys act as a catalyst for the reaction of sodium amalgam with aqueous solutions. The reduction proceeded in excellent yield to give a mixture of two racemates, one of which easily was isolated pure in 62% yield by fractional crystallization. The remainder of the reduced acids consisted of a difficultly separable mixture.[9]

The ketone VI was prepared in 81% yield by an intramolecular Friedel–Crafts condensation of the chloride of V. Upon Clemmensen reduction the known *cis* 5,6,11,12,13,14-hexahydrochrysene,[7] m. p. 76.8–77.8°, corr., was obtained. This fact forms the basis for assigning the *cis* structure to the acid V and the ketone VI. The formation of chrysene by heating this hydrocarbon with selenium[7] was confirmed. By treating the ketone VI with the appropriate Grignard reagent, followed by dehydration and dehydrogenation, both 6-methylchrysene,[10] m. p. 161.0–161.4°, and 6-ethylchrysene,[11] m. p. 126.4–126.8°, were prepared in 82 and 50% yields, respectively.

Upon oxidation, 6-methylchrysene gave a mixture of products from which a small yield of 6-methyl-11,12-chrysenequinone, m. p. 210–212°, dec., was obtained. This structure is assigned on the basis of the fact that the quinone readily formed a yellow phenazine derivative, m. p. 220–221°, with *o*-phenylenediamine. For comparison the phenazine derivative of chrysenequinone, m. p. 215–216°, was prepared, the mixed melting point being depressed over 20°, whereas a mixed melting point of the two quinones showed no depression.

An interesting variation leading to the formation of the acetates of 6-chrysenol and 11,12-dihydro-6-chrysenol is indicated below.

The dehydrogenation of the unsaturated acid IV to IX by heating with sulfur proceeded in 79% yield and the cyclization by a new application of the procedure of Fieser and Hershberg[12] yielded the acetate of 6-chrysenol, X, in 80% yield. The yields in the alternate procedure were 87% for the acetylative cyclization and 50% for the dehydrogenation. On hydrolysis, X and XI were converted into 6-chrysenol,[13] m. p. 248–250° with decomposition, and 11,12-dihydro-6-chrysenol, m. p. 156.2–156.6°, respectively. The former yielded chrysenequinone on oxidation and 6-methoxychrysene,[14] m. p. 127.2–127.8°, on methylation.

Experimental[15]

α-Phenyl-β-benzoylpropionitrile.—Conditions were found which make possible the preparation of this intermediate in much less time than recommended.[16] A solution of 108 g. of potassium cyanide in 200 cc. of water was added under the surface to a solution at 55° of 135 g. of benzalacetophenone in 700 cc. of alcohol. The addition was made over a period of five minutes with continual shaking. After five minutes, the contents were warmed to 60°, the flask was wrapped with several towels and allowed to stand undisturbed for ninety to one hundred minutes, the temperature being maintained at 60° by the heat of reaction. After cooling the crystals were collected by filtration and washed colorless with cold 50% alcohol. The yield was 146 g. (95%) of material melting at 124.4 to 126°.

α,γ-Diphenylbutyric Acid.—The above nitrile was converted into methyl α-phenyl-β-benzoylpropionate[17] and hence to the free acid by alkaline hydrolysis.

In a typical reduction[18] the product obtained from 120 g. of α-phenyl-β-benzoylpropionic acid was distilled at 3 mm. The fraction, 101 g., boiling at 199–203° was dissolved in 250 cc. of warm petroleum ether (b. p. 65–110°) and on cooling 91 g. of white crystals, m. p. 68–71°, was obtained. From the mother liquor only 2 g. more of good product crystallized, making the yield 82%. On one recrystallization the melting point rose to 72–3°[19] with little loss. In an experiment in which the entire crude product at each stage was used directly for the next step, there was obtained 128 g. (62%) of α,γ-diphenylbutyric acid, m. p. 72–73°, from 183 g. of benzalacetophenone. Separate attempts were made to hydrolyze and reduce α-phenyl-β-benzoylpropionitrile, and methyl α-phenyl-β-benzoylpropionate in one step using the Clemmensen procedure but the yield of reduced acid was small, a considerable amount of both starting materials being recovered.

1-Keto-2-phenyl-1,2,3,4-tetrahydronaphthalene, III.—In the best of several experiments 91 g. of α,γ-diphenylbutyric acid was converted into the acid chloride with 83 g. of phosphorus pentachloride. After removing all volatile phosphorus compounds on the water pump at 100°, the pale yellow oil was dissolved in 380 cc. of thiophene-free benzene and 53 g. of aluminum chloride was added during one-half hour (external cooling). After stirring for three hours at room temperature, the deep red reaction mixture was heated to 40° several times during the next seven hours, cooled, and poured on ice and hydrochloric acid. The benzene was removed by steam and the organic matter collected and dissolved in 300 cc. of alcohol. The first crop of pale buff crystals was distilled, b. p. 182–183 at 2.5–3 mm. The product in the mother liquors was also distilled and the combined distillates yielded a total of 73.0 g. (87%) of white plates, m. p. 76–77°. If the entire reaction product were distilled before a preliminary crystallization the yield was reduced from 5 to 10%. On standing the ketone frequently took on a pink tinge. A sample recrystallized for analysis melted at 76.2–77.0°.

*Anal.** Calcd. for $C_{16}H_{14}O$: C, 86.45; H, 6.34. Found: C, 86.11; H, 6.61.

The **semicarbazone** melted with decomposition at 250–251.4° after sintering at 245°.

3,4-Dihydro-2-phenyl-1-naphthaleneacetic Acid, IV.—In a typical experiment, a mixture of 10 g. each of ketone and granulated zinc, 16 g. of ethyl bromoacetate, 40 cc. of dry thiophene-free benzene, and a pinch of the copper salt of the enol form of ethyl acetoacetate was heated until reaction commenced, after which the heat of reaction was sufficient to reflux the solvent. In larger runs cooling was necessary. After ten minutes, the mixture was heated on the steam-bath for thirty minutes. The cooled reaction mixture was poured into dilute hydrochloric acid and the organic matter collected in the benzene layer. After removing the solvent, the product was dehydrated by heating with a small crystal of iodine at 210–215° for thirty minutes under 100 mm. pressure, following which a pale yellow viscous oil, b. p. 180–200° at 3 mm., was distilled. The distillate was saponified with alcoholic potassium hydroxide. By crystallization and recrystallization from benzene there was obtained 8.1 g. (68%) of the acid IV as dense colorless prisms which contained benzene of crystallization removed by drying at 100°. The melting point was 155–156° and a portion was crystallized from benzene and alcohol to a constant melting point of 156.2–156.8°.

Anal.† Calcd. for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10. Found: C, 82.17; H, 5.98.

A carbon tetrachloride solution of the acid readily decolorized bromine.

An ozonolysis, for which the author is indebted to Dr. Shinowara, was carried out in acetic acid. The neutral portion of the products of ozonolysis yielded only intractable oils from which no semicarbazone could be obtained. The acid fraction consisted mainly of starting unsaturated acid, m. p. 152–156°.

***cis*-2-Phenyl-1,2,3,4-tetrahydro-1-naphthaleneacetic Acid, V.**—Attempts were made to reduce IV using both platinum and palladium catalysts in acetic acid and in 95% alcohol. There was no further absorption of hydrogen after the catalyst was reduced. The entire crude acid as recovered from the solvent had a melting range of 20° but on one crystallization from benzene, over 65% was recovered with a good melting range, 152–156°, not depressed by the authentic acid. No better results were obtained using the methyl ester in alcohol solution or the sodium salt in aqueous solution. Further unsuccessful attempts at reduction involved the Clemmensen reduction and boiling with phosphorus and hydriodic acid. In a typical reduction with sodium amalgam, 4.90 g. of acid IV was dissolved in 20 cc. of 95% alcohol (distilled over potassium hydroxide), and an equivalent amount of sodium hydroxide in 200 cc. of water was added, followed by 360 g. of 2% sodium amalgam (made by dropping mercury on molten sodium under sulfur-free xylene). After standing for three days at 35–40°, the solution was heated to 100° to dissolve the insoluble sodium salt which had crys-

tallized. The acids precipitated on acidification were crystallized from 80 cc. of benzene. The first crop melted at 170–172° and the next two crops somewhat lower. On recrystallization from alcohol a total of 3.06 g. (62%) of white needles, m. p. 171–172°, was obtained. A portion recrystallized for analysis melted at 172.0–172.8°.

Anal.† Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81. Found: C, 81.26; H, 6.74.

The acids in the mother liquors were saturated as shown by a failure to decolorize bromine in carbon tetrachloride. These acids undoubtedly formed a mixture of the two racemates.

***cis*-6-Keto-5,6,11,12,13,14-hexahydrochrysene, VI.**—In the best experiment, 4.29 g. of acid V was warmed with 3.5 g. of phosphorus pentachloride for one hour after which phosphorus compounds were removed under reduced pressure on the water-bath at less than 90°. The pale yellow acid chloride was dissolved in 30 cc. of dry sulfur-free benzene and 2.18 g. of powdered aluminum chloride added in portions. The reaction mixture warmed up and took on a green color. After three hours at 30–50°, the mixture was poured into dilute hydrochloric acid and the benzene layer separated and washed successively with hydrochloric acid, sodium hydroxide, water, and saturated sodium chloride solution. After removing the benzene the product crystallized from alcohol. In all 3.23 g. (81%) of ketone which crystallized in dense prisms, m. p. 74.4–76.4°, was obtained. A sample recrystallized for analysis melted at 75.8–76.8° and formed colorless prisms.

Anal.† Calcd. for $C_{18}H_{16}O$: C, 87.06; H, 6.50. Found: C, 86.53, 87.53; H, 6.74, 6.58.

The semicarbazone formed very small crystals from pyridine–alcohol, m. p. 255–258°, dec., after sintering at 251°.

Anal.† Calcd. for $C_{19}H_{19}ON_3$: N, 13.76. Found: N, 13.74.

***cis*-5,6,11,12,13,14-Hexahydrochrysene, VIII.**—By a modified[18] Clemmensen reduction, from 1.0 g. of *cis*-ketone, VI, there was obtained 0.52 g. (55%) of hexahydrochrysene, m. p. 74.4–75.8°. After two recrystallizations from alcohol, thick white plates, m. p. 76.8–77.8°, were obtained. Ramage and Robinson[7] give the melting point for *cis*-hexahydrochrysene as 75°. A mixture of VI and VIII melted at 61–66°.

6-Methylchrysene, VII (R = CH_3).—To a solution of 0.461 g. of VI in 3 cc. of ether and 3 cc. of benzene was added 2 cc. of 2.7 *M* methylmagnesium bromide in ether. A white complex separated immediately but soon dissolved. After thirty minutes of refluxing, the reaction mixture was decomposed with dilute hydrochloric acid and the organic material heated at 220° for ten minutes to effect dehydration. The residue was heated with 0.120 g. of sulfur at 230° for twenty minutes during which time hydrogen sulfide was evolved copiously. Distillation at 3 mm. yielded a yellow distillate which immediately solidified. By crystallization from benzene there was obtained a total of 0.368 g. (82%) of **6-methylchrysene**, m. p. 160.2–161.2°. Recrystallization from benzene–alcohol resulted in colorless stout needles, m. p. 161.0–161.4°. **The picrate,** from benzene–alcohol, formed bright orange needles, m. p. 170.0–170.6°.

6-Methylchrysene-11,12-quinone.—6-Methylchrysene (0.32 g.) was oxidized by boiling with 1 g. of sodium dichromate and 10 cc. of acetic acid for five hours. The red oxidation product was recrystallized until its behavior on melting remained constant. The product obtained in very small amount formed beautiful bright red needles which, when the temperature of the melting point bath was raised slowly, darkened slightly above 200° and melted with much decomposition at 210–212°. The temperature of decomposition was higher, the faster the rate of heating and on rapid heating it melted at 218–220°. The decomposition point was not affected by mixing the sample with authentic chrysenequinone, m. p. 242–242.6°. The color of the solution of 6-methylchrysenequinone in cold concentrated sulfuric acid was blue-violet and not quite as pronounced as the deep blue color of chrysenequinone under the same conditions.

Anal.† Calcd. for $C_{19}H_{12}O_2$: C, 83.81; H, 4.44. Found: C, 83.75; H, 4.74.

Chrysophenazine and 5-Methylchrysophenazine.[20]—Condensation products of chrysenequinone and 6-methylchrysenequinone with *o*-phenylenediamine in alcohol–acetic acid were obtained easily. After recrystallization from pyridine–alcohol **chrysophenazine** formed long silky yellow needles, m. p. 215–216°.

*Anal.** Calcd. for $C_{24}H_{14}N_2$: N, 8.48. Found: N, 8.40.

5-Methylchrysophenazine formed small yellow needles, m. p. 220–221°, and a mixed melting point with the above was depressed 20°.

Anal.† Calcd. for $C_{25}H_{16}N_2$: N, 8.14. Found: N, 8.45.

6-Ethylchrysene, VII, (R = C_2H_5).—In a manner entirely analogous to that used in the preparation of 6-methylchrysene there was obtained from 0.765 g. of VI, 0.378 g. of 6-ethylchrysene, m. p. 124–125°. On recrystallization from benzene–alcohol colorless needles, m. p. 126.4–126.8°, were obtained. A solution in warm concentrated sulfuric acid had a blue-violet color as mentioned by Funke.[11] The picrate, bright orange needles, m. p. 136.2–136.8°, was prepared in and recrystallized from benzene–alcohol.

*Anal.** Calcd. for $C_{26}H_{19}O_7N_3$: N, 8.66. Found: N, 8.64, 8.65.

2-Phenyl-1-naphthaleneacetic Acid, XI.—A mixture of 2.64 g. of IV and 0.32 g. of sulfur was heated at 220–225° for ninety minutes. Hydrogen sulfide was evolved copiously for the first twenty minutes but if the reaction were stopped at this point the yield was greatly decreased. The slightly colored reaction product was crystallized from benzene yielding a total of 2.07 g. (79%) of the desired acid IX as colorless prisms, m. p. 192–193°.

*Anal.** Calcd. for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38. Found: C, 81.99; H, 5.52.

6-Chrysenyl Acetate, X.—A solution of 1.60 g. of IX and a small amount of anhydrous zinc chloride in 8 cc. of

acetic anhydride and 8 cc. of acetic acid[12] was refluxed for one hour, cooled, and diluted with water. On further cooling there crystallized in colorless needles 1.39 g. (80%) of **6-chrysenyl acetate**, m. p. 157–158°. A sample recrystallized for analysis melted at 158.6–159.2°.

Anal.† Calcd. for $C_{20}H_{14}O_2$: C, 83.89; H, 4.93. Found: C, 83.58; H, 5.02.

6-Chrysenol.—The acetate was converted into 6-chrysenol by heating with alcoholic potassium hydroxide for five minutes. The cooled yellow solution was diluted with dilute hydrochloric acid, whereupon the color almost disappeared. Soon 6-chrysenol separated in almost colorless needles in quantitative yield. Upon recrystallization from acetone–benzene, 6-chrysenol[13] formed colorless needles, m. p. 248–250°, with decomposition. Darkening and sintering took place as low as 240°. Upon oxidation with sodium dichromate in acetic acid, 6-chrysenol was converted in theoretical yield to chrysenequinone.

*Anal.** Calcd. for $C_{18}H_{12}O$: C, 88.50; H, 4.95. Found: C, 88.61, 88.75; H, 5.13, 5.26.

6-Methoxychrysene.—An aqueous methyl alcoholic solution of 0.515 g. of 6-chrysenol containing 1 cc. of 50% potassium hydroxide was treated with two 0.5-cc. portions of dimethyl sulfate. After a time pale yellow crystals separated. The reaction mixture was warmed, diluted with water, and cooled in an ice-bath. By crystallization of the reaction product from benzene–alcohol there was obtained 0.464 g. (85%) of white needles, m. p. 125–127°. A sample recrystallized from benzene–alcohol melted at 127.2–127.8°.[14]

*Anal.** Calcd. for $C_{19}H_{14}O$: C, 88.35; H, 5.46. Found: C, 88.16; H, 5.48.

11,12-Dihydro-6-chrysenyl Acetate, XI.—Under conditions similar to those used in the preparation of 6-chrysenyl acetate, X, 3.00 g. of IV was cyclized to yield 2.80 g. (87%) of XI, m. p. 94–96°. A sample recrystallized from alcohol melted at 95.6–96.2°.

Anal.† Calcd. for $C_{20}H_{16}O_2$: C, 83.31; H, 5.59. Found: C, 83.31; H, 5.96.

Under conditions identical to those used in the dehydrogenation of IV to IX, **11,12-dihydrochrysenyl acetate** was converted in 50% yield into **6-chrysenyl acetate.**

11,12-Dihydro-6-chrysenol.—By saponification with alcoholic potassium hydroxide for one hour, 0.342 g. (80%) of 11,12-dihydro-6-chrysenol, m. p. 155.6–156.4°, was obtained from 0.50 g. of XI. A sample recrystallized for analysis from alcohol formed colorless elongated prisms, m. p. 156.2–156.6°.

*Anal.** Calcd. for $C_{18}H_{14}O$: C, 87.77; H, 5.73. Found: C, 87.67, 88.15; H, 5.72, 5.85.

An attempt at methylation resulted in the formation of an uninviting brown viscous oil.

Fluorescence in Ultraviolet Light.—The following compounds exhibited vivid blue fluorescence when viewed in ultraviolet light: 2-phenyl-3,4-dihydro-1-naphthaleneacetic acid, *cis*-6-keto-5,6,11,12,13,14-hexahydrochrysene, *cis*-5,6,11,12,13,14-hexahydrochrysene, 6-methylchrysene, 6-chrysenol, and 6-methoxychrysene.

Summary

A new synthesis for hydrocarbons containing the chrysene nucleus is described. The starting material is benzalacetophenone which is converted by well-known reactions into α,γ-diphenylbutyric acid. This acid is cyclized to 1-keto-2-phenyl-1,2,3,4-tetrahydronaphthalene. By the Reformatsky reaction, followed by dehydration and saponification, this ketone is converted into 3,4-dihydro-2-phenyl-1-naphthaleneacetic acid which on reduction with sodium amalgam yields *cis*-2-phenyl-1,2,3,4-tetrahydro-1-naphthaleneacetic acid. Upon cyclization this acid yields *cis*-6-keto-5,6,11,12,13,14-hexahydrochrysene from which, by reaction with methyl- and ethylmagnesium bromides, followed by dehydration and dehydrogenation, there is obtained, respectively, 6-methyl- and 6-ethylchrysene. 6-Methylchrysene on oxidation yields 6-methylchrysene-11,12-quinone.

By dehydrogenation with sulfur, 3,4-dihydro-2-phenyl-1-naphthaleneacetic acid is converted into 2-phenyl-1-naphthaleneacetic acid from which is formed 6-chrysenyl acetate by acetylative cyclization. The latter is hydrolyzed to 6-chrysenol, in turn methylated to 6-methoxychrysene. On acetylative cyclization 3,4-dihydro-2-phenyl-1-naphthaleneacetic acid yields 11,12-dihydro-6-chrysenyl acetate which is hydrolyzed to 11,12-dihydro-6-chrysenol and is dehydrogenated to 6-chrysenyl acetate.

Hydrogen Fluoride as a Condensing Agent. II. The Alkylation of Benzene by Olefins

BY J. H. SIMONS AND S. ARCHER

In a previous communication[1] we announced the successful alkylation of benzene using hydrogen fluoride as the condensing agent. The first successful alkylation of aromatic compounds by olefins was reported by Balsohn in 1879.[2] Since that time acidic substances such as sulfuric acid,[3] phosphoric acid,[4] and phosphorus pentoxide[5] have been used to effect such condensations. Hydrogen fluoride has been used as a promoter with boron fluoride in the alkylation of paraffins by olefins.[6]

Ipatieff[3] stated that in the case of the condensation reaction catalyzed by sulfuric acid, there were three competing reactions. These were, first, alkylation of the aromatic hydrocarbon, second, polymerization of the olefin, and, third, the reaction of the unsaturated compound with the acid to form an ester. Since it has been shown that hydrogen fluoride polymerizes olefins,[7] and also adds to double bonds,[8] we believe that similar side reactions also can take place in the case of alkylation catalyzed by hydrogen fluoride. However, under the conditions employed, no evidence was found for any reaction except alkylation. If polymerization or addition of hydrogen fluoride occurred, they were in relatively small amounts.

The reaction mixture after removal of the acid and subsequent drying, was always clear and almost colorless. Fractionation proceeded smoothly and efficiently in all cases, and no compounds boiling at temperatures between those of benzene and the alkylbenzenes were found. The olefins used were propylene, isobutene, pentene-2, trimethylethylene, and cyclohexene. All, except propylene, were prepared by dehydration of the proper alcohol. The alkylbenzenes formed were characterized by means of physical constants and by conversion to the monoacetamino derivative as described by Ipatieff and Schmerling.[9]

Experimental

General Method.—One to five mols of relatively dry hydrogen fluoride was distilled from the container through a water-cooled copper coil into a copper flask in an ice-bath. Two to five mols of benzene was then added and a rubber stopper inserted. This stopper carried an inlet and an outlet tube of copper and a copper stirrer provided with a mercury seal. One-half to one mol of olefin was then added slowly with stirring. The stirring was continued for three to five hours usually at 0°, but sometimes the reaction was allowed to warm to room temperature. The mixture was poured onto ice and neutralized with sodium carbonate. After washing the benzene layer with sodium carbonate solution, it was separated, dried with potassium carbonate or magnesium sulfate, and distilled. The product was then redistilled and a portion converted into the acetamino derivative. The yields and certain physical properties of the products are given in Table I.

Conclusions.—As indicated in a previous communication, hydrogen fluoride has been found to be useful as an agent for the alkylation of benzene by olefins. Although the reactions were performed using sufficient hydrogen fluoride to give two liquid layers, the reaction probably takes place in the hydrocarbon layer. The amount of hydrogen fluoride could be varied within wide limits without affecting the results, and other experiments which have been performed in this laboratory indicate that the reactions proceed rapidly with only sufficient hydrogen fluoride to form a saturated solution in the hydrocarbon.

As no great care was taken to ensure high yields and as the reactions were not studied to find the conditions for maximum yield, the yields obtained were surprisingly high. These probably could be increased to practically the theoretical by using greater care and larger reaction mixtures.

Extreme precautions to ensure anhydrous conditions were not taken. In some cases the reaction mixtures were exposed to moist laboratory air for considerable periods of time without affecting the results. Aqueous solutions of hy-

Hydrogen Fluoride as a Condensing Agent. III. Alkylation of Aromatics with Aliphatic Halides

BY J. H. SIMONS AND S. ARCHER

In a previous communication[1] we have indicated the use of hydrogen fluoride to promote the reaction between benzene and alkyl halides. A more detailed account of reactions between aromatic compounds and alkyl halides can now be reported.

The use of aluminum chloride and other metallic halides to catalyze condensations between alkyl halides and aromatic compounds is very well known.[2] However, a search of the literature failed to reveal any instance wherein sulfuric or other acidic catalysts have effected such a condensation. It is worthy of note, therefore, that hydrogen fluoride can promote such a condensation.

When tertiary chlorides are used, only extremely mild conditions are required. The reaction proceeds smoothly at 0° and at atmospheric pressure. When secondary halides are employed, higher temperatures are necessary to bring about a reaction. At 25° a small amount of propylated benzenes was formed from the reaction between isopropyl chloride and benzene. Primary halides did not react detectably at either 0 or 25°. At higher temperatures, however, *n*-propyl bromide does react readily with benzene.

In addition to alkylation two other reactions might be expected. When metallic halides are used in reactions involving aromatic compounds, condensation of the rings occurs and resins and tars are formed. In these reactions using hydrogen fluoride no such residues were found. In another experiment reported from this Laboratory,[3] it was found that either *t*-butyl chloride or *t*-amyl chloride, when treated with hydrogen fluoride, produced a complicated mixture of higher boiling compounds. Fortunately in the presence of the aromatic compound in excess these reactions took place to a negligible extent if at all.

The halides used were isopropyl chloride, *t*-butyl chloride, *t*-amyl chloride and *n*-propyl bromide.

TABLE I

ALKYLATION OF AROMATICS BY ALIPHATIC HALIDES USING HYDROGEN FLUORIDE

Halide	Product	Yield, %	B. p., °C.	Press., mm.	n^{20}	M. p. of acetamino deriv., °C.
n-Propyl[a] bromide	Propylbenzene[b]	48	150–153	740	....	...
Isopropyl chloride	Polyisopropylbenzene[c]	..	155–175	740	....	166
t-Butyl chloride	Mono-*t*-butylbenzene	10	167–170	740	1.4908	169–170
	Di-*t*-butylbenzene	60	77–78[d]			
t-Amyl chloride	Mono-*t*-amylbenzene	41.5	71– 74	12		139–140.5
	Di-*t*-amylbenzene	21.5	127–130	12		
t-Butyl chloride	*p*-*t*-Butyltoluene[e]	75	72–72.5	12	1.4919	163.5–164.5[f]
			188	740		
t-Butyl chloride	Mono-*t*-butylnaphthalene[g]	46	142–143	14		
	Di-*t*-butylnaphthalene[h]	8	148[d]			
	Di-*t*-butylnaphthalene	28	80–81[d]			

[a] This reaction was run in a copper bomb at 80°. [b] This was a mixture of 88% isopropylbenzene and 12% normal propylbenzene determined from the melting point 80–92° of a sulfonamide derivative. The technique of this identification is given in the following paper of this series. [c] This reaction proceeded very slowly at 25°; only a small amount of product was obtained, which distilled over a considerable range. The acetamino derivative was made of the highest boiling portion which is probably a polysubstituted benzene. [d] Melting point. [e] The aromatic used was toluene. [f] This is the melting point of *p*-*t*-butylbenzoic acid made from the product by oxidation with (1:2) nitric acid. Its determined neutral equivalent was 179, calcd. 178. [g] The aromatic used was naphthalene. It was dissolved in carbon tetrachloride for the reaction. [h] Two isomeric di-*t*-butylnaphthalenes were obtained. See Gump, THIS JOURNAL, **53**, 380 (1931).

The aromatic compounds employed were benzene, toluene and naphthalene.

Experimental

General Method.—The method used was similar to that reported in the second paper of this series.[4] The reactions, however, usually required two to three times as long. Hydrogen chloride was evolved in the reactions using chlorides and this was tested for in the escaping gases with a bead of silver nitrate solution. The reactions were stopped when this test was negative. Table I gives the collected results of the experiments.

Conclusion.—Hydrogen fluoride has been found to be an unusually effective agent to promote the reaction between alkyl halides and aromatic compounds. The reaction has been found to be most rapid with tertiary halides and least rapid with primary halides. The yields are relatively high although no effort has been made to obtain high yields and no study has been made of the best conditions for the reactions. The yields probably could be greatly improved. The amount of hydrogen fluoride necessary is probably greater than when olefins are used but only because some of it is lost in the escaping gas. Great care for the exclusion of moisture was not taken and small amounts of water apparently do not prevent the reaction.

Hydrogen fluoride has several advantages over the use of metallic halides for these reactions. Polymerization of the aromatic compounds is avoided and this results not only in higher yield but also in greater ease of separation and purification of the products. For aromatic compounds such as naphthalene that are solid at temperatures at which most of the reactions take place, a very convenient solvent (carbon tetrachloride) can be used with no apparent reaction between it and the other reagents. This solvent cannot be employed when aluminum chloride is used instead of hydrogen fluoride.

Summary

Hydrogen fluoride has been found to be an effective agent to promote the reaction between alkyl halides and aromatic compounds. The halides used were *n*-propyl bromide, isopropyl chloride, *t*-butyl chloride and *t*-amyl chloride, and the aromatic compounds were benzene, toluene and naphthalene.

Hydrogen Fluoride as a Condensing Agent. IV. The Reaction of Cyclopropane with Benzene

BY J. H. SIMONS, S. ARCHER AND ELIZABETH ADAMS

In the two previous papers in this series[1] it was shown that hydrogen fluoride was an efficient agent to promote the reaction between either olefins and aliphatic halides and aromatic compounds.

Of considerable interest is the reaction of cyclopropane and benzene. Ipatieff and Grosse[2] carried out this reaction using aluminum chloride and found that only the normal propylbenzenes were formed. We have used hydrogen fluoride to cause the same reaction and have found a similar result, *i. e.*, the normal compound is the only product.

It is believed that cyclopropane does not isomerize to form propylene before alkylation.[2] A possible mechanism to account for the formation of the normal rather than the iso compound may be given. The cyclopropane molecule, being under strain, will be the center of an abnormal electromagnetic field, as is indicated by its magnetic susceptibility.[3] This may cause it to add a proton to form a hypothetical and transitory propyl ion. The additional strain may cause the ring to break and irrespective of where it breaks a normal propyl positive ion will be formed. The reaction of this ion with benzene will produce normal propylbenzene and a proton.

In the reaction between paraffins and olefins catalyzed by boron trifluoride with hydrogen fluoride as a promoter, Grosse and Linn[4] assumed that the initial step in the mechanism was the addition of the acid to the double bond, followed by the removal of hydrogen fluoride as the alkyl fluoride condensed with the saturated hydrocarbon. A similar mechanism may be postulated for the reaction between olefins and aromatics, as catalyzed by hydrogen fluoride. However, the suggested course of reaction does not adequately explain the reactions of cyclopropane. When this hydrocarbon reacts with hydrogen fluoride, *n*-propyl fluoride is predominantly formed, along with a small but significant amount of isopropyl fluoride. If it is the alkyl fluoride that reacts with the aromatic hydrocarbon, then one should expect both the normal and the iso compound to be formed when cyclopropane reacts with benzene. Yet it has been shown that no isopropylbenzenes are found in the reaction products. It is therefore assumed that the organic reactions catalyzed by hydrogen fluoride proceed through some ionic mechanism similar to those postulated by Whitmore for polymerizations and rearrangements.

Experimental

Sulfonamide Method of Identification.—In order to evaluate the composition of a possible mixture of normal and isopropylbenzene, a method employing the melting points of the sulfonamide derivatives was employed.

The sulfonamides were usually prepared in triplicate. A 3-g. sample was shaken with twice its volume of concd. sulfuric acid until the hydrocarbon dissolved completely. A saturated salt solution was added to precipitate the sulfonic acid and the latter was washed free of sulfuric acid with more of the salt solution. After drying at 110°, the sulfonic acid was treated with 8 to 10 g. of phosphorus pentachloride; and the mixture was then heated on the steam-bath for four hours. At the end of this time, the mass was poured into water, extracted with ether, washed with water and dried over sodium sulfate. Ammonia was passed onto the sulfonyl chloride for one hour. The ammonium chloride was filtered off and the solution dried again over sodium sulfate. The ether was evaporated and a melting point taken without recrystallization: m. p. of *n*-propyl sulfonamide, 102.5°; m. p. of isopropyl sulfonamide, 98°; m. p. of 57:43 mixture of iso and normal, respectively, 73°. The latter was the lowest point on the melting point curve. Mixtures of varying percentages of each were made and the melting points taken. From the data, a temperature–composition diagram was constructed. From this diagram, the percentage of both components in a mixture of the two can be determined.

Cyclopropane and Benzene.—The technique was similar to that described for reactions between olefins and benzene.[1] Fractionation gave the following

Compound	B. p., °C.	n^{20}	Yields, %
Monopropylbenzene	154–157	1.4920	42
Dipropylbenzene	97–98 (16 mm.)	1.4928	20
Tripropylbenzene	130–131 (14 mm.)	1.4950	3

The sulfonamide of the monopropylbenzene melted at 99–105°, 99–105.2°. A mixed melting point with the corresponding derivative of pure isopropylbenzene was 80–92°. Thus cyclopropane gave the only normal propyl benzenes.

Summary

Cyclopropane has been found to react with benzene catalyzed by hydrogen fluoride to give normal propylbenzenes in good yield. A possible mechanism for the reaction is postulated.

Hydrogen Fluoride as a Condensing Agent. V. Reactions of Compounds Containing Oxygen and Reactions of Tertiary Halides with Olefins

BY J. H. SIMONS, S. ARCHER, AND H. J. PASSINO

In the preceding papers of this series[1] the usefulness of hydrogen fluoride has been shown as a condensing agent for reactions between aromatic compounds and either unsaturated compounds or halides. That this reagent will promote many other reactions can now be shown. It appears that it catalyzes the same reactions that acidic reagents such as sulfuric acid catalyze and also the reactions that metallic halides such as aluminum chloride or boron trifluoride catalyze. For some reactions it is not only more convenient technically but also produces higher yields. There are reactions that hydrogen fluoride promotes that have not been reported using other reagents. One of these is a reaction between an aliphatic halide and an olefin. Two examples of this reaction are reported here in preliminary form. These are the reactions of tertiary butyl chloride with trimethylethylene and with cyclohexene.

The reactions of compounds containing oxygen are somewhat different from reactions of compounds that do not. Due to the peculiar properties of hydrogen fluoride, one cannot predict its effect in these reactions. To show the usefulness of hydrogen fluoride for them an account of the following reactions is included. Tertiary butyl alcohol has been caused to react with benzene to form tertiary butyl benzene, tertiary butyl chloride has reacted with phenol to form tertiary butyl phenol, and tertiary butyl chloride has been made to react with ethyl furoate. For these reactions larger quantities of hydrogen fluoride are required.

Many other types of reactions undoubtedly can be performed by means of hydrogen fluoride but the variety that has now been accomplished shows the general usefulness of this reagent in organic reactions. The reasons for its apparent uniqueness probably can be found in its physical and chemical properties. These have been summarized by Simons.[2] Despite its apparent weakness in aqueous solutions, it is a very powerful acidic substance. This property of donating protons makes it a useful reagent for organic reactions such as polymerizations and rearrangements in which a positive organic ion is the intermediate. The fact that the other halogen halides are insoluble in it accounts for the reactions in which a halogen halide is eliminated. Its unusual ability to form addition compounds, which is so evident in its numerous complex inorganic compounds, probably accounts for its usefulness in reactions involving aromatic compounds. A complex intermediate similar to those postulated for reactions using aluminum chloride may be the active agent. It is certainly much more soluble in benzene than would be expected from its high dielectric constant. It is readily eliminated during the course of many organic reactions in which not more than one fluorine atom is attached to the same carbon atom, not because the carbon fluoride bond is weak but because the energy of formation of hydrogen fluoride is so very high.

Experimental

The same techniques were used as previously described[1] with the following exceptions. Tertiary butyl alcohol was added at one time as it clogged the delivery tube if added slowly. Ethyl furoate was used in solution in carbon tetrachloride. Much larger quantities of hydrogen fluoride were required in reactions involving oxygen containing compounds, and the reactions required a longer time. The reaction of ethyl furoate required about one hundred and fifty hours.

Tertiary Butyl Chloride and Trimethylethylene.—Distillation of the reaction products gave a constant boiling fraction of refractive index 1.4279–1.4315. It boiled 63–65° at 19 mm. This product was definitely an olefin with physical properties corresponding to the expected nonenes. The remainder of the material boiled over a continuous range of temperatures both above and below the constant boiling fraction. Apparently many products

[2] Simons, *Chem. Rev.*, **8**, 213 (1931).

TABLE I

CONDENSATION REACTIONS USING HYDROGEN FLUORIDE INVOLVING OXYGEN CONTAINING COMPOUNDS

Alkyl compounds	Aromatic compound	Product	Yield, %	B. p., °C.
t-Butyl alcohol	Benzene	Mono-*t*-butylbenzene	3	165
		Di-*t*-butylbenzene	8	78–78.5[a]
t-Butyl chloride	Phenol	*p*-*t*-Butylphenol	85	234–238[b]
t-Butyl chloride	Ethyl furoate	Ethyl 5-*t*-butylfuroate	54	116–117 (16 mm.)[c]

[a] Melting point. A mixed melting point with known *p*-di-*t*-butylbenzene was 77–78°. [b] The *p*-*t*-butylphenol melted at 97–98°, *p*-toluenesulfonate of it melted at 108–109°. [c] n^{20} 1.4749, the ester on saponification gave 5-*t*-butylfuroic acid which melted at 105–105.5°.

are formed, and this reaction requires further study. The constant boiling fraction represents about 18% yield.

Tertiary Butyl Chloride and Cyclohexene.—Distillation of the reaction products gave a fraction boiling 40–42° under a pressure of 18 mm. and at 141.5–142° at 739 mm. The refractive index of this fraction was 1.4578. It decolorized bromine water and gave only a very weak chloride ion test. Since neither boiling point nor refractive index checks whatsoever with di- or triisobutylene, and since it appears to be an olefin, it is very probable that polymerization has occurred between the tertiary butyl chloride and the cyclohexene to give either a tertiary butyl cyclohexene or a substituted cyclohexyl ethylene.

The yield of this fraction was 31% of the theoretical. A triisobutylene fraction of less than 10% was also obtained.

Conclusions.—The general usefulness of hydrogen fluoride as a reagent in organic reactions has now been well established. The technique of its use is somewhat different than that of other similar reagents but its utility seems to be much greater than any of them. There are reactions such as that between an olefin and a tertiary chloride which it promotes that have not been previously reported.

Summary

Hydrogen fluoride has been found useful to catalyze reactions between tertiary butyl chloride and both trimethylethylene and cyclohexene. It also has been found to catalyze reactions involving oxygen containing compounds. Tertiary butyl alcohol has been caused to react with benzene, tertiary butyl chloride formed tertiary butylphenol upon reaction with phenol, and ethyl 5-*t*-butylfuroate was formed from tertiary butyl chloride and ethyl furoate.

An explanation for the general utility of hydrogen fluoride in organic reactions is sought in its chemical and physical properties.

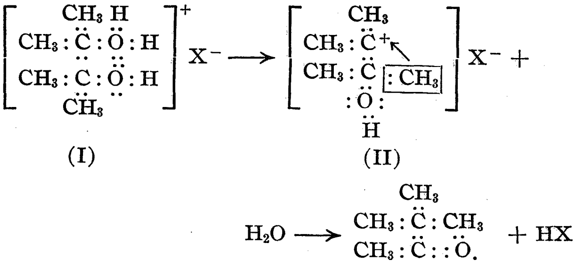
The Pinacol–Pinacolone Rearrangement: the Preparation and Rearrangement of Tetramethylethylene Bromohydrin

BY GEORGE W. AYERS, JR.[1]

The Stieglitz mechanism[2] of the pinacol–pinacolone rearrangement assumes that an intermediate oxonium salt (I) loses water to leave a nucleus[3] (II) in which one of the carbon atoms possesses only three pairs of electrons. This "fault" in the molecule is then repaired by the migration of a negative methyl group, with its full complement of electrons, from the adjacent carbon atom to the electron deficient carbon atom



$$\left[\begin{array}{c} \mathrm{CH_3}\ \ \mathrm{H} \\ \mathrm{CH_3}:\ddot{\mathrm{C}}:\ddot{\mathrm{O}}:\mathrm{H} \\ \mathrm{CH_3}:\mathrm{C}:\ddot{\mathrm{O}}:\mathrm{H} \\ \mathrm{CH_3} \end{array}\right]^{+} \mathrm{X}^{-} \longrightarrow \left[\begin{array}{c} \mathrm{CH_3} \\ \mathrm{CH_3}:\ddot{\mathrm{C}}^{+}\nwarrow \\ \mathrm{CH_3}:\ddot{\mathrm{C}}\ \boxed{:\mathrm{CH_3}} \\ :\ddot{\mathrm{O}}: \\ \ddot{\mathrm{H}} \end{array}\right] \mathrm{X}^{-} +$$

(I) (II)

$$\mathrm{H_2O} \longrightarrow \begin{array}{c} \mathrm{CH_3} \\ \mathrm{CH_3}:\ddot{\mathrm{C}}:\mathrm{CH_3} \\ \mathrm{CH_3}:\ddot{\mathrm{C}}::\ddot{\mathrm{O}}. \end{array} + \mathrm{HX}$$

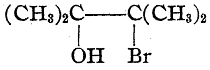
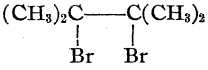
dized, is a manifestation of the tendency of compounds in an intermediate stage of oxidation or reduction to revert, through migrations of electrons, to a state of complete oxidation or reduction. As a corollary of this mechanism it should be possible to bring about the rearrangement of halohydrins by elimination of halide ion, to the corresponding ketone. Adams observed that tetramethylethylene chlorohydrin did not decompose at 150°, and that only at 175°, in benzene solution, did any noticeable decomposition take place. Since halide ion can be separated more easily from an alkyl bromide than from the corresponding chloride, it was of interest to ascertain whether rearrangement of tetramethylethylene bromohydrin (IV) can be induced by heating. This hitherto unknown compound was found to lose hydrogen bromide, even at 100°, to yield pinacolone. The corresponding iodohydrin[1] was stable only in solution; the solid, which resisted purification, decomposed spontaneously to pinacolone and other products.



$$\begin{array}{cc}(CH_3)_2C\text{——} & C(CH_3)_2\\ | & |\\ OH & Br\end{array}$$

(IV)



$$\begin{array}{cc}(CH_3)_2C\text{——} & C(CH_3)_2\\ | & |\\ Br & Br\end{array}$$

(V)

The preparation of tetramethylethylene bromohydrin (IV) from anhydrous pinacol and gaseous hydrogen bromide provided several interesting observations. Dependent on dilution, nature of the solvent and rate of addition of hydrogen bromide, a variety of products could be isolated. In the absence of solvent a mixture of bromohydrin (IV) and dibromide (V) was obtained. In anhydrous ether, primarily, a mixture of pinacol hydrobromides was formed, which, upon continued passage of hydrogen bromide, was converted to bromohydrin (IV). Further reaction with hydrogen bromide brought about formation of dibromide (V). In chloroform, the same reagents caused precipitation of a white crystalline compound, the composition of which corresponded to (I), in which X^- is bromide. This hydrobromide was unstable, losing water from the solid state within a few hours, and passed over into the bromohydrin (IV). The corresponding hydrochloride was made in a similar manner by Harries,[4] who observed that it decomposed at 55° but failed to identify the products. Finally, in ligroin or carbon tetrachloride there was formed a crystalline compound, stable for several weeks at room temperature, which had a composition corresponding to dipinacol hydrobromide, $[(C_6H_{14}O_2)_2H]Br$. Formation of a dimolecular product indicated that pinacol itself might be dimolecular in certain solvents, and this was found to be the case in benzene. This dipinacol hydrobromide can also be separated from the mixture of hydrobromides formed in anhydrous ether, since pinacol hydrobromide (I) is converted to bromohydrin (IV) which volatilizes, leaving the pure dimolecular compound.

The pure bromohydrin (IV) is quite unstable, decomposing slightly even on standing overnight in the refrigerator. In an open tube at 110° it rearranges to pinacolone. When mixed with dry sodium bicarbonate, to remove any trace of catalyzing acid formed by decomposition, the bromohydrin (IV) showed evidence of decomposition even at 100°. After extremely thorough drying of a benzene solution of the bromohydrin, the latter rearranged to pinacolone when the solution was heated at 100° for six hours. Rearrangement to pinacolone also took place when an ether solution of the bromohydrin was shaken with aqueous solutions of silver nitrate or sodium thiosulfate, or with silver oxide.

The properties of pinacol hydrobromide (I) (X = Br) lend support to the Stieglitz mechanism of the pinacol rearrangement. Under the ordinary conditions of the acid catalyzed rearrangement in aqueous solution the small amount of pinacol hydrohalide must be in the form of the highly ionized oxonium salt (I). In water the oxonium and halide ions are separated by so many intervening water molecules that the "fault" occurring in the molecule (II) when water is split off can be adjusted only by rearrangement to pinacolone. On the other hand, in the crystalline hydrobromide, the bromide ions are within atomic distances of the oxonium ions, and can, when water is lost by the latter, slip to the positively charged carbon atom, with formation of the bromohydrin (IV).

Experimental

Anhydrous Pinacol.—Pinacol hydrate was prepared according to "Organic Syntheses."[5] The best yields were obtained when most of the acetone was added before the reaction started. Dehydration[6,2f] was effected

---

[4] Harries, *Ann.*, **383**, 183 (1911).

[5] "Org. Syntheses," Vol. V, 1926, p. 87; Coll. Vol. I, 1932, p. 448.

as follows. The hydrate, in a large round-bottomed flask, was heated with an oil-bath to 110°; suction was then applied with a water-pump until evaporation of water stopped. The flask was returned to atmospheric pressure, the bath temperature raised by 10° and the previous operation was repeated. The same series of operations was repeated until a high-boiling liquid started to condense on the walls of the flask. The pinacol was then distilled at atmospheric pressure and the fraction boiling at 170–175° collected as anhydrous pinacol, yield, *ca.* 30%. About 50% of the charge was recovered from the condensate formed in dehydration or as partially hydrated pinacol in the fore-run of the distillation.

The water-white product solidified upon standing, and could be used for most purposes without further treatment. Absolutely anhydrous pinacol, m. p. 38°, b. p. 172°,[7] was obtained by redistillation at atmospheric pressure.

Tetramethylethylene Bromohydrin.—A rapid stream of hydrogen bromide was passed continuously through a solution of 25 g. of anhydrous pinacol in 375 cc. of anhydrous ether. The white precipitate which started to form in one minute settled as a faintly yellow, viscous liquid. After twenty-five minutes the whole mixture became homogeneous and was washed immediately with four portions of distilled water and dried over sodium sulfate. The filtered solution was concentrated, either under reduced pressure or by evaporation in a gentle stream of air, to a pasty crystalline mass. This was dried in a desiccator on porous plate, over calcium chloride and paraffin; yield, 21–27% (8–10.4 g.). The melting point of the impure bromohydrin varied with different preparations from 66 to 71°. The purest samples were obtained in small preparations with low yields. The crude bromohydrin was recrystallized from ligroin in the same manner that it was originally isolated from ether solution. It was thus obtained as a fluffy white crystalline powder, which, after drying over calcium chloride and paraffin, melted at 70.5°. Large pure crystals of the same melting point were obtained as a sublimate from impure samples of the bromohydrin, which had been stored in the refrigerator.

Anal. Calcd. for $C_6H_{13}OBr$: Br, 44.13. Found: Br, 44.22, 44.24.

The solid bromohydrin is extremely volatile, with a camphoraceous odor and lachrymatory properties. If it contains traces of water it develops brown specks, on standing overnight, with lowering of the melting point. However, perfectly dry samples can be preserved for some time.

Pinacol Hydrobromide, $C_6H_{14}O_2{\cdot}HBr$.—Gaseous hydrogen bromide was passed into an ice-cold solution of 5 g. of anhydrous pinacol in eight volumes of chloroform. The solution remained clear for some time, when it suddenly solidified. Hydrogen bromide was passed through for an additional minute; the mixture was filtered with suction, washed once with chloroform and sucked dry. The crystals were pressed on porous plate and dried over calcium chloride and paraffin.

Anal. Titration with 0.09632 *N* KOH. Calcd. for $C_6H_{14}O_2{\cdot}HBr$: HBr, 40.65. Found: HBr, 40.88.

Pinacol hydrobromide is a colorless, crystalline solid, soluble in water and fuming in moist air. A sample, kept in a desiccator on porous plate, over calcium chloride and paraffin, for two days, disappeared to leave only a trace of material which contained only 35.9% of hydrogen bromide. That it had been converted to bromohydrin (IV) was evident from the odor of the latter and the absence of hydrogen bromide.

Dipinacol Hydrobromide, $(C_6H_{14}O_2)_2{\cdot}HBr$. **(A).**—A solution of 5 g. of anhydrous pinacol in 125 cc. of ligroin (30–50°) was treated with hydrogen bromide until precipitation was complete. The sticky white product was washed four times with ligroin and dried overnight on a porous plate over sulfuric acid and paraffin.

(B).—A solution of 5 g. of anhydrous pinacol in 75 cc. of carbon tetrachloride was treated with hydrogen bromide until the primarily formed oily layer, after becoming extremely viscous, changed to a granular solid. The solid was washed four times with carbon tetrachloride, pressed on porous plate and dried overnight over calcium chloride and paraffin.

Anal. Titration with 0.4363 *N* KOH, phenolphthalein indicator. Calcd. for $(C_6H_{14}O_2)_2{\cdot}HBr$: HBr, 25.5. Found: HBr, A, 25.3; B, 25.4.

Freshly precipitated dipinacol hydrobromide is granular, changing, on standing, to well-defined crystals, m. p. 52–54°. Under anhydrous conditions it is stable, showing no change in composition after two weeks. It dissolves instantly in water, and deliquesces in the air to form a solution of the components.

Dipinacol hydrobromide was also isolated from the mixture of hydrobromides formed, as a viscous liquid, in the first stage of the preparation of the bromohydrin (IV). On standing for several days in a desiccator, over calcium chloride and paraffin, the true hydrobromide became converted to bromohydrin (IV), which sublimed to leave pure dipinacol hydrobromide.

Molecular Weight of Anhydrous Pinacol.—The molecular weight was determined cryoscopically in benzene.

Expt.	Weight of pinacol	Weight of benzene	ΔT	Molecular weight Found	Calcd. $(C_6H_{14}O_2)_2$
1	24.138	526.4	0.960°	245	236
2	23.201	554.4	0.927°	231	236

Thermal Rearrangement of Tetramethylethylene Bromohydrin.—Equal volumes (10 cc.) of a solution of 1.12 parts of bromohydrin in 10 parts of benzene, previously dried over sodium sulfate for eighteen days in the refrigerator, were sealed in four Pyrex tubes and heated for six hours, two at 100° and two at 150°. All were then acid to methyl orange and gave copious precipitates with Nessler's solution, indicating pinacolone formation. More voluminous precipitates were obtained from the tubes heated at 150° than from those at 100°, indicating more nearly complete rearrangement at the higher temperature.

An analytical sample (1 g.) of the bromohydrin decomposed when heated in an open glass tube in a bath at 110°. This experiment was repeated with a sample that had been mixed with four parts of sodium bicarbonate, and ketone formation was demonstrated with Nessler's solution.

---

(7) "Int. Crit. Tables," Vol. I, 1926, p. 204, gives m. p. 38° and b. p. 172.8°.

Rearrangement of Tetramethylethylene Bromohydrin by Chemical Reagents.—Portions of a solution of bromohydrin in absolute ether were treated with aqueous solutions of (1) silver nitrate and (2) sodium thiosulfate and (3) an aqueous suspension of silver oxide. After treatments (1) and (3) gave precipitates of silver bromide, excess sodium chloride solution was added and the precipitates were removed by filtration. In treatment (2) the ether was decanted from the turbid aqueous layer. All three then gave copious precipitates with Nessler's solution. A fourth sample, untreated otherwise, gave no precipitate with this reagent, nor did an aqueous solution of pinacol hydrate, which had been previously treated, as above, with silver nitrate and sodium chloride.

Summary

1. Depending on the reaction conditions, the action of gaseous hydrogen bromide on anhydrous pinacol leads to tetramethylethylene bromohydrin, tetramethylethylene dibromide, pinacol hydrobromide or dipinacol hydrobromide. Pinacol hydrobromide is the intermediate in bromohydrin formation, as well as the postulated intermediate in the hydrobromic acid-catalyzed rearrangement of pinacol to pinacolone.

2. Tetramethylethylene bromohydrin rearranges to pinacolone on heating or on treatment, at room temperature, with halide abstracting reagents. This lends support to the Stieglitz mechanism of the pinacol–pinacolone rearrangement.

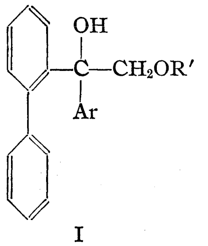
Synthesis of Phenanthrene Derivatives. I. 9-Phenyl- and 9-*p*-Tolylphenanthrene

BY CHARLES K. BRADSHER AND ALLAN K. SCHNEIDER

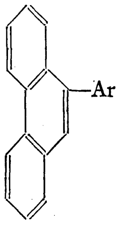
With the exception of the elaborate Pschorr[1] synthesis, all of the methods usually employed for the synthesis of phenanthrene derivatives have a common disadvantage. They involve one step in which hydrophenanthrenes are dehydrogenated at high temperatures by the action of sulfur, selenium or platinum. Frequently a desired phenanthrene derivative is incapable of surviving such a treatment, and it was in the hope of providing a means for the synthesis of such derivatives that this research was undertaken.

A new cyclization reaction has been discovered giving promise of accomplishing this end. When compounds of type I were treated with mineral acids they lost the elements corresponding to one molecule of water and one molecule of methyl alcohol or phenol to form the corresponding 9-arylphenanthrene (II).



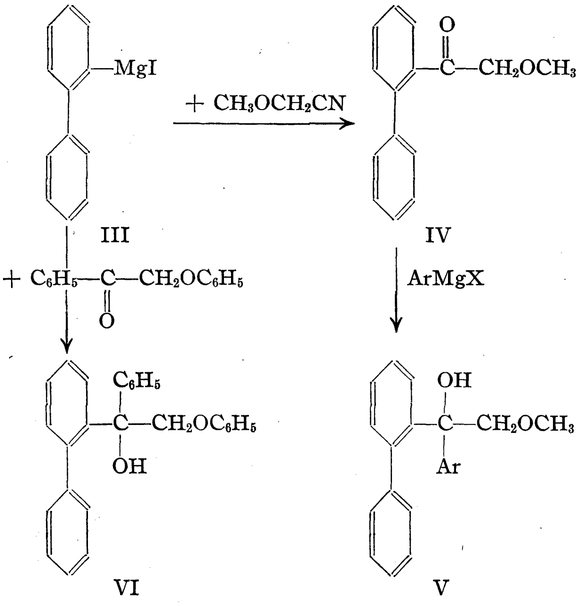
I

(R' = CH_3 or C_6H_5)



II

The carbinols used were prepared by two methods.



In the first, 2-xenylmagnesium iodide (III) was treated with methoxyacetonitrile. Upon hydrolysis the reaction product gave 2-(ω-methoxyaceto)-biphenyl (IV). This upon treatment with phenyl- or *p*-tolylmagnesium bromide gave the corresponding carbinol (V).

In the second method, ω-phenoxyacetophenone was treated with 2-xenylmagnesium iodide (III) to form 1-phenyl-1-(2-xenyl)-2-phenoxyethanol-1 (VI).

When treated with concentrated sulfuric acid

---

(1) Pschorr, *Ber.*, **29**, 496 (1896).

the methoxyethanols (V) underwent cyclization to give the corresponding hydrocarbons, 9-phenyl- and 9-*p*-tolylphenanthrene. The phenoxyethanol (VI) lost only the elements of water when treated with concentrated sulfuric acid. The structure of this new compound has not been determined. When VI was refluxed for twenty-two hours with constant-boiling hydrobromic acid, 9-phenylphenanthrene was obtained in good yield. This hydrocarbon has been prepared previously by Koelsch,[2] by Bergmann[3] and by Weizmann.[4] The 9-*p*-tolylphenanthrene is a new hydrocarbon and was found to melt slightly lower than the corresponding phenyl compound.

Further work is in progress on the development of this synthesis.

The authors are indebted to the Monsanto Chemical Company for a gift of 2-aminobiphenyl.

Experimental

2-(ω-Methoxy)-acetobiphenyl (IV).—A Grignard reagent was prepared in an atmosphere of nitrogen by the action of 2.7 g. of magnesium turnings on 28 g. of 2-iodobiphenyl[5] in 100 cc. of anhydrous ether. When the formation of the reagent was complete, about two-thirds of the ether was distilled from the reaction mixture. A solution of 7.1 g. of methoxyacetonitrile[6] in 100 cc. of dry benzene was added and the mixture refluxed for fifteen hours. At the conclusion of this period the magnesium salt was decomposed by the addition of a mixture of ammonium hydroxide and ammonium chloride solution. The ether-benzene layer was separated and extracted with 0.1 *N* hydrochloric acid. Concentrated hydrochloric acid was then added and the mixture refluxed for two hours. The ketone was taken up in ether, dried and distilled. The product was a slightly yellow oil, b. p. 159–162° (4 mm.); yield, 13.3 g. (60%).

Anal. Calcd. for $C_{15}H_{14}O_2$: C, 79.61; H, 6.24. Found: C, 79.92; H, 6.35.

1-Phenyl-1-(2-biphenyl)-2-methoxyethanol-1 (V).—A solution of 4 g. (0.018 mole) of 2-(ω-methoxy)-acetobiphenyl in 20 cc. of dry ether was added to 0.03 mole of phenylmagnesium bromide and the mixture refluxed for thirty minutes. A solution of ammonium chloride was then added and the ether layer separated and dried. After removal of the ether under reduced pressure there remained about 3 cc. of a red-brown oil. No effort was made to purify this material further.

9-Phenylphenanthrene.—Approximately 0.75 cc. of the above carbinol was dissolved at room temperature in 5 cc. of concentrated sulfuric acid. After thirty minutes the dark brown sirup was poured on 25 g. of ice. The hydrocarbon was extracted with ether and isolated by vacuum sublimation. A small amount of a white substance was obtained which, twice recrystallized, melted at 104–105°.

Anal. Calcd. for $C_{20}H_{14}$: C, 94.49; H, 5.51. Found: C, 94.24; H, 5.59.

The picrate crystallized as orange-red needles, m. p. 114°. It decomposed on attempted recrystallization. Upon decomposition of the picrate in ether with dilute ammonium hydroxide the hydrocarbon was recovered; m. p. 104–105°.

1-*p*-Tolyl-1-(2-biphenyl)-2-methoxyethanol-1 was made in the same manner as the corresponding phenylcarbinol, using *p*-tolylmagnesium bromide. The resulting light brown oil was not purified.

9-*p*-Tolylphenanthrene.—Three cubic centimeters of the oil obtained above was mixed with 8 cc. of concentrated sulfuric acid and allowed to stand for thirty minutes. The remainder of the procedure was identical with that used for the preparation of the phenylphenanthrene. Large, rhombic, transparent crystals were obtained from ether–petroleum ether, m. p. 90–91°.

Anal. Calcd. for $C_{12}H_{16}$: C, 94.03; H, 5.97. Found: C, 94.14; H, 6.06.

A picrate was made in the usual manner. Fine orange-red needles precipitated after an hour in an ice–salt bath. These melted at 126–127°.

1-Phenyl-1-(2-biphenyl)-2-phenoxyethanol-1 (VI).—A Grignard reagent was prepared from 20 g. of 2-iodobiphenyl. To this was added a solution of 15.2 g. of ω-phenoxyacetophenone[7] in 50 cc. of dry benzene. The mixture was refluxed for one hour and then decomposed with a 20% solution of ammonium chloride. After removal of the solvents under reduced pressure the carbinol was crystallized from ether–petroleum ether. Irregular white crystals, m. p. 93–95°, were obtained. The yield was 17.1 g. (65% of the theoretical). An analytical sample prepared by repeated crystallization melted at 94–95°.

Anal. Calcd. for $C_{26}H_{22}O_2$: C, 85.24; H, 6.01. Found: C, 85.06; H, 6.10.

Reaction of VI with Sulfuric Acid.—One gram of the above carbinol was suspended in 7 cc. of concentrated sulfuric acid and the mixture heated at about 100° until the oil formed at first had resolidified. The mixture was poured on ice and the product collected and crystallized from acetic acid as white prisms with m. p. 148–149°. The yield was 0.3 g. Twice recrystallized the product melted at 150–152°.

Anal. Calcd. for $C_{26}H_{20}O$: C, 89.65; H, 5.75. Found: C, 89.54; H, 5.96.

Cyclization of VI with Hydrobromic Acid.—To a boiling solution of 3.4 g. of VI in 20 cc. of acetic acid, 10 cc. of constant boiling hydrobromic acid was added. The mixture was refluxed for twenty hours, poured into water and taken up in ether. The phenol was extracted with dilute alkali and the ethereal solution evaporated. The residue, once recrystallized from ethyl alcohol, melted at 103–104° and was shown to be **9-phenylphenanthrene** by a mixed melting point determination; yield, 2 g. (84%).

Summary

Two phenanthrene hydrocarbons, 9-phenyl- and 9-*p*-tolylphenanthrene, have been prepared from 2-iodobiphenyl by a synthesis involving a new type of ring closure.

URBANA, ILLINOIS RECEIVED SEPTEMBER 26, 1938

Studies in the Phenanthrene Series. XXII. Derivatives of Dibenzisoquinoline and Naphthisoquinoline[1]

BY ERICH MOSETTIG AND EVERETTE L. MAY[2]

In previous communications from this Laboratory we described the synthesis of a number of hydrogenated and N-methylated benzofuroquinolines[3] and naphthoquinolines,[4] which we hoped might exhibit an analgesic effect because of their superficial structural similarity to morphine. These compounds, however, proved to be either very weak analgesics or were entirely ineffective.[5] Since morphine may be interpreted as an isoquinoline derivative, a higher analgesic effectiveness—within the series of tetracyclic compounds consisting of three isocyclic rings and one nitrogen-containing ring—may be expected of phenanthrene derivatives in which the nitrogen is located in β-position to one of the benzene nuclei, *i. e.*, of compounds that include in their structure the isoquinoline system.

Apparently, the most practicable methods for preparing isoquinoline derivatives are those in which compounds of the general type R—C—C—N— are employed as starting materials. In various attempts to prepare compounds of this type we found that the phenanthrene derivatives $C_{14}H_9$-$CHOCH_3CH_2NH_2$ (IV, V) were relatively easily accessible by the method of Rosenmund,[6] which was later somewhat modified by Mannich and coworkers.[7] We employed in the second step of this preparation—the reduction of the corresponding nitro ether—platinum oxide as catalyst successfully, and alcohol as solvent. Attempts to cyclize the formyl derivatives of IV and V and the benzoyl derivative of V, according to Mannich and coworkers,[7] in order to obtain isoquinoline derivatives, by simultaneous loss of water and methanol, were unsuccessful, in spite of manifold experimental variations in respect to solvent and condensing agent. The resulting reaction mixtures consisted of colored, tarry, or partly charred products.

Equally unsuccessful were the attempts to cyclize the formyl derivatives of the β-phenanthryl ethyl amines VII and VIII to dihydroisoquinoline derivatives by the Bischler–Napieralski method. Also in this series of experiments we employed many variations such as those devised by Pictet, by Decker, and by Späth.[8] After several practically unsuccessful attempts to prepare the ethylamine derivatives (VI, VII, VIII) by the Hofmann or Curtius degradation of β-phenanthrylpropionic acids,[9] we finally obtained these amines, according to the method of Slotta and Szyszka,[10] by electrolytic reduction of the corresponding nitrostyrene derivatives (I, II, III). The 3-derivative (VII) was also prepared by chlorination of 3-(2-amino-1-hydroxyethyl)-phenanthrene and subsequent catalytic dechlorination.

By cyclizing the formaldehyde condensation products of VI and VIII with dilute aqueous hydrochloric acid according to the method of Decker and Becker,[11] we obtained the expected tetrahydroisoquinoline derivatives (IX, X)[12] in satisfactory yields. The cyclization apparently proceeded in both series (2 and 9) only in one di-

rection. No tetrahydroisoquinoline ring closure could be accomplished in the 3-series, with the formaldehyde condensation product of VII. Under the conditions employed in the 2- and 9-series only hydrolysis took place, the whole starting material, the β-phenanthrylethylamine VII, being recovered unchanged. Forcing the reaction (concentrated hydrochloric acid, longer reaction time) led to amorphous hydrochlorides of a brown, muddy color which resisted all attempts of purification. 3-Methyl-1,2,3,4-tetrahydronaphth-[1,2-h]isoquinoline (XII) and 2-methyl-1,2,3,4-tetrahydrodibenz[f,h]isoquinoline (XIV) were prepared readily and in good yields by converting IX and X to the quaternary methiodides XI and XIII and subsequently decomposing the latter by heating in a vacuum.

There hardly can be any doubt concerning the structure of X, since the alternative ring closure from position 9 to position 8 of phenanthrene would necessarily result in a seven-membered nitrogen-containing ring. For the isoquinoline derivative, obtained from the formaldehyde condensation product of VI, we advance for reasons of analogy the structural formula IX, since, to our knowledge, all cyclizations of side chains as —C—C—C, —C—C—C—C, and —N—C—C—C— attached to position 2 of phenanthrene take place in position 1.[4b]

We also attempted to cyclize the formaldehyde condensation products of the amino ethers IV and V, respectively, according to the method of Decker and Becker,[11] but no cyclization took place and IV and V were recovered unchanged from the reaction mixture.

Because of present lack of material only 2-methyl-1,2,3,4-tetrahydrodibenz[f,h]isoquinoline XIV was investigated pharmacologically by Dr. Eddy at the University of Michigan.[13] Noteworthy, besides the marked analgesic effect of this substance (M. E. D. 20 mg./kg. cat), is its great hypnotic effect (M. E. D. 5 mg./kg. cat) which unfortunately is accompanied by an equally marked emetic effect when the substance is administered orally.

Experimental

3-(2-Nitrovinyl)-phenanthrene[14] (II).—To a solution of 10 g. of 3-phenanthrene aldehyde[15] in 375 cc. of alcohol was added 6.3 g. of nitromethane. The mixture was cooled (0–5°) and an ice cold solution of 5 g. of potassium hydroxide in 100 cc. of alcohol was dropped in with mechanical stirring during half an hour (the temperature was not allowed to rise above 15°). The precipitate (potassium salt of the condensation product) was brought into solution with ice water, and the nearly clear solution was poured slowly into 200 cc. of 10% hydrochloric acid which had

been cooled previously to 10°. The yellow, finely divided crystalline solid was collected, washed with water, and recrystallized from benzene; yellow needles, m. p. 180–180.5° (corr.), yield 90%.

Anal. Calcd. for $C_{16}H_{11}O_2N$: C, 77.10; H, 4.45. Found: C, 77.19; H, 4.06.

2-(2-Nitrovinyl)-phenanthrene (I).—This compound was prepared like the 3-isomer, but, owing to the lesser solubility of the phenanthrene-2-aldehyde, more solvent was necessary (5 g. of aldehyde in 350 cc. of alcohol). It showed a tendency to precipitate at first, in an amorphous state, when poured into the hydrochloric acid. It is decidedly more soluble in benzene than the 3-isomer and was purified by crystallization from benzene–petroleum ether as yellow needles, m. p. 134.5–137° (corr.), yield 80%.

Anal. Calcd. for $C_{16}H_{11}O_2N$: C, 77.10; H, 4.45. Found: C, 76.80; H, 4.18.

9-(2-Nitrovinyl)-phenanthrene (III).—The preparation was carried out as above, but more solvent was required (5 g. of aldehyde in 420 cc. of alcohol). The nitrostyrene derivative was recrystallized from benzene–petroleum ether: yellow needles, m. p. 173–173.5° (corr.), yield 95%.

Anal. Calcd. for $C_{16}H_{11}O_2N$: C, 77.10; H, 4.45. Found: C, 77.50; H, 4.66.

This compound has been prepared recently in essentially the same manner by Reichert and Wegner,[16] who report the m. p. 173°.

9-(1-Methoxy-2-nitroethyl)-phenanthrene.—To an ice cold (0–5°) suspension of 5.0 g. of finely divided III in 125 cc. of methanol was added, under mechanical stirring, 33 cc. of a sodium methoxide solution prepared from 4.5 g. of sodium and 100 cc. of methanol. A clear solution was obtained in about one-half hour. It was decanted from a small amount of unchanged starting material and acidified with 5 cc. of glacial acetic acid. The solution was evaporated in a water-pump vacuum to dryness at a temperature as low as possible, 500 cc. of water was added to the residue, and the resulting pale yellow precipitate was filtered, washed with water, and recrystallized from ethyl alcohol: pale yellow plates, m. p. 134–134.5° (corr.), yield nearly quantitative.

Anal. Calcd. for $C_{17}H_{15}O_3N$: OCH_3, 11.02. Found: OCH_3, 10.59.

3-(1-Methoxy-2-nitroethyl)-phenanthrene.—This compound was prepared like the 9-isomer, except that the reaction mixture was kept at 0 to −5° for two hours. The purification of the final precipitate (from water) offered some difficulties. It was dissolved in warm alcohol and gradually cooled to room temperature, whereby some oily material was deposited. The solution was decanted, and on further cooling more oil precipitated. The solution was again decanted until finally a clear solution resulted, from which, on standing overnight, pale yellow crystals separated. They were recrystallized from alcohol: pale yellow circular plates, m. p. 102–104° (corr.), yield 55%.

Anal. Calcd. for $C_{17}H_{15}O_3N$: OCH_3, 11.02. Found: OCH_3, 10.67.

3-(1-Methoxy-2-aminoethyl)-phenanthrene (IV).—Four grams of the corresponding nitro ether and 0.15 g. of platinum oxide suspended in 200 cc. of alcohol absorbed the required amount of hydrogen in twenty to thirty hours. The resulting clear, colorless solution was filtered from the catalyst and evaporated to dryness in a vacuum. The oily base was dissolved in alcoholic hydrogen chloride and the hydrochloride was precipitated with ether. It crystallized from alcohol–ether in short colorless needles of m. p. 232–233° (dec.), yield 85%.

Anal. Calcd. for $C_{17}H_{18}ONCl$: Cl, 12.32. Found: Cl, 12.03.

9-(1-Methoxy-2-aminoethyl)-phenanthrene (V).—This compound was prepared like the 3-isomer. Its hydrochloride crystallized from alcohol–ether in colorless needles, m. p. 252–253° (dec.), yield 95%.

Anal. Calcd. for $C_{17}H_{18}ONCl$: Cl, 12.32. Found: Cl, 12.09.

Picrate, m. p. 215–217° (dec.).

Anal. Calcd. for $C_{23}H_{20}O_8N_4$: N, 11.66. Found: N, 11.73.

Formyl Derivative.—To an ethereal solution of V (prepared from 3 g. of hydrochloride) was added 0.6 g. of anhydrous formic acid. The crystalline formate was filtered and heated in a metal bath at 150° for about thirty minutes. The resulting brown oil turned to a crystalline brittle mass on cooling. It was dissolved in a little benzene and precipitated with petroleum ether; colorless leaflets, m. p. 138–140° (corr.), yield 70%.

Anal. Calcd. for $C_{18}H_{17}O_2N$: N, 5.01. Found: N, 4.90.

Benzoyl Derivative.—A mixture of V (prepared from 1 g. of hydrochloride), 0.6 g. of benzoyl chloride, and 4 cc. of 0.5 *N* sodium hydroxide solution was cooled and shaken. The crystalline mass that formed within a few minutes was filtered and washed with water. It crystallized from methanol–water in white leaflets of m. p. 147.5–148.5° (corr.), yield 80%.

Anal. Calcd. for $C_{24}H_{21}O_2N$: C, 81.09; H, 5.96. Found: C, 80.72; H, 5.92.

3-(2-Aminoethyl)-phenanthrene (VII).—The electrolytic reduction was carried out in an apparatus which was essentially the same as that described by Slotta and Szyszka.[10] A suspension of 7 g. of very pure 3-(2-nitrovinyl)-phenanthrene in a mixture of 50 cc. of alcohol, 80 cc. of glacial acetic acid, and 12 cc. of concentrated hydrochloric acid was introduced into the cathode compartment containing a prepared lead electrode of 60 sq. cm., while the anode compartment, containing a cooling spiral, was filled to the same level with 20% sulfuric acid. The current was kept at 3.5 amperes for three hours, at 4.5 amperes for two hours, and at 5 amperes for about five hours, temperature between 50 and 60°. The resulting clear solution at the cathode was decanted and evaporated nearly to dryness in a vacuum. The brown oily residue was dissolved in water and the solution was made alkaline and extracted with ether. The oil obtained from the ethereal solution was distilled slowly at 120–130° at a pressure of about 0.1 mm. The oily distillate was dissolved in a small volume of ether and allowed to stand in the cold for a few hours. A small amount of crystalline material (probably of higher molecular weight) precipitated and was filtered off. By addition of alcoholic hydrogen chloride to the filtrate, the

[16] Reichert and Wegner, *Ber.*, **71**, 1254 (1938).

amine hydrochloride precipitated in crystalline form. It crystallized from alcohol–ether in white, short matted needles, m. p. 254–256°, yield 50%.

Anal. Calcd. for $C_{16}H_{16}NCl$: C, 74.55; H, 6.26. Found: C, 74.50; H, 5.97.

Formyl Derivative.—This compound was prepared like the corresponding derivative of V. It crystallized from benzene–petroleum ether in small white leaflets, m. p. 122–124° (corr.), yield 61%.

Anal. Calcd. for $C_{17}H_{15}ON$: N, 5.62. Found: N, 5.84.

9-(2-Aminoethyl)-phenanthrene (VIII).—This compound was prepared like its 3-isomer. Its hydrochloride crystallized from alcohol–ether in colorless needles, m. p. 307–309° (dec.), yield 57%.

Anal. Calcd. for $C_{16}H_{16}NCl$: C, 74.55; H, 6.26. Found: C, 74.78; H, 6.13.

Formyl Derivative.—Small, white leaflets, m. p. 111–112°, yield 70%.

Anal. Calcd. for $C_{17}H_{15}ON$: N, 5.62. Found: N, 5.56.

2-(2-Aminoethyl)-phenanthrene (VI).—This compound was obtained by electrolytic reduction, like the 3- and 9-isomers, but under somewhat different conditions. Three grams of 2-(2-nitrovinyl)-phenanthrene was suspended in a mixture of 40 cc. of alcohol, 75 cc. of glacial acetic acid, and 8 cc. of concentrated hydrochloric acid. The temperature was kept at 25–30° for the first two hours and at 30–40° for the remainder of the time (nine hours). A current of 3.1 amperes was maintained throughout the whole reaction. No clear solution was obtained, varying amounts of a brown fluffy solid always remaining in the cathode compartment. The amine hydrochloride crystallized from alcohol–ether in colorless leaflets, m. p. 317–318°; average yield 35–40%.

Anal. Calcd. for $C_{16}H_{16}NCl$: C, 74.55; H, 6.26; Cl, 13.76. Found: C, 74.67; H, 6.18; Cl, 13.79.

The picrate crystallized from alcohol in large yellow needles, m. p. 225–226°.

Anal. Calcd. for $C_{22}H_{18}O_7N_4$: N, 12.44. Found: N, 12.09.

3-(2-Amino-1-chloroethyl)-phenanthrene Hydrochloride.—Five grams of finely powdered 3-(2-amino-1-hydroxyethyl)-phenanthrene[9] was added in small amounts to a suspension of 6 g. of phosphorus pentachloride in 50 cc. of dry chloroform (vigorous mechanical stirring is necessary). The amino alcohol dissolved immediately and the hydrochloride of the chloro compound began to precipitate. The stirring was continued for another half hour and ether was added to the suspension in order to facilitate the filtration of the hydrochloride. It was recrystallized from alcohol–ether as colorless square plates, m. p. 219–220° (dec.), (the melt resolidifies at 225° and melts then gradually in the wide range of 226–295°); yield 73%.

Anal. Calcd. for $C_{16}H_{15}NCl_2$: Cl, 24.27. Found: Cl, 24.20.

Conversion to 3-(2-Aminoethyl)-phenanthrene, VII.—After varying the catalyst (palladium, palladium on charcoal or calcium carbonate, platinum oxide) and the concentration of the alcohol (100, 95, 90, 75, 50%) in the catalytic dechlorination, the phenanthrylethylamine (VII) finally was obtained in a satisfactory yield (approximately 75%) by employing 0.02 g. of platinum oxide and 25 cc. of 70% alcohol per gram of hydrochloride of the chloro compound. After the hydrogen absorption came to a standstill the resulting clear solution was filtered from the catalyst and evaporated to dryness. The crystalline residue was dissolved in water and the solution made alkaline and extracted with ether. The ether residue was distilled slowly in an oil-pump vacuum at 120°. The oily distillate was dissolved in a very small amount of ether in order to remove the by-product, which crystallized gradually from this solution. The hydrochloride of the 3-(2-aminoethyl)-phenanthrene was prepared and purified as described above and was identical in every respect with the compound prepared from 3-(2-nitrovinyl)-phenanthrene. The crystalline by-product was shown by melting point, mixture melting point with an authentic sample, and analysis to be 3-(2-amino-1-hydroxyethyl)-phenanthrene.

1,2,3,4-Tetrahydrodibenz[f,h]isoquinoline (X).—In the preparation of the tetrahydroisoquinoline derivatives we followed partly Buck's[17] directions developed for the preparation of various tetrahydroisoquinoline derivatives substituted in the benzene nucleus with O-alkyl groups.

A mixture of VIII prepared freshly from 8.5 g. of the hydrochloride, and 3.4 cc. of 40% formaldehyde solution, was heated on the steam-bath for one-half hour. The reaction mixture was evaporated in a vacuum to dryness. To the condensation product was added 12 cc. of 23% hydrochloric acid and the mixture was heated for one-half hour on the steam-bath. The hydrochloride of the tetrahydroisoquinoline compound precipitated almost at the start of heating as a white and voluminous mass. The reaction mixture was diluted with water, made alkaline, and extracted with benzene. The residue from the benzene solution was treated with alcoholic hydrogen chloride and ether. The hydrochloride was recrystallized from alcohol–ether, m. p. 304–306° (dec.), average yield 65%.

Anal. Calcd. for $C_{17}H_{16}NCl$: C, 75.69; H, 5.98. Found: C, 75.96; H, 5.96.

The free base may be obtained with loss by evaporating the benzene extract to a small volume and allowing it to stand in the cold. It consists of white needles, m. p. 223–225°.

Methiodide of 2-Methyl-1,2,3,4-tetrahydrodibenz[f,h]-isoquinoline (XIII).—To a solution of X, prepared from 0.6 g. of the hydrochloride, in 5 cc. of acetone was added 0.8 cc. of methyl iodide and 0.35 g. of potassium hydroxide. The quaternary salt began to precipitate immediately. After four hours 0.2 cc. of methyl iodide was added and the reaction mixture was allowed to stand for ten hours. The methiodide was filtered off, recrystallized first from water containing some potassium iodide, and finally from alcohol: colorless, square plates, m. p. 268–270° (dec.), yield 86%.

Anal. Calcd. for $C_{19}H_{20}NI$: I, 32.60. Found: I, 32.96.

This methiodide was also formed by merely mixing XIV (below) and methyl iodide in acetone solution.

2-Methyl-1,2,3,4-tetrahydrodibenz[f,h]isoquinoline (XIV).—One and five-tenths grams of the methiodide described above was heated in an oil-pump vacuum at 200–220°, whereby the N-methyl derivative distilled very

---

[17] Buck, This Journal, 56, 1769 (1934).

slowly and practically no residue was left in the distillation bulb. The crystalline distillate was washed with water and taken up in ether. The ether residue sublimed in colorless needles, m. p. 113.5–114° (corr.), yield nearly quantitative.

Anal. Calcd. for $C_{18}H_{17}N$: N, 5.67. Found: N, 5.47.

The hydrochloride was prepared in the usual manner. It crystallizes from alcohol–ether in colorless lozenges.

Anal. Calcd. for $C_{18}H_{18}NCl$: C, 76.18; H, 6.39. Found: C, 75.80; H, 6.36.

1,2,3,4 - Tetrahydronaphth[1,2 - h]isoquinoline? (IX).—The free base VI obtained by liberation with alkali from 1.8 g. of the hydrochloride was condensed with formaldehyde and the condensation product was cyclized as described above in the "9-series." The resulting hydrochloride was converted to the base, which was extracted with benzene. The benzene solution left on evaporation a semi-solid base which was not very stable and was, therefore, transformed with alcoholic hydrogen chloride to the hydrochloride. This hydrochloride appeared to be not homogeneous and apparently contained a small amount of starting material, the phenanthrylethylamine hydrochloride. The difference in solubility of the hydrochlorides and picrates of the two bases was not marked enough for a practical separation. Therefore the crude hydrochloride was converted via the methiodide XI to the N-methyl compound which could be purified readily. The crude hydrochloride was obtained in a yield of 70% and melted at 270–290°. For analytical purposes a small sample was recrystallized repeatedly from alcohol–ether: white plates, m. p. 313–315° (dec.).

Anal. Calcd. for $C_{17}H_{16}NCl$: C, 75.69; H, 5.98. Found: C, 75.57; H, 6.28.

The mixture melting point with the hydrochloride of VI of m. p. 317–318° was indefinite, 275–314°.

Methiodide of 3-Methyl-1,2,3,4-tetrahydronaphth[1,2-h]isoquinoline (XI).—Eight-tenths gram of crude hydrochloride of m. p. 270–290° (see above) was converted to the quaternary methiodide as described in the preparation of XIII. After one crystallization from water, 0.7 g. of methiodide of m. p. 227–233° was obtained. For analysis it was recrystallized twice from alcohol as white plates, m. p. 244.5–246° (dec.).

Anal. Calcd. for $C_{19}H_{20}NI$: I, 32.60. Found: I, 32.41.

3 - Methyl - 1,2,3,4 - tetrahydronaphth[1,2 - h]isoquinoline (XII).—Five-tenths gram of an impure methiodide (m. p. 235–240°) was decomposed in an oil-pump vacuum at 200°. The oily distillate was taken up in ether and the ether residue was converted into the hydrochloride in the usual manner. This crude hydrochloride (0.25 g., m. p. 232–242°) was recrystallized first from a small volume of alcohol and then from alcohol–ether: white hexagonal crystals, m. p. 257–259° (dec.).

Anal. Calcd. for $C_{18}H_{18}NCl$: C, 76.18; H, 6.39. Found: C, 76.13; H, 6.38.

In some instances, particularly when a less pure methiodide was decomposed, it was possible to isolate from the mother liquors of the hydrochloride of XII, 2-(2-dimethylaminoethyl)-phenanthrene hydrochloride of m. p. 247–249°.

Anal. Calcd. for $C_{18}H_{20}NCl$: C, 75.62; H, 7.05. Found: C, 75.41; H, 6.91.

A compound in every respect identical with this hydrochloride (melting point and mixture melting point) was prepared by complete methylation of VI and subsequent heat decomposition of the resulting methiodide. The mixture melting point with the hydrochloride of XII was at 230–240°.

The above description of the preparation of IX and its derivatives is a typical average of twelve experiments each starting with from 1 to 3 g. of the 2-(2-aminoethyl)-phenanthrene (VI). In one instance, the tetrahydroisoquinoline derivative IX was obtained as the only reaction product in the cyclization of the formaldehyde condensation product. In another instance, when an impure phenanthrylethylamine was used, no cyclization took place and practically all of the starting material could be recovered.

Summary

The synthesis of phenanthrylethylamines $C_{14}H_9$-$CH_2CH_2NH_2$ and phenanthrylethylamino ethers $C_{14}H_9CHOCH_3CH_2NH_2$ is described.

Cyclizations to isoquinoline derivatives were attempted according to the general methods of Bischler–Napieralski and of Decker and Becker. Only the method of Decker and Becker applied to the phenanthrylamines of the 2- and 9-series gave positive results.

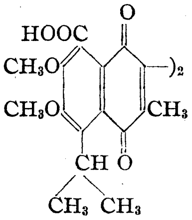
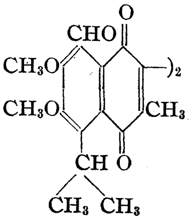
Structure of Gossypol. XVI. Reduction Products of Gossypolone Tetramethyl Ether and Gossypolonic Acid Tetramethyl Ether[1]

BY ROGER ADAMS, T. A. GEISSMAN AND R. C. MORRIS

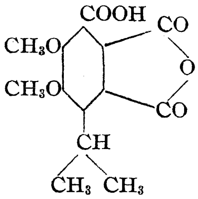
Gossypolonic acid tetramethyl ether, obtained by the oxidation of gossypol hexamethyl ether with dilute nitric acid,[2] was assigned the structure I, and gossypolone tetramethyl ether, derived from gossypol hexamethyl ether by chromic acid oxidation,[2] was assigned the structure II.[1]



I



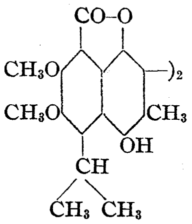
II



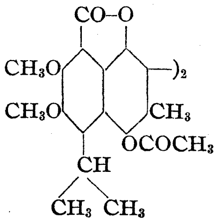
III

These structures were assumed largely on the basis of the analytical figures, coupled with the facts that I was easily soluble in sodium bicarbonate solution, II formed an anilino derivative, mild oxidation converted II into I and that both I and II yielded gossic acid (III) on oxidation with potassium permanganate. No direct evidence was presented to show that the compounds were quinones, though by a comparison of these and their degradation products with apogossypolone tetramethyl ether, desapogossypolone tetramethyl ether and their degradation products,[3] quinone structures appeared likely. The results described in this paper offer more direct evidence for the correctness of the structures I and II for these compounds.

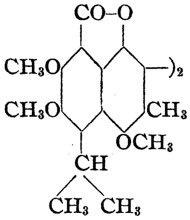
Gossypolonic acid tetramethyl ether can be reduced with zinc and acetic acid to a compound having the properties of the hydroxy lactone (IV) and reductively acetylated with zinc and acetic anhydride to the acetoxy lactone (V). It is also possible to obtain V by acetylation of IV with acetic anhydride in pyridine.



IV

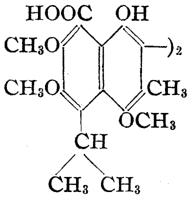


V



VI

Methylation of the hydroxy compound (IV) yielded the methoxy lactone (VI). This compound was insoluble in cold alcoholic alkali but dissolved on warming. When the alkaline solution was acidified, the hydroxy acid (VII) was obtained as a colorless crystalline compound, soluble in cold, dilute aqueous alkali. This establishes the presence of the lactone grouping in VI and by analogy in IV and V.



VII

The free hydroxy compound (IV) is readily soluble in cold, dilute alcoholic alkali to a deep wine-red solution which on warming becomes first brown, then a deep blue-green identical in appearance with that obtained by dissolving gossypolonic acid tetramethyl ether (I) in alcoholic alkali of the same strength. This points to an opening of the lactone linkage followed by air oxidation. The blue-green solution contains decomposition products of gossypolonic acid tetramethyl ether since none of this compound could

---

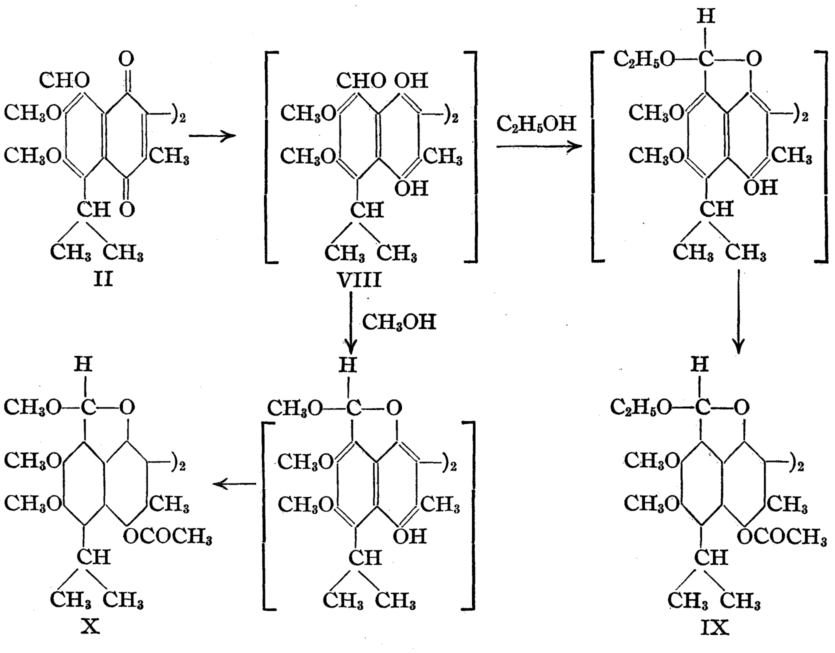
[1] For previous paper see Adams, Morris, Geissman, Butterbaugh and Kirkpatrick, THIS JOURNAL, **60**, 2193 (1938).

[2] Adams, Morris and Kirkpatrick, *ibid.*, **60**, 2170 (1938).

[3] Adams and Butterbaugh, *ibid.*, **60**, 2174 (1938).

be obtained from it on acidification. The free hydrogossypolonic acid tetramethyl ether (hydroquinone of I) could not be obtained crystalline.

The reduction of gossypolone tetramethyl ether (II) was much more difficult because of the extreme sensitivity of the compound. It was finally accomplished by adding an aqueous solution of sodium hydrosulfite to its ethanolic solution; reduction took place smoothly, the solution, deep yellow at first, becoming deep brown and then changing to a pale yellow. Rapid isolation of the unstable reduction product by means of ether extraction followed by treatment with pyridine and acetic anhydride in the cold led to the isolation of a colorless crystalline compound. This compound, however, did not give analytical figures consistent with a simple reduction and acetylation of the quinone linkage, but it was readily reconverted into the original quinone (II) by oxidation with chromic acid, indicating that no deep-seated change had taken place. By carrying out the reduction in methanol solution, following the same procedure as outlined above, a different compound was obtained, lending support to the assumption that acetal formation had occurred in the primary reduction product (VIII). The compound obtained, therefore, when the reduction was carried out in ethanol was diacetoxy gossypol tetramethyl diethyl ether (IX), and in methanol was diacetoxy gossypol hexamethyl ether (X)



Experimental

Improved Procedure for the Preparation of Gossypol Hexamethyl Ether.—Gossypol hexamethyl ether has been one of the important derivatives of gossypol used in degradation studies. An improved method of preparation has been found which deserves detailed description.

A solution of 25 g. of once recrystallized gossypol-acetic acid is prepared by gentle warming in a mixture of 80 cc. of methanol and 80 cc. of redistilled dimethyl sulfate. The solution is cooled under the tap and 110 cc. of 10% methanolic potassium hydroxide is added in 10-cc. portions with continued cooling. After all of the alkali is added the mixture is allowed to stand at room temperature, with occasional shaking, for two days. The solid which precipitates is collected on a filter and washed with methanol, then thoroughly with water. There remains undissolved 21–23 g. of yellowish, crystalline tetramethyl ether melting around 165° and giving a scarlet color with concentrated sulfuric acid.

This crude material is methylated further by dissolving it in a mixture of 100 cc. of benzene and 60 g. of dimethyl sulfate and adding to the warm solution a 20% solution of potassium hydroxide in methanol until the solution is alkaline. An additional 40 g. of dimethyl sulfate is then added, followed by 20% methanolic potassium hydroxide until the solution is again alkaline. The mixture is then evaporated to a sludge on the steam-bath (with stirring), methanol being added frequently and the evaporation continued until most of the benzene has been removed. The final sludge is cooled and filtered. The solid is washed with methanol until the filtrates are colorless and then washed thoroughly with water to remove potassium salts. The product remaining on the filter is white, crystalline hexamethyl ether. The yield in this step is nearly quantitative. The product is pure enough for most purposes. It gives a yellow-orange color with concentrated sulfuric acid and melts, depending upon the purity of the gossypolacetic acid used, at from 195–210°. It can be recrystallized most conveniently from ligroin (b. p. 90–110°), from which it is obtained in clusters of long white needles, m. p. 175°.

Hydroxygossylic Acid Lactone Tetramethyl Ether (IV).—To a solution of 0.50 g. of gossypolonic acid tetramethyl ether[1] in 10 cc. of boiling glacial acetic acid, zinc dust was added in small portions. The solution first turned a reddish-yellow color and on continued addition of zinc dust became a clear pale yellow. Yellow crystals separated from the hot solution. The zinc dust was removed by filtration and boiled several times with small portions of acetic acid to remove admixed reduction product, and the combined filtrates diluted to incipient cloudiness and cooled. The product (0.38 g.) was purified from glacial acetic acid and formed tiny canary-yellow prisms melting at 320° (bloc Maquenne).

Anal. Calcd. for $C_{34}H_{34}O_{10}$: C, 67.77; H, 5.65. Found: C, 67.60; H, 5.64.

The compound gives a deep yellow color with concentrated sulfuric acid and a deep wine-red solution in methanolic potassium hydroxide.

Acetoxygossylic Acid Lactone Tetramethyl Ether (V). (a).—To a mixture of 0.5 g. of gossypolonic acid tetramethyl ether, 0.5 g. of fused sodium acetate and 5 cc. of boiling acetic anhydride, zinc dust was added in small portions until the color of the solution had become a pale yellow. The solution was filtered onto ice and allowed to stand until the acetic anhydride had decomposed, the product collected and triturated with boiling methanol. The pale yellow prisms obtained weighed 0.40 g. After two recrystallizations from acetone–methanol the product formed tiny rosets of colorless prisms, m. p. 231–233° (corr.).

Anal. Calcd. for $C_{38}H_{38}O_{12}$: C, 66.47; H, 5.54. Found: C, 66.32; H, 5.50.

The product gives a deep yellow color in concentrated sulfuric acid. It is insoluble in cold methanolic alkali, but dissolves on heating with the formation of a deep wine-red solution.

(b).—The same compound is formed when the hydroxy lactone (IV) is acetylated with acetic anhydride in pyridine.

Methoxygossylic Acid Lactone Tetramethyl Ether (VI).—To a suspension of 0.5 g. of hydroxygossylic acid lactone tetramethyl ether in a cooled mixture of 5 cc. of dimethyl sulfate and 5 cc. of methanol was added 7 cc. of 10% methanolic potassium hydroxide. The solution, originally deep red, gradually turned yellow. The addition of further 1-cc. portions of alcoholic alkali was continued until a further addition no longer produced the red color. The mixture was concentrated under reduced pressure to a mush, filtered, the solid washed with methanol and the salt removed by washing with water. There remained on the filter 0.30 g. of yellow crystalline product. After several recrystallizations from dilute acetic acid and from acetone–methanol, the compound formed pale yellow needles, m. p. 273–274° (corr.).

Anal. Calcd. for $C_{36}H_{38}O_{10}$: C, 68.57; H, 6.03. Found: C, 68.46; H, 6.01.

The compound gives a clear yellow color with concentrated sulfuric acid and is insoluble in cold alcoholic alkali.

Methoxygossylic Acid Tetramethyl Ether (VII).—A solution of 0.20 g. of methoxygossylic acid lactone tetramethyl ether (VI) in 10 cc. of 10% methanolic potassium hydroxide was boiled with a pinch of zinc dust and a few cubic centimeters of water until the originally red-brown color had faded to yellow. The solution was filtered into dilute sulfuric acid and extracted with ether. The ether solution was dried, concentrated and diluted with petroleum ether (b. p. 30–60°). The hydroxy acid separated as tiny white needles, weighing 0.1 g. After recrystallization from ether–petroleum ether it formed tiny, soft white needles which sintered over a broad range and melted at 270–272° (corr.). When a sample was plunged into a bath preheated to 250° it melted instantly with vigorous decomposition, crystallized on cooling, then remelted at 273–274° (corr.).

Anal. Calcd. for $C_{36}H_{42}O_{12}$: C, 64.83; H, 6.36. Found: C, 64.70; H, 6.36.

The compound is readily soluble in cold, dilute sodium hydroxide solution. It gives no color with ferric chloride and a pale yellow color with concentrated sulfuric acid. The methoxy lactone (VI) is regenerated on warming the hydroxy acid in acetic anhydride.

Reduction and Acetylation of Gossypolone Tetramethyl Ether in Ethanol (Compound IX).—An aqueous solution of sodium hydrosulfite was added in portions to a hot solution of 1.0 g. of gossypolone tetramethyl ether in 25 cc. of absolute ethanol. The solution first became deep brown in color and upon continued addition of the reducing agent changed to a pale yellow color. At this point, it was poured into iced water, quickly extracted with ether, the ether solution washed with a solution of sodium hydrosulfite and dried by shaking it with anhydrous sodium sulfate. The ether was removed quickly, at first on the hot-plate, then under reduced pressure, and to the residual dark red oil was added a mixture of 15 cc. of pyridine and 7 cc. of acetic anhydride. The bright red solution was allowed to stand at room temperature for two hours, poured into water and the pink solid collected. The product was dissolved in warm methanol, from which it crystallized quickly as short white needles, weighing 0.18 g. After recrystallization from acetone–methanol the compound formed soft white needles, m. p. 264–265° (corr.).

Anal. Calcd. for $C_{42}H_{50}O_{12}$: C, 67.52; H, 6.75. Found: C, 67.18, 67.37; H, 6.91, 6.50.

Reduction by means of zinc dust and acetic acid in presence of sodium acetate, zinc dust in acetic anhydride with sodium acetate, zinc dust in pyridine and acetic anhydride and zinc dust in ethanolic calcium chloride was unsuccessful. Acid reducing agents were excluded, as gossypolone tetramethyl ether is converted to uncrystallizable tars in acid solution.

Oxidation of this compound with 10% aqueous chromic acid in acetic acid gave a yellow crystalline compound which was proved by melting point, mixed melting point, preparation of the anilino derivative and color in sulfuric acid to be identical with II.

Reduction and Acetylation of Gossypolone Tetramethyl Ether in Methanol (Compound X).—The reduction was run in exactly the same manner as given above when ethanol was used as the solvent. The crude crystalline material obtained from methanol formed tiny pink nodules and weighed 0.23 g. Recrystallized from acetone–methanol it formed tiny, soft white needles, m. p. 266–267° (corr.).

Anal. Calcd. for $C_{40}H_{46}O_{12}$: C, 66.85; H, 6.41. Found: C, 66.65; H, 6.34.

A mixture of the ethyl acetal (IX), m. p. 264–265°, and of the methyl acetal (X), m. p. 266–267°, melted at 245–253°.

The compound gives a yellow-orange color in concentrated sulfuric acid.

Oxidized with chromic acid it yielded gossypolone tetramethyl ether (II).

Summary

1. Support for the previously proposed structures of gossypolonic acid tetramethyl ether and of gossypolone tetramethyl ether as quinones has now been furnished. These products have been converted to reduction products.

2. Gossypolonic acid tetramethyl ether gives hydroxy gossylic acid lactone tetramethyl ether which may be acetylated to the corresponding acetyl derivative or methylated to the methyl ether. The latter can be transformed by the action of alkali into the corresponding gossylic acid derivative; thus the presence of the lactone linkage is demonstrated.

3. Gossypolone tetramethyl ether is a much more sensitive compound and most alkaline and acid reducing agents cause decomposition. However, a solution of sodium hydrosulfite in ethanol and methanol gives successful results. Diacetoxygossypol tetramethyl diethyl ether forms when ethanol is used as a solvent, and diacetoxygossypol hexamethyl ether when methanol is employed.

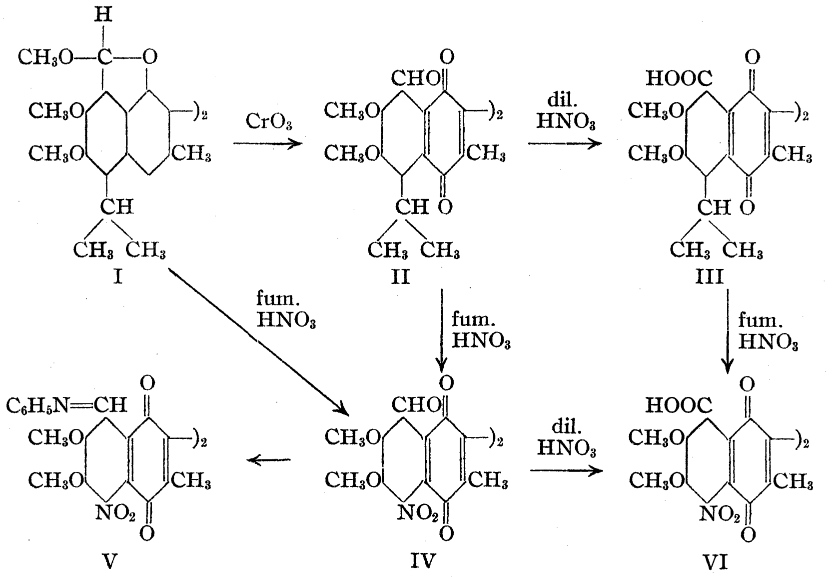
Structure of Gossypol. XVII. Nitration Products of Gossypol Hexamethyl Ether, Gossypolone Tetramethyl Ether and Gossypolonic Acid Tetramethyl Ether[1]

BY ROGER ADAMS, T. A. GEISSMAN AND R. C. MORRIS

The structural relationship between gossypol hexamethyl ether (I), gossypolone tetramethyl ether (II) and gossypolonic acid (III) has been substantiated in part by studies of oxidation[2] and other degradation reactions[3] of gossypol derivatives and by the coördination of these structures in a consistent picture of the properties and reactions of gossypol.[1,4]



Further confirmation has been found in a study of the action of fuming nitric acid on these compounds, products being obtained whose analyses and properties allow their formulation in accord with the above structures.

By the action of fuming nitric acid on gossypol hexamethyl ether (I), there is obtained a crystalline compound to which has been assigned the structure IV, since it forms an anilino derivative formulated as V. Compound IV also results from the action of fuming nitric acid on gossypolone tetramethyl ether (II). Treatment of gossypolonic acid tetramethyl ether (III) with fuming nitric acid under similar conditions results in the formation of an acidic compound (VI) which is assumed to be the carboxylic acid corresponding to the aldehyde (IV). This assumption is substantiated by the fact that oxidation of IV with dilute nitric acid results in the formation of the acid (VI). This is exactly analogous to the oxidation of gossypolone tetramethyl ether (II) to gossypolonic acid tetramethyl ether (III) by means of dilute nitric acid.

The replacement of an isopropyl group by a nitro group during nitration has been observed in other, although not strictly analogous, cases. The nitration of *p*-cymene has been found to yield nitrated toluenes along with simple nitration products,[5] while dinitrothymol yields trinitro-*m*-cresol upon further nitration.[6] A similar elimination of the isopropyl group from a gossypol derivative has been observed in the formation of desapogossypol hexamethyl ether from apogossypol hexamethyl ether by the action of concentrated sulfuric acid,[7] although the elimination by means of sulfuric acid may follow a different course from that in the replacement by a nitro group during nitration.

Experimental

Nitration of Gossypol Hexamethyl Ether; Compound IV.—To 15 cc. of fuming nitric acid (sp. gr. 1.50) cooled to −5° was added 1 g. of gossypol hexamethyl ether. The compound dissolved instantly to give a deep red-brown solution which was immediately poured onto ice. The product from five such runs was collected, dried and dissolved in a small amount of boiling methanol. A yellow crystalline material separated and after cooling was filtered; weight 0.5 g. It was purified from acetone–methanol, forming bright yellow prisms. The product has no sharp melting point but when placed in a preheated bath darkens at about 220° and decomposes at 257–262° (corr.).

Anal. Calcd. for $C_{28}H_{20}O_{14}N_2$: C, 55.26; H, 3.29; N, 4.60. Found: C, 54.91, 54.90, 55.28; H, 3.41, 3.33, 3.22; N, 4.47, 4.64, 4.86.

The compound gives a clear brownish-red color with concentrated sulfuric acid and reduces Tollens' reagent quickly in pyridine solution in the cold. It is insoluble in alcoholic alkali, although it decomposes slowly on standing in contact with the reagent.

Nitration of Gossypolone Tetramethyl Ether; Compound IV.—To 5 cc. of fuming nitric acid (sp. gr. 1.50) cooled in ice–salt was added in small portions 0.25 g. of gossypolone tetramethyl ether. As soon as solution had taken place, the red-brown reaction mixture was poured onto ice. The insoluble material was collected and dissolved in a small amount of methanol, from which 0.1 g. of yellow crystalline material separated. After recrystallization from acetone–methanol bright yellow, flat prisms were obtained.

The compound gave the same type of decomposition as the product previously described, alone or when mixed with the product made by the other procedure. It also gave the same analytical results and the same color in sulfuric acid.

Anilino Derivative of Compound IV; Compound V.—An excess of aniline was added to a suspension of compound IV in boiling benzene. A red solution formed. After a few minutes ligroin (b. p. 90–110°) was added and the mixture concentrated and cooled. The product which separated was recrystallized from benzene–ligroin. It forms tiny, brownish-orange prisms which do not melt, but darken at about 210° and become charred at about 260°.

Anal. Calcd. for $C_{40}H_{30}O_{12}N_4$: C, 63.32; H, 3.96; N, 7.39. Found: C, 63.92; H, 4.17; N, 7.63.

The compound gives a yellow-orange color in concentrated sulfuric acid.

Nitration of Gossypolonic Acid Tetramethyl Ether; Compound VI.—To 2.5 cc. of yellow fuming nitric acid (sp. gr. 1.5) at 0° was added in portions with stirring 0.1 g. of gossypolonic acid tetramethyl ether. Solution took place rapidly and, as soon as complete, the reaction mixture was poured onto ice. The precipitate was washed, dried and recrystallized from methanol. It forms light yellow crystals which become brown at about 220° and darken at 260–270°; yield 0.04 g.

Anal. Calcd. for $C_{28}H_{20}O_{16}N_2$: C, 52.50; H, 3.12; N, 4.38. Found: C, 52.18; H, 3.43; N, 4.43.

The product gives no color with cold concentrated sulfuric acid and a green-violet color upon heating.

Oxidation of Compound IV to Compound VI by Means of Dilute Nitric Acid.—Two procedures for this oxidation were used:

(a).—To a solution of 0.20 g. of compound IV in 5 cc. of acetic anhydride was added gradually 20 cc. of a mixture of equal parts of acetic acid, concentrated nitric acid and water. The acetic anhydride decomposed vigorously at the beginning and when complete the remainder of the 20 cc. was added all at once. A small amount of compound V crystallized and was filtered. The filtrate was treated with 10 cc. of concentrated nitric acid and the solution refluxed for two hours. Upon cooling, the product V separated. It was purified by dissolving in acetic anhydride, decomposing the anhydride with water and diluting. About 0.05 g. of shining buff leaflets was obtained. The compound does not melt up to 320° (bloc Maquenne).

Anal. Calcd. for $C_{28}H_{20}O_{16}N_2$: C, 52.50; H, 3.12. Found: C, 52.42; H, 3.32.

The product is soluble in sodium bicarbonate solution; it gives no color with concentrated sulfuric acid in the cold but a green color upon warming.

(b).—A solution of the compound IV in hot, concentrated nitric acid was diluted with a few drops of water. A small amount of material separated. The mixture was heated for an hour on the steam-bath. Enough concentrated nitric acid was then added to bring all the solid into solution at the boiling point, the solution boiled a short time, diluted with water and cooled. The solid was recrystallized as in (a), and was identical in solubility in sodium bicarbonate solution, color in sulfuric acid and melting point behavior with VI as prepared above.

Anal. Calcd. for $C_{28}H_{20}O_{16}N_2$: C, 52.50; H, 3.12. Found: C, 52.69; H, 3.71.

Summary

1. Gossypol hexamethyl ether by the action of fuming nitric acid is converted into a derivative of gossypolone tetramethyl ether in which the iso-

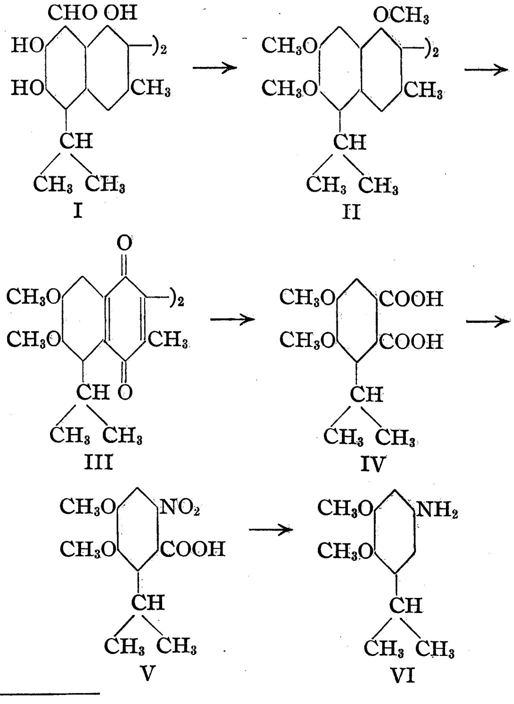
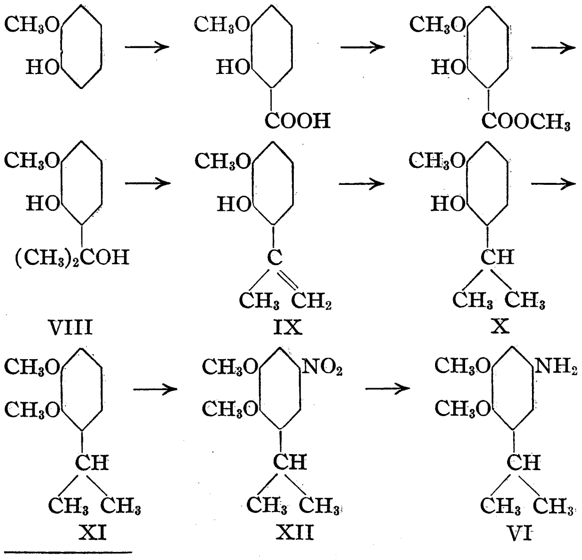
Structure of Gossypol. XVIII. Synthesis of 1,2-Dimethoxy-3-isopropyl-5-aminobenzene, a Degradation Product of Gossypol[1]

BY ROGER ADAMS, MADISON HUNT AND R. C. MORRIS

Structure I has been assigned to gossypol.[2] By the action of concentrated alkali, gossypol loses two aldehyde groups and is converted into the unstable apogossypol. The latter product is stabilized by the formation of the hexamethyl ether. Apogossypol hexamethyl ether (II) upon oxidation with chromic acid gives apogossypolone tetramethyl ether (III) which is further oxidized with potassium permanganate to apogossypolic acid (IV). Nitration of this last product results in a mononitro monocarboxylic acid (V) which upon reduction and sublimation of the product gives a decarboxylated amine (VI).[3] The amine is converted to a diacetyl derivative by the action of acetic anhydride and sodium acetate. Whether the 5-carboxyl or the 4-carboxyl in apogossypolic acid (IV) is replaced by a nitro group was not certain so that the amine which was assigned structure VI might have an isomeric formula, with the amino group in the 4-position.



The compound 1,2-dimethoxy-3-isopropyl-5-aminobenzene has now been synthesized by methods leaving little doubt as to its complete structure and no doubt as to the relative positions of the two dimethoxy and the isopropyl groups. It proved to be identical with the compound VI obtained by degradation of gossypol as shown by melting point and mixed melting points of the two amines and their acetyl derivatives. The synthesis employed is shown by the following series of reactions



---

[1] For previous paper see Adams, Geissman and Morris, THIS JOURNAL, **60**, 2970 (1938).

[2] Adams, Morris, Geissman, Butterbaugh and Kirkpatrick, *ibid.*, **60**, 2193 (1938).

[3] Adams, Morris, Butterbaugh and Kirkpatrick, *ibid.*, **60**, 2191 (1938).

The structure of compound XI, 1,2-dimethoxy-3-isopropylbenzene, cannot be questioned. The 5-position for the nitro group in compound XII was assigned after consideration of the nitration of the analogous 1,2-dimethoxy-3-methylbenzene which was proven in two ways to give the 1,2-dimethoxy-3-methyl-5-nitro derivative.[4] The amino group in compound VI is, therefore, in the 5-position.

The identity of the synthetic product, 1,2-dimethoxy-3-isopropyl-5-aminobenzene, and the gossypol degradation product allows important conclusions to be drawn concerning the gossypol molecule. It confirms (1) the presence of isopropyl groups, and (2) the relative positions of two hydroxyls to the isopropyl groups in the gossypol molecule.

If these established facts are considered in conjunction with the method of preparation and relationship of gossic to apogossypolic acid, it may be deduced that the aldehyde groups in gossypol are in the same rings as the isopropyl groups and indeed *para* to these groups. The lactone formation in gossypol derivatives containing the aldehyde groups oxidized to carboxylic acid groups makes positive the presence of hydroxyl groups in the positions *peri* to the aldehyde groups. Thus, proof of the substituent groups in the 1-, 5-, 6-, 7- and 8-positions of the two naphthalene nuclei of gossypol is conclusive.

Experimental

3-Methoxysalicylic Acid.—To a mole equivalent of sodium in absolute ethanol, 124 g. of guaiacol was added. The alcohol was removed by distillation and the residue washed with dry ether. The solid product was dried *in vacuo* at room temperature. The solid sodium guaiacolate was finely ground and heated for eight hours under pressure at 115° with excess of carbon dioxide. The reaction mixture was dissolved in 400 cc. of water and the solution extracted with ether to remove unchanged guaiacol. The aqueous layer was acidified with hydrochloric acid, and the product separated. The yield was 55 g. (33%) which melted low and required a crystallization from water to bring it up to 150° (corr.). The yield depends to a large extent on the dryness of the sodium guaiacolate. Heyden reported a melting point of 148–150°.[5]

Methyl 3-Methoxysalicylate.—The esterification was carried out by refluxing for twelve hours a mixture of 25 g. of crude 3-methoxysalicylic acid, 65 cc. of methanol and 5.7 cc. of concentrated sulfuric acid. Dilution with ether and extraction of the ether solution with aqueous sodium bicarbonate, then distillation, gave essentially a quantitative yield of product, b. p. 134–136° (2 mm.). The distilled product solidified and was purified by crystallization from dilute methanol, m. p. 61° (corr.). Fritsch reported a melting point of 63°.[6]

Dimethyl-(3-methoxy-2-hydroxyphenyl)-carbinol (VIII).—A dry ether solution of 22 g. of methyl 3-methoxysalicylate was added with cooling to a cooled solution of Grignard reagent prepared from excess methyl chloride and 13.9 g. of magnesium. The reaction mixture was then refluxed for three hours. It was decomposed with dilute acetic acid and the product extracted with ether. After washing with water and aqueous 5% sodium bicarbonate, the ether solution was dried over anhydrous magnesium sulfate and the ether removed. The solid residue was purified by crystallization from benzene–petroleum ether (b. p. 60–110°) and formed white needles, m. p. 126° (corr.); yield, 10.5 g. (48%).

Anal. Calcd. for $C_{10}H_{14}O_3$: C, 65.89; H, 7.75. Found: C, 65.86; H, 7.80.

1-Methoxy-2-hydroxy-3-isopropenylbenzene (IX).—Upon heating 5 g. of the dimethyl-(3-methoxy-2-hydroxyphenyl)-carbinol for ten minutes at 195–200°, water was lost. The product distilled at 122–124° (14 mm.); n^{20}_D 1.5518; d^{20}_{20} 1.072; yield, 4.2 g. (93%).

Anal. Calcd. for $C_{10}H_{12}O_2$: C, 73.13; H, 7.37. Found: C, 73.14; H, 7.50.

1-Methoxy-2-hydroxy-3-isopropylbenzene (X).—A solution of 4 g. of 1-methoxy-2-hydroxy-3-isopropenylbenzene in 25 cc. of 95% ethanol was hydrogenated at 2–3 atm. pressure with Raney nickel as a catalyst. The product distilled at 123–125° (8 mm.); n^{20}_D 1.5203; d^{20}_{20} 1.049; yield, 3.8 g. (94%).

Anal. Calcd. for $C_{10}H_{14}O_2$: C, 72.25; H, 8.49. Found: C, 72.38; H, 8.50.

1,2-Dimethoxy-3-isopropylbenzene (XI).—To a solution of 2.3 g. of 1-methoxy-2-hydroxy-3-isopropylbenzene in 14 cc. of normal sodium methylate was added 1.3 cc. of dimethyl sulfate. The solution was refluxed for ten minutes and then treated with a second similar portion of sodium methylate and dimethyl sulfate and the heating repeated. After evaporating almost to dryness, the reaction mixture was treated with 15 cc. of water and extracted with ether. After extraction of the ether solution twice with 10% aqueous sodium hydroxide, the solvent and then the product was distilled; b. p. 119–121° (24 mm.); n^{20}_D 1.5068; d^{20}_{20} 1.019; yield, 2.1 g. (84%).

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.28; H, 8.95. Found: C, 73.34; H, 8.99.

1,2-Dimethoxy-3-isopropyl-5-nitrobenzene (XII).—To a cold solution of 1 g. of 1,2-dimethoxy-3-isopropylbenzene in 8 cc. of glacial acetic acid was added 0.24 cc. of nitric acid (sp. gr. 1.50). The mixture was kept at 0° for thirty minutes and then was poured into 35 cc. of ice water. The oil which separated was extracted with ether and the ether solution washed with bicarbonate solution. After drying and removing the ether, the residue was dissolved in methanol. Upon cooling in an ice–salt mixture, the product separated and was recrystallized from methanol, yellow crystals, m. p. 53° (corr.); yield, 0.85 g. (68%).

Anal. Calcd. for $C_{11}H_{15}NO_4$: C, 58.64; H, 6.72; N, 6.22. Found: C, 58.91; H, 6.60; N, 6.36.

1,2-Dimethoxy-3-isopropyl-5-aminobenzene (VI).—The corresponding nitro compound was reduced in absolute ethanol solution at 2–3 atm. with Raney nickel as catalyst. The product was purified by sublimation, white crystals, m. p. 75° (corr.). The yield was 0.055 g. from 0.1 g. of nitro compound.

Anal. Calcd. for $C_{11}H_{17}O_2N$: C, 67.70; H, 8.72; N, 7.18. Found: C, 67.55; H, 8.77; N, 7.14.

This substance gave no depression in melting point when mixed with the compound assumed to have this structure and prepared from apogossypolic acid.[3]

1,2-Dimethoxy-3-isopropyl-5-diacetaminobenzene.—The amine was acetylated with acetic anhydride and sodium acetate in an 81% yield. The product was purified by washing the ether solution with 5% hydrochloric acid, evaporation of the solvent and sublimation. It formed white crystals, m. p. 86° (corr.).

Anal. Calcd. for $C_{15}H_{21}O_4N$: C, 64.52; H, 7.53; N, 5.02. Found: C, 64.57; H, 7.41; N, 5.01.

A mixed melting point of this product with the diacetyl derivative of the amine obtained by degradation of apogossypolic acid gave no depression.[3]

1,2-Dimethoxy-3-isopropyldinitrobenzene.—By nitrating 1,2-dimethoxy-3-isopropylbenzene as previously described except that excess nitric acid was used, a dinitro derivative was obtained. It was purified from methanol in yellow crystals, m. p. 106° (corr.).

Anal. Calcd. for $C_{11}H_{14}N_2O_6$: N, 10.31. Found: N, 10.10.

Whether the two nitro groups are both in the benzene ring or one in the ring and the other replacing the tertiary hydrogen of the isopropyl group was not determined. By analogy to the dinitro derivative of 1,2-dimethoxy-3-methylbenzene, it is probable that the two nitro groups occupy the 5-, 6-positions.[4b]

1,2-Dimethoxy-3-isopropyldiaminobenzene.—The reduction of the dinitro compound in absolute ethanol with Raney nickel as catalyst gave a diamine which was purified by sublimation to white crystals, m. p. 75° (corr.). This product was very unstable to atmospheric oxygen and turned brown rapidly.

Anal. Calcd. for $C_{11}H_{18}O_4N_2$: N, 13.13. Found, N, 13.14.

Summary

The synthesis of 1,2-dimethoxy-3-isopropyl-5-aminobenzene has been accomplished. It proved to be identical with the compound prepared from apogossypolic acid by nitration, subsequent reduction and sublimation.

This synthesis confirms the character of the functional groups in the 1-, 5-, 6-, 7- and 8-positions of the naphthalene nuclei in the previously postulated formula for gossypol.

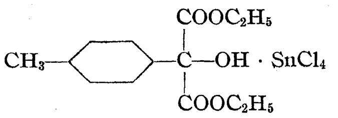
The Preparation of Substituted Mandelic Acids and their Bacteriological Effects. II

BY J. L. RIEBSOMER, ROBERT BALDWIN, JACK BUCHANAN AND HOWARD BURKETT

It has been shown previously by work in this Laboratory[1,2] that alkyl substituted mandelic acids can be prepared readily from alkyl benzenes and ethyl oxomalonate when treated in the presence of anhydrous stannic chloride or certain other condensing agents. The intermediate condensation products are hydrolyzed and decarboxylated to form the corresponding mandelic acids. The purpose of the present work was to extend the studies reported in the first paper of this series[2] and to point out certain additional observations made on the general reaction mentioned above.

In nearly every case when anhydrous stannic chloride is added to an alkyl benzene–ethyl oxomalonate mixture a thick sticky solid separates out. With the hope that a knowledge of the composition of such a typical solid might contribute to an understanding of the mechanism of the general reaction, the solid which separated when toluene, ethyl oxomalonate and stannic chloride were mixed was purified and analyzed. This solid was very hygroscopic and immediately decomposed when added to water with the production of an oily layer. The aqueous solution gave qualitative tests for tin and chloride. The oily layers when hydrolyzed produced *p*-methylmandelic acid. A quantitative analysis for chloride indicated the compound to be an addition product as follows



This result is what would be expected from a consideration of the work of Voskresenskaya[3] who showed that the esters of several dibasic acids react with stannic chloride to form similar addition

products in a mole to mole ratio. Unfortunately, however, this discovery lends only little to an understanding of the mechanism of the condensation reaction. In fact it seems probable that the formation of this precipitate hinders rather than promotes the reaction because after its formation mixing is less efficient. This probably would help to account for the fact that the yields in these reactions are seldom greater than 60% of the theoretical and usually less.

When stannic chloride was mixed with ethyl oxomalonate a solid was produced which was probably another ester–stannic chloride addition product. It proved to be so unstable that an analysis was impossible. It would be difficult to explain how the formation of this product could promote the condensations.

Another condensing agent, boron trifluoride, was tried in the place of anhydrous stannic chloride. In general the yields of mandelic acids were low.

It was found that chloro-, bromo- and iodobenzene would each condense with ethyl oxomalonate by following the usual procedure. These condensation products hydrolyzed to form the corresponding *p*-halogen substituted mandelic acids. The yields in all cases were discouragingly low. But preliminary experiments indicate that benzene derivatives containing both a halogen and an alkyl substituent condense with ethyl oxomalonate to give respectable yields.

Experimental

Analysis of the Precipitate Formed when Stannic Chloride Was Added to a Mixture of Toluene and Ethyl Oxomalonate.—In a 200-cc. round-bottomed flask was placed 25 g. of toluene and 8.7 g. of ethyl oxomalonate. Ten cc. of anhydrous stannic chloride was added with stirring at a temperature of 0°. A white precipitate was formed which after two hours' stirring was filtered using a suction filter. The precipitate was washed with toluene several times and finally with petroleum ether (b. p. 30–40°). The product was transferred immediately to a vacuum desiccator and dried thoroughly under vacuum. Approximately 0.2-g. samples were weighed, water added to them and the solution titrated with standard silver nitrate. Calcd. % Cl for $CH_3C_6H_4C(OH)(CO_2C_2H_5)_2 \cdot SnCl_4$: 26.93; found, 26.83, 26.75.

Another portion of this solid was hydrolyzed with 20% aqueous potassium hydroxide, the product acidified and warmed as in the usual procedure, extracted with ether, the ether distilled off and the solid recrystallized from benzene, m. p. 145°. A mixed melting point with *p*-methylmandelic acid showed no depression.[4]

The method of preparation of these compounds was with minor alterations the same as reported in the first paper of this series.[2] Since pentamethylbenzene and tetramethylbenzene are solids, the preparation of the intermediates in these cases was carried out in chloroform solution. Chloroform had previously been shown to be satisfactory for this purpose.

Boron trifluoride instead of anhydrous stannic chloride was used to prepare the *p*-bromomandelic acid. In a typical experiment 45 g. of bromobenzene and 8.7 g. of ethyl oxomalonate were mixed in a flask and 2.5 g. of boron trifluoride was added under anhydrous conditions and at 0°. The resulting mixture was allowed to stand overnight and the product isolated in the usual way. The yield was about 9%. Similar experiments were made with chloro- and iodobenzene which resulted in even poorer yields. When stannic chloride was used in the place of boron trifluoride to produce *p*-bromomandelic acid a yield of 4% was obtained. Correspondingly low yields of *p*-chloro- and *p*-iodomandelic acids were obtained when anhydrous stannic chloride was used as the condensing agent.

Boron trifluoride was also used in the place of anhydrous stannic chloride with benzene and toluene in the general reaction, but in each case with poor results.

Table I presents a summary of the properties of the compounds. The yields were all calculated on the basis of the ethyl oxomalonate used.

In order to prove the structure of the *p*-*n*-propyl, *p*-*n*-butyl, *p*-*n*-amyl, *p*-isoamyl and *p*-*t*-amyl mandelic acids each of these compounds was treated with excess alkaline permanganate solution.[5] The acids so produced were converted into the methyl esters. In each case the ester melted at 140°, indicating dimethyl terephthalate. This established the para position for each of the alkyl groups.

---

[4] The authors are indebted to Mr. John Bishop for this analysis.

[5] Mulliken, "Identification of Pure Organic Compounds," Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1904, p. 85.

In the cases of the tetra- and pentamethyl derivatives, the method of synthesis was regarded as sufficient proof of their structures.

p-Bromo- and *p*-iodomandelic acids are well known, hence their melting points and neutral equivalents were considered to be sufficient to identify these compounds.

A summary of the bacteriological data is presented in Table II. These tests were made *in vitro* on three different organisms (*B. coli*). The activities are compared with mandelic acid as a standard.

TABLE II

Mandelic acid derivative	Activity
Mandelic	1
p-*n*-Propyl	1 or less
p-*n*-Butyl	1 or less
p-*n*-Amyl	1 or less
p-Isoamyl	1 or less
p-*t*-Amyl	1 or less
Pentamethyl	No activity
2,3,5,6-Tetramethyl	Less than 1
p-Bromo	2–4
p-Iodo	2–4

The first seven of the compounds listed in Table II are so costly to prepare and show so little activity that further experimentation with them would appear fruitless. The two halogen derivatives possess sufficient activity to warrant animal tests to determine their efficacy as urinary tract antiseptics.

The authors are glad to acknowledge the coöperation of Dr. Robert S. Shelton of the Wm. S. Merrell Co., of Cincinnati, Ohio, who performed the bacteriological work, and wish to thank Dean William M. Blanchard of this department who was instrumental in securing financial aid from The National Research Council and from Mr. J. K. Lilly of Indianapolis, Indiana.

Summary

1. Nine substituted mandelic acids have been prepared and compared with mandelic acid with regard to bacteriological activity. Only the *p*-bromo- and *p*-iodomandelic acids show any promise as medicinals.

2. Ando's method for the synthesis of substituted mandelic acids has been extended for alkyl derivatives and has been shown to work poorly for halogen derivatives.

3. Boron trifluoride is not satisfactory to use in the place of anhydrous stannic chloride as the condensing agent.

Amide Hydrolysis with High Concentrations of Mineral Acids

BY VERNON K. KRIEBLE AND KARL AUGUST HOLST

The hydrolysis of amides in dilute acid solutions has been studied repeatedly. There are, however, few studies on record for acid concentrations greater than normal, and these have nearly all been made on acetamide.

Benrath[1] had some indications that the velocity of hydrolysis of acetamide reached a maximum by increasing the acid concentration. This was definitely shown by Taylor[2] for both hydrochloric and hydrobromic acids although he did not find such a maximum for sulfuric acid. As we have been interested in the hydrolysis of nitriles it seemed worth while to extend the study to amide hydrolysis.

Materials and Procedure

Amides.—These were bought from well-known manufacturers and further purified. We did not try to remove all the water from formamide. This was allowed for in weighing out samples of this particular amide.

Formaldehyde.—Merck U. S. P. grade was used.

Calcium Hypochlorite.—The grade marked "H. T. H." and manufactured by the Mathieson Alkali Works was used. All other chemicals were of the blue label or reagent grade.

Procedure.—Exactly 200 cc. of acid, carefully standardized in terms of molality, was delivered to a glass-stoppered flask which was placed in a thermostat for one-half hour before the experiment was started. Enough amide was weighed out to make the solution contain from 0.5 to 0.8 mole of amide if the formol method of analysis was to be used and 0.05 mole if the oxidation method was to be used to follow the hydrolysis. The acid was poured on the amide which quickly dissolved. The solution after thorough mixing was poured into a series of Pyrex tubes. These were closed with rubber stoppers, wired down, and then put back in the thermostat. When a sample was to be taken, a tube was removed and a definite quantity pipetted into a titration beaker containing enough water to dilute the solution sufficiently to stop the reaction. This

---

[1] Benrath, *Z. anorg. allgem. Chem.*, **151**, 53 (1926).

[2] Taylor, *J. Chem. Soc.*, 2741 (1930).

diluted solution was immediately cooled, neutralized, and analyzed for ammonia.

Method of Analysis.—When the amide is hydrolyzed the corresponding organic acid and ammonia are produced. Consequently, it is possible to follow the progress of the hydrolysis by estimating the ammonia present in the hydrolytic solution. This can be done in various ways, but in this investigation it was done by the oxidation of the ammonia with an hypohalite or else by the Sörensen formol titration. In the oxidation method the ammonia reacts with a standard hypochlorite solution releasing nitrogen.

$$4NH_3 + 3Ca(OCl_2) \longrightarrow 2N_2 + 3CaCl_2 + 6H_2O$$

The excess hypochlorite is estimated by adding potassium iodide and titrating the liberated iodine with standard sodium thiosulfate. It was found that the procedure given by Kolthoff and Stenger,[3] was to be preferred to others recorded in the literature. This method was used for most of the rates studied in connection with acetamide and with propionamide where sulfuric acid was the catalyst. It, however, could not be used in the hydrolysis of formamide, which was oxidized by the hypochlorite as well as the ammonia. So the Sörensen formol titration method following the directions given by Hawk and Bergeim[4] was tried. Here formaldehyde reacts with ammonium salts in a neutral solution forming hexamethylenetetramine and liberating an equivalent of the mineral acid which then can be titrated with a standard base.

$$6H_2CO + 4NH_4Cl \longrightarrow 4HCl + 6H_2O + N_4(CH_2)_6$$

This proved to be an excellent method. In any given experiment the velocity constants for various time intervals were much more consistent than by the oxidation method. It was used exclusively with formamide and would have been used with the other amides had we been familiar with its accuracy when the research was started. The rates for acetamide with 1.5 and 3 molal hydrochloric acid were followed by this method and are in line with those determined by the oxidation method.

Order of the Reaction.—The velocity constants were calculated by the monomolecular formula

$$K = \frac{1}{t} \ln \frac{a}{a - x}$$

the time being taken in hours. For the same acid concentration equally good constants were obtained even though the amide concentration varied from 0.05 to 0.8 mole. Benrath also found that whenever the acid concentration exceeded that of the amide the monomolecular formula held. Taylor likewise used this formula in dealing with high concentration of mineral acids on acetamide. Table I illustrates two typical hydrolyses and shows that the velocity is well maintained to more than 85% of completion.

TABLE I

H_2SO_4, 2.0 molal $HCONH_2$, 0.52 mole			HCl, 9.5 molal $HCONH_2$, 0.8 mole		
t, hrs.	% hydrolyzed	*K*	*t*, hrs.	% hydrolyzed	*K*
0.166	16.9	1.11	0.26	27.2	1.23
.416	37.0	1.11	.42	39.4	1.20
.75	55.0	1.06	.58	51.8	1.25
1.18	70.4	1.02	.75	61.3	1.26
1.50	80.9	1.10	1.00	72.5	1.29
1.75	85.4	1.10	1.25	79.5	1.26
2.00	88.4	1.07	1.50	85.5	1.28

In any experiment the velocity constant recorded represents an average of at least six time intervals taken between 18 and 85% of complete hydrolysis. It was seldom that any points averaged varied more than 5% from the mean.

Discussion

The results obtained for the hydrolyses of the different amides may be discussed from several angles. In every case there is a concentration in which the rate of hydrolysis of the amide is maximum. This concentration is not the same for different amides nor is it the same for hydrochloric acid and sulfuric acid. In each case the molality of the hydrochloric acid at its highest rate is greater than the molality of sulfuric acid for its highest rate.

This is the first time that maximum rates have been observed in the hydrolysis of formamide and propionamide and also for acetamide where sulfuric acid is the catalyst. It is, therefore, probably true for all amides. Benrath and Taylor investigated the hydrolysis of acetamide in concentrations up to 7 *N* sulfuric acid and found no indication of a maximum rate while both found maximum values for hydrochloric acid at approximately 3 *N* concentration. It should be pointed out that a comparison of rates of hydrolysis where high concentrations of acid are involved on a normality basis has little meaning. In the first place, the ratio of water molecules to acid molecules, for example, in a 7 *N* sulfuric acid and a 7 *N* hydrochloric acid solution is quite different and the activity of water in the higher concentrations cannot be ignored. In the second place, polybasic acids in these concentrations function only as monobasic acids. It is much better to make the comparison on a molality basis.

Comparing the effects of the same molal concentrations of the same acids on the different amides, it is apparent that the order of decreasing activity for these amides is formamide, propionamide and acetamide. It is interesting to note that propionamide is hydrolyzed faster than acetamide just as propionitrile is hydrolyzed faster than acetonitrile. This was noted by Crocker[5] also. The reverse is the case when alkali is the catalyst, as Crocker and Lowe and Calvet have pointed out.[6]

All the rates studied show that the velocity constant is not a simple function of the molality of the acid and consequently not of the acidity function of the acid. It is to be noted, however, that before the maximum velocity is reached sulfuric acid, which has a higher acidity than hydrochloric acid, is the better catalyst. After the maximum velocity hydrochloric acid is the better catalyst. In other words, acidity is an aid to the reaction up to the maximum velocity and after that a retarding influence. The maximum velocity is reached by both acids at approximately the same acidity as Table VIII shows.

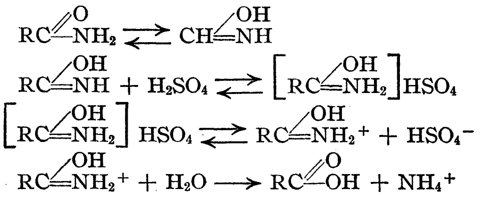
TABLE VIII

MOLALITIES AND ACIDITIES OF SOLUTIONS AT MAXIMUM VELOCITIES

Amide	Acid	Molality	H_0
Formamide	HCl	6	−1.75
Formamide	H_2SO_4	4.75	−1.70
Acetamide	HCl	3.25	−1.02
Acetamide	H_2SO_4	2.5	−0.90
Propionamide	HCl	3.20	−1.00
Propionamide	H_2SO_4	2.40	−0.88

While the velocity of amide hydrolysis, therefore, does not vary directly as the acidity, it is an important factor in the control of the velocity.

Mechanism of Reaction.—In amide hydrolysis, according to former investigators, we are possibly dealing with the following reactions



$$\mathrm{RC}\Big\langle{}^{\mathrm{O}}_{\mathrm{NH_2}} \rightleftarrows \mathrm{CH}\Big\langle{}^{\mathrm{OH}}_{\mathrm{NH}} \qquad (1)$$

$$\mathrm{RC}\Big\langle{}^{\mathrm{OH}}_{\mathrm{NH}} + \mathrm{H_2SO_4} \rightleftarrows \left[\mathrm{RC}\Big\langle{}^{\mathrm{OH}}_{\mathrm{NH_2}}\right]\mathrm{HSO_4} \qquad (2)$$

$$\left[\mathrm{RC}\Big\langle{}^{\mathrm{OH}}_{\mathrm{NH_2}}\right]\mathrm{HSO_4} \rightleftarrows \mathrm{RC}\Big\langle{}^{\mathrm{OH}}_{\mathrm{NH_2}^+} + \mathrm{HSO_4}^- \qquad (3)$$

$$\mathrm{RC}\Big\langle{}^{\mathrm{OH}}_{\mathrm{NH_2}^+} + \mathrm{H_2O} \longrightarrow \mathrm{RC}\Big\langle{}^{\mathrm{O}}_{\mathrm{OH}} + \mathrm{NH_4}^+ \qquad (4)$$

Hantzsch and Geidel[7] conclude from their absorption experiments in the ultraviolet that at equilibrium the imino form is in large excess, particularly in the aromatic amides. Pauling and Sherman[8] have calculated from the heats of formation that amides are resonating molecules and Kumler[9] that acetamide at least is largely a dimer held by hydrogen bonds. Hantzsch and Geidel also conclude that the salt formed when acid is added to the amide is the salt of the imino form because the absorption spectra agree with the salt of the imino ether. From freezing point measurements they show that the salt is highly ionized. Benrath, and Euler and Ölander,[10] and others have

come to the conclusion that it is the amide cation that hydrolyzes to the acid.

Even if all these reactions are in evidence when an amide is added to a mineral acid, it does not explain why the velocity of hydrolysis reaches a maximum and then falls off with increased acid concentration. Benrath came to the conclusion that the velocity was greatest when sufficient acid was added to convert all the amide into a cation. When the acid is increased beyond this point the cation combines with the anion to form an undissociated salt which does not react with water and hence the velocity of hydrolysis falls off. Taylor comes to a somewhat similar conclusion as he says that increased acid concentration caused the formation of an unhydrolyzable complex between the acid and the amide. If this were the true explanation, then the molality of the acid at maximum velocity should vary with the concentration of the amide, but this does not appear to be the case. Benrath used a concentration of 2.4 *N* acetamide while Taylor used 0.05 *N* and we used 0.05 to 0.8 *N*. Benrath had his maximum velocity at 3.18 molal hydrochloric acid and Taylor at 3.0 and we at 3.25.

There is another reaction of the amides which is apparently closely associated in mechanism with their hydrolysis, namely, their reaction with nitrous acid. Plimmer[11] showed that amides do not react with nitrous acid in acetic acid. We have confirmed this statement. They will not react until enough mineral acid has been added to make the solution 2 *N* according to Plimmer. Taylor[12] reports that an aqueous solution must be 4 *N* with respect to mineral acid before decomposition takes place. On the other hand, amines, amino acids and urea react with nitrous acid in acetic acid without addition of mineral acids. The alpha amino group in amino acids reacts completely in five to thirty minutes according to Van Slyke. In these compounds we have an amino group which apparently is lacking in the amides until a certain acidity is attained. It is for this reason that Plimmer concludes that the amide in solution is in the imino form, but when sufficient mineral acid is added the equilibrium is shifted in (1) to the left in favor of the true amide which then reacts with nitrous acid. If this is the true explanation for amide decomposition with nitrous acid, it also offers a plausible explanation for the maximum velocity phenomena for amide hydrolysis. From unpublished results in this Laboratory it is known that the maximum velocity for amide hydrolysis in acetic acid requires a much lower mineral acid concentration than in aqueous solutions just as it does for nitrous acid decomposition. It appears, therefore, that amide decomposition with nitrous acid and amide hydrolysis at maximum velocity are correlated with the same mineral acid concentration and perhaps with the amide imide equilibrium of reaction (1), the supposition being that increased acidity favors the  $\mathrm{RC(\!=\!O)NH_2}$ tautomer and thus lowers the cation  $\mathrm{RC(OH)\!=\!NH_2^+}$ concentration and hence the rate of hydrolysis. It is equally plausible that, so far as the nitrous acid reaction is concerned, the reason that amines and amino acids react in acetic acid while amides do not is due to the fact that the former are much more basic and therefore form salts more readily and hence react while amides do not form salts and therefore do not react.

Dr. C. D. Coryell has suggested that the abnormal amide hydrolysis might depend on the activity of water. The activity of water drops to 0.51 in an 8 molal hydrochloric acid solution and to 0.48 in the same molal concentration of sulfuric acid. According to this idea, with increase in acid concentration the ratio of the velocity to the activity of water should increase so long as the concentration of the amide cation increases faster than the proper power of the activity of water de-

creases. When, however, the amide has all been converted into a cation the velocity should decrease at the same rate as the power of activity of water or the ratio of K to the activity function of water should remain a constant. Unfortunately, the data on velocities beyond the maximum are very meager. Benrath studied the action of hydrochloric acid on acetamide up to 6 N or 6.75 molal and we studied sulfuric acid on propionamide to 11.2 molal. Table IX shows the ratio of the velocity constants to the square of the activity of water.

The constancy of the ratio of the rate constant to the square of the activity of water is striking and indicates that there may be two molecules of water involved in the hydrolysis of the amide cation. It is necessary to have more experimental data to establish definitely this point of view.

We are extending the investigation to include: (1) the action of nitrous acid on amides with varying mineral acid concentrations; (2) the hydrolysis of disubstituted amides; (3) the hydrolysis of acetamide with varying activities of water.

Summary

A study has been made of the hydrolysis of formamide, acetamide and propionamide under the influence of high concentrations of hydrochloric acid and of sulfuric acid.

Each amide has a maximum velocity of hydrolysis at one particular acid concentration. This acid concentration is not the same for both hydrochloric acid and sulfuric acid nor is it the same for different amides. The molality of hydrochloric acid is higher at maximum velocity than for sulfuric acid.

The maximum velocity is reached at about the same acidity for both acids irrespective of the amide. Formamide, however, required a higher acidity than acetamide or propionamide.

Various explanations for the maximum velocity are discussed. A new suggestion has been put forward, namely, that the decrease in the activity of water accounts for the decrease in the velocity of hydrolysis at the higher acid concentration.

The Microstructure and the Diffraction Pattern of Basswood Ash[1]

BY E. A. PARKER,[2] W. E. PATZER[3] AND GEO. J. RITTER[3]

In the burning of wood to ash it was found that an ash residue retaining the fine structure of the original wood could be obtained by carefully controlling a current of oxygen–ozone in the furnace.

Ash residues were prepared from basswood cross sections for determining the microstructure of the ash and the location of the ash-forming constituents. Ash retaining the structure of wood cubes was also made for comparison of its crystalline arrangement with that of ash from wood sawdust. Further, ash was prepared from acid-hydrolyzed wood sections to determine whether the hydrolysis affected the microstructure of the ash constituents.

Previous workers had made ash from thin wood sections in air at glowing furnace temperatures. Brown[5] believed the ash contained considerable siliceous material in the form of rodlike structures arranged parallel with the fibers. The ash structure was similar to that photographed by Ritter.[6] Uber and Goodspeed[7,8] concluded that the ash-forming constituents were distributed throughout the cell wall, but doubted their existence in the middle lamella.

Experimental

Microstructure of the Ash.—Wood specimens in the present study were burned carefully in a slow current of oxygen containing a small percentage of ozone which was generated by an ozonizer connected with the furnace (Fig. 1). The gas mixture was brought in direct contact with the specimen in the furnace, which was electrically heated to 300 to 325°. Excessive shrinkage of the thin wood sections during the burning was prevented by mounting each specimen on a glass object slide by means of a

drop of oil consisting of equal parts of ash-free linseed oil and turpentine. The oil was then hardened in a current of the oxygen–ozone at room temperature so as to hold the specimen in place.

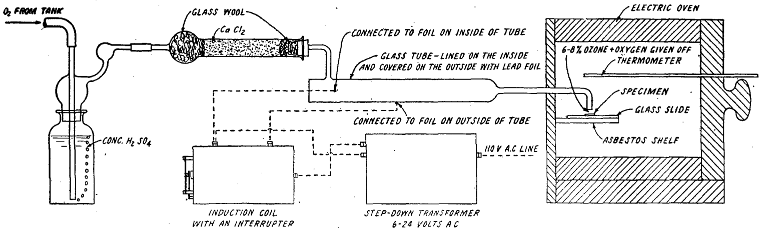

Fig. 1.—A diagram of apparatus used for ashing wood samples.

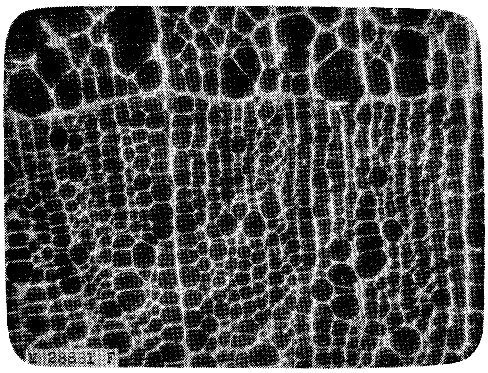
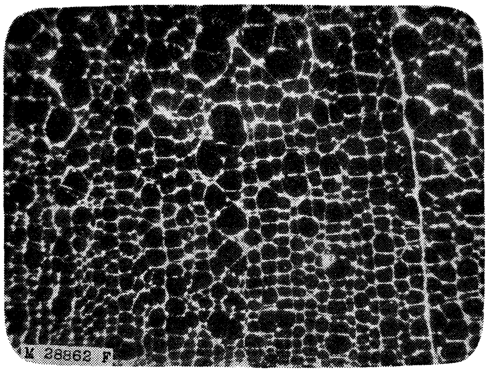
The ash from a transverse wood section 5 to 10 microns thick retained a pattern of the wood except for having thinner walls (Fig. 2a).

The ash residue from a cross section of wood treated with 35% hydrofluoric acid at 20° for seven days, then with boiling 3.0% hydrochloric acid for three hours, and finally washed with water also produced an intact pattern of the wood (Fig. 2b). Its walls were slightly thinner than those of the ash from the wood having had no acid treatment previous to burning.



(a) Ash residue from an untreated wood section (approximately 87 ×).



(b) Ash residue from wood previously treated with hydrofluoric acid, hydrochloric acid and water (approximately 87 ×).

Fig. 2.—Ash residues from transverse sections of wood.

The ash-forming constituents in wood appeared to be located throughout the cell wall. Although the walls of the final ash residue were thinner than those of the wood, microscopical examinations of cross sections in different stages of burning showed a white ash residue on the surface of the entire cell wall. As the burning proceeded to completion, the ash in the secondary wall apparently shrank toward the primary wall.

When cross esctions of wood 10 microns thick were burned, occasional checks were observed between some of the adjacent walls of the ash, whereas numerous checks were observed between the walls of the ash from wood sections 5 microns thick. The numerous checks in the thinner sections confirmed the results noted by Uber and Goodspeed,[8] whose work was confined to the thinner type of wood specimens. The many checks in the ash suggested to them that possibly no ash-forming constituents are located in the middle lamella. However, the contrast between the number of checks in the ash from the thin and the thicker wood specimens, as observed in the present study, indicates that the checks were caused by mechanical means during the sectioning of the specimens and that they became prominent during the subsequent ashing procedure.

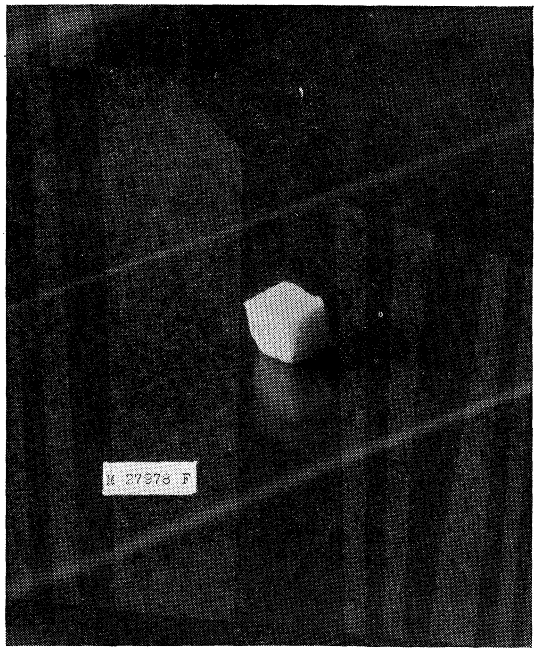


Fig. 3.—Ash residue from a wood cube.

Crystal Arrangement of the Ash.—The well-preserved structure of the ash obtained from a wood cube 3 mm. on edge (Fig. 3), suggested that the crystalline ash constituents might have a preferred orientation. Accordingly, a photographic pattern of the ash cube was made by

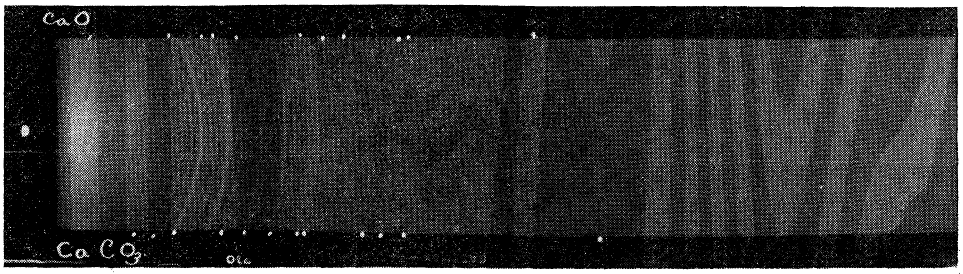

Fig. 4.—Diffraction pattern produced by ash from basswood sawdust. Lines produced by calcium oxide checked at top of pattern; lines produced by calcium carbonate checked at bottom of pattern.

passing an X-ray beam through the block perpendicular to the long axis of the fibers. The diffraction pattern, which was recorded on a flat film, indicated random arrangement of the ash crystals, the same as the arrangement of ash from sawdust of the same wood sample.

In order to facilitate the identification of the ash constituents recorded on the film, an X-ray pattern was made under the conditions employed for making reference patterns of known compounds. In this case a circular camera having a 6.4 cm. radius was used in conjunction with a fine-structure tube having a copper target, operating on 36 p. k. v. and 23 m. a. The pattern (Fig. 4) obtained under these conditions was compared with reference patterns of constituents found, in general, in wood ash. The comparison indicated that the oxide and the carbonate of calcium produced all the lines recorded. The oxide lines are checked on the top and the carbonate lines on the bottom of Fig. 4 by means of the white dots.

Why other ash constituents are not recorded on the pattern is not known. One reason advanced is that any ash constituent, other than the two of calcium, is present in too small a percentage to produce diffraction lines. Another reason is that the lattice spacing of some of the constituents might have been destroyed by a partial fusing during the preparation of the ash. We offer these reasons with no definite proof of their accuracy.

Summary

The ash residue obtained from the burning of wood forms intact skeletons of the original wood. An ash residue of a transverse wood section has walls considerably thinner than those of the original wood section. As the organic material of the cell wall burns, a lateral shrinkage of the ash cell wall occurs, the ash in the secondary layer being drawn toward the middle lamella.

It is believed that the occasional checks between two adjacent cell walls of the ash are caused by the sectioning of the wood and are no indication of the absence of ash in the middle lamella.

Ash residues from transverse wood sections indicate that the ash-forming minerals in wood are located in both the cell wall and the middle lamella.

Small blocks of the ash residue retain the shape of the original wood.

X-ray diffraction patterns of ash cubes indicate a random arrangement of the ash crystals.

By a comparison of the diffraction pattern of the ash with those of known compounds, it has been shown definitely that the carbonate and the oxide of calcium produced the only visible diffraction lines.

The Thermodynamics of Bi-univalent Electrolytes. III. Zinc Iodide in Aqueous Solution[1]

BY ROGER G. BATES[2]

The thermodynamic behavior of zinc iodide in aqueous solution is of interest in relation to the problem of the intermediate electrolyte. Cadmium iodide has been shown[1b,3,4] to represent an extreme case of incomplete dissociation in solution. Little is known, however, regarding the degree to which this abnormality extends to zinc iodide.

Van Name and Brown found[5] that the tri-iodide equilibrium constant determined with zinc iodide–iodine solutions retained its normal value over a considerable range of electrolyte concentration. Grimm has likewise reported[6] lattice energy calculations for zinc iodide that lead one to expect a high degree of electrolytic dissociation of the salt in solution. A forty-eight-hour exposure of a concentrated zinc iodide solution failed to yield any perceptible Raman lines,[7] although a strong iodine coloration may have interfered.

The transference studies of Hittorf, on the other hand, have shown[8] that the transference number of zinc becomes negative in strong solutions of zinc iodide, while Van Rysselberghe, Grinnell and Carlson found[9] that the conductivities of zinc iodide–potassium iodide mixtures showed large deviations from the mixture rule above a total concentration of 4 *N*.

Measurements of the electromotive force of the cell

$$\text{Zn–Hg (2-phase)}/\text{ZnI}_2\ (m)/\text{AgI–Ag} \qquad (1)$$

have been made at 5° intervals from 5 to 40°, inclusive, and over a range of zinc iodide molality extending from 0.005 to 0.8. From the results, the standard potential of the cell has been evaluated, and calculations of the activity coefficients, relative partial molal heat content and relative partial molal specific heat of the salt have been made. Zinc iodide in aqueous solution has been found to behave as a normal bi-univalent electrolyte over the range of concentration studied.

Experimental Methods

An amalgam containing 5% of zinc by weight was used in most of the cells, although preparations containing as little as 4.5% zinc or as much as 5.5% were tried without noticeable difference in results. According to Puschin,[10] these amalgams are saturated over the temperature range studied. The best grade of Kahlbaum zinc and thrice-distilled mercury were employed, and the preparations were stored under hydrogen in an amalgam pipet. Previous to the preparation of each electrode, the pipet was warmed in an oven until its contents were entirely fluid; a portion of amalgam was then drawn through an ungreased stopcock of large bore into the evacuated cell vessel. The electrodes used in this work were shown to be identical with a zinc amalgam electrode prepared from a sample of spectroscopically pure zinc kindly furnished by the Research Laboratory of the New Jersey Zinc Co.

The silver–silver iodide electrodes were formed on small platinum spirals by the thermal decomposition of a paste composed of 90% silver oxide and 10% silver iodide. Ten to fifteen minutes at about 450° was found to be a satisfactory decomposition time. Silver iodide was prepared by precipitation and was digested three days under water at about 80°. It was found necessary to employ electrodes of 20–25% silver iodide for measurements in zinc iodide solutions stronger than 0.2 molal. The solubility of silver iodide in iodide solutions rises extremely rapidly as the iodide ion concentration is taken above about 0.4 gram ions per liter.

Electrodes prepared by the decomposition of oxide–iodate mixtures by the method of Owen[11] were tried and found to be less reproducible in the more concentrated zinc iodide solutions than those prepared from oxide–iodide mixtures. It has been shown recently[12] that silver iodate decomposes at about 390° but that a period of one to two hours is required for complete decomposition at 400 or 450°. Table I gives a comparison of the decomposition temperatures of the silver salts commonly used for thermal electrodes. It is evident that the high temperatures requisite for the complete and rapid decomposition of the iodate may cause considerable loss of silver iodide, whereas the same temperature is quite satis-

factory for the formation of silver bromide and silver chloride.

Several zinc iodide stock solutions were used. These solutions were prepared by dissolving the salt, recrystallized from oxygen-free conductivity water, in a quantity of boiled conductivity water through which purified hydrogen had been bubbled for some time. The careful exclusion of air at all times was imperative. Zinc iodide reacts with oxygen and with carbon dioxide and is oxidized rapidly when in contact with cellulose, both in solution and in the solid condition.[13] Sintered glass filters were used in all filtrations.

Weighed samples of the stock solutions were analyzed for iodide by the Volhard method. All solutions were kept under hydrogen in flasks from which they could be expelled by hydrogen pressure as desired. Weighed amounts of water were added to weighed quantities of stock solution in making the dilutions. Vacuum corrections were made for all weighings. No precipitation of hydroxide or basic salt was observed.

The cells vessels were similar to those described by Bates and Vosburgh.[1a] To permit the use of the vessels in water thermostats, the electrode contacts were made through mercury wells. The use of Pyrex glass with tungsten contacts served to prevent the occasional breakage of vessels observed when zinc amalgam is in contact with sealed-in platinum wires.[14]

The process of making a cell was carried out entirely in the absence of air. The vessel, containing a silver iodide electrode and a portion of amalgam, was evacuated with an oil pump for ten to fifteen minutes and filled with hydrogen. Two portions of cell solution were admitted from a saturator flask to each arm of the vessel and expelled through the side tubes provided for the purpose. The cell electrolyte was then introduced.

Cells were made in triplicate at each concentration. Within the optimum range of concentration (0.01 to 0.2 m) triplicate cells deviated from the mean electromotive force by less than 0.1 mv. when equilibrium conditions had been attained, usually within two to five hours. Between 0.2 and 0.8 m, where the solubility of silver iodide in the electrolyte is large, the agreement was as satisfactory, but the time of attainment of equilibrium and the life of the cell were much shorter than was the case at the lower concentrations. Below 0.01 m the cells ordinarily required overnight to come to satisfactory equilibrium. The reproducibility was of the order of 0.2 mv. Temperature coefficient runs were completed within a period of ten hours after they were begun. It was observed that most of the cells began to decrease slowly in electromotive force after approximately thirty-six hours. A separate temperature run was made for each group of three cells. Upon change of temperature most of the cells attained constant values in twenty to thirty minutes, although marked hysteresis was noted in those with electrolytes more dilute than 0.005 molal. The temperature of initial measurement was 25°, and all cells were brought back to this temperature at the completion of the run. The original 25° values were usually satisfactorily resumed, and the results for cells showing unusual drifts during the run were rejected as unreliable.

The electromotive forces were measured by means of a Leeds and Northrup Type K potentiometer. The standard cell was frequently checked against the laboratory standards. Thermometers were standardized against a calibrated platinum resistance thermometer. The temperatures were probably accurate to ±0.03°.

Experimental Results

The electromotive forces obtained in the best runs are recorded in Table II. These values were fitted to the quadratic equation

$$E_t = E_{25} + a(t - 25) + b(t - 25)^2 \qquad (2)$$

---

[13] Berridge, *B. A. Rep.*, 658 (1895).

[14] Cowperthwaite and La Mer, THIS JOURNAL, **53**, 4333 (1931).

by the method of Harned and Nims.[15,16] The electromotive forces at 25° at round molalities were read from a large scale plot of E *versus* $\log m$. These values are recorded in Table III with the smoothed a and b constants.

The Standard Potential of the Cell

The electromotive force of cell (1) may be represented by the equation

$$E = E^0 - 2.3026(RT/2F) \log \mathbf{a}_{\mathrm{ZnI_2}} = E^0 - k \log 4m^3\, \gamma_\pm^{\,3} \qquad (3)$$

in which E^0 is the standard potential of the cell, E the observed electromotive force, $\mathbf{a}_{\mathrm{ZnI_2}}$ the activity of zinc iodide in a solution of molality m, k equals $2.3026(RT/2F)$ and $\gamma_\pm$ is the stoichiometrical activity coefficient of zinc iodide.

The evaluation of E^0 may be accomplished, as pointed out by Hitchcock,[17] by the substitution of the Debye–Hückel limiting law

$$-\log \gamma_\pm = u'\sqrt{c} + Pc = u'\sqrt{md} + Pmd \qquad (4)$$

in the right-hand term of equation (3) and extrapolating this function of the original electromotive forces to zero concentration, bearing in mind that in dilute solutions c, the molar concentration, is very nearly equal to md, where d is the density of the solution. The expression for $E^{0\prime}$, the apparent standard potential, then becomes

$$E^{0\prime} = E^0 + 3kPmd = E + k \log 4 + 3k \log m - 3k\, u'\sqrt{md} \qquad (5)$$

in which u' is the limiting slope of the Debye–Hückel theory, varying inversely as $(DT)^{3/2}$, where D is the dielectric constant of the solvent[18] and T is the absolute temperature. P is an empirical constant. Equation (4) is valid only at extremely low concentrations of zinc iodide.

Scatchard and Tefft have shown[19] that the incomplete dissociation of the intermediate ion, MX^+, of a bi-univalent salt causes a hump in the plot of $E^{0\prime} - E^0$ against $c^{1/2}$. By the matching of theoretical plots constructed for various values of K_2, the dissociation constant of the intermediate ion, with the plot of experimental data it is possible to obtain an estimate of the second dissociation constant of the salt.[20] The character of the zinc iodide results when treated in this manner indicated a high degree of dissociation, with a constant greater than 10 for the ZnI^+ ionization process. Therefore, in the further treatment of the results complete ionization was assumed.

The activity coefficient in equation (3) may be represented with somewhat more accuracy by the Hückel equation[21]

$$-\log \gamma_\pm = \frac{u\sqrt{3c}}{1 + A\sqrt{3c}} + Bc - \log(1 + 0.054m) \qquad (6')$$

or, less exactly

$$-\log \gamma_\pm = \frac{u\sqrt{\mu d}}{1 + A\sqrt{\mu d}} + B''\mu d \qquad (6)$$

where μ is the ionic strength, $\mu = \sum m_i z_i^{\,2}/2 = 3m$, u is a constant related to u' of equation (4) by the expression, $u' = u\sqrt{3}$, B and B'' are empirical constants and

$$A = Ka \qquad (7)$$

K is a quantity varying as $(DT)^{-1/2}$ and a is the mean distance of approach of the ions. This ion size parameter for a highly dissociated electrolyte is independent of temperature over the ordinary range of measurement.[14,22]

Since $3k \log (1 + 0.054m)$ amounts only to 0.09 mv. for $m = 0.05$, the highest concentration employed in obtaining E^0, the omission of the third term on the right of equation (6′) is of no appreciable influence on the course of the extrapolation. Combining equation (3) with equation (6) gives

$$E^{0'} = E^0 + B'\mu d = E + k \log 4 + 3k \log m - \frac{3ku\sqrt{\mu d}}{1 + A\sqrt{\mu d}} \quad (8)$$

where $B' = 3kB''$.

Values of $E^{0'}$ were calculated by equation (8) and were extrapolated to zero ionic strength to obtain E^0. Figure 1 shows the extrapolations at the eight temperatures. The values of the various parameters of Hückel's equation are listed in Table IV, together with the a values that best fitted the experimental results. Approximate densities of the zinc iodide solutions were obtained from "International Critical Tables."[23]

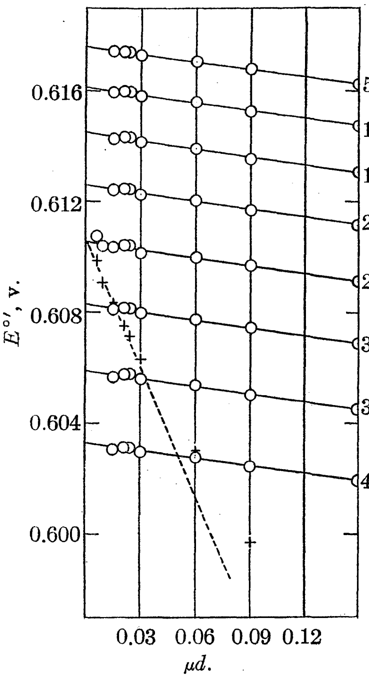

Fig. 1.—Extrapolation functions for cell (1). Circles represent plots of $E^{0'}$ according to equation (8). Crosses represent $E^{0'}$ according to equation (5). Diameter of circles, 0.4 mv.

TABLE IV

PARAMETERS OF EQUATIONS (6) AND (7)

t	u	$-B''$	$K \times 10^{-8}$	$a \times 10^8$ (cm.)
5°	0.9785	0.113	0.325	6.09
10	.9866	.111	.326	6.07
15	.9944	.109	.327	6.05
20	1.003	.107	.328	6.04
25	1.012	.105	.329	6.02
30	1.022	.103	.330	6.00
35	1.032	.102	.331	5.98
40	1.043	.100	.332	5.96

The crosses of Fig. 1 indicate $E^{0'}$ points at 25° calculated by equation (5), and the broken line has been drawn to intersect the equation (8) plot at $\mu = 0$. It is evident that the extrapolation with the use of the Debye–Hückel limiting law is rather uncertain. The E^0 obtained by the use of the extended equation, however, is thought to be quite reliable.

The standard potentials of cell (1) may be expressed by the equation

$$E_t^0 = E_{25}^0 + a_0(t - 25) + b_0(t - 25)^2 \quad (9)$$

with an average deviation of 0.03 mv. The numerical values of the constants of this equation appear at the bottom of Table III.

Standard Potentials of Zinc Electrodes

In the second and third columns of Table V are listed the standard potentials, E^0, of the zinc–silver iodide cell at 5° intervals from 5 to 40°. The potentials of the electrode, Zn–Hg (2-phase)/Zn^{++}(a = 1), are represented by $E^{0''}$ and are given in the fourth and fifth columns. These values were computed by subtracting the standard potentials of the hydrogen–silver iodide cell[11] from the standard potentials of cell (1) at corresponding temperatures. For the former cell, Owen has given the equation

$$E^0_{HI} = -0.15219 - 328 \times 10^{-6}(t - 25) - 3.6 \times 10^{-6}(t - 25)^2 \quad (10)$$

TABLE V

STANDARD POTENTIALS

Zn–Hg/ZnI_2(a = 1)/AgI–Ag, E^0

Zn–Hg/Zn^{++}(a = 1), H^+(a = 1)/E_2, $E^{0''}$

t, °C.	E^0	E^0 (Eq. 9)	$E^{0''}$	$E^{0''}$ (Eq. 11)
5	0.6176	0.61755	0.76472	0.76462
10	.6161	.61609	.76415	.76417
15	.6145	.61444	.76370	.76371
20	.6126	.61259	.76322	.76323
25	.6105	.61055	.76275	.76274
30	.6083	.60831	.76226	.76223
35	.6059	.60588	.76176	.76171
40	.6033	.60325	.76117	.76117

Subtraction of this equation from equation (9) gives

$$E^{0''} = E^0_{Zn\text{-}Hg/Zn^{++}} = 0.76274 - 0.0001(t - 25) - 0.00000031(t - 25)^2 \quad (11)$$

Since Clayton and Vosburgh[24] have shown that the electromotive force of the cell, Zn(s)/Zn^{++}/Zn–Hg (5%), is zero, it is evident that $E^{0''}$ likewise represents the standard potentials of the zinc metal electrode.

---

[23] "International Critical Tables," McGraw-Hill Book Co., Inc., New York, N. Y., 1928, Vol. III, p. 65.

[24] Clayton and Vosburgh, THIS JOURNAL, **58**, 2093 (1936).

Recorded standard potentials for the zinc amalgam electrode do not agree well. Shrawder, Cowperthwaite and La Mer[25] computed the potential of this electrode from the standard potential of the zinc amalgam–lead sulfate cell[14] and an E^0 for the lead amalgam–lead sulfate electrode[26] finding a value of 0.7614 v. at 25°.

From measurements of the cell

$$\text{Zn–Hg (2-phase)/ZnCl}_2\ (m)\text{/AgCl–Ag} \qquad (12)$$

at 25° and accepted data on the Ag–AgCl electrode, Scatchard and Tefft[19] found a zinc amalgam electrode potential of 0.7610 v., while Brüll[27] calculated a value of 0.7596 v. from electromotive forces of zinc amalgam-mercurous chloride cells with zinc chloride electrolytes. The low result of Brüll can be attributed largely to the use of too high a calomel electrode potential (0.2700 v.) for the computation. Gerke[28] and Randall and Young[29] agree that the mercury–mercurous chloride electrode is 0.0455 v. more positive than the silver–silver chloride electrode, which has a value of 0.2224 v. at this temperature.[22] Subtraction of 0.2679 v. from the standard potential of Brüll's cell gives 0.7617 v. for the potential of the zinc amalgam electrode.

The E^0 of Scatchard and Tefft, and of Brüll as well, was obtained by the Hitchcock method, using an extrapolation function similar to equation (5). Since the Hückel equation gives a much more valid representation of the activity coefficient of zinc chloride than does the limiting law in solutions more concentrated than 0.005 M, it seemed worthwhile to extrapolate the results with the use of equation (8). The circles of Fig. 2 represent $E^{0\prime}$ values of Scatchard and Tefft, while the crosses indicate values of the quantity $E^{0\prime} - 0.0455$ calculated from Brüll's electromotive forces. The broken line again shows the course of the Hitchcock extrapolation. An apparent ionic diameter of 5.4 Å. made equation (8) fit the results to best advantage. Triangles represent $E^{0\prime}$ values when the parameter a is 4.0 Å., and dots were calculated for a = 6.1 Å. Inspection of $E^{0\prime}$ points computed with the three different a parameters shows that the μ = 0.13 point lies about 1 mv. too high. With this exception, the results of Scatchard and Tefft between 0.007 and 0.1 m give an unambiguous straight line extrapolation to an E^0 of 0.9850 v.; the three results of Brüll in the same range of concentration lie about 0.5 mv. higher. Below 0.007 m the $E^{0\prime}$ values of both investigations show a decrease. Scatchard and Tefft observed[19] the decreasing electromotive force of cell (12) when air was allowed to come in contact with the amalgam. Although imperfect exclusion of oxygen from the dilute solutions would explain the drop in $E^{0\prime}$, it is possible that failure of the cells to attain equilibrium conditions during the period of measurement was responsible.

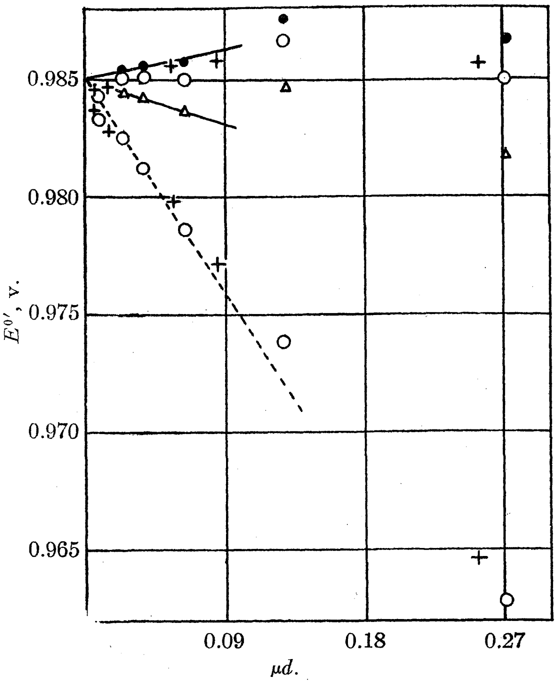

Fig. 2.—Extrapolation of electromotive forces of cell (12) to zero ionic strength at 25°. Crosses represent $E^{0\prime}$ − 0.0455 computed from measurements of Brüll.[27] Dots, circles and triangles represent $E^{0\prime}$ from data of Scatchard and Tefft.[19] Lower points were calculated by equation (5), upper points by equation (8) using a = 6.1 Å. (dots), 5.4 Å. (circles) and 4.0 Å. (triangles). Diameter of circles, 0.5 mv.

It seems likely that Scatchard and Tefft, in extrapolating to 0.9834 v., placed undue weight upon a low 0.003 m (μ = 0.009) point. On the other hand, the extrapolation to 0.9850 v. by equation (8) places considerable weight on the three next higher concentrations, μ = 0.023, 0.037 and 0.064. These points, however, represent electromotive force measurements within the optimum concentration range of zinc chloride.

Figure 2 makes it seem probable that the standard potential of cell (12) at 25° lies between

.8	.787	.775	.766	.754	.740	.724	.706	.687

0.9845 and 0.9852 v. and, consequently, that the zinc amalgam electrode potential has a value lying between 0.7621 and 0.7628 v. This conclusion is in satisfactory accord with the value of 0.7627 v. obtained in this investigation.

Activity Coefficients

The stoichiometrical activity coefficients of zinc iodide have been calculated by equation (3) and are given in Table VI.

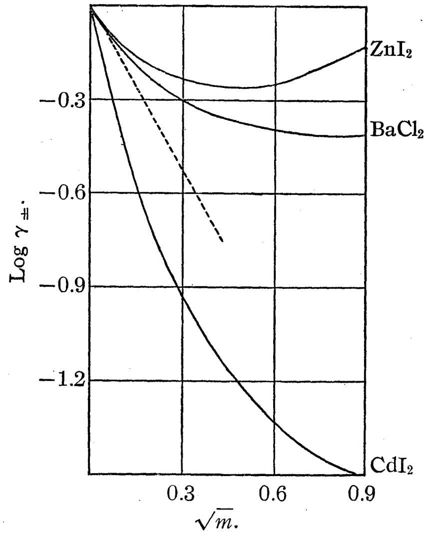

Fig. 3.—Logarithm of the stoichiometrical activity coefficients of zinc iodide, barium chloride and cadmium iodide as a function of the square root of the molality. The Debye–Hückel limiting slope is indicated by the broken line.

From an inspection of the slopes of the extrapolation plots of Fig. 1 it is clear that B' of equation (8) changes little with the temperature and has a value of -0.0093. The corresponding B'' values of equation (6) have been evaluated by dividing this quantity by $3k$ at each temperature and are given in the third column of Table IV. Equation (6), with the use of the parameters given in Table IV and a d value of unity, represents the activity coefficient of zinc iodide over the entire range of molality studied with an accuracy better than 1%.

In Fig. 3 is plotted log $\gamma_\pm$ at 25° against $m^{1/2}$. Plots of the barium chloride activity coefficients as determined by Tippetts and Newton[30] and of the cadmium iodide results of Bates and Vosburgh[1a] have been included for comparison. The broken line indicates the Debye–Hückel limiting slope. The activity of zinc iodide in solution is somewhat greater than that of barium chloride at the same molality and is considerably greater than that of the slightly dissociated cadmium iodide.

Relative Partial Molal Heat Content

The partial molal heat content (heat of transfer) relative to an infinitely dilute solution of zinc iodide was computed from the temperature coefficients of electromotive force by the use of the Gibbs–Helmholtz equation

$$\bar{L}_2 = \bar{H}_2 - \bar{H}_2^0 = \Delta H - \Delta H^0 = -nF\left[E - E^0 - T\left(\frac{\mathrm{d}E}{\mathrm{d}T}\right) + T\left(\frac{\mathrm{d}E^0}{\mathrm{d}T}\right)\right] \quad (14)$$

With the substitution of $t = T - 273.1$, the quadratic equations (2) and (9) were made to express the variation of electromotive force (or standard potential) as a function of absolute temperature:

$$E_T = A + BT + CT^2 \quad (15)$$
$$E_T^0 = A_0 + B_0T + C_0T^2 \quad (16)$$

These relationships are valid only between T =

---

(30) Tippetts and Newton, THIS JOURNAL, **56**, 1675 (1934).

278.1 and 313.1°K. Equations (15) and (16) were substituted in equation (14), and the indicated differentiation was performed. Since $n = 2$ for zinc iodide, the expression becomes

$$\overline{L}_2 = -2F(A - A_0) + 2F(C - C_0)T^2 = \alpha + \beta T^2 \quad (17)$$

Equation (17) is the equation of Harned and Thomas.[31] Values of α and β for zinc iodide solutions from 0.005 to 0.8 m are given in Table VII.

TABLE VII

CONSTANTS OF EQUATIONS (17) AND (19). $\overline{L}_2$ AND $\overline{C}_p - \overline{C}_p^0$

m	$-\alpha$	$\beta \times 10^4$	$(\overline{L}_2)_{298}$ (calories)	$(\overline{C}_p - \overline{C}_p^0)_{298}$ (calories)
0.005	739	106	204	6
.007	848	125	259	7
.008	895	134	294	8
.01	1152	166	324	10
.02	1719	240	413	15
.03	2095	291	488	18
.05	2623	360	576	22
.07	3009	411	640	25
.1	3381	461	720	28
.2	4291	586	917	35
.5	6852	932	1432	56
.7	8740	1200	1922	72
.8	9405	1301	2160	78

Figure 4 is a plot of $\overline{L}_2$ against $m^{1/2}$ at 5, 15, 25 and 40°. The broken line shows the Debye–Hückel limiting slope for $\overline{L}_2$ at 25°

$$\overline{L}_2 = 3041\ c^{1/2} \quad (18)$$

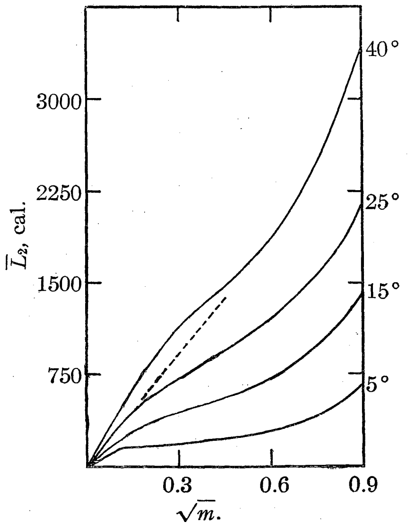

Fig. 4.—The relative partial molal heat content, $\overline{L}_2$, as a function of the square root of the molality. The broken line represents the limiting slope at 25°.

Unfortunately, no extensive calorimetric determinations of the heat contents of zinc iodide solutions have been made, and no estimate of the accuracy of the other quantities derived from the electromotive force data can be obtained from that source.

Relative Partial Molal Specific Heat

The values of the relative partial molal specific heat of zinc iodide were calculated by the equation

$$\overline{C}_p - \overline{C}_p^0 = \left(\frac{\partial \overline{L}_2}{\partial T}\right)_p = 2\beta T \quad (19)$$

The change of $\overline{C}_p - \overline{C}_p^0$ with temperature is small in the dilute solutions and amounts to but 0.5 calorie per degree at 0.8 m. The $\overline{L}_2$ and $\overline{C}_p - \overline{C}_p^0$ values for zinc iodide solutions at 25° are given in Table VII. The latter values, computed from second derivatives of the experimental results, must be considered as only approximate.

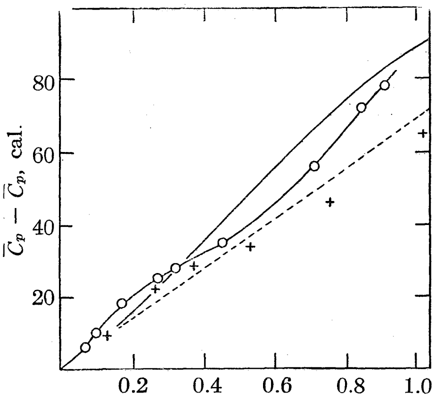

Fig. 5.—Relative partial molal specific heat at 25° as a function of the square root of the molality. Circles represent zinc iodide; crosses are for barium chloride, unbroken line for sodium sulfate. The broken line shows the limiting slope.

In Fig. 5, $\overline{C}_p - \overline{C}_p^0$ for zinc iodide is compared with the relative partial molal specific heat of sodium sulfate, computed by Randall and Rossini[32] from calorimetric data. The crosses represent values of the same quantity for barium chloride calculated by the author from the specific heats given by Richards and Dole.[33] The limiting slope of the Debye–Hückel theory is indicated by the broken line.

Grateful acknowledgment is made of the kind assistance of Professor Herbert S. Harned.

Summary

1. Electromotive force measurements of the cell

$$Zn\text{-}Hg\ (2\text{-phase})/ZnI_2\ (m)/AgI\text{-}Ag$$

have been made at 5° intervals from 5 to 40° and at molalities of zinc iodide from 0.005 to 0.8.

2. The standard potential of the cell has been evaluated, and from it the electromotive forces of the hypothetical cells

$$Zn\ (s)/Zn^{++}\ (a = 1),\ H^+\ (a = 1)/H_2,\ \text{and}$$
$$Zn\text{-}Hg\ (2\text{-phase})/Zn^{++}(a = 1),\ H^+\ (a = 1)/H_2$$

have been computed from 5 to 40°.

3. Calculations of the stoichiometrical activity coefficient, relative partial molal heat content and relative partial molal specific heat of zinc iodide in aqueous solution have been made.

4. Zinc iodide has been shown to be a normal bi-univalent electrolyte in aqueous solutions more dilute than 0.8 molal. Whereas the abnormalities of incomplete dissociation and complex ion formation indicated by transference and conductivity studies of strong zinc iodide solutions cause profound changes in the behavior of the salt in the concentrated range, they are of inappreciable influence below 0.8 *m*.

[CONTRIBUTION FROM THE CHEMICAL LABORATORIES OF WASHINGTON SQUARE COLLEGE, NEW YORK UNIVERSITY]

A Rapid Method for Traces of Metals by the Dropping Mercury Electrode[1]

BY RALPH H. MÜLLER AND JOHN F. PETRAS

Introduction

In developing and testing the cathode ray tube polarograph[2] the authors required some means for obtaining the conventional Heyrovsky current–potential curves. It is obvious that these can be obtained manually and indeed the earliest studies were made in this fashion. It was to relieve the tedium of this procedure that Heyrovsky developed the automatically recording polarograph. The polarograph has the further advantage of providing a permanent record. On the other hand, the "manual" curves may be obtained with relatively inexpensive and commonly available equipment. The marked symmetry of the curves at once suggests a simple and rapid increment method for determining the concentration of a given ion.[2a] The object of this paper is to demonstrate the validity of the increment method and to illustrate its applicability.

Apparatus

It is common knowledge that a potentiometer will deliver at its e. m. f. terminals the potential which is set on the dials. In our work a Leeds and Northrup student-type potentiometer was used to deliver the desired potentials. The working current of the potentiometer was balanced against a standard cell in the usual manner. The e. m. f. terminals were connected to the electrode vessel in series with a wall-type galvanometer L and N Type P, 103 megohm sensitivity, resistance 126 ohms, period 8.9 sec. The latter was used in conjunction with an Ayrton shunt carefully adjusted to provide the critical damping resistance. The suspension was turned so that readings could be taken over more than half the scale length. The entire assembly was calibrated for linearity of response and used over that range. The electrode was of the type commonly used in polarographic work,[3] and consisted of a small Erlenmeyer flask with a platinum wire inseal for making connection with the mercury anode, and a bubbler inseal for flushing the contents of the vessel with hydrogen. The capillaries for the dropping mercury cathode were hand drawn from 1-mm. capillary tubing. They were graded for suitable lumen by examination under a low power microscope fitted with a micrometer ocular. The vessel was also provided with a salt bridge communicating with a saturated calomel electrode. In this way the anode potential could be measured. A switching arrangement enabled the operator to check the anode potential with the potentiometer. The mercury dropping rate was controlled by the pressure unit previously described.[2] It was found to be far more convenient and flexible.

Solutions

The solutions used in this work were prepared from reagent quality chemicals without further purification. Eastman purified de-ashed gelatin was added to all solutions to give a final concentration of 0.2%. A wide choice of addition agents is feasible. In routine work,

[2a] After this paper was submitted for publication the authors learned of similar work by Petering and Daniels in which the increment technique has been applied to the micro-analysis of oxygen. Their application undoubtedly precedes this contribution, and we regard our work as a general confirmation of the validity of the increment principle. The senior author is indebted to Professor Daniels for helpful discussion and exchange of opinions at the Milwaukee meeting and subsequently at his laboratory in Madison.

common glue has been found satisfactory by some investigators. A fairly complete list of suitable supporting solutions is given in Hohn's monograph. The indifferent electrolyte which was used in each case is indicated in the appropriate place. Oxygen was removed from all solutions just before use by bubbling pure hydrogen through the vessel. The formation of persistent bubbles due to the gelatin content was very annoying, but it was eliminated completely by the addition of a trace of caprylic alcohol. We were agreeably surprised to note that neither the dropping rate nor values of the potentials were adversely affected.

Experimental Results

A typical current–voltage curve is shown in Fig. 1. In this case equal amounts of cadmium and zinc nitrates were used with 0.1 *M* potassium chloride as the indifferent electrolyte. At each applied potential the galvanometer deflections are pulsating due to the dropping of the mercury at the cathode. The recorded values represent the maximum "throw" or excursion of the galvanometer. These are highly reproducible and it was rarely necessary to observe more than two or three "throws." The "Halbwellen" potential, defined as that potential on the curve corresponding to one-half the distance between the horizontal plateaus, is indicated in Fig. 1, for each ion. From each potential the anode correction of 0.04 v. was subtracted, yielding Cd = −0.64 v., and Zn = −1.07 v.

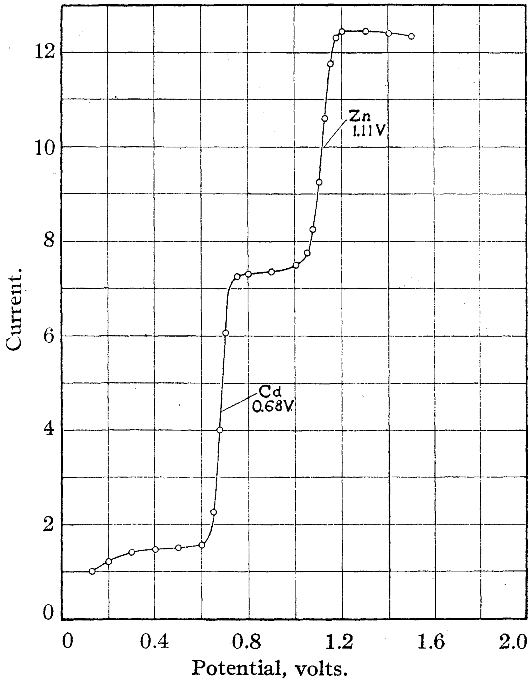

Fig. 1.—0.001 *M* $Zn(NO_3)_2$, 0.001 *M* $Cd(NO_3)_2$, 0.1 *M* KCl, 0.2% gelatin.

Figure 2 shows a family of curves obtained in this manner for cadmium at various concentrations. It is customary in polarographic work to draw the best straight line through each plateau and then estimate the difference in height (ΔI). Alternative schemes for estimating the correct wave height are discussed in the above monographs and in the paper by Borcherdt, Meloche and Adkins.[4] Due to the marked symmetry of the curves, it would seem that the current values obtained for two potentials more or less equidistant from the characteristic "Halbwellen" potential would yield a ΔI value which is equally reliable.

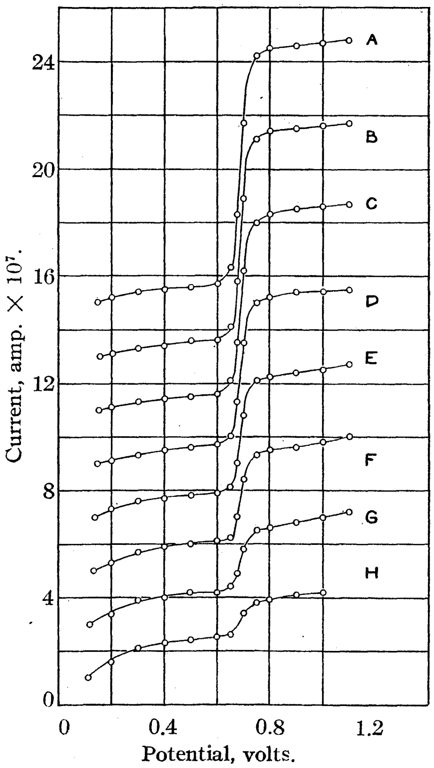

Fig. 2.—Concn. $CdCl_2$: A, 30 × 10^{-5} *M;* B, 27 × 10^{-5} *M;* C, 23 × 10^{-5} *M;* D, 19 × 10^{-5} *M;* E, 15 × 10^{-5} *M;* F, 11 × 10^{-5} *M;* G, 7.5 × 10^{-5} *M;* H, 4.0 × 10^{-5} *M.* All 0.1 *M* $BaCl_2$, 0.2% gelatin.

A cross plot of Fig. 2 is shown in Fig. 3. By inspection it was decided to select 0.6 and 0.8 v. For each concentration of cadmium the difference in current obtained at 0.8 and 0.6 v. was interpolated. These ΔI values were plotted against the

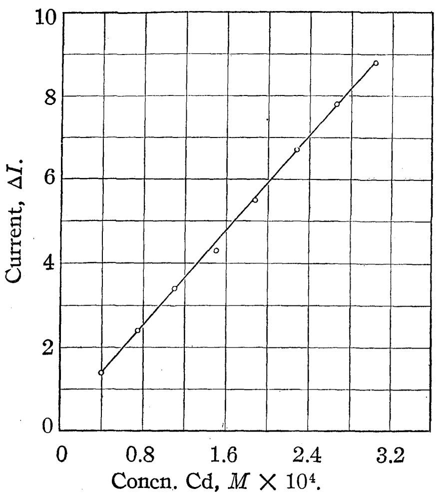

Fig. 3.—Cross plot of data in Fig. 2, illustrating linearity obtained by the increment method.

concentration of cadmium. With one exception the points lie closely on a straight line. This represents the worst condition for checking the relationship, in that considerable time elapsed in taking the whole family of curves. Succeeding runs with the simplified technique of merely measuring the respective currents for applied potentials of 0.6 and 0.8 v., amply confirmed this point.

A typical example is shown in Fig. 4. In this and all subsequent runs, a titration procedure was used to change the concentration. Specifically (Fig. 4), the electrolyte contained 0.1 M barium chloride as the indifferent electrolyte, 0.2% gelatin and to it were added from a microburet successive portions of 0.01 M cadmium chloride in 0.1 M barium chloride containing 0.2% gelatin. The final concentrations of cadmium ion were corrected for the small change in total volume.

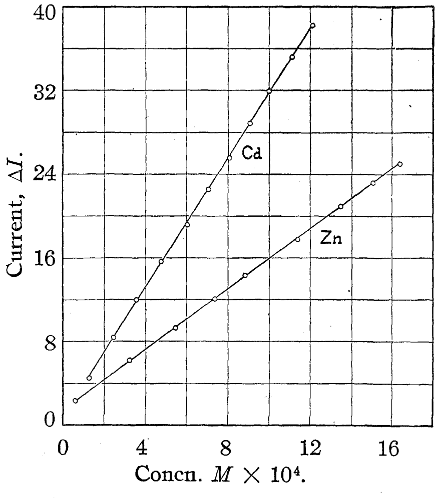

Fig. 4.—Upper curve: 0.01 M $CdCl_2$ in 0.1 M $BaCl_2$ + 0.2% gelatin titrated into 0.1 M $BaCl_2$ + 0.2% gelatin. Lower curve: 0.01 M $ZnCl_2$ in 1.0 M KOH + 0.2% gelatin titrated into 1.0 M KOH + 0.2% gelatin.

The method is quite satisfactory for traces of one ion in the presence of a large amount of other ions, provided the latter are reduced at higher potentials, and further that the interval between the respective potentials is great enough. In general the same limitations that apply to polarographic methods apply here, and certain cases can only be treated after preliminary separation or after conversion to suitable complex ions, etc.

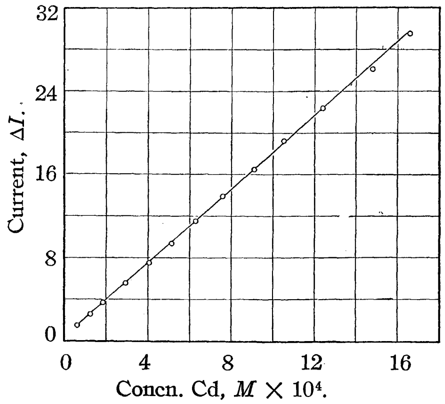

Fig. 5.—Traces of Cd in a large amount of zinc: 0.01 M $Cd(NO_3)_2$ in 0.1 M $ZnCl_2$ + 0.2% gelatin titrated into 0.1 M $ZnCl_2$ + 0.2% gelatin.

Figure 5 illustrates the results for small amounts of cadmium in the presence of a large but constant amount of zinc. It will be observed that the slopes for the ΔI–concn. curves for Cd^{++} ion in Fig. 4 and Fig. 5 are quite different. The actual slope depends upon the size of the mercury drop, the dropping rate, the concentration and nature of the indifferent electrolyte, and the galvanometer sensitivity. In a given run these factors are constant. To the extent that they might be reproduced in subsequent runs, the slopes would be correspondingly similar. For routine work this would seem to be a source of great trouble and inconvenience. This is a general limitation of all existing polarographic methods; they all assume that a preliminary calibration has been made under conditions closely approximating the intended analysis.

It is always possible, however, to include within the solution of the indifferent electrolyte a suitable "indicator" ion in known amount, preferably one which is not likely to be present in the "unknown." The indicator ion may then be used to evaluate the prevailing constants of the apparatus, thus furnishing a factor for the observed slopes.

Figure 6 shows results obtained for lead in strong alkaline solution. A complete curve for lead is shown merely to illustrate the choice of the two symmetric potentials which were selected for the analysis by the increment method. The adjoining curve shows the ΔI values as a function of lead concentration.

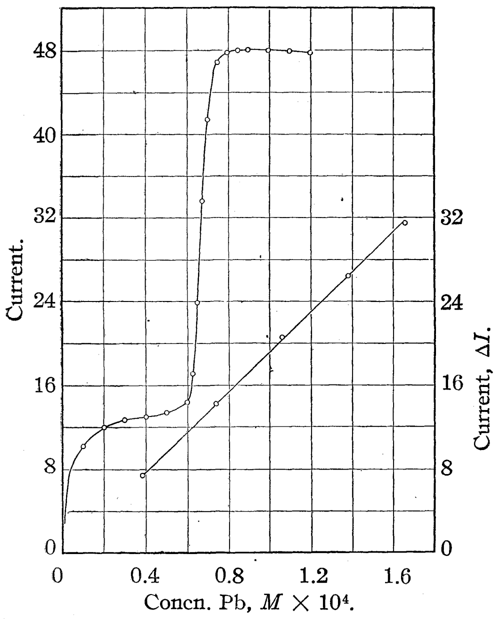

Fig. 6.—Upper curve: typical current–voltage curve for lead in alkaline solution. Lower curve: increment method, 0.01 M $Pb(NO_3)_2$ in 1.0 M KOH + 0.2% gelatin titrated into 1.0 M KOH + 0.2% gelatin.

Figure 4 is the incremental plot as a function of zinc concentration in alkaline solution and Fig. 7 shows the behavior of small amounts of lead in the presence of a large but constant amount of zinc, again in alkaline solution.

Discussion

The increment method which has been suggested for the evaluation of current–potential curves for the dropping mercury electrode has been shown to be reliable for three commonly occurring ions and mixtures of the same in neutral and alkaline solutions. In principle it is exactly similar to the practice of evaluating curves which have been recorded on a polarograph. It is extremely simple and rapid and merely assumes a reasonable degree of symmetry in the curve. Its applicability can be ascertained very quickly in any case. For cases in which the deposition potentials are too close, difficulties will be encountered to the same extent that they are in the conventional method. The use of gelatin or related substances, and the de-oxygenation by a stream of hydrogen are essential to success; the well-defined plateaus are largely dependent upon these factors.

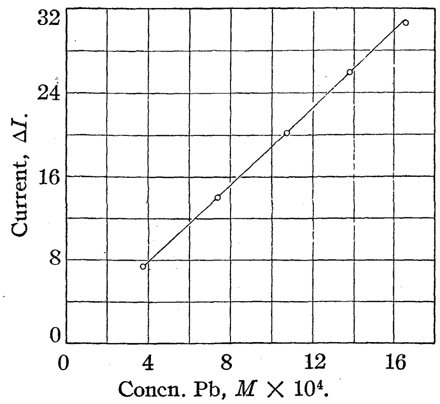

Fig. 7.—Traces of Pb in a large amount of zinc (alkaline solution): 0.01 M $Pb(NO_3)_2$ + 0.1 M $Zn(NO_3)_2$ in 1.0 M KOH + 0.2% gelatin titrated into 0.1 M $Zn(NO_3)_2$ in 1.0 M KOH + 0.2% gelatin.

For anyone slightly acquainted with electrical instruments, it will be apparent that a good potentiometer is not essential for this method. Any simple voltage divider with suitable means for adding and subtracting the required v.'s will suffice. In this general investigation we retained the more elegant arrangement because of its greater convenience and flexibility.

Summary

1. Current–potential curves may be obtained from the dropping mercury electrode with very simple equipment.

2. The marked symmetry of these curves suggests a simple increment method in which the change in current is noted for two applied potentials more or less equidistant from the characteristic "Halbwellen" potential. The current increments are a linear function of the concentration of the given ion.

3. The presence of other ions does not interfere with this relationship to any greater extent than it does with conventional polarographic methods.

4. The method has been illustrated with lead, zinc and cadmium ions, and pairs of these in neutral and alkaline solution.

The Heat Capacity of Potassium Sodium Tartrate Tetrahydrate from 15 to 340°K.[1]

By J. F. G. Hicks, Jr.,[2] and J. Gilbert Hooley[3]

The heat capacity of Rochelle salt ($KNaC_4H_4O_6·4H_2O$) in the regions about the Curie points (+24 and −18°) is of interest in correlating the remarkable dielectric properties of this compound.[4]

The present investigation was carried out at the suggestion of Professor Hans Mueller and was designed to cover not only the temperature region −30 to +30°, but the entire range at our disposal. Mueller,[5] by means of his phenomenological theory of Rochelle salt behavior, was able to calculate approximately the change in heat capacity at the upper Curie point. His figure,[6] $\Delta c \sim 1.5 \times 10^5$ ergs/cc./degree∼0.5 cal./mole/degree is rather too small to be positively shown by our measurements. The heat capacity of the salt at the upper Curie point where our experimental accuracy is 0.5%, is 92.5 cal./mole/degree. On the other hand, Kobeko and Nelidow[7] and Rusterholz[8] report a sharp discontinuity in the heat capacity–temperature curve at 26°. In both of these investigations the observed rise in heat capacity above the normal is about 5%.

Material.—The salt was of c. p. reagent quality and contained less than 0.01% impurities. It was allowed to stand, being mixed frequently, for two weeks at room temperature in a desiccator over 40 wt. per cent. sulfuric acid (vapor pressure 13.5 mm.) to ensure the presence of the single solid phase, $KNaC_4H_4O_6·4H_2O$.[9] Subsequently, it was found that the material at our disposal did not require this treatment.

Analysis for water by loss of weight in vacuum ($\sim 10^{-4}$ mm. and 180 to 200°) showed 25.52 and 25.49%; theoretical, 25.54. For purposes of analysis, we were unable to drive off more than 3.8 of the 4 moles of water by heating in a drying oven at 130° for one week, but found that conditions under which the tartrates themselves exhibited incipient decomposition were necessary to remove the last bit of water.

Analysis for sodium plus potassium by ignition and conversion to the chlorides showed the sample to be 99.98 and 100.06% Rochelle salt.

A solution containing 20.0 g. of Rochelle salt per 100.0 ml. of solution gave $[\alpha]^{25}_D$ +22.2° ml./gram decimeter.

All measurements were made on a single calorimeter loading of 88.760 g. *in vacuo*, or 0.31459 mole, the molecular weight of $KNaC_4H_4O_6·4H_2O$ taken as 282.14.

Method.—The apparatus, method of measurement, and calorimeter all have been described in an earlier paper of this series.[10] The temperatures were measured by means of the platinum–rhodium resistance thermometer-heater having the laboratory designation R197. It had been calibrated previously against a helium gas thermometer,[11] and the ice-point resistance showed no appreciable departure from its calibration value.

In loading the calorimeter, special precautions were taken to avoid any decomposition arising from heating the salt above 40°.[12] The two ring seals of soft solder joining the monel lid to the monel collars of the calorimeter barrel[10] were made while the calorimeter and weighed contents were immersed to within 15 mm. of the top in ice and water. The solder was then flowed on as rapidly as possible. In this manner, a tight seal could be made without the salt ever attaining the temperature of 15°. However, the contents could not be recovered without decomposition. Prior to the above operation, several centimeters of thin-walled nickel–silver tubing had been sealed to the bottom of the empty calorimeter and the end of the tube closed. After soldering the lid to the barrel, the free end of the tube was opened, cemented to the vacuum line, the calorimeter and its contents cooled to 80°K., and exhausted. After several flushings with pure helium, sufficient helium was finally admitted to exert a pressure of one atmosphere at room temperature. The calorimeter was allowed to warm, the tube clipped and soldered, and the unit suspended in the apparatus.

The e. m. f.'s were read on an Eppley microvolt potentiometer having a range of one-ninth volt to one microvolt on the dials.

The calorie used in this work is defined equal to 4.1833 int. joules. The absolute temperature of the ice-point is assumed to be 273.19°.

Heat Capacity Measurements.—The data are presented in chronological order in Table I. Series I has been omitted because of the large error in reproducibility of these points. The inaccura-

[12] Lowry and Morgan[9] and van Leeuwen, *Z. physik. Chem.*, **23**, 33 (1897), observed that the vapor pressures of Rochelle salt at lower temperatures were not reproducible, if at any previous time the salt had been held above 40°. Lowry and Morgan do not state the composition of the other solid phase in equilibrium with Rochelle salt and water vapor when reproducible vapor pressures are obtained.

cies were traced to a poor contact in one of the potentiometer dials and the defect was remedied before observations labelled Series II.

Before Series II, the calorimeter was held for two weeks at 80°K. and between Series II and III, the calorimeter was cooled directly to hydrogen temperatures and was below 80°K. for about two days during the course of Series IV measurements. It was then allowed to warm up slowly over a period of four days to 245°K. where it was held for six days. Series V data were then taken. Following these runs the calorimeter was immediately cooled to 240°K. and held just below 250°K. for one week after which Series VI observations were made. Thereafter, Series VII and the heat of transition were measured; these required three days. It is evident from the data that the variety of thermal treatments produced no effect on the heat capacity below 310°K.

The data of Table I are shown graphically in Fig. 1. The data of Series III and V are displaced, but all three curves are identical. The three dots are from Wilson's[13] work; his straight line is indistinguishable from that portion of our curve when the data are plotted on this scale. Figure 2 is a deviation plot with ordinate the observed heat capacity minus that calculated from the straight line, $C_p = 0.300T + 7.00$. The lengths of the vertical lines represent 0.5% of the total heat capacity at that temperature. The upper curve in Fig. 2 is the portion of the deviation curve from 240 to 300°K. replotted on a larger scale abscissa so that the experimental points can be distinguished.

The measurements of Series VI are listed in Table II and plotted in Fig. 3. They represent relative total heat capacities of the full calorimeter in the neighborhood of the lower Curie temperature. Each heating period was made through approximately a 0.3° interval with the shield sur-

rounding the calorimeter maintained within ±0.2° of the calorimeter and the temperature of both rising at the same rate. The calorimeter temperature was measured by means of the attached thermocouple, the resistance thermometer not being used as such in these measurements. The data fall on a straight line within experimental error.

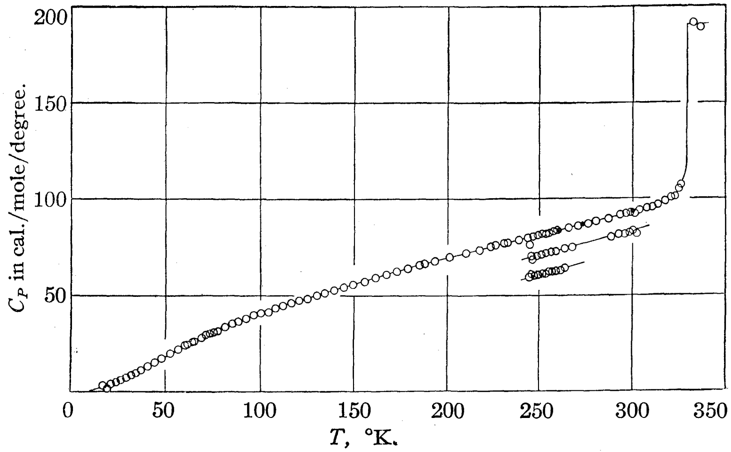

Fig. 1.—○, this research; ●, Wilson's curve.

Our data in their final form cannot be interpreted as suggesting a small anomaly at the lower Curie point as was stated previously.[14] The two low points around 245°K. and those two around 300°K. cannot be accounted for, but repeat determinations in these regions have fallen on the curve. Within experimental error, no discontinuities in the heat capacity–temperature curve are apparent at either the upper or lower Curie points. The accuracy of measurement is about that reported earlier with this apparatus,[10] *viz.*, 0.3% from 40°K. to room temperature and correspondingly lower outside this region.

Table III lists molal heat capacities at even temperatures as read from the smoothed deviation curve reproduced in Fig. 3.

Heat of Transition.—The transition (presumably decomposition into the mixed hydrated tartrates and their saturated solution) occurs sharply at 328.78°K. (55.6°C.) ±0.05°. A single measurement of the heat of transition yielded 10,218 cal. per mole absorbed. Because of the rapidly increasing slope of the curve just below 328.8°K., the method of arriving at 10,218 cal. per mole is somewhat arbitrary. However, 10,820 cal. is the measured amount of heat required to raise one mole of Rochelle salt from 328.14 to 331.62°K. In the absence of check determinations, it is difficult to assign a probable error to this figure, but it is believed to be good to ±20 cal.

Two and one-half hours were required to heat the calorimeter through the transition and during that period the maximum variation of the calorimeter thermocouple was 0.15°. At each end of the heating period, the calorimeter surface was 0.15° hotter than at the middle of this period; while during the middle two-thirds of the transition, the thermocouple did not vary by more than 0.02°.

The transition temperature has been reported by others to lie between 54 and 59°.[15]

Discussion.—The disagreement of our data with those of the European workers, and the excellent accord with Wilson's[13] work, have already been reported.[14] However, at 22°, the data of this research agree well with those of Kobeko and Nelidow[7] but are 11% lower than those of Rusterholz;[8] while our values and Wilson's[13] agree within 0.3% over the temperature interval covered by Wilson. We believe that if any discontinuities

(15) "I. C. T.," Vol. III, p. 374.

in specific heat exist below the melting point and above 15°K., they are less than 0.5%, about ten times less than the one reported by Kobeko and Nelidow and Rusterholz[8] at the upper Curie temperature. We are unable to reconcile the previous data with our own.

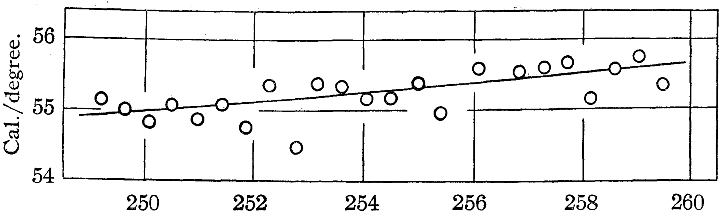

Fig. 3.—Series VI.

Additional determinations of the heat capacity between 310 and 328°K. with a wide variation in the thermal treatment of the sample would settle the question of whether or not the large slope is a characteristic of the pure salt or due to its slow decomposition. The work of Lowry and Morgan[9] and others[15] indicates decomposition, while Mueller[5] found that a Rochelle salt crystal could be annealed for several hours at 45° without impairing its "Seignette electric" properties. Because of the possibility of decomposition, the present sample was heated without repetition of measurements from 310 to 340°K. Our apparatus is not well suited to repeated loadings and maintaining the calorimeter at constant temperature in this region for periods of many hours. It is therefore not improbable that our curve between 310 and 328°K. is dependent upon the history of the sample.

A complete study of the ternary system sodium tartrate, potassium tartrate, water with special emphasis on the Rochelle salt composition would be desirable. Although it is stated in the "International Critical Tables"[15] that the transition at *ca.* 54° consists in the decomposition into sodium and potassium tartrates, both present as the dihydrates, we infer from the vapor pressure measurements undertaken by Lowry and Morgan[9] that $K_2C_4H_4O_6 \cdot {}^1/_2H_2O$ is the potassium salt to be expected.

It would be of interest to measure the heat capacities of other "Seignette electric" substances such as $NH_4H_2AsO_4$ and KH_2PO_4[14] to discover whether a marked gradual rise occurs just above the upper Curie point. In these cases no complications rising from decomposition would be encountered. It is also possible that the change in heat capacity of these salts at their Curie points would be a larger percentage of the total and therefore more susceptible to detection.

Summary

The heat capacity of Rochelle salt from 15 to 340°K. has been measured. A single measurement of the heat of transition at 328.78°K. (55.6°C.) has been made. The transition is sharp. No discontinuous changes in heat capacity were observed at the Curie points. The observations at the upper Curie point are in conflict with those reported by Kobeko and Nelidow and Rusterholz. The desirability of further investigations on Rochelle salt and other "Seignette electric" compounds has been pointed out.

Measurement of Sedimentation Velocity in Simple Air-driven Tops as Ultracentrifuges

BY JAMES W. MCBAIN AND F. A. LEYDA

The ultracentrifuge is any centrifuge of low or high power in which convection does not occur, and in which it is possible to measure any redistribution of the contents. It has become one of the most important tools for investigations in colloid systems, non-aqueous systems, immunology, biochemistry, and even in simple molecular solutions. It is therefore gratifying that simple air-driven spinning tops have now been developed as ultracentrifuges, at such low cost that they may be made available in every laboratory. The very great advantage of these opaque ultracentrifuges is that they possess no optical system and require no accessories other than those everywhere to be found. They yield accurate results. Direct analysis is made by any appropriate physical, chemical or biological method.

The time would seem to be approaching when experiments with the ultracentrifuge may be included in practical courses in biochemistry, colloid and physical chemistry.

The essential feature of our ultracentrifuges is the immobilization of the liquid, usually between horizontal surfaces placed sufficiently close together that friction inhibits convection.[1] Elsewhere[1] we have reviewed the methods adopted by other investigators and also have pointed out the great possibilities of the original one-piece spinning top.

The present communication describes a simple opaque ultracentrifuge of general applicability. Two problems had to be solved: first, the design of a liquid-tight rotor, and, second, the design of suitable immobilizing inserts to place in the rotor.

The Two-Piece Rotor with Tight Seal

The rotor, shown in Fig. 1, consists of two pieces made of 4 UMA steel, a chrome manganese alloy made by the Republic Steel Corporation. The steel is oil-quenched from 1525°F. and drawn at 850°F. after making up. The top part, A, is 32.5 mm. in outside diameter and 11.5 mm. high. Its inner well into which the various inserts for immobilization are fitted is 28 mm. in diameter and 9 mm. deep.

The shell A screws into the rotor cone B to a depth of 4 mm. Thus in the centrifugal field, when the rotor is assembled, the thinner longer annular walls of the upper part bend elastically outward, engaging still more tightly into the lower part. The angle of the cone walls is 100°. The largest diameter is 38 mm. A cylindrical space 14 mm. in diameter is cut in the bottom of the cone, with screw threads to fit onto a holding jig and handle serving as a wrench for assembling the rotor, the upper shell being held by a strap wrench, or better a split ring tightened by a screw and held in a vise. In experiments of longer duration the screw threads should be kept dry, or be oiled to avoid rusting or seizing. The flutes or grooves in the conical walls of the rotor cone against which the driving air is directed are cut with one side vertical, the other sloping, and are about 8–10 mm. long. All threads on the rotor are 32 per inch (2.54 cm.).

The degree of polish on the rotor greatly affects the speed. It was found that, after a high polish had been obtained, keeping the rotor in any convenient oil, or petroleum ether, was effective in preserving the polish. If kept in oil, the rotor was washed with petroleum ether before use. The insides of both parts of the rotor are made indifferent to the materials studied by several coats of Bakelite lacquer, applied unthinned, allowed to dry in air for forty-five minutes and then baked at 135° for thirty minutes. In applying the lacquer care must be taken that none of the lacquer touches the lower edge of the upper part of the rotor that will make contact in the joint. This Bakelite coating must be replaced whenever damaged in any way.

Assembly of the Rotor.—To achieve a seal which is always leak proof, even in petroleum systems, a pliofilm or other plastic disk C, shown in Fig. 1, a loose metal disk D, 0.020 in. (0.5 mm.) thick, and a loose metal ring E, 0.0125 in. (0.3 mm.) thick, are used. The pliofilm, 250 gage P5A supplied by Goodyear Rubber Company, or even cellophane, is initially cut slightly larger than the outer diameter of the top part of the rotor. The rotor is assembled upside down. After the insert is placed in the upper shell, the plioform disk is put in place. Then while holding the cellophane by one edge, the metal disk is gently slid over the top of it, squeezing out the excess liquid. After the metal disk is carefully centered, the cellophane is trimmed to exact size with a razor blade. The metal ring is then put in place and the rotor cone screwed on. This seal has been shown to be perfectly tight, the filled rotor weighing the same within ±0.0001 g. before and after a run of many days. One or more grooves are sometimes cut the entire way around the bottom surface of the top half of the rotor, allowing the pliofilm gasket to be forced into the depressions and possibly making the seal even more ideal.

---

Phys. Chem.*, **42**, 1063 (1938).

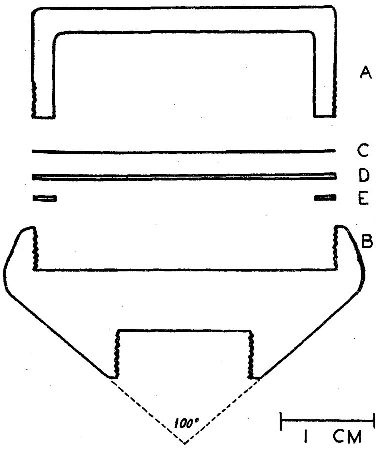

Fig. 1.—Cross section through rotor showing: A cover, B rotor cone, C film of plastic material, D loose metal disk, and E loose metal washer to facilitate slipping when assembling.

The Stator.—The stator, A, shown in Fig. 2, is made of Duralumin 17ST with a brass insert at the top edge of the inner walls for longer wear. The cone walls make an angle of 90°. The thickness of the walls may vary, being usually from about 2 to 4 mm. The air ports are so placed that they will strike at approximately the mid-point of the grooves or flutes cut in the lower part of the rotor. It is essential that the grooves do not reach the outer edge of the stator cone. The orientation of the air ports may be described by two angles, the angle with the horizontal plane through the center of the outlet of the air port and the axis of the stator being 35°, and that with the vertical plane 65°. Six to twelve of these air ports may be cut at equal distances apart around the stator.

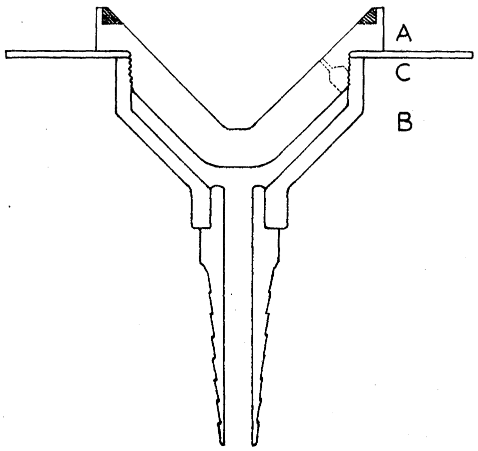

Fig. 2.—Simple form of stator showing: A the stator, B the manifold or air box, and C the steadying disk; also cross section of an air-jet and a brass inset to minimize chance wear on upper part of cone.

The stator is held in the manifold or air box B with a disk C placed in the joint. This assembly is placed in a metal guard, the disk C being steadied by sponge rubber (that used for bath mats has been found most convenient) to dampen vibration, and the central air inlet of the manifold connected to the air supply by means of heavy pressure tubing securely clamped on.

The manifold was also made of 17ST Duralumin. Its walls are about 2 mm. thick, the angle of the conical walls being 90°. The supporting disk was made of Duralumin, or Bakelite, or any convenient metal or fiber.

Whereas the stator shown in Fig. 2 is usually satisfactory, the form shown in Fig. 3 is sometimes better, especially for taller rotors, since adjustment of the air sucked in through the central tube (partly closed) with a thin rubber tube and screw clamp prevents "blooping" and sometimes increases the speed by 10% for a given pressure of driving air. The latter is fed in through the side tube.

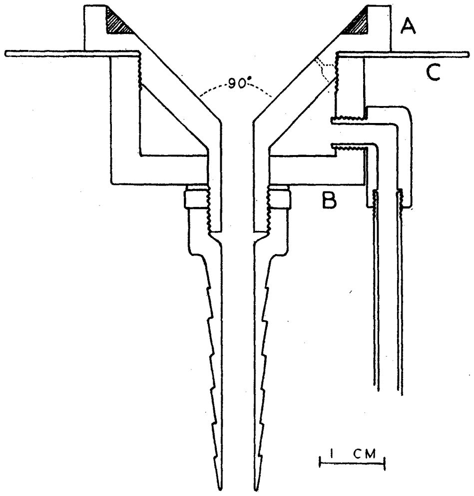

Fig. 3.—Alternative stator with adjustable central inlet for allowing air partially to relieve the vacuum below the rotor.

Temperature Control

The temperature control of these opaque ultracentrifuges is unique in that it is positive and is as accurate as a thermostat. It is that designed for the McBain–O'Sullivan transparent ultracentrifuge[2] and consists simply of passing the constant pressure driving air through a copper coil immersed in a thermostat at any desired temperature. The rotor maintains itself at the temperature of the slipstream.

The Immobilizing Inserts

While for measurement of sedimentation equilibrium it does not matter what the size or shape of the container for the liquid may be, provided that convection is suppressed and that no mixing occurs, before the samples are withdrawn for analysis, the additional conditions for sedimentation velocity are more stringent. In the first place, the radial movement of the sedimenting particles in the line of the centrifugal force must

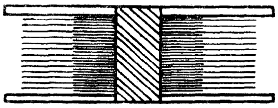

Fig. 4.—Insert consisting of piles of disks for general use in sedimentation velocity or equilibrium.

---

(2) McBain and O'Sullivan, THIS JOURNAL, **57**, 2631 (1935).

be unobstructed. This is achieved by using horizontal surfaces unobstructed over the complete range of 360°, utilizing circular disks or annular washers spaced uniformly apart by others of different diameter.

In the second place, the mechanical baffles must be so far apart that there are no wall effects upon the motion of the particle. Spaces 0.08 mm. wide are 20,000 times the diameter of the smaller proteins. Experience has shown that the sedimentation velocity observed within these spaces is the same as that given by the transparent ultracentrifuges. Much wider spacings are probably satisfactory, certainly so for the more viscous petroleum systems. Narrower spacings have not yet been studied.

A further requirement for the mechanical baffles is that they must be of material, such as plastic or metal, that will not flow in the centrifugal field. For this reason pure silver, platinum, or monel metal are satisfactory for smaller diameters, but must be replaced by stainless steel or coin silver or platinum-iridium for diameters approaching three centimeters. The insert if made of metal should be all of one kind of metal to avoid electric couples.

Insert 1, Generally Useful for Velocity or Equilibrium.—The liquid to be studied may be immobilized most simply by using as insert a central pile of disks, alternately wide and narrow with a larger disk just fitting inside the rotor at top and bottom to keep them central. A vertical axial pin runs through the central solid pile of metal, holding it together. The axial pin may be replaced by a screw permitting a change of the spacing pieces to obtain a wider sedimenting column.

This insert as used for the present measurements is shown diagrammatically in Fig. 3. The disks are made of coin silver (or stainless steel), the larger ones of metal 0.004″ (0.102 mm.) thick, the smaller ones 0.003″ (0.076 mm.) thick. The larger disk at top and bottom was of metal 0.030″ (0.762 mm.) thick. The insert is made so that it just fills the space left in the top section of the rotor, as many disks being used as can be fitted in. A convenient diameter for the larger disks is 24.6 mm. and 13.6 mm. for the smaller ones. To make it possible to obtain for analysis a sample at the bottom of the sedimenting column without disassembling the rotor, a hole 1 mm. square is cut on opposite sides of the larger top disk of the insert, matching holes being cut in the bottom disk. A sample is then taken with a hypodermic pipet or syringe after the rotor is stopped.

A convenient method of filling the baffles with the solution to be studied is to place them in a small metal case filled with solution and placed in an ordinary centrifuge for a few minutes. Preliminary work on various nonaqueous solvents and stainless steel (-18-8-) baffles has given excellent results in filling by capillarity.

Insert 2, for Monodisperse Sedimentation Equilibrium Only.—This is fully described by McBain and Tostado,[1] the immobilized sedimenting liquid lying between horizontal annular washers of coin silver spaced at uniform known distances apart by using alternately narrow and wide washers. Convection is permitted in the liquid in contact and in equilibrium with the innermost part of the sedimentation column. Analysis of this liquid before and after gives the molecular weight of any monodisperse substance. For sucrose 341 was found (theory, 342). A window[1] is a convenience but by no means a necessity. It is obvious that the same method of calculation of sedimentation equilibrium is applicable to Insert 1, which is also generally more convenient.

Insert 3, for Equilibrium Only, Including Polydisperse Systems.—This is a modification of 2, permitting analysis of the liquid above and below the sedimenting column, especially for use in polydisperse systems. Here the annular washers are all alike and are merely piled loosely upon each other. They are kept centered by perforated buttresses or bosses, or by pillars, on the container. The rotor is stopped for analysis, and the liquid from the middle and the exterior withdrawn at approximately the same rate to avoid mixing.

Other Inserts.—Several other inserts have been designed and briefly referred to,[1] and they will be described in more detail when the corresponding measurements are published.

The Sedimentation Velocity of Egg Albumin

Salt-free isoelectric egg albumin was prepared by Dr. Eloise Jameson, who followed Hopkins and Pinkers' method, using acetic instead of sulfuric acid. The material was twice crystallized and furnished us in a more or less solid form mixed with ammonium sulfate. This sample was dialyzed in running distilled water during the daytime and set aside overnight in the refrigerator in distilled water saturated with toluene. The first batch dialyzed was in the process perhaps a day and a half, at the end of which it gave no test for sulfate with barium chloride. The second batch was dialyzed in a similar manner but the process lasted about two and a half days, after which it gave no test for sulfate. The first batch tested 1.36% egg albumin as first prepared and was used only on run 1. Most of it was wasted in attempts to fill the baffles by capillarity. The second batch tested 5.4%. Portions of this were diluted and used in all the remaining runs. One portion approximately 1% was used on runs 2–8 inclusive, and another similar portion was used in runs 9–15 inclusive. All 15 runs on egg albumin were completed well within a month after the samples had been prepared.

Concentrations were determined refractometrically. The refraction of proteins (at least in the concentrations and concentration range studied) follows a linear law. The relation is given by

$$(n - n_1) = ac$$

where $(n - n_1)$ is the difference in refractive index of the solution and solvent, c is the grams of protein per 100 cc. of solution, and a the constant giving the change in refractive index of solvent on the addition of 1% protein. As to the numerical value of a for egg albumin in 0 to 2% solutions, Haas[3] obtained a value of 0.00177 ± 0.00006 with a Pulfrich refractometer. Barker[4] using a Zeiss dipping refractometer obtained a value of 0.001851 ± 0.000020, and this result was used.

In assembling, care was taken to avoid entrapping air bubbles. Any liquid that was in the threads was wiped off before the rotor cone was screwed on. The assembled rotor was weighed before and after the run. This was a check not only upon the completeness of the filling, but also a proof that no evaporation occurred. The small volume of liquid above and below the insert was included in calculations in the outer non-immobilized liquid. Whether it was immobilized or not during the run was of no consequence for it ran together with the rest of the non-immobilized liquid when the rotor was taken apart for sampling.

The rotor was started at approximately 20 lb. (1.3 atm.) pressure and gradually speeded up to about 2000 r. p. s. This is easily done within a minute. In stopping the rotor, the pressure is gradually reduced to 20 lb., after which it was allowed to remain there and by placing the fingers around the rotor and exerting a slight pressure it was stopped quite smoothly. An estimated correction for the time in starting and stopping was made. An essential detail in stopping is not to allow the last few revolutions to end too abruptly. If this happens the non-immobilized liquid may have a tendency to swirl into the immobilized space and displace some of this liquid. However, only a moderate amount of care in this respect is needed.

Method of Calculation.—In the opaque ultracentrifuge all that is measured is the number or weight of molecules or particles that pass through a given radius during a given time. In complete contrast to the requirements for the transparent ultracentrifuge, it is a matter of indifference whether or not a boundary is formed or whether it is sharp or blurred by diffusion, as long as its influence does not extend to the external radius of the immobilizing disks.

Two methods of calculation were used. The first is a relation given by Tiselius, Pedersen, and Svedberg[5] requiring a knowledge of the initial concentration of the solution.

$$s_{(\text{obsd.})} = -\frac{1}{2\,\omega^2 t}\ln\left(1 - \frac{2\Delta}{q\,x\,c_0}\right)$$

where ω = angular velocity = $2\,\pi$ (r. p. s.), t is the time in seconds, Δ is the change in amount of substance above or below the level at which the separation is made, x is the distance in centimeters of this level from the center of rotation (radius of larger disks), q is the cross-sectional area of the cell at this level, and c_0 is the original concentration within the cell. ω, t, x, and q are obtained readily from the dimensions of the baffles and observations during the run. c_0 is determined by analysis. The density of the dilute solutions used was considered unity within the experimental error. Δ in grams is then given by the following relation

$$\frac{|n_f - n_i|}{0.00185} \times \frac{V_1}{100}$$

where n_f and n_i are the refractive indices of the final and initial samples of outer liquid, respectively, and V_1 is the volume of the outer convecting liquid.

After sampling the outer liquid, the rotor was thoroughly cleaned and dried. The excess solution on the outside of the baffles was wiped off. The rotor was then reassembled and allowed to spin for a minute or so to force out the liquid in the baffles to give a second sample. Then a similar formula was applied to the change in concentration of the immobilized liquid.

The second method involves calculation of the theoretical position of the idealized boundary within the immobilized liquid, as if there were no effect of diffusion. Here the boundary will be at a position x_2 between the radii a and b of the smaller and larger disks, respectively. The average concentration c_2 as measured over the whole of the immobilized liquid, V_2, between the radii a and b is determined by direct analysis of that liquid. It is likewise determinable by analysis of the outer convective liquid c_1, of total volume V_1, for

$$c_2 = \frac{(V_1 + V_2)c_0 - V_1c_1}{V_2}$$

where c_0 is the original uniform concentration.

Since the concentration decreases with time in centrifugal sedimentation, the concentration c_t at the time t beyond the sedimenting boundary x_2 is related to the original concentration c_0 by the equation

$$c_t = \frac{a^2}{x_2^2}\,c_0$$

but the total volume of the immobilized liquid

—inner					52	.0059	3.62		3.40
15—outer[b]	1950	4140	20.5	178	258	.0056	3.69	.988	3.65
—inner					56	.0058	3.94		3.89

Average s_{20} from outer liquid 3.60

Average s_{20} from inner liquid 3.56

Average 3.58×10^{-13}

[a] No sample from inner liquid was taken. [b] In this run a metal disk was placed in the rotor to fill up the space between the top of the baffles and the pliofilm disk. In the other runs this space was taken up by solution. Volume of liquid in outer space in this run was 1.29 cc.

below the boundary is proportional to $b^2 - x_2^2$. Therefore the total amount of material present at the time t is proportional to

$$c_0(b^2 - x_2^2)\, a^2/x_2^2 = c_2(b^2 - a^2)$$

where c_2 is again the average concentration that is measured over the whole of the immobilized liquid. From this equation the position of the boundary

$$x_2 = \sqrt{b^2H/(P + H)}$$

where H is $a^2/(b^2 - a^2)$, and $P = c_2/c_0$.

The sedimentation constant

$$s = \frac{dx}{dt}\,\frac{1}{\omega^2 x} = \frac{2.303\ (\log x_2 - \log a)}{39.48\ (\text{r.p.s.})^2\ t}$$

Results were given the usual correction of multiplying the observed value of s by

$$\frac{\eta}{\eta_{20}} \times \frac{1 - \bar{V}\rho_{20}}{1 - \bar{V}\rho}$$

where η and η_{20} are the viscosities of the solvent and of pure water at the observed temperature and at 20°, respectively, and ρ and ρ_{20} are the corresponding densities. $\bar{V}$ for egg albumin is taken as 0.749.

The following are the numerical constants of the cell used: $V_1 = 1.40$ cc., $V_2 = 0.89$ cc., $a = 0.797$ cm., $b = 1.20$ cm., $H = 0.789$, $q = 2.626$ cm.^{2}.

The Results.—The results are given in Tables I and II as calculated by methods 1 and 2, respectively, for runs 11 to 15 in which temperature control was used. It should be noted that in method 1 the concentration is explicitly derived from the refractive index, whereas in method 2 the observed increment of refractive index is used directly with no reduction to concentration.

Summary

1. Simple opaque ultracentrifuges capable of measuring sedimentation velocity or equilibrium in all systems with accuracy are described. They require no optical accessories, and run at constant temperature if the driving air passes through a thermostat.

2. A simple two-piece rotor with liquid-tight seal is used with any suitable immobilizing insert of which several are described.

3. The sedimentation velocity of egg albumin in water at pH 4.63 was measured as $s_{20} = 3.56 \times 10^{-13}$ in agreement with Svedberg's most recent result[6] 3.55×10^{-13}.

The Relative Stability of Aromatic and Aliphatic Monoglycerides

BY B. F. DAUBERT AND C. G. KING

Since the early investigations of Fischer[1] and associates, it has been evident that aliphatic β-monoglycerides tend to rearrange to the corresponding α-isomers, but there has been very little information available concerning the factors that accelerate the change, or concerning the relative ease of migration of the acyl group in aromatic β-mono esters.

Helferich and Sieber[2,3] prepared the β-monobenzoate of glycerol from α,α'-di-(triphenylmethyl)-β-benzoylglycerol by treatment with hydrogen bromide in glacial acetic acid, apparently with no evidence of migration. Bergmann and Carter[4] reported no shift of the β-monobenzoate, during treatment with anhydrous hydrogen chloride for drying. Hibbert and Carter,[5] however, observed a rearrangement of the β-monobenzoate, β-*p*-bromobenzoate, and β-*p*-nitrobenzoate to the α-isomers in 0.025 *N* hydrochloric acid during hydrolysis of the benzylidene compounds in 50% alcoholic solution at 80°. Jackson and King[6] observed a complete β- to α-shift of the palmityl group at temperatures as low as $-30°$ when removing (hydrogen bromide in acetic acid) the triphenylmethyl group from the α-trityl ether of 1,2-dipalmitin. In agreement with Helferich and Sieber, however, no shift was observed when the ether group was hydrolyzed from analogous aromatic esters by the use of cold hydrogen bromide–acetic acid solution. Stimmel and King[7] found that β-monopalmitin rearranged quantitatively to the α-isomer on standing for twenty-four hours at room temperature in an alcoholic solution of 0.05 *N* hydrochloric acid or 0.1 *N* ammonium hydroxide. A number of important observations concerning changes in the molecular structure of β-glycerides have been made by Verkade and associates[8] and by Fairbourne.[9]

During the course of the present investigation, in addition to studying the β- to α-changes in molecular structure, α-monopalmitin, and glycerol α-*p*-bromobenzoate were prepared with good yields, using 1,2-benzylidene glycerol as a very satisfactory intermediate for α-ester synthesis. Since the 1,2-type compound is the dominant one obtained by direct condensation, the method is a valuable one to follow in parallel with β-glyceride syntheses.

Experimental

Preparation of Esterified Acetals.—1,3-Benzylidene glycerol was prepared essentially by the method of Hibbert and Carter,[5] and purified by crystallization first from a mixture of benzene and heptane (1:1), and then from water.

2-Palmityl-1,3-benzylidene glycerol, m. p. 63.5°, was prepared by the method of Bergmann and Carter.[4] 2-*p*-Bromobenzoyl-1,3-benzylidene glycerol, m. p. 146°, was prepared by the method of Hibbert and Carter.[5]

The benzene–heptane solution remaining after the separation of 1,3-benzylidene glycerol was treated with an excess of silver hydroxide, shaken intermittently over a period of twelve hours, and suction filtered. After removing the benzene and heptane, the oily residue was fractionally distilled at 2 mm., the 1,2-benzylidene glycerol boiling at 139–141°.

To 5 g. of 1,2-benzylidene glycerol there was added 10 cc. of dry pyridine, followed by the slow addition of 7.6 g. of palmityl chloride. After allowing the mixture to stand for thirty minutes, 400 cc. of ice water was added to remove most of the pyridine. The acetal of the β-ester separated as a white solid. After washing with ice water until free from pyridine, and drying in a vacuum desiccator, the 1-palmityl-2,3-benzylidine glycerol was crystallized from absolute alcohol, m. p. 34.5°, yield 10 g. (86%).

Anal. Calcd. for $C_{26}H_{24}O_4$: C, 74.79; H, 10.12. Found: C, 74.57, 74.48; H, 10.06, 10.08.

Bergmann and Carter prepared the same compound by condensing α-monopalmitin with benzaldehyde (m. p. 35°).

1-*p*-Bromobenzoyl-2,3-benzylidene glycerol, m. p. 73°, was prepared from 1,2-benzylidene glycerol as described by Hibbert and Carter (m. p. 72°).

α-Monopalmitin and glycerol α-*p*-bromobenzoate were prepared from the above esterified acetals by the following method, given in detail for α-monopalmitin. Concentrated hydrochloric acid (25 cc.) was added, with cooling, to 8 g. of 1-palmityl-2,3-benzylidene glycerol dissolved in 20 cc. of ether. The α-monopalmitin separated as a white solid, upon the addition of 400 cc. of ice water. It was washed free of acid, dried in a vacuum desiccator, and crystallized from ether several times, m. p. 77°; yield, 7 g. (87%).

Preparation of β-Monoglycerides.—β-*p*-Bromobenzoate and β-monopalmitin were prepared by reduction of the corresponding esterified acetals essentially by the method of Bergmann and Carter, except that in the former case ethyl acetate was used as the solvent. It was found, as reported by Stimmel and King, that 0.5 g. of palladium black was sufficient for the reduction of approximately 10 g. of the esterified acetal.

The β-*p*-bromobenzoate (new) was crystallized twice from ethyl acetate, then from a 1:1 mixture of ether and petroleum ether, as short, colorless, prismatic crystals, m. p. 95.2°; yield, 79.2%.

Anal. Calcd. for $C_{10}H_{11}O_4Br$: Br, 29.06. Found: Br, 29.01, 29.15.

Migration of Acyl Groups.—β-Monopalmitin (0.5 g.) was dissolved in 20 cc. of alcoholic hydrochloric acid of the desired normality. After standing for twenty-four hours at room temperature (22–25°), the solution was cooled until essentially complete crystallization occurred. The crystals were suction filtered and dried in a vacuum desiccator for twenty-four hours, after which the melting points were determined. The same procedure was followed with alcoholic ammonium hydroxide. The β-*p*-bromobenzoate was recovered quantitatively from ether–petroleum ether after removal of the original alcohol under reduced pressure.

To check the effect of moderate heating, melting point tubes were filled partially with β-monopalmitin and β-*p*-bromobenzoate, and the tubes placed in an oven for periods of one, twelve, and twenty-four hours at approximately 7° above their melting points. After removal from the oven all of the tubes were kept at room temperature for twelve hours to permit recrystallization. Neither compound changed sufficiently to alter the melting point within one hour, but both compounds showed a marked drop in melting point after twelve hours. Neither compound changed completely to the α-isomer on prolonged heating.

Preparation of Triglycerides.—1-*p*-Bromobenzoyl-2,3-dipalmitin, m. p. 68.8°, was prepared from palmityl chloride and the above α-*p*-bromobenzoyl ester.[5]

Anal. Calcd. for $C_{42}H_{71}O_6Br$: Br, 10.63. Found: Br, 10.59, 10.51.

The symmetrical isomer, 2-*p*-bromobenzoyl-1,3-dipalmitin, m. p. 50°, was prepared both from the symmetrical dipalmitin and from the β-*p*-bromobenzoyl ester by esterification with the corresponding acyl halide. The two isomers afford another illustration of the reversal of melting point relationship between symmetrical and unsymmetrical mixed triglycerides, in comparing aromatic esters with aliphatic esters. In our experience with the latter type, the symmetrical isomers always had the higher melting point.

Anal. Calcd. for $C_{42}H_{71}O_6Br$: Br, 10.63. Found: Br, 10.54, 10.66.

Solubilities.—It is of interest to note from the data in Table I that the aromatic and aliphatic monoglycerides are reversed in their solubility ratios for α- and β-isomers. In the former case (aromatic) the β-form is less soluble, but α-monopalmitin is less soluble than β-monopalmitin. In an earlier investigation[10] it was found that the unsymmetrical mixed triglycerides of aliphatic acids were distinctly more soluble than the higher melting symmetrical isomers.

TABLE I

SOLUBILITIES OF MONOGLYCERIDES

Compound	Solvent	Temp., ±0.01° C.	Soly., g. per 100 ml.
α-*p*-Bromobenzoate	Ether	26	3.50
β-*p*-Bromobenzoate	Ether	26	3.02
α-*p*-Bromobenzoate	Alcohol	26	16.05
β-*p*-Bromobenzoate	Alcohol	26	4.41
α-Monopalmitin	Ether	25	2.75
β-Monopalmitin	Ether	25	11.15

Summary

The use of 1,2-benzylidene glycerol as an intermediate for the synthesis of α-monoglycerides was found to be satisfactory for both aliphatic and aromatic esters.

Tenth normal hydrochloric acid and ammonium hydroxide in alcoholic solution caused both aromatic and aliphatic monoglycerides to undergo a complete shift from the beta to the alpha position in a short time at room temperature. In more dilute acid or alkali, however, a marked contrast between aromatic and aliphatic β-esters was evident: *N*/150 hydrochloric acid and *N*/80 ammonium hydroxide were about as effective upon an aliphatic ester (β-monopalmitin) as *N*/20 hydrochloric acid and *N*/15 ammonium hydroxide were upon an aromatic ester (β-*p*-bromobenzoate).

Neither aromatic nor aliphatic β-esters exhibited a shift to the α-isomer when held at 7° above their melting points for one hour in the dry state.

The symmetrical and unsymmetrical *p*-bromobenzoyldipalmitins afford another example of a mixed aromatic symmetrical isomer having a

---

(10) Robinson, Roche and King, THIS JOURNAL, **54**, 705 (1932).

lower melting point than the unsymmetrical isomer, a reversal of the relationship for analogous aliphatic esters.

The aromatic β-monoglyceride was less soluble and had a higher m. p. than the α-isomer, in contrast to the reverse relationship for α- and β-monopalmitins.

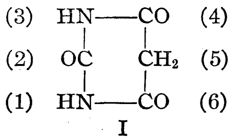
The Synthesis of Colored Derivatives of Nirvanol

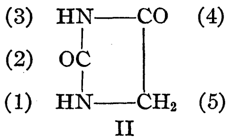
BY JAMES J. SPURLOCK[1] WITH HENRY R. HENZE

Reports are to be found in the literature of attempts to synthesize colored compounds of pronounced physiological activity. Rising[2] and collaborators have extended this type of investigation to the field of barbituric acid derivatives and have produced, from phenobarbital, mono- and dis-azo dyes in which the chromophoric grouping is attached to a phenyl radical linked to the 5-carbon atom of the barbituric acid nucleus. Buck[3] has attacked the same problem from a different angle by producing azo dyes in which the chromophore is attached to a phenyl grouping which replaces hydrogen linked to a nitrogen atom in the 1-position of the nucleus.

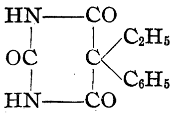
The definite structural similarity of barbituric acid (I) and hydantoin (II) is well known, as is also the close analogy in the existence of compounds derived from substitution of identical groupings for the hydrogen atoms in the 1-, 3- and 5,5-positions of both heterocycles. Likewise, in at least one instance, substitution of ethyl and phenyl for the hydrogens attached at the 5,5-positions in both nuclei has produced useful sedatives, namely, phenobarbital (III) and nirvanol (IV), respectively. It seemed of interest, therefore, to attempt to convert nirvanol into azo dyes whose pharmacological properties might be studied subsequently.



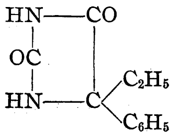
I



II



III



IV

Nirvanol was nitrated and yielded a material whose behavior during recrystallization indicated it to be a mixture, and a pure mononitro derivative was not obtained even after ten recrystallizations. Although this mixture could be reduced catalytically, fractional crystallization proved to be unsatisfactory as a means of separating the isomeric amines formed.

Since the structure of these products, obtained from nirvanol by nitration and subsequent reduction, was uncertain, it appeared best to approach this problem from simpler compounds of established structure. Following the nitration of propiophenone, the meta derivative[4] was separated readily from its alkali-insoluble isomers and converted into 5-*m*-nitrophenyl-5-ethylhydantoin by means of the procedure of Bucherer.[5] In turn, the nitrated hydantoin was reduced in the presence of the Adams catalyst, the anticipated *m*-amine crystallizing from water as a monohydrate.

The 5-*m*-aminophenyl-5-ethylhydantoin has been diazotized and coupled with β-naphthol, β-naphthylamine, dimethylaniline and G Salt, respectively, to form azo compounds. The dyes derived from β-naphthylamine and from dimethylaniline dye wool and silk from either acid or alkaline solution; that derived from 2-naphthol-6,8-disulfonic acid dyes only from acid solution. The azo derivative of β-naphthol possesses no dyeing properties from either alkaline solution or glacial acetic acid solution.

Experimental

Nitration of Phenylethylhydantoin.—Phenylethylhydantoin was prepared according to the method of Bucherer[5]

and was dissolved in concd. sulfuric acid, cooled to −10° and nitrated with fuming nitric acid. After pouring into water, separating and drying the solid was twice recrystallized from alcohol; the yield represented 84% of the theoretical. After ten additional recrystallizations, the product, still not homogeneous, was reduced catalytically and yielded a mixture which could be fractionated by tedious recrystallization. The amines could be diazotized and coupled with β-naphthol forming a mass of deep red-colored crystals; analysis of the latter indicated that the hydantoin nucleus is stable toward diazotization and coupling.

Preparation of *m*-Nitrophenyl Ethyl Ketone.—One hundred twenty cc. of concd. sulfuric acid was placed in a 500-cc. three-necked flask fitted with a mechanical stirrer, dropping funnel and thermometer so placed that the bulb was immersed in the liquid in the flask. The acid was cooled to −5° and 26.8 g. (0.20 mole) of phenyl ethyl ketone was added during a period of ten minutes. There was then added, during a period of six minutes, a cooled mixture of 15 cc. of concd. sulfuric acid and 19.65 g. (0.22 mole) of 70% nitric acid. The temperature was at no time allowed to rise above 4°, and during most of the time it remained below 0°. The mixture was stirred for five minutes and poured over about 400 g. of cracked ice in a beaker. The oily mixture was allowed to come to room temperature and was then extracted three times with ether and the extracts washed with a 5% aqueous solution of sodium bicarbonate until the aqueous layer was no longer colored. This treatment removed the alkali-soluble isomers. The ether layer was washed with water, dried and the ether removed by evaporation on a steam cone. The resulting oil was dissolved in hot benzene, and petroleum ether then added until the solution began to cloud. Six and seven-tenths grams of light yellow crystals, m. p. 97–100°, was obtained, and, in addition, 7 g. of unreacted ketone was recovered. Based on the quantity of ketone which reacted, the yield of *m*-nitrophenyl ethyl ketone was 25%. Further recrystallization gave a product melting at 99–100° (corr.) as compared with 98° reported by Comanducci and Pescitelli,[4] and 100° recorded by Barry.[6]

Preparation of 5-*m*-Nitrophenyl-5-ethylhydantoin.—This compound was prepared by the method of Bucherer,[5] *i. e.*, by the interaction of ammonium carbonate, alkali cyanide and ketone. Two grams (0.011 mole) of *m*-nitrophenyl ethyl ketone (m. p. 99–100°), 1.0 g. (0.015 mole) of potassium cyanide and 4.0 g. (0.035 mole) of ammonium carbonate were placed in a 125-cc. flask together with 20 cc. of 95% ethyl alcohol and 10 cc. of water. The flask was fitted with an air condenser and the mixture heated at a temperature of 58–60° for a period of ten hours. The flask was shaken at intervals in order to facilitate solution and reaction of the ketone. At the end of this time the condenser was removed and the temperature raised to 85° in order to decompose the excess of ammonium carbonate and to evaporate much of the alcohol. After half an hour, 15 cc. of water was added, the solution cooled, acidified with dilute hydrochloric acid and filtered. After washing with water and drying, 2.7 g. of material, melting at 210–213°, was obtained. Recrystallization from dilute alcohol yielded 2.2 g. of white crystals melting at 219–220° (corr.); this amount represents a yield of 80% of the theoretical.

Anal. Calcd. for $C_{11}H_{11}N_3O_4$: C, 53.01; H, 4.45; N, 16.86. Found: C, 53.10; H, 4.36; N, 16.94.

Preparation of 5-*m*-Aminophenyl-5-ethylhydantoin.—Four grams (0.016 mole) of 5-*m*-nitrophenyl-5-ethylhydantoin was suspended in 200 cc. of acetone and reduced catalytically in the presence of the Adams catalyst at room temperature and about one atmosphere pressure, the reduction being complete in two hours. The acetone was removed on a steam cone and the resulting residue crystallized from water, yielding 2.7 g. of light yellow crystals melting at 82–83° (corr.); on further heating the fused mass lost water at about 120°, solidified, and remelted at 165–166° (corr.).

Anal. Calcd. for $C_{11}H_{13}N_3O_2.H_2O$: C, 55.68; H, 6.37; N, 17.71. Found: C, 55.62; H, 6.54; N, 17.59.

Since the results of analysis of this compound indicate a monohydrate, the yield based on the amount of monohydrate theoretically obtainable is 71%. The hydrate was found to be somewhat unstable at room temperature and was dried *in vacuo* at 100° under 3 mm. pressure to obtain the anhydrous form; m. p. 165–166° (corr.).

Anal. Calcd. for $C_{11}H_{13}N_3O_2$: C, 60.26; H, 5.98; N, 19.17. Found: C, 60.51; H, 5.98; N, 19.13.

Preparation of 5-β-Naphthol-*m*-azophenyl-5-ethylhydantoin.—One gram (0.004 mole) of 5-*m*-aminophenyl-5-ethylhydantoin was dissolved in a mixture of 5 cc. of concd. hydrochloric acid and 50 cc. of water and cooled to −5°. Thirty-five hundredths gram (0.005 mole) of sodium nitrite was dissolved in 15 cc. of water, the solution cooled and added to that of the amine. The resulting solution of the diazonium salt was then added to 0.70 g. (0.005 mole) of β-naphthol dissolved in 100 cc. of ethyl alcohol. The mixture became light orange in color and on the addition of 10 g. of hydrated sodium acetate, dissolved in 25 cc. of water, a bulky orange-red precipitate formed. The product was allowed to stand for six hours before being filtered and recrystallized from acetic acid. The compound crystallized in bright red needles melting at 276–277° (corr.) with slight decomposition. A yield of 1.05 g., representing 67% of the theoretical, was obtained. The azo compound is very easily soluble in dilute alkali with the formation of a deep red color, is slightly soluble in glacial acetic acid, very slightly soluble in ethanol and insoluble in water.

Anal. Calcd. for $C_{21}H_{18}N_4O_3$: C, 67.37; H, 4.85; N, 14.96. Found: C, 67.31; H, 4.66; N, 15.00.

Preparation of 5-β-Naphthylamine-*m*-azophenyl-5-ethylhydantoin.—One gram (0.004 mole) of 5-*m*-amino phenyl-5-ethylhydantoin was dissolved, as before, in a solution of 5 cc. of concd. hydrochloric acid and 50 cc. of water, and cooled to −5°. There was then added the cooled solution of 0.35 g. of sodium nitrite in 20 cc. of water. After five minutes 0.3 g. of urea was added to the solution of the diazonium salt and the mixture allowed to stand for fifteen minutes, during this time some gas formation was noted. The solution was then added to one of 0.76 g. (0.005 mole) of β-naphthylamine in 100 cc. of ethyl alcohol. The solution became yellow in color, and upon the addition of 10 g. of crystalline sodium acetate, as before, an orange precipitate formed. The reaction mixture was allowed to warm slowly to room temperature and

---

[6] Barry, *Ber.*, **6**, 1007 (1873).

was heated finally at 55° for five hours, cooled and filtered. Recrystallization from ethanol and ethyl acetate resulted in 1.21 g. of orange needles, a yield of 77%. On slow heating these needles sinter at 220°, then show no further change until they melt at 247–248° (corr.). When the crystals are placed in a bath at a temperature slightly below 220°, they melt at 220–221° (corr.), resolidify and melt again at 247–248° (corr.). The azo compound is soluble in concd. hydrochloric acid to form a deep red solution and in alkali to yield a bright orange solution. Also, it is slightly soluble in ethanol and in ethyl acetate, but insoluble in water.

Anal. Calcd. for $C_{21}H_{19}N_5O_2$: C, 67.55; H, 5.13; N, 18.76. Found: C, 67.48; H, 5.33; N, 18.80.

Preparation of 5-Dimethylaniline-*m*-azophenyl-5-ethylhydantoin.—One gram (0.004 mole) of 5-*m*-aminophenyl-5-ethylhydantoin was diazotized as before, with addition to the solution of diazonium salt derived from 0.56 g. (0.46 mole) of dimethylaniline dissolved in 1 cc. of concd. hydrochloric acid and 20 cc. of water. An orange precipitate formed on the addition of 10 g. of hydrated sodium acetate. The mixture was allowed to warm to room temperature, was filtered and the solid crystallized from ethanol and then from ethyl acetate. One and eleven-hundredths grams of light orange needles melting at 233–235° was obtained, or 75% of the theoretical yield. The azo dye is soluble in dilute hydrochloric acid, somewhat less soluble in dilute alkali, slightly soluble in ethanol and ethyl acetate and insoluble in water.

Anal. Calcd. for $C_{19}H_{21}N_5O_2$: C, 64.93; H, 6.02; N, 19.93. Found: C, 64.94; H, 5.92; N, 19.89.

Preparation of 5-[2-Naphthol-6,8-disulfonic acid-*m*-azophenyl]-5-ethylhydantoin.—Three grams (0.013 mole) of 5-*m*-aminophenyl-5-ethylhydantoin was diazotized using 1 g. of sodium nitrite and to the solution was added 7 g. of G Salt dissolved in 50 cc. of water. No appreciable color change was noted until the solution was made alkaline with sodium hydroxide, after which it gradually became deep red in color. The reaction mixture was allowed to stand for twenty-four hours at 0°, when an unsuccessful attempt was made to salt-out the sodium salt through addition of sodium chloride. Six grams of barium chloride dissolved in 20 cc. of water was added and the solution allowed to stand for twenty-four hours, during which time orange material separated from solution. The solid was filtered and recrystallized from water, 4.15 g. of product being obtained. Analysis of this material, dried at room temperature, indicated it to be the octahydrated barium salt; on this basis the yield represented 40% of the theoretical.

Anal. Calcd. for $C_{21}H_{16}N_4O_9S_2Ba.8H_2O$: Ba, 16.88; S, 7.88; N, 6.89. Found: Ba, 16.91; S, 8.13; N, 7.76.

The free sulfonic acid, obtained by decomposing the barium salt with the calculated amount of sulfuric acid, is very soluble in water; the aqueous solution is colored deep red by alkali and orange by acid. Because of its extremely hygroscopic nature it was not possible to prepare the disulfonic acid in a state of analytical purity.

Summary

Colored meta-azo derivatives of nirvanol have been synthesized.

The Mutarotation of *d*-Galactose[1]

BY B. CLIFFORD HENDRICKS AND ROBERT E. RUNDLE

The mutarotation of *d*-galactose has received more attention than other sugars in recent years[2–6] due to its reaction being other than the traditional first order type.

Two groups[4,6] of investigators have developed independently what might be termed a three-sugar postulate. In the language of one group[7] "our method of analysis enables us to calculate: (1) the proportions of these sugars in the final equilibrium mixture; (2) the velocity coefficients of the four unimolecular actions by which they are converted into one another; and (3) the approximate rotatory power of the unknown intermediate sugar." The constants thus deduced by these two groups, however, do not agree. Riiber and co-workers made their deductions from dilatometer studies of *d*-galactose mutarotations while Lowry and his assistants derived theirs from polarimetric data.

One of the authors[8] has shown that the constants reported by Lowry can be used to compute the rotations of "thermal-mutarotations" and of predetermined proportions of α-*d*-galactose and β-*d*-galactose mixtures. The computed data are shown to agree with the observed values made by Isbell and Pigman[9] in a very satisfactory way while calculations made for the same conditions

using the Riiber constants do not at all follow the observed data. Neither of the two groups referred to presumes to state the nature of the third or "labile" sugar of the system.

A recent paper[10] proposes a pyranose–furanose interconversion as a part of the mechanism of the complex mutarotation of sugars. If such a transformation were essential in the rotations of a greater complexity than first order changes it would follow that tetramethyl hexoses would never show other than first order mutarotation. This paper reports a study of the mutarotation of tetramethyl *α-d*-galactopyranose.

The tetramethyl *α-d*-galactopyranose was prepared as indicated in another communication.[11] The constants of the sugar were: initial rotation $[\alpha]^{25}_{\mathrm{D}}$ 146.0, $[\alpha]^{0}_{\mathrm{D}}$ 150.5; equilibrium rotation $[\alpha]^{25}_{\mathrm{D}}$ 112.1°, $[\alpha]_{\mathrm{D}}$ 119.9°; and melting point 70.5–71.5°.

The polarimetric measurements were made with a Goerz instrument, which could be read to 0.01°, using a two-decimeter glass metal-jacketed tube. The light was from a General Electric sodium arc lamp. The temperature was controlled by pumping water from a bath maintained to a ±0.1° constancy at the higher temperature. The lower temperature was controlled by a water–alcohol mixture circulated through the tube jacket and a salt–ice bath with a temperature constancy of ±0.2°. The usual method of preparing the sugar solutions was used, care being exercised that volumetric flasks, water and tubes were at correct temperature during the time for dissolving the sugar. The "thermal mutarotation" procedure of Isbell and Pigman[12] was modified. The equilibrium solution was poured into a pre-cooled flask, placed in an ice-bath and shaken until the solution reached 0.0°, after which it was placed in a cold tube. This operation never took more than five minutes.

The authors consider the rotation velocity constant, $k_1 + k_2$, calculated as indicated elsewhere,[9] a means of recognizing departure from the first order type of mutarotation, hence its inclusion in the tables which follow.

Results listed in Tables I, II and III are representative samples of several runs for each type of experiment. Data from other experiments were consistent with those given above. The deviations of these values from the first order rate are smaller than for the unmethylated *α-d*-galactose and for the 25° temperature the deviations practically disappear. The suggested deviations of the rotation–time observations at 0.0° are supported by the "thermal mutarotation" measurements, though, unfortunately, in that study the change of rotation is so small that the experimental error is magnified in the calculated velocity constants. Even so it is relatively less

than the difference between the velocity constants of the first and second parts of the reaction and the consistent nature of this difference of the various determinations is such that the authors consider it a real difference.

The tetramethyl α-*d*-galactopyranose cannot have a furanose ring since the fourth carbon is methylated. In consequence if the differences in the mutarotation velocity constants of Tables II and III are real, then the complex mutarotation of tetramethyl α-*d*-galactose cannot require a galactofuranose as one of the sugars in the interconversion. This does not imply, however, that galactofuranose may not be involved in the complex mutarotation of unmethylated *d*-galactose.[13]

Summary

The mutarotations of solutions of tetramethyl α-*d*-galactopyranose have been studied for 25 and 0°. Velocity constants for the first part of the mutarotation at 0.0° show slightly but consistently higher values than for changes nearer the equilibrium.

"Thermal mutarotation" for tetramethyl α-*d*-galactopyranose for a 25 to 0° change has been investigated. The rotation constant, $k_1 + k_2$, is consistently larger at the first than at the last of the change by an amount which is considered in excess of the experimental error.

It is suggested that the assumed pyranose–furanose interconversion as a part of the mechanism of complex mutarotation can hardly be perfectly general.

[13] Diacetone mannose has been reported by Irvine and Skinner [*J. Chem. Soc.*, 1095 (1926)] as having a complex mutarotation. The authors repeated their work at 17° and found agreement with that report. The changes in specific rotation go from 9 to −3° back to 1°. This change hardly could be attributed to a pyranose–furanose interconversion.

Studies of Cellulose Hydrolysis by Means of Ethyl Mercaptan. III[1]

BY M. L. WOLFROM AND JOHN C. SOWDEN[2]

Previous publications[3] from this Laboratory have described a study of the course of hydrolysis of the cellulose molecule. The method consisted of allowing a solution of high viscosity cotton linters in fuming hydrochloric acid to hydrolyze at 16° and following the course of hydrolysis by mercaptalation with ethyl mercaptan at various time intervals. Sulfur analyses on the resulting mercaptalated hydrolyzed celluloses then gave an estimate of their average molecular size. Cuprammonium viscosity measurements on the non-mercaptalated hydrolyzed products, isolated after corresponding periods of hydrolysis in the fuming hydrochloric acid, were also employed to estimate the average chain lengths by application of the formula of Kraemer and Lansing.[4] A comparison of the average molecular sizes as determined by the two methods was thus available.

The studies at 16° indicated that the sulfur analytical method gave appreciably lower values for the chain lengths than those calculated from cuprammonium viscosity data, for hydrolyzed products of above 100 glucose units in size. Thus, it is of interest to study further the earlier stages of the hydrolysis, in order to determine the nature of this difference in chain lengths as calculated by the two methods for products having degrees of polymerization greater than 100 glucose units.

[4] E. O. Kraemer and W. D. Lansing, *J. Phys. Chem.*, **39**, 164 (1935).

In the work herein reported, the course of hydrolysis of the same sample of cotton linters previously studied was followed during the first eight and one-half hours in fuming hydrochloric acid at 0°. The lower temperature resulted in a much slower rate of hydrolysis than that previously observed at 16°, and the products isolated had average chain lengths in the range of 100 to 300 glucose units.

A cuprammonium viscosity measurement on a sample of our stock of high viscosity cotton linters showed that no degradation had occurred during storage. In order to assure comparable conditions in the preparation of the mercaptalated and non-mercaptalated products, a stock solution of the linters in the fuming acid was prepared at 0° and divided into two equal parts. An excess of ethyl mercaptan, to provide continuous mercaptalation of the hydrolyzed celluloses, was added to one part and the hydrolysis allowed to progress at 0°. Simultaneous removal and neutralization of samples from the two hydrolysis mixtures at various time intervals then resulted in mercaptalated and non-mercaptalated products which had been subjected to comparable hydrolytic conditions in the fuming acid.

As in the previous studies at 16°,[3] ash analyses were made on the washed products to determine their sodium chloride content. Precise sulfur analyses were then made on the mercaptalated hydrolyzed products by the Parr bomb method and the viscosities of both the mercaptalated and non-mercaptalated hydrolyzed products were determined in cuprammonium solution at a concentration of 0.1%. These data are recorded in Tables II and III. Due to the opacity of the hydrolysis mixture at 0°, it was impossible to follow the course of the hydrolysis polarimetrically. Thus, the time of addition of the fuming hydrochloric acid to the linters was taken as the zero time of the hydrolysis.

The copper numbers (Hägglund–Bertrand) of the mercaptalated and non-mercaptalated hydrolyzed celluloses were determined and are recorded in Table IV. No explanation is yet at hand for the fact that the mercaptalated products, which would be expected to have a zero copper number, exhibit a low but definite reducing power. The original cotton linters were found to have a very low reducing power, as evidenced by a copper number of approximately 0.2.

In Table I are recorded the degrees of polymerization in glucose units, calculated from cuprammonium viscosity data by the formula of Kraemer and Lansing,[4] for both the mercaptalated and non-mercaptalated hydrolyzed celluloses, and also those calculated for the mercaptalated products from sulfur analytical data. The degrees of polymerization, as calculated from viscosity data, show fair agreement, the values for the mercaptalated products tending to be approximately twenty glucose units greater than those for the non-mercaptalated products.

TABLE I

DEGREE OF POLYMERIZATION (D. P.) IN GLUCOSE UNITS OF MERCAPTALATED AND NON-MERCAPTALATED HYDROLYZED CELLULOSES CALCULATED FROM SULFUR ANALYSES AND CUPRAMMONIUM VISCOSITY DATA

Time of hydrolysis, min.[a]	Mercaptalated products D. P. by S content	Mercaptalated products D. P. by viscosity	Non-mercaptalated products D. P. by viscosity
270	190	276	260
310	148[b]	255	233
350	104	228	229
390	87	226	206
430	95	218	196
470	101[b]	204	187
510	98[b]	198	174

[a] Initial time taken as time of addition of acid to the cellulose.

[b] The results of two closely agreeing sulfur analyses (see Table II) were averaged and the D. P. calculated from this average.

The average degrees of polymerization of the mercaptalated product mixtures as calculated from their sulfur content are definitely lower than those of the corresponding non-mercaptalated products as calculated from cuprammonium viscosity data. The degree of polymerization calculated from sulfur analytical data on a nonhomogeneous mixture constitutes a number average and would thus be expected to be somewhat lower than that calculated from cuprammonium viscosity based on ultracentrifuge measurements, which represents a weight average (4). This difference will not be appreciable if the degrees of polymerization of the components of the mixture do not extend over a wide range.

In the calculation of the average degree of polymerization (D. P.) from the sulfur analyses, the assumption is made that all free reducing groups have reacted completely to form thioacetals (mercaptals). Any correction of the data for incompleteness of reaction or for the reaction resulting in the formation of thioglycosides instead of thioacetals, would lead to still lower degrees of polymerization as calculated from the sulfur content. The presence of adsorbed ethyl mercaptan would lead, however, to a calculated degree of polymerization that was too low. The absence of adsorbed ethyl mercaptan in the products analyzed was accordingly demonstrated. Several of the samples were analyzed before and after extensive drying at 56.5° in high vacuum. Also, one mercaptalated product was analyzed before and after prolonged soaking in absolute ethanol. Neither of these treatments, which would be expected to remove any adsorbed ethyl mercaptan, had any appreciable effect on the observed sulfur content.

The relationship between the degrees of polymerization by the two methods with increasing time of hydrolysis is shown in Fig. 1. The difference in the values obtained by the two methods, which was observed in the range of products of 100 to 200 glucose units in size during the previous work at 16°,[3] apparently does not tend to increase in the range of degraded celluloses from 200 to 300 glucose units in size. The nature of the curves in Fig. 1 is such that extrapolations to zero time cannot be made on the basis of the data at hand.

Experimental

Cellulose Characterization.—The degree of polymerization of our stock cotton linters[5] was redetermined by measuring the viscosity of a 0.1% solution in cuprammonium solvent and applying the formula of Kraemer and Lansing:[4]

Average time of flow, solution	402.5 sec. at 25°
Average time of flow, solvent	184.9 sec. at 25°
D. P.	2023

This compares with the values 1980 and 2008 found for the same stock in the previous work.[3]

Hydrolysis and Mercaptalation of Linters.—The cotton linters (75.0 g., moisture-free basis) in a glass-stoppered bottle at 0° were treated with fuming hydrochloric acid (1500 cc.; d^{16}_4 1.205; % HCl, approx. 41) previously cooled to 0°. The mixture was maintained at 0° with occasional shaking. After three hours the resulting opaque, homogeneous mixture was equally divided and placed in two 1-liter, 3-necked flasks at 0°, equipped for rapid mechanical stirring and for rapid removal of samples through a delivery tube. One flask contained well-purified ethyl mercaptan (100 g.) at 0° to provide continuous mercaptalation of the degraded cellulose as the hydrolysis progressed. The two mixtures were stirred rapidly and maintained at 0° throughout the duration of the hydrolysis. After two hundred and seventy minutes of hydrolysis, samples of approximately 85 cc. were withdrawn simultaneously every forty minutes from each flask. The samples were withdrawn to calibrated bottles by application of suction and immediately poured, with stirring, into separate mixtures of sodium bicarbonate (96 g.) and water (300 cc.). In this way, seven samples each of mercaptalated and non-mercaptalated hydrolyzed celluloses were obtained, the time of contact with the fuming acid varying from 270 to 510 minutes. The products were collected and washed in the manner described in our previous work.[3]

[a] See footnote *a*, Table I. [b] Calculated on vacuum-dried (63°) and sodium chloride free basis. [c] Part of product lost mechanically during washing operations.

Ash and Sulfur Analyses.—The ash content of the mercaptalated and non-mercaptalated hydrolyzed celluloses was determined by ashing 0.3- to 0.4-g. samples with 2 cc. of concentrated sulfuric acid in platinum crucibles. The results were calculated in terms of sodium chloride and are recorded in Tables II and III.

The sulfur analyses were performed by the Parr bomb method in the manner described in the previous publications.[3] In the present work, somewhat larger samples were employed for the sulfur determinations, however. Two samples of approximately 0.5 g. each, on an ash free, moisture free basis, were fused separately and then dissolved in the same solution for precipitation of the barium sulfate.

From the sulfur analyses, the degree of polymerization in glucose units was calculated from the approximation

$$\text{D. P.} = \frac{100 \times 2\text{S}}{\%\text{S} \times \text{C}_6\text{H}_{10}\text{O}_5} = \frac{40}{\%\text{S}}$$

The sulfur content of the various mercaptalated products is recorded in Table II, and the degrees of polymerization calculated from these data, in Table I.

Cuprammonium Viscosities.—The viscosities of the mercaptalated and non-mercaptalated hydrolyzed celluloses were observed in cuprammonium solution[6] at 25 ± 0.03° as described previously.[3] In all instances, a concentration of 0.1% was employed. The constants of the Ostwald type viscometer used were given in the former publications.[3]

From the viscosity measurements, the degree of polymerization in glucose units was calculated by the formula of Kraemer and Lansing.[4] The results are tabulated in Tables I, II, and III.

In order to determine the effect of marked non-homogeneity on the degree of polymerization (D. P.) as determined by cuprammonium viscosity, the following experiments were performed. A mixture consisting of 49.1% of a hydrolyzed cellulose product of observed D. P. 266 and 50.9% of observed D. P. 181 gave an observed D. P. of 226 (calcd. by weight average, 223; calcd. from theoretical sulfur content, 215). A mixture consisting of 40.8% of the hydrolyzed cellulose product of observed D. P. 266 and 59.2% anhydrous glucose gave an observed D. P. of 108 (calcd. by weight average, 109).

Copper Numbers.—The copper numbers of the mercaptalated and non-mercaptalated products were determined by the Hägglund–Bertrand[7] method. Samples of 0.3 to 0.5 g., on an ash free, moisture free basis, were employed. The results are recorded in Table IV.

The copper number of the stock cotton linters, used as starting material, was also determined, in duplicate. A copper number of approximately 0.2 was observed for the original linters.

Table IV

Copper Number[a] (Hägglund–Bertrand) of Mercaptalated and Non-mercaptalated Hydrolyzed Celluloses

Time of hydrolysis, min.[b]	Mercaptalated products, copper no.[c]	Non-mercaptalated products, copper no.[c]
0		0.2[d]
270	0.90	5.26
310	1.03	5.96
350	0.49	6.75
390	1.27	7.64
430	0.58	7.89
470	.59	7.59
510	.50	8.12

[a] Copper no. is grams of copper reduced from cupric to cuprous state by 100 g. of sample. [b] See footnote *a*, Table I. [c] Calculated to a moisture free and sodium chloride free basis. [d] Original linters.

The authors are indebted to E. I. du Pont de Nemours and Company, Inc., for the fellowship grant which made this research possible.

Summary

1. High viscosity cotton linters have been hydrolyzed with fuming hydrochloric acid at 0° in the presence of an excess of ethyl mercaptan. The resulting mixtures of mercaptalated hydrolyzed celluloses were isolated at various time

---

(6) Prepared according to the standards of the Cellulose Division of the American Chemical Society.

(7) E. Hägglund, *Cellulosechemie*, **11**, 1 (1930).

intervals during the first eight and one-half hours of the hydrolysis.

2. Corresponding non-mercaptalated hydrolyzed celluloses were prepared under exactly similar conditions, except that the ethyl mercaptan was omitted.

3. Sulfur analytical data indicated that the average degrees of polymerization of the mercaptalated products varied from 190 glucose units after 270 minutes to approximately 100 glucose units after 510 minutes.

4. The degrees of polymerization calculated, according to the formula of Kraemer and Lansing, from the cuprammonium viscosity data for the corresponding non-mercaptalated hydrolyzed celluloses were consistently higher than those calculated from the sulfur analytical data, and varied from 260 glucose units after 270 minutes to 174 glucose units after 510 minutes.

5. The mercaptalated hydrolyzed celluloses showed low but definite copper numbers, varying from 0.5 to 1.3. The non-mercaptalated celluloses had copper numbers increasing in value with increasing time of hydrolysis, and ranging from 5.3 to 8.1.

The Bitter Constituents of Navel and Valencia Oranges

BY RALPH H. HIGBY

The production of oranges in California is largely of two varieties, the Valencia, a seeded summer orange, and the Washington Navel, a seedless winter ripening variety. The Valencia and Navel are equally good for general use but the juice from this latter variety is not used extensively for canning or for the manufacture of other juice products because of the bitter taste and astringency which develops in the juice when it is allowed to stand exposed to air, or when it is pasteurized. The degree of bitterness is largely dependent upon the maturity of the fruit, most pronounced in early season, but usually disappearing entirely with warm weather in March and April. Bitterness is found also in the juice of unripe Valencia oranges, but never in fruit of this variety which has reached commercial maturity.

Although the presence of a bitter constituent in the edible portion of the Navel orange has long been recognized, no record of its isolation or identification has appeared in the literature. Naringin, the bitter glucoside of grapefruit has long been known, it is commercially available and its properties and structure are fairly well established.

The bitter substances of citrus seeds have also been investigated rather extensively. As early as 1841, Bernay[1] isolated a strongly bitter substance from the seeds of several varieties of citrus (*C. Aurantium Risso, C. Limonum Risso,* and *C. Bigardia Loisl.*) which he named limonin and erroneously thought to be an alkaloid. Since that time, various other workers, C. Schmidt,[2] Paternò and Oglialoro,[3] and Peters and Frerich,[4] have prepared this substance and made some study of its properties. In a recent publication, Koller and Czerny[5] have reported the results of a rather comprehensive investigation of limonin, from orange seeds, and have announced the isolation of a second bitter substance, from the same source, which they have named isolimonin. Shortly thereafter Feist and Schulte[6] separated what was thought to be a third bitter substance from lemon seeds, calling it citrolimonin. Similarity in equivalent weight and specific optical rotation have led Koller and Czerny[7] to believe that limonin and citrolimonin are identical despite a considerable discrepancy in the reported melting point.

As one part of a research program directed toward the commercial utilization of Navel orange juice, a study has been made of the bitter constituents of the orange, particularly those contained in the edible portion. Bitter crystalline substances have been extracted from the pulp of the Navel orange, and from both pulp and seeds of the Valencia orange. These substances have

been purified and many of their properties determined.

Experimental

Isolation and Properties of the Bitter Principle of the Navel Orange.—By shaking out portions of bitter Navel orange juice with relatively immiscible solvents it was found that the bitter constituent could be extracted in benzene, toluene, butyl or amyl alcohol, butyl or isopropyl acetate or chloroform. It was not extracted by petroleum ether, gasoline or limonene. In most cases the carotenoid pigment was extracted with the bitter. Since petroleum ether readily dissolves the pigment, extraction in benzene, and treatment with petroleum ether offered a suitable means of separation.

About 22 kg. of immature Washington Navel oranges, picked November 1st, were peeled to remove the flavedo, and the peeled fruit ground in a food chopper. The mixture of albedo, pulp and juice was covered with thiophene-free benzene, stirred thoroughly and allowed to stand for sixteen hours at room temperature. The benzene and juice were separated from the pulp by pressing, and the benzene separated from the juice by decantation. The comparatively dry pulp was reëxtracted with benzene, the benzene fractions combined, washed with water to remove acid, and filtered. After concentration to a volume of about 500 ml., the bitter substance was precipitated by the addition of three volumes of petroleum ether. The amorphous precipitate was filtered off, dissolved in a mixture of equal parts of alcohol and benzene, evaporated to small volume, and allowed to crystallize. The crystals obtained were rather large colorless needles.

Several methods of purification were used.

1. Solution in acetone and precipitation by dilution with water produced shining square plates, melting at 240–242°[8] with evolution of gas.
2. Solution in dilute alcoholic alkali and precipitation by acidification with dilute hydrochloric acid produced colorless needles, m. p. 259–261° with decomposition.
3. Solution in hot alcohol and recrystallization by partial evaporation and cooling produced shining rhombic plates, m. p. 262–264° with decomposition.

The final purification of the bulk of the material was by successive application of all three methods in the order named. Variations in the melting point with method of crystallization may be due to the presence of water of crystallization, although this is not indicated by drying the material in air for sixteen hours at 105°.

The crystals resulting from this treatment were almost completely insoluble in water, slightly soluble in alcohol and benzene, moderately soluble in chloroform and easily soluble in acetone. The taste of these crystals is not bitter due to insolubility, but when dissolved in a little alcohol and diluted with water, the solution is approximately 75% as bitter as a similar solution of quinine sulfate.

Tests on the pure substance were negative for nitrogen, halogen, sulfur, and for phenol, aldehyde and ketone groups. A negative Molisch test showed that it was not a glucoside. It reduced Fehling's solution with boiling, and formed a yellow osazone, m. p. 221–225°, indicating carbonyl groups. A negative Zeisel test showed no alkoxyl groups, and failure to brominate indicated a probable absence of aliphatic double bonds. In neutral alcohol the bitter substance was non-acidic, and not titrable with a 0.1 N sodium hydroxide in the cold. Saponification with an excess of alkali in alcoholic solution gave a typical lactone titration.

The saponification values were obtained by dissolving the substance in 25 ml. of neutral alcohol, adding 10 ml. of 0.1004 N sodium hydroxide, refluxing on a hot-plate for two hours, and then titrating the excess alkali. The refluxing was then repeated with 5 ml. additional alkali to be sure the reaction was complete. A blank determination was run in parallel. Molecular weight was calculated as two equivalents. The molecular weight was also determined from depression of the melting point, using the method of Rast, as modified by Smith and Young.[9] Optical rotation of the pure compound was measured in a 200-mm. tube containing 0.2 g. of substance made up to 25 ml. with anhydrous acetone.

Anal. Calcd. for $C_{26}H_{30}O_8$: C, 66.35; H, 6.43; O, 27.22; mol. wt., 470. Found: C, 66.62; H, 6.24; O (by diff.), 27.14; equiv. wt. (by NaOH titration), 226, 227; mol. wt. (f. p. in camphor), 467, 477. *Optical rotation:* 0.2 g. in 25 ml. of acetone in 200 mm. tube, rotation −1.784°, giving specific rotation at 22° as −111.5°. Koller and Czerny report the following values for isolimonin from orange seeds—calcd. for $C_{23}H_{28}O_7$: C, 66.31; H, 6.78; mol. wt., 416. Found: C, 65.92, 66.25; H, 6.87, 6.83. The melting point was 264° in an evacuated tube.

Lacking further information, it is impossible to state definitely that our substance is identical with the isolimonin of Koller and Czerny, but the similarity of melting point makes this strongly probable. Our own data indicate that the substance is isomeric with limonin, having the same molecular weight and empirical formula. A higher carbon content is shown than that reported by them, corresponding with the formula $C_{26}H_{30}O_8$ which Feist and Schulte have suggested for citrolimonin. The compound contains two lactone groups.

Location of the Bitter Constituent in the Fruit.—From the standpoint of commercial utilization, the location of the bitter principle in the fruit is of considerable importance. To determine this, a dissection was made of moderately green Navel oranges. Three types of tissue were carefully prepared. These were: (1) the albedo, free from flavedo, and the major veins, which lie next to the section covering; (2) center fibrovascular bundle and white material of the same nature surrounding the Navel, free from section covering; (3) section covering free from albedo.

These portions were extracted with acetone, most of the acetone boiled off, and the residue diluted with water. Slight dilution brought down a copious precipitation of hesperidin, which was filtered off, before more water was added for tasting. All three extractions were extremely bitter. It appears that the bitter principle occurs in the albedo, in the center bundle and in the veins of the carpellary membrane.

---

[8] All of the melting point determinations reported here were made in open tubes, using a 360° thermometer, calibrated for 70-mm. immersion, which had been checked and found correct at 285°.

[9] J. H. C. Smith and W. G. Young, *J. Biol. Chem.*, **75**, 289–298 (1927).

Since the juice from Navel oranges becomes bitter only after rupture of the cell structure, and then only after standing or heating, the existence of the bitter-forming substance in the juice itself is improbable. Tests were made in which the juice was extracted by burring, then screened immediately through a 70-mesh screen to remove broken cell tissue, and heated to 70° for fifteen minutes to develop the bitterness. Under these conditions the screened juice from immature fruit became slightly bitter, while samples containing pulp were intensely bitter. Apparently the momentary contact with the broken cell tissue was sufficient to extract some of the bitter-forming substance into the screened juice.

Since the juice was not bitter when first extracted, it is apparent that an easily water-soluble non-bitter parent substance must exist in the comparatively neutral albedo and section covering, which upon contact with the juice is extracted, and in this acid medium is then slowly converted to the intensely bitter lactone.

The acetone extraction of albedo from completely mature Navel oranges gave an extremely heavy yield of hesperidin, but no bitter substance. Hence, disappearance of the bitter substances in the fruit can be determined by acetone extraction of these portions. Until the pulp and albedo become free from bitterness, the immediate separation of pulp from the extracted juice is of primary importance in the production of non-bitter Navel juice.

Acid Hydrolysis of Navel Isolimonin.—One gram of the pure Navel isolimonin was dissolved in 50 ml. of acetone, 10 ml. of 6 *N* hydrochloric acid added and refluxed on the steam-bath for six hours. Lead carbonate was added to neutralize the acid, and the resulting precipitate filtered off. The acetone filtrate was evaporated to small volume, diluted with water and again heated. A crystalline precipitate came down, leaving an opalescent solution. The crystals were filtered off, and the filtrate allowed to stand. Overnight a white amorphous substance precipitated which was filtered off. Further evaporation of the filtrate and cooling gave nothing but a small additional quantity of the amorphous material.

This amorphous substance was purified by solution in benzene, and precipitation with petroleum ether, and several reprecipitations from hot water. From petroleum ether it separated in waxy lumps, and from ethyl ether by evaporation, it came out as a shining brittle brownish glass. This substance was readily soluble in alcohol and benzene, and moderately soluble in hot water, very slightly soluble in cold. From hot water it separated out upon cooling as cream colored, highly refractive globules, which, under the microscope, gave the water suspension the appearance of an oil in water emulsion. Water solutions were intensely bitter. It was distinctly more acidic than the other bitter substances, being partially titrable with 0.1 *N* sodium hydroxide in the cold. The substance recovered from water, after drying for two days at 45°, sintered with gas evolution at 139–140° to form a brownish wax, which melted at 175–177°. Titration gave an equivalent weight of 240. This figure and the melting point correspond exactly with those of hexahydrolimoninic acid, as reported by Koller and Czerny, who obtained this substance by the hydrogenation of limonin. The substance was found to be optically active, showing a specific rotation of −70° in acetone.

The crystalline substance was purified in the same manner as the Navel isolimonin. From hot alcohol it separated in colorless shining hexagonal leaflets, which melted at 292° with decomposition. From the appearance, crystalline structure, and high melting point, it was thought probable that this substance was limonin, as described by Koller and Czerny. Further identification is made in the following portion dealing with the bitter constituents of the Valencia orange.

Isolation of Bitter Substances from Valencia Oranges.—Approximately 11 kg. of green Valencia oranges were peeled to remove the flavedo, which was discarded. The fruit was then halved and burred to remove the juice, which was immediately screened to take out the pulp. Seeds were removed from the pulp by coarse screening, after which the pulp was mixed with the white albedo and ground in a food chopper. The seeds were similarly ground to an oily paste. Seeds, juice and pulp were then separately extracted with benzene, the extracts evaporated to small volume, and precipitated with petroleum ether. A good yield of an apparently amorphous white bitter substance was obtained from the pulp, a moderate yield from the seeds, but none from the juice, which yielded only a non-bitter brownish wax.

The bitter precipitates from the pulp, and from the seeds, were purified separately by the methods which were used for the purification of the Navel isolimonin. Both fractions crystallized from hot alcohol in thin hexagonal leaflets, m. p. 290° with decomposition. It was evident both from appearance and from the melting points that these two fractions were identical, and that they were also identical with the crystalline substance which had been obtained by the acid treatment of the Navel isolimonin. A mixed melting point of 291–292° for these three fractions establishes their identity beyond question. The solubility was similar to that of isolimonin, except for somewhat greater solubility in benzene. Water-alcohol solutions were intensely bitter.

Like isolimonin this substance formed water-soluble sodium salts with alcoholic sodium hydroxide, and was precipitated in its original form when the solution was acidified. Analysis of the three fractions separately showed equivalent weights by saponification of 229, 230, and 231. Determined molecular weights were 445, 449, and 468, respectively. Two lactone groups are indicated.

Limonin, as described by Koller and Czerny, crystallizes in thin shining rhombohedral leaflets, melting at 280° with decomposition. Titration gives an equivalent weight of 235, and two lactone groups are indicated. Feist and Schulte report that citrolimonin crystallizes in thin shining leaflets, m. p. 304°. From the combustion analysis the formula was calculated as $C_{26}H_{30}O_8$ (molecular weight 470), and by titration two lactone groups were indicated. It seems highly probable, as admitted by Koller and Czerny, that these investigators are dealing with the same substance.

The existence of the substance isolated by us as the major bitter constituent of the orange seed, is good evidence that it is actually limonin. This is confirmed by the crystalline form, by the melting point, which falls midway

between the temperatures reported by the above workers, and by its solubility and chemical properties.

Formation of Non-bitter Salts.—By the saponification procedure which was used for the determination of equivalent weight, all the bitter substances formed easily water-soluble non-bitter sodium salts. Acidification with dilute hydrochloric acid reprecipitated the original substance. Further experimentation showed that Navel isolimonin was capable of forming similar salts with calcium, barium or magnesium hydroxide, calcium and barium chloride, and with triethanolamine. Because of scarcity of material, limonin and hexahydrolimoninic acid were tested only with sodium hydroxide.

To determine at what *p*H values the transition from the non-bitter salt to the bitter lactone took place, several series of samples were prepared containing 10% sugar, 1% citric acid, and 0.008% of the Navel isolimonin, which had been previously treated with sodium hydroxide to convert it to its tasteless form. Various amounts of sodium hydroxide were added to neutralize a portion of the acidity in each sample, producing a series of varying *p*H. These samples were heated for one hour on the steam-bath, cooled, tasted, and *p*H values determined. Bitterness developed in all samples having a *p*H value below 6.00. A similar series prepared from the bitter lactone instead of the salt showed that an excess of alkali was necessary to convert the lactone to the tasteless salt. Repetition of these tests using calcium salts instead of sodium gave similar results.

Discussion

The comparative analytical data obtained on the various bitter substances which have been prepared in this study are shown in Table I, together with the corresponding values reported by Koller and Czerny, and by Feist and Schulte for the similar bitter substances isolated by them.

A consideration of these values leaves little doubt that the Navel bitter constituent, which we have called isolimonin, is a true isomer of the citrolimonin described by the last-named workers. This is shown by apparent identity in equivalent weight, molecular weight and empirical formula. Koller and Czerny have not yet published sufficient data regarding the isolimonin obtained by them to make it entirely certain that these two substances are the same, but agreement in melting point makes it highly probable.

Navel isolimonin is precipitated in somewhat different form by dilution of an acetone solution with water. The crystals obtained in this way have a lower melting point and apparent molecular weight than those from hot alcohol, and are probably a hydrated form of the lactone. No tests have been made to determine whether this is actually the hydroxy acid or whether the differences in melting point and apparent molecular weight are merely due to the presence of water of crystallization.

From the analytical data it seems certain that the citrolimonin of Feist and Schulte is identical with the crystalline substance which we have prepared from Valencia orange seeds, from Valencia orange pulp, and by treatment of the Navel isolimonin with dilute hydrochloric acid. Since Koller and Czerny recently have acknowledged the likelihood that the limonin isolated by them is identical with citrolimonin, advancing as evidence the fact that by titration they obtained a molecular weight of 470, which corresponds with the formula $C_{26}H_{30}O_8$ as suggested by Feist and Schulte, it seems reasonable to assume that these substances are identical. The discrepancy in melting point can be attributed to difference in method, and perhaps to the degree of purity of the material used. Koller and Czerny performed all of their melting point determinations in evacuated tubes, Feist and Schulte used the micro-melting point apparatus of Kofler, while the writer used the regular open tube method. The variation in nomenclature by these investigators is unfortunate, tending to promote confusion. For this reason, it seems logical to eliminate the name "citrolimonin," referring to this compound as limonin, as originally proposed by Bernay.

From a comparison of the physical characteristics, the melting points, and equivalent weights, there can be little doubt that the apparently amorphous substance which was obtained by the acid treatment of isolimonin is identical with the hexahydrolimonic acid which Koller and Czerny prepared by the hydrogenation of limonin. Data obtained by them indicated that this substance was formed by the addition of six hydrogen atoms and one molecule of water to the limonin molecule to give an empirical formula of $C_{23}H_{34}O_8$ for the hexahydrolimoninic acid. Accepting their revised views regarding the formula for limonin ($C_{26}H_{30}O_8$) this addition would bring the empirical formula for hexahydrolimoninic acid to $C_{26}H_{38}O_9$. This is difficult to understand, since this substance also resulted from the treatment of isolimonin with hydrochloric acid.

The relationship between these three bitter substances is not clear. Although limonin has been known and subjected to investigation for almost a century, no structural formula for the substance has as yet been advanced. Recent workers agree that the substance contains two lactone groups, and Koller and Czerny point out a probable analogy of structure with columbin, and hence with the strophanthic and crotonic substances, but this has not been definitely established.

For isolimonin Koller and Czerny have suggested a formula $C_{23}H_{28}O_7$ containing two active hydroxyl groups, and differing from limonin only in degree of hydrogenation. The substance which we have designated as Navel isolimonin, with an identical melting point, corresponds more nearly with the formula for limonin, $C_{26}H_{30}O_8$, indicating that these substances differ only through some rearrangement in the molecule. Hexahydrolimoninic acid apparently results from the splitting of one of the lactone rings and the formation of a carboxyl group. The scope of our present project does not include further investigation of the structure and relationship of these bitter substances.

It has been shown that the bitter substances of the pulp and peel of the orange are either identical with or closely related to the previously isolated bitter constituents of the seeds. In the edible portion of the fruit these substances apparently occur in easily water-soluble, non-bitter form. Hydrolysis to the bitter lactone takes place slowly in the acid juice, or in water with heating.

The nature of the non-bitter parent substance has not been investigated. Hall[10] hypothesized that hesperidin occurred in the fruit as an easily hydrolyzed complex, containing in addition glucose, and a third substance. It seems possible that this substance may be isolimonin.

In the Valencia orange the bitter-forming constituent apparently exists in less soluble form than in the Navel, since the juice, even from immature fruit, is not prone to become bitter.

It is hoped that in the near future an investigation can be made regarding the nature of the non-bitter parent substance in both Navel and Valencia oranges, its probable function in the plant, and the end-products of its natural enzymic hydrolysis.

Acknowledgment.—The writer wishes to express his appreciation to his co-workers, Dr. E. F. Bryant and Mr. R. L. Logg, for their aid in the analysis and isolation of these bitter substances.

Summary

The bitter principle of the Navel orange has been isolated and identified as isolimonin, a

---

[10] J. A. Hall, THIS JOURNAL, **47**, 1191 (1925).

previously reported constituent of orange seeds. This substance occurs in the albedo, the center fibrovascular bundle, and in the section covering of the fruit, in non-bitter water-soluble form. When these tissues are ruptured it is extracted into the juice, where it is slowly converted to the intensely bitter lactone form. It is shown that this substance has a higher molecular weight than that previously reported, corresponding to the formula $C_{26}H_{30}O_8$. It is apparently an isomer of limonin, and of citrolimonin. The probable identity of these last named substances is discussed.

Limonin, which has heretofore only been reported in the seeds of citrus fruit has been isolated also from the pulp of the Valencia orange.

Both limonin and isolimonin form non-bitter water-soluble salts with alkali and alkaline earth metals, from which they are precipitated unchanged upon acidification.

Treatment of isolimonin with dilute hydrochloric acid in acetone solution gave fractions of limonin, and of hexahydrolimoninic acid. This latter substance has been obtained previously only by the catalytic hydrogenation of limonin. It appears that limonin results from a molecular rearrangement in the isolimonin, and that hexahydrolimoninic acid is produced by the splitting of a lactone ring, to form a carboxyl group.

The Action of Chlorine Water on Some β-Amyloses

BY HARRY H. FLETCHER[1] AND T. CLINTON TAYLOR[2]

Introduction

Industrial technologists have known for over ten years that if chlorine water is mixed with a starch dispersion, the viscosity of the dispersion drops after ten to twenty minutes of treatment.[3] The appearance of this chlorine-treated starch, the optical rotation of its dispersion, and the blue color with iodine remain unchanged. Nevertheless, the viscosity drop indicates that the chlorine water probably has begun to break the starch particles into smaller ones,[4,5] although this breakdown is still in too early a stage to be detected by other means. With two exceptions, the chemical and physical nature of the action of chlorine water on starch has not been investigated. Craik[6] found that the optical rotation of a potato starch dispersion gradually increased during several days' contact with hypochlorous acid at room temperature. However, the optical rotation is not so sensitive to slight changes in the structure of the starch as is the viscosity. Recently Rassow and Lobenstein measured the viscosity decrease during the reaction between potato starch and an alkaline hypochlorite solution.[7] They noticed also that the dispersion became more acidic during the course of the reaction. This they attributed to oxidation of aldehyde groups to carboxylic acids with concurrent reduction of the hypochlorous acid to hydrochloric acid.

Rassow and Lobenstein determined the reducing power of their starch dispersions after alkaline treatment only. The work described herein extends it into acid regions. As will be shown later, the results obtained in solutions of *p*H less than 7 were, so far as we are aware, entirely new and unexpected.

Outline of Procedure

Rassow and Lobenstein used Fehling's solution to measure the reducing power of their dispersions. As this reagent is not very satisfactory for rapid analysis,[8] the recently standardized alkali-labile procedure was used in these new determinations.[9] When the hot alkaline digestion is omitted, the iodine consumption of the carbohydrate, determined and calculated in the usual manner, will be

expressed in this paper as the "initial reducing value."

Three requirements must be met if the first stages of the reaction between β-amylose (used instead of starch because of its greater homogeneity) and any desired reagent are to be followed quantitatively. (1) The reagent must act slowly; chlorine water and alkaline hypochlorite were used at 30°. (2) A simple process for stopping the reaction quickly and completely must usually be devised; such a process will be given later in this paper. (3) Methods of magnifying and estimating slight physical or chemical changes in the carbohydrate must be employed; viscosity determinations were used for following physical changes, and the estimation of the "initial reducing value" and alkali-labile value was used for magnifying chemical changes in reducing power.

Outline of Experimental Results

By these means it was found that the reducing power and viscosity changed in two distinct ways depending on the *p*H of the halogen solution.

(1) In alkaline solutions (*p*H 10 or above) the reducing power of the β-amylose decreased gradually from that of the untreated β-amylose to substantially zero after several days' contact with the hypochlorite. The viscosity was not affected.

(2) In a neutral or acid solution the reducing power and viscosity changed in an entirely different and hitherto unsuspected way. During the first few minutes after mixing any one of four β-amylose dispersions with chlorine water almost nothing appeared to happen. The quiescent period lasted for three or four hours unless a phosphate buffer was added in order to keep the *p*H near 7. In the presence of the buffer this period was shortened to two minutes. This inactive phase of the reaction was terminated in every case by a sudden, large change in the reducing power and viscosity. The reducing power, measured both as "initial reducing value" and as alkali-labile value, rose sharply. Simultaneously, the viscosity dropped markedly. Hatschek[5] has pointed out that the viscosity of highly hydrated colloidal materials, such as starch or β-amylose,[10] varies directly with particle size. Consequently, the close inverse relationship found between reducing power and viscosity indicates strongly that the sensitivity of β-amylose to chemical attack is at least partly dependent on its particle size. This point will be developed further.

After this sudden reaction was complete, the reducing power and viscosity of the unbuffered dispersions remained relatively constant throughout thirty days' further contact with chlorine water. However, the reducing power of the buffered dispersions dropped gradually toward zero just as it did in the alkaline solutions mentioned above. The viscosity likewise was unaffected.

Theory of Reaction Mechanism

These changes in reducing power and viscosity, both in alkaline and in acid solution, can most easily be understood if we accept the micellar structure of starch proposed by Meyer and Mark[11] and elaborated by Taylor and Keresztesy.[12,13]

By using this concept of the starch micelle the action of chlorine water on β-amylose in both alkaline and acid solutions can be accounted for as the effect of one or more of three reactions—oxidation, disassociation and degradation.

In alkaline medium the major reaction is the oxidation of aldehyde groups to carboxylic groups. Hatschek's correlation[5] between viscosity and particle size, mentioned previously, leads us to the conclusion that there has been little disassociation of the micelle. Otherwise the viscosity would not have been found to remain constant throughout the reaction.

In a neutral or slightly acid medium the reaction possibly begins in the same manner as in an alkaline one: *viz.*, oxidation of aldehyde groups. However, it seems necessary to postulate that the chlorine water acts in a second, and more important, manner on the β-amylose micelle. This reagent seems to catalyze the working of the water molecules between the glucoside chains, thereby swelling the micelle and putting it under strain. As long as this strain is less than that necessary to break the coördinate linkages, the micelle will remain intact. Further swelling causes the micelle to be ruptured abruptly into its constituent chains, uncovering the shielded aldehyde groups. This disassociation should, and does, cause the re-

[12] Taylor and Keresztesy, *Ind. Eng. Chem.*, **28**, 502 (1936).

[13] Throughout this paper the terms "disassociation" and "hydrolytic scission" will be used as they are by Taylor and Keresztesy. The term "degradation" will be used to refer to a shortening of the glucoside chains when we do not wish to distinguish between hydrolytic carbon–oxygen scission and carbon–carbon scission of a type similar to that proposed by Evans [*Chem. Rev.*, **6**, 28 (1929)] for the action of dilute alkali on glucose.

ducing power to rise and the viscosity to drop.

Before disassociation the micelle is probably not subject to much degradation because the most sensitive portions of the chains, the aldehyde groups and the glucoside ether linkages, are shielded from attack. However, after the sudden separation of the particle into the individual chains, degradation should proceed much more easily. The extent of degradation can be found approximately by subjecting the dispersion, after treatment with chlorine water, to the standard procedures for hydrolyzing the carbohydrate to glucose[14] and estimating it as such.[15] Although it was found that the "initial reducing value" has no simple stoichiometric relation to the β-amylose, it can be used to estimate glucose quantitatively by means of the equation

$$C_5H_{11}O_5CHO + I_2 + 3NaOH \longrightarrow C_5H_{11}O_5COONa + 2NaI + 2H_2O$$

The calculated "initial reducing value" for the glucose obtained from $(C_6H_{10}O_5)_x$ is 163.3. If we assume with Hirst[16] that the average chain contains 25 glucose residues, and that every aldehyde group is oxidized to carboxylic acid before carrying out the hydrolysis to glucose, the "initial reducing value" would drop approximately 4% to 156.8. Any experimentally obtained value much lower than this figure can be explained only by assuming either that the chain length is less than that given by Hirst or that degradation has occurred. The former assumption is considered to be untenable because Hirst's exhaustive methylation experiments prove rather conclusively that 25 is a *minimal* value which may possibly be considerably less than the true one.

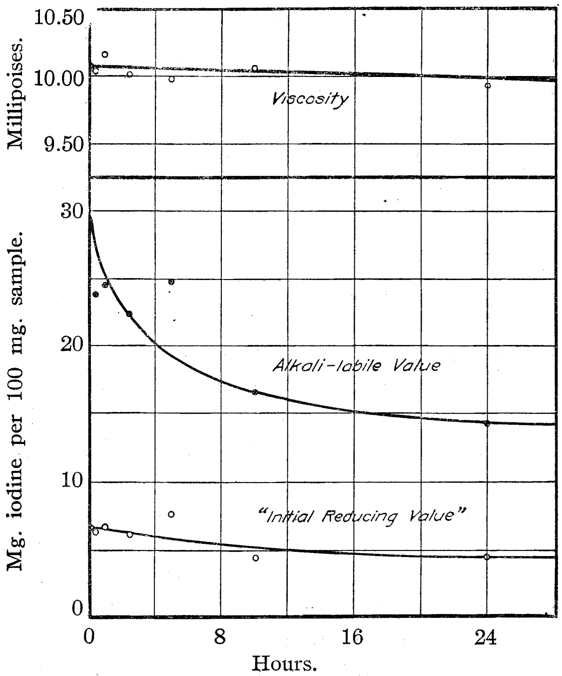

Fig. 1.—Action of alkaline hypochlorite solution on corn β-amylose ground one week.

Action of Alkaline Hypochlorite

A more detailed examination of our experimental results will now be made. In order to obtain these results it became necessary to devise a simple and rapid method of stopping all reaction at any desired time after mixing a water-dispersed β-amylose with a standardized sodium hypochlorite solution at 30°. Our method consisted in acidifying the solution with hydrochloric acid, followed by removal of most of the liberated chlorine as Cl_2 with nitrogen. The last traces of hypochlorous acid were removed from solution by reaction with ethylene, the excess of which was in its turn removed by a second addition of hydrochloric acid and nitrogen. After neutralization and dilution to standard volume the viscosity, "initial reducing value" and alkali-labile value were measured.[17]

The manner in which these three properties changed during the reaction between a sodium hypochlorite solution of *p*H greater than 13 and a dispersion of corn β-amylose ground for one week is easily seen from Fig. 1. Over thirty days' time the "initial reducing value" and the alkali-labile value dropped gradually and smoothly toward zero, while the viscosity remained constant within the limits of precision of the experiment.[18]

It should be observed that the alkali-labile value always was greater than the "initial reducing value" of the same solution. The importance of this observation will be apparent later.

On hydrolyzing[14] and estimating as glucose[15]

---

[15] Klein and Acree, *Bur. Standards J. Research*, **5**, 1063 (1930).

[16] Hirst, Plant and Wilkinson, *J. Chem. Soc.*, 2375 (1932).

[17] So far as we are aware, the reaction between hypochlorous acid and ethylene has never before been used in quantitative analysis. The function of each reagent in this process will be given under "Experimental Details."

[18] The variations in the viscosity were caused by the differences in the amount of hydrochloric acid used to stop the hypochlorite reaction. As it seemed imperative that the freed chlorine and hypochlorous acid be removed from solution as rapidly as possible in order to eliminate the possibility of their reacting with the β-amylose, the second addition of hydrochloric acid—5 cc. concd. acid—was made by graduated cylinder with no attempt at high precision. The variations of the "initial reducing value" and alkali-labile value from the smoothed curves are of the expected order of magnitude.[9]

the material remaining after reaction for thirty days at room temperature between β-amylose and hypochlorite, the "initial reducing value" was found to be 90.2. This is only 55% of that calculated for hydrolyzed $(C_6H_{10}O_5)_x$ and only 58% of that calculated for hydrolyzed $C_6H_{11}O_6\cdot(C_6H_{10}O_5)_{23}\cdot C_5H_{10}O_4\cdot COOH$, the acid we have assumed would be formed from Hirst's glucoside chain containing 25 glucose residues.[16]

Another sodium hypochlorite solution of *p*H 10 instead of *p*H 13 was mixed with aliquots of the same corn β-amylose dispersion and tested in the same way in order to find out whether this oxidation–degradation reaction required a strongly alkaline medium. The "initial reducing value," alkali-labile value and viscosity of these aliquots changed in a manner almost identical with those shown in Fig. 1, and the hydrolytic treatment indicated that degradation took place to about the same extent.

Action of Chlorine Water on β-Amyloses

However, as indicated previously, when the reaction between hypochlorite and β-amylose was carried out in a medium more acid than *p*H 7 the viscosity and reducing power changed in a very different manner. In order to study these changes in slightly acid solutions the experimental procedure was modified by bubbling chlorine gas through the dispersions for a few minutes each day until the reaction was to be quenched. The rest of the procedure was identical with that described above.

The marked discontinuity of the viscosity, "initial reducing value" and alkali-labile value of a dispersion of corn β-amylose (ground for two weeks) is strikingly shown in Fig. 2. It will be observed that a high "initial reducing value" is always associated with a high alkali-labile value and a low viscosity, showing that there is a close correlation between reducing power and particle size. It is impossible to show in Fig. 2 the course of the reaction after the first seven hours' contact between chlorine water and carbohydrate. The viscosity and "initial reducing value" were found to remain constant within the limits of the precision of the measurement up to thirty days' reaction time, the final values being, respectively, 38.6 mg. of iodine per 100 mg. of sample and 8.97 millipoises. The alkali-labile value dropped gradually from its peak of 59.5 to a final value of 38.7.

As it might be thought that the absence of sodium ion during this reaction of β-amylose with chlorine water was responsible for the great differences between Figs. 1 and 2 this experiment in acid medium was repeated in the presence of the same amount of sodium ion, as sodium chloride, which was used in the solutions of *p*H 13. The viscosity and reducing power curves so obtained were similar to those of Fig. 2. The salt raised the viscosity of all the solutions to the same extent.

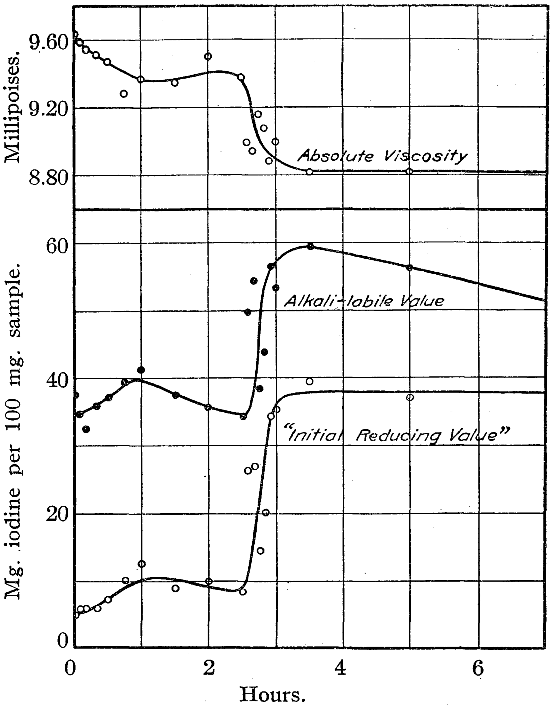

Fig. 2.—Action of chlorine water on corn β-amylose ground two weeks.

A dispersion of β-amylose from corn starch ground for one week behaved in a manner almost identical with that of the dispersion ground for two weeks except that the sudden change in magnitude of the viscosity and reducing power occurred one hour later—between two hundred and ten and two hundred and forty minutes after beginning to bubble chlorine into the dispersion. This agrees with the observation[12] that grinding of starch for a time longer than one week continues to break it down in some way not yet well understood.

Dispersions of β-amylose from tapioca and potato starches ground two weeks were also subjected to the action of chlorine water under the same conditions. The tapioca β-amylose behaved in the same manner as the corn β-amylose shown in Fig. 2. The potato β-amylose had a somewhat higher "initial reducing value" and alkali-labile value, and lower viscosity before treatment with chlorine water than the corn or tapioca. Furthermore, during the course of the reaction of chlorine water on potato β-amylose these three properties changed less abruptly and less in magnitude.

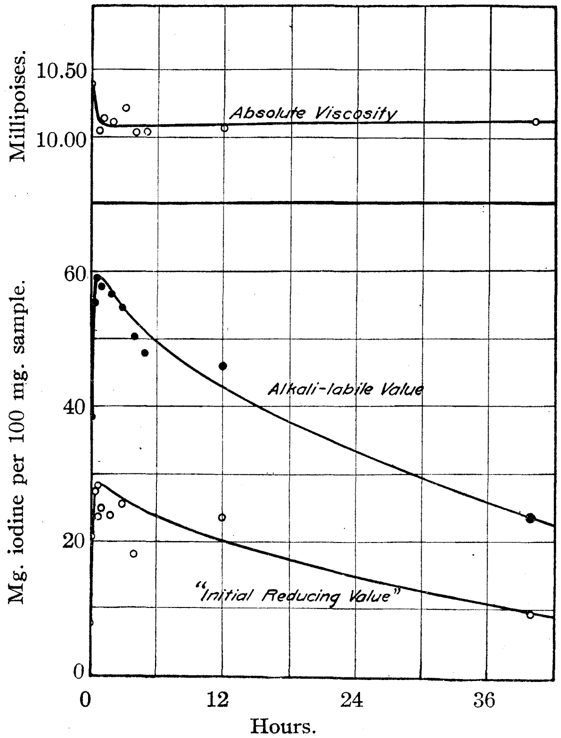

Fig. 3.—Action of chlorine water buffered by potassium phosphate on corn β-amylose ground one week.

As all four of the β-amylose dispersions mentioned above had considerable reducing power even after thirty days of contact with chlorine water—both the "initial reducing value" and alkali-labile value were between 30 and 40 in every case—it was thought probable that one or more of the products had stopped all reaction. Bunzel and Mathews[19] have shown that hydrogen ion has exactly this effect on the reaction between glucose and chlorine water. Therefore, a potassium phosphate buffer of *p*H 7 was mixed with a β-amylose dispersion from corn starch ground for one week. Table I shows to what extent the buffer held the *p*H constant. Solubility limitations forbade the use of more buffer.

TABLE I

*p*H OF β-AMYLOSE AND BUFFER SOLUTIONS AFTER MIXING WITH CHLORINE

Material	No chlorine	Chlorine for 1 hour	Chlorine for 5 hours	Chlorine for 40 hours
β-Amylose dispersion[a]	7.2	1.50	1.06	..
β-Amylose dispersion + buffer[b]	...	2.49	..	2.08

[a] From cornstarch ground for one week, 4.000% by weight. [b] Another 25.00-cc. aliquot of the same β-amylose to which had been added 4.36 g. of K_2HPO_4 and 1.22 g. of KH_2PO_4. A solution of the same quantities of these two salts in 25.00 cc. of distilled water had a *p*H of 6.92.

However, even this relatively minor change in *p*H between the buffered and unbuffered solutions of corn β-amylose was sufficient to accelerate the chlorine water reaction tremendously and to drive it practically to completion in so far as reducing power is a criterion.[20] A comparison of Figs. 3 and 2 indicates this difference in a striking manner. (The change of grinding time of the corn starch from two weeks to one is insignificant as regards the contrast between Figs. 2 and 3.) The "initial reducing value" and alkali-labile value continued to drop, although less rapidly because the hydrogen ion concentration was rising, during reaction periods longer than forty hours, the final point shown in Fig. 3. The viscosity remained almost constant. The three values after six hundred seventy-two hours of reaction time were, respectively, 3.0 and 9.7 mg. of iodine per 100 mg. sample and 9.95 millipoises. Treatment of a portion of this sample with hot hydrochloric acid did not change the reducing values, indicating that degradation had been so complete that all the chains had been broken into fragments of less than six carbons.

It is not possible to say whether this degradation is hydrolytic or not. However, we tend toward the view that it proceeds largely by scission of carbon–carbon bonds, perhaps by some mechanism related to the "enolization" breakdown of glucose in the presence of alkali as postulated by Evans.[21] We feel that the observation that all the reactions between glucose[19] or β-amylose and chlorine water are decreased in velocity by the presence of acid lends weight to this viewpoint. Further-

---

(19) (a) Bunzel and Mathews, THIS JOURNAL, **31**, 464 (1909); (b) Bunzel, *J. Biol. Chem.*, **7**, 157 (1909).

(20) There is no indication that these changes in reaction rate and degree of conversion to material without reducing power are due *solely* to the action of the phosphate *as a buffer*. Phosphate *ion* greatly catalyzes the breakdown of glucose by chlorine water or hypochlorite to products containing less than six carbons at the expense of the formation of gluconic acid [Bleyer and Braun, *Biochem. Z.*, **180**, 105 (1927); **183**, 310 (1927); **199**, 186 (1928); Bernhauer and Schön, *ibid.*, **202**, 159 (1928)]. Apparently no one has heretofore considered the possibility of an analogous action of phosphate *ion* on starch or β-amylose.

(21) Evans, *Chem. Rev.*, **6**, 28 (1929).

more, Table II shows that hydrochloric acid had almost no effect on the "initial reducing value" and alkali-labile value of a dispersion of corn β-amylose ground for two weeks. This observation confirms that of Daish.[22]

Action of Chlorine Water on Glucose

The conclusions already drawn concerning the mechanism of the reaction between β-amylose and chlorine water from the data presented above were deduced in part from a similar investigation of the reaction between glucose and chlorine water. It has been well established[23] that glucose is attacked in two distinct ways by chlorine or bromine water, dependent on the presence or absence of other substances. In the presence of a weakly alkaline buffer, such as barium carbonate, glucose is oxidized chiefly to gluconic acid without much carbon–carbon scission.[24] In the presence of a strong base or phosphate ion, and in the absence of any reagent other than the chlorine water itself, glucose is degraded completely into one- and two-carbon acids.[19,23]

From Fig. 4 it will be observed that glucose is converted gradually to products without reducing power, as indicated by the drop in the "initial reducing value" and alkali-labile value. The viscosity remained almost constant. Superficially these curves are similar to those of Fig. 1, but there is one fundamental difference. The "initial reducing value" of the glucose solutions is always *higher* than the corresponding alkali-labile value, whereas the "initial reducing value" of each β-amylose solution is always *lower* than the corresponding alkali-labile value. This agrees with previous work[14b] and indicates that the material present after treatment of β-amylose with alkaline hypochlorite or chlorine water cannot be glucose. Due to lack of space, Fig. 4 does not show the course of the reaction beyond the first seven hours with chlorine water. The "initial reducing value" and alkali-labile value continued to drop, although more slowly, because, as already mentioned, the rising concentration of hydrogen ion tends to stop all reaction. The viscosity showed no trend. The final values after thirty days of treatment were: "initial reducing value" 20.9 mg. iodine per 100 mg. sample, alkali-labile value 21.6, and viscosity 8.73 millipoises. The possibly fortuitous identity of the "initial reducing value" and the alkali-labile value suggests that there may be some close connection between the mechanism of the chlorine water reaction on glucose (or possibly β-amylose) and the mechanism of the alkali-labile digestion. This possibility was not investigated.

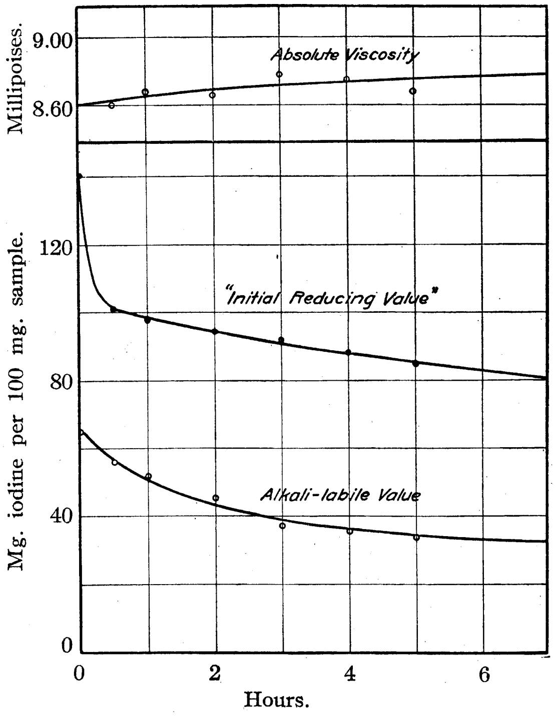

Fig. 4.—Action of chlorine water on glucose.

It was pointed out above that other workers have found that gluconic acid is not formed to any extent from glucose by chlorine water in the absence of other reagents. Table III substantiates this observation to the extent that it indicates that gluconic acid, if formed at all, is attacked in its turn. No attempt was made to follow this investigation further.

TABLE III

ACTION OF CHLORINE WATER ON *d*-GLUCONIC ACID[a]

Treatment	"Initial reducing value" mg. iodine per 100 mg. sample	Alkali-labile value mg. iodine per 100 mg. sample
None	1.5	1.8
2.5 hours chlorine water at 30°	29.1	19.6
25.0 hours chlorine water at room temperature	25.9	20.8

[a] Prepared according to the directions of Isbell and Frush [*Bur. Standards J. Research,* **11,** 649 (1933)], seeding with crystals furnished by Dr. Isbell; m. p. 125.7°, corr. It was dissolved in distilled water in a concentration of 4.000 g. per 100 cc. of solution just before use.

Experimental Details

Commercial whole starches were ground in a ball mill[25] for the designated periods of time and then dispersed in hot distilled water. The α-amylose was removed by electrophoretic separation,[26] using platinum electrodes. Each dispersion was made up to 4.000 ± 0.005 g. per 100 cc. of solution (determined by evaporating 50-cc. samples to dryness at 80°, followed by three hours at 100° or to constant weight). Toluene was added to prevent bacterial action.

For each determination 25.00 ± 0.02 cc. of the dispersion, free from toluene droplets, was pipetted into a 250-cc. Drexel tall form gas wash bottle modified by sealing a tube containing glass beads onto the outlet in place of the regular exit tube to reduce loss by spattering to a negligible amount. All reactions lasting less than eight hours were carried out in a water-bath kept at 30.00 ± 0.03°. Reactions of longer duration were done at room temperature in the dark. Chlorine was bubbled through the dispersion for forty minutes[27] at 0.75 liter per minute (N. T. P.). More chlorine was added from time to time to be sure that an excess was always present. The reaction[27] was stopped by the following procedure:

Operation	Rate of bubbling in liters per minute (N. T. P.)	Operation time, min.
Nitrogen cylinder connected	...	0.25
Nitrogen (A. R. Co.) bubbled	2.0	2.0
Cylinders interchanged	...	0.25
Ethylene (Ohio Chem. Co. anaesthesia) bubbled	1.6	6.0
Cylinders interchanged and 5.0 cc. concd. HCl added	...	0.5
Nitrogen bubbled	2.0	30.0
Total quenching time 39.0 minutes (stop watch)		

The dispersion was then neutralized to phenolphthalein (0.05% in 50% synthetic methanol) as quickly as possible with almost saturated sodium hydroxide solution, nitrazine yellow[28] added and neutralization completed with 0.1 *M* hydrochloric acid.[29] The solution was then made up to 100.0 cc., protected against bacteria with two drops of toluene, and kept in glass-stoppered bottles for analysis.

The alkaline hypochlorite solutions were made as follows: A. Fifty grams of sodium hydroxide in 250 cc. of distilled water was treated with excess chlorine with chilling, and then 20 g. more sodium hydroxide was added. The solution was diluted to 600 cc. and kept in a "Nonsol" bottle in the ice-box until used. Available chlorine—4.33 g. Cl/100 cc. solution[30]; *p*H—above 13 (with La-Motte Purple indicator).

B. Eighteen grams of sodium hydroxide and 40 g. of anhydrous sodium carbonate in 400 cc. of distilled water were partly neutralized by 20 g. of chlorine with chilling. The solution was made up to 500 cc. and handled like "A." Available chlorine—3.20 g. Cl/100 cc. solution. *p*H—9.7 (corrected for the effect of the potassium ion on the glass electrode).

5.00 cc. of one of these two hypochlorite solutions was added to the β-amylose dispersion by pipet. To stop the reaction 2.0 cc. of concentrated hydrochloric acid was added just before beginning the nitrogen–ethylene procedure.

The viscosity was measured with an Ostwald viscometer having a time of outflow for distilled water of sixty to sixty-five seconds at 30.00 ± 0.03°. Each viscosity figure is the average of those obtained on at least two aliquots from the same sample. Each aliquot was run through the viscometer 5 or 6 times, a. d. 0.5–1.0%. The average readings of the two aliquots were within 2% of each other. The density determinations were made as directed by Findlay,[31] using a pycnometer containing about 7 cc. of solution. Weighings were made to the nearest milligram, corrected for the buoyancy of air.

The alkali-labile determinations[32] were made by the standard method[9] except for two minor changes. (1) 5.00-cc. aliquots of the carbohydrate solution (1.000 g. carbohydrate per 100 cc. solution) were pipetted into test-tubes with 5.00 cc. of standardized 0.2 *N* sodium hydroxide. (2) During the first ten minutes of the alkaline digestion in boiling water the corks were removed from the test-tubes to allow the remaining ethylene or other volatile reducing material to steam off. This procedure gave a smaller and more reproducible alkali-labile value for the blank determinations, and had no effect on the value for untreated β-amylose.

(25) Taylor and Beckmann, THIS JOURNAL, **51,** 294 (1929).

(26) Taylor and Iddles, *Ind. Eng. Chem.,* **18,** 713 (1926).

(27) Reaction time is the period from the beginning of chlorine or hypochlorite addition to the beginning of the quenching process. In some cases it is less than forty minutes. Nitrogen alone will not remove all of the chlorine (hypochlorite), giving low reducing values. If the hydrochloric acid is not added the ethylene will not be completely removed by the nitrogen in any reasonable length of time, giving high and less reproducible reducing values.

(28) Wenker, *Ind. Eng. Chem.,* **26,** 350 (1934).

(29) If the latter indicator is added earlier it will be inactivated at the point where the concentrated alkali strikes the solution. Even without an indicator the solution can be approximately neutralized because it turns darker yellow rather suddenly when made alkaline. This color change is reversible in acid.

(31) Findlay, "Practical Physical Chemistry," 6th ed., Longmans, Green and Co., New York, 1935, p. 72.

(32) As the ordinary determination of the alkali-labile value, in which 50-mg. samples of the starch or β-amylose are weighed into the test-tubes, does not take into account the water content of 8–10% in most starches the values for untreated β-amyloses reported in this paper are approximately 10% higher than comparable ones reported earlier.[9]

The following blank values were subtracted from the observed reducing values to correct for the non-removable reducing material introduced by the nitrogen–ethylene quenching process.

Solution	"Initial reducing value," mg. iodine/100 mg. sample	Alkali-labile value, mg. iodine/100 mg. sample
Unbuffered chlorine water	0.02 ± 0.01	0.08 ± 0.02
Chlorine water buffered by phosphate	0.04 ± 0.01	0.05 ± 0.01
Alkaline hypochlorite solution	0.02 ± 0.01	0.08 ± 0.01

The hydrolysis of β-amylose dispersions was carried out as follows: 5.00 cc. of the chlorine-treated solution containing 1.000 g. of carbohydrate per 100 cc. of solution of *p*H 7 were pipetted into a Pyrex test-tube and mixed with 5 cc. of 2 *M* hydrochloric acid. The mixture was heated in a boiling water-bath for thirty-five minutes, cooled, almost neutralized with almost saturated sodium hydroxide solution and accurately neutralized with 0.1 *N* alkali to nitrazine yellow. The "initial reducing value" was then determined as usual.

Acknowledgment.—The authors wish to thank Prof. J. M. Nelson, Dr. A. F. Knoll and Dr. C. O. Beckmann for their valuable assistance in preparing this paper. They are grateful also to Dr. H. B. Hardt for carrying out the *p*H measurements, using the glass electrode circuit of Ellis and Kiehl.[33]

Summary

1. The action of chlorine water and of alkaline hypochlorite on β-amylose has been followed quantitatively throughout its course at room temperature by measurement of the reducing power and viscosity of the β-amylose.

2. In alkaline medium the reaction is primarily an oxidation of the aldehyde groups at the ends of the glucoside chains, but is accompanied by some disintegration of the carbohydrate.

3. In acid medium the reaction proceeds differently. After a short time during which no apparent reaction occurs there is a sudden rise in reducing power and simultaneous drop in viscosity. If the acid generated during the reaction is neutralized this abrupt reaction is followed gradually by a complete breakdown of the carbohydrate to products without reducing action toward alkaline hypoiodite reagent.

4. These changes in the reducing power and viscosity can be explained easily by assuming that β-amylose exists in the form of the micelle postulated by Meyer and Mark.

5. A rapid method for the quantitative removal of hypochlorous acid from aqueous solutions has been described.

Nitrogen Compounds from Petroleum Distillates. XII. Fractional Sulfiting of Bases and Fractional Degassing of their Acid Sulfites[1,2]

BY STILES M. ROBERTS AND J. R. BAILEY

Introduction

It is well known that acid sulfites of organic nitrogen bases dissociate on heating their aqueous solutions into base, sulfur dioxide and water.

$$\text{Base } H_2SO_3 \longrightarrow \text{Base} + SO_2 + H_2O$$

In this paper, there is described how, by employing the velocity of dissociation of acid sulfites at variable temperature levels, a process of "Fractional Degassing" has been developed which can be used to advantage in resolution or organic nitrogen base mixtures into component types. This procedure is applicable especially to petroleum and coal tar base fractions.

As an experimental background for the process, a crude fraction of kero bases (kerosene bases) in the 270–280° boiling range was selected. Here have been isolated previously 2,3- and 2,4-dimethylquinoline,[3] 2,3,8-trimethylquinoline,[4] 2,4,-8-trimethylquinoline,[5] and a $C_{16}H_{25}N$ naphthenic base.[6]

The 270–280° fraction of kero bases may be arranged in three different types.

---

A	B	C
Aromatics Two di- and two trimethylquinolines	A $C_{16}H_{25}N$ base, probably of naphthenic structure	A complex mixture of unknown composition and representing about 70% of this fraction

The velocities of degassing at 33° of the A, B and C components are in the approximate order of 1:9:30. After degassing had practically ceased at this temperature level, it was continued by progressively raising the temperature of the sulfite brine. Around 80° evolution of sulfur dioxide stopped abruptly, although it was known that the component base acid sulfites degas readily at this temperature. The inhibition to degassing was revealed in that qualitative tests were negative for *sulfites* and positive for *sulfates*. This observation suggested that the oxidizing effect of aeration could be circumvented by carrying out degassing with the aid of inert gases such as nitrogen, carbon dioxide or natural gas. This forecast has been confirmed experimentally.

Fractional sulfiting, as shown in the Experimental Part, is comparable in efficiency to degassing and was tried on the same material as was used in the latter process. Since a combination of the two methods involves the *use* of sulfur dioxide in the first phase and its *recovery* in the second phase, an economical and practical cyclic method of resolution of base mixtures, without any consumption of chemicals, is presented.

Our results and the results of Axe and Bailey (see following paper) emphasize how cumulative extraction[5] supplements in a favorable way sulfiting and degassing in processing petroleum base fractions of straight-run distillates.

Experimental Part

Degassing Acid Sulfites of the 270–280° Kero Base Fraction.—Into a mixture of 1 liter of bases and 3 liters of water sulfur dioxide is led until complete solution results. Through this solution cooled to 20°, air is passed at approximately 0.5 liter per minute until evolution of sulfur dioxide practically ceases. The bases which layer out as a supernatant oil were withdrawn in seven fractions ranging from 20 to 147 cc., as shown in Table I. The degassing proceeded rapidly for some time and then slowed down progressively, as can be inferred from twenty-four hours being required for the separation of fraction 7 (20 cc.). Fraction 8 required three hours of degassing at 50° and fraction 9 required six hours at 80° when, due to a complete sulfite–sulfate conversion, the evolution of sulfur dioxide ceased.

TABLE I

DEGASSING OF BASES OF 270–280° BOILING RANGE

Fraction	Temp. of brine, °C.	Vol., cc.	n^{25}_{D}
1	20	59	1.5132
2	20	105	1.5183
3	20	70	1.5214
4	20	147	1.5258
5	20	40	1.5263
6	20	32	1.5276
7	20	20	1.5281
8	50	96	1.5277
9	80	18	1.5281
Residual bases from sulfates		413	1.5303
Original bases		1000	1.5267

From fraction 9 there separated 2 g. of a crystalline salt which yielded, on treatment with sodium hydroxide, 2,3,8-trimethylquinoline. The latter was identified by the usual comparison with an authentic sample.

The bases (413 cc.) recovered from the residual sulfate brine (fraction 9) were dissolved in 240 cc. of 6 *N* hydrochloric acid and seeded with 2,3,8-trimethylquinoline hydrochloride. After eighteen hours in the ice-box, 12 g. of the pure hydrochloride had separated. This characteristic salt is difficultly soluble in water as compared with the hydrochlorides of the associated kero quinolines.

The smeary residue obtained by evaporation of the filtrate was washed with five portions of hot acetone (total 75 cc.) and the bases (n^{20}_{D} 1.5142) were recovered from the solvent. The acetone insoluble hydrochlorides yielded 53 cc. of bases (n^{20}_{D} 1.5228) which were further processed through cumulative extraction.[5]

The n^{20}_{D} values, 1.5143 and 1.5501, of 22 cc. from the chloroform layer, and 30 cc. from the water layer, respectively, emphasize the efficiency of cumulative extraction in combination with sulfiting and degassing.

Table II comprises degassing data on the acid sulfite solutions of base fractions 1, 2 and 8 (Table I).

TABLE II

Source of acid sulfite	Fraction	Degassing temp. of brine, °C.	Bases liberated Vol., cc.	n^{20}_{D}
A composite of fraction 1 and 2.	1a	0	28	1.5086
	2a	0	25	1.5120
	3a	20	25	1.5152
	4a	20	19	1.5175
	5a	20	9	1.5208
	6a	..	22	1.5300
Fraction 8	1b	20	16	1.5197
	2b	20	13	1.5203
	3b	20	25	1.5218
	4b	..	42	1.5303

The residual fractions 6a and 4b underwent sulfite-sulfate conversion. However, from 6a, there separated on standing a crystalline acid sulfite from which 7 g. of 2,3,8-trimethylquinoline was obtained. Here the residue, from the evaporation of the filtrate and leaching out the smeary residue with cold acetone, yielded an additional 3 g. of the same acid sulfite.

Fractional Sulfiting of the 270–280° Kero Base Fraction.—One liter of bases was fractionally neutralized with 100-cc. portions of 8% aqueous sulfurous acid under vigor-

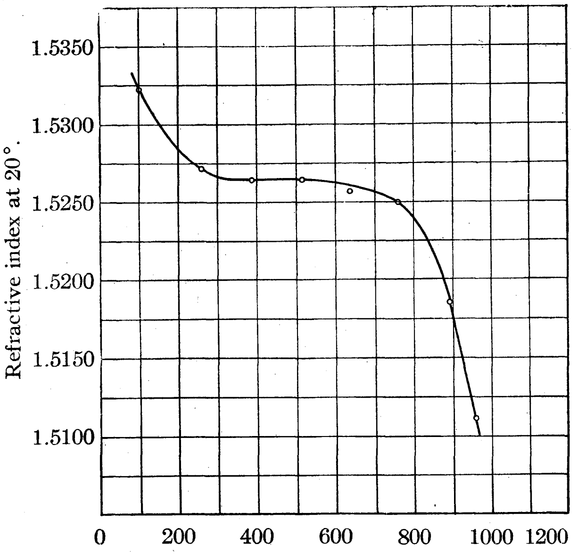

Fig. 1.—Sulfiting of crude base fraction.

ous agitation over ninety-minute periods. At the end of each extraction the aqueous layer was drawn off and the bases were liberated. The results obtained are presented in Table III.

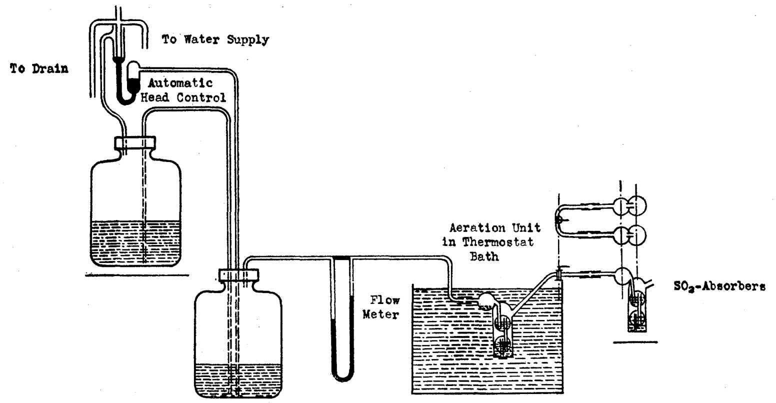

Fig. 2.—Apparatus for determination of degassing rates.

The recombinations, A, B and C, of the nine fractions corresponding to the three pronounced slopes in Fig. 1, were further processed through cumulative extraction by agitation for several hours of the base fractions, with 6 *N* hydrochloric acid and chloroform in the volume ratio of 1:1:1.2, respectively. The results are presented in Table IV.

Since a crystalline hydrochloride separated from the aqueous layer of both B and C before liberation of the bases, the 25-cc. and the 17-cc. fractions were reconverted to the hydrochlorides with the result that 7 and 3 g., respectively, of pure 2,3,8-trimethylquinoline as hydrochloride precipitated. The refractivity of the 66 cc. of non-aromatics from B approached that of the $C_{16}H_{25}N$ base ($n^{20}D$ 1.5129). In order to confirm the presence of this substance, this fraction was converted to anhydrous hydrochlorides, smeary admixtures were leached out with cold acetone, and the crystalline residue was extracted with 400 cc. of hot acetone. After filtering off the undissolved hydrochlorides, the filtrate was concentrated to a small volume, whereupon 17 g. of practically pure $C_{16}H_{25}N{\cdot}HCl$ separated.

Determination of Dissociation Rates of Base Acid Sulfites.—In order to make a thorough study of the rate of dissociation of acid sulfites of nitrogen bases, a method was devised whereby solutions of the salts could be used even though there were present an undetermined excess of sulfur dioxide. This scheme was effected by consideration of the difference in the rate of evolution of sulfur dioxide during degassing from solutions containing (1) an insufficiency and (2) an excess of sulfur dioxide for salification of the base.

Through 10 cc. of an aqueous solution of a weighed quantity of base in an excess of sulfurous acid a quantity of air is passed at a constant rate (see Fig. 2). The vapor from the aeration unit is led into the sulfur di-

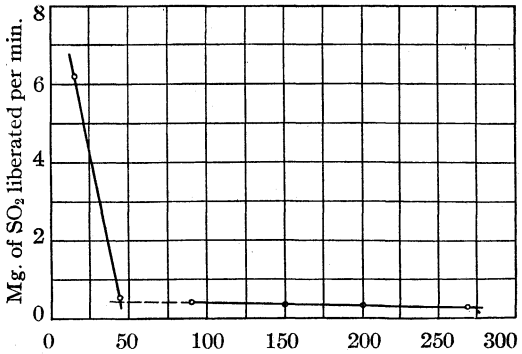

Fig. 3.—Degassing rate of the $C_{16}H_{25}N$ base acid sulfite.

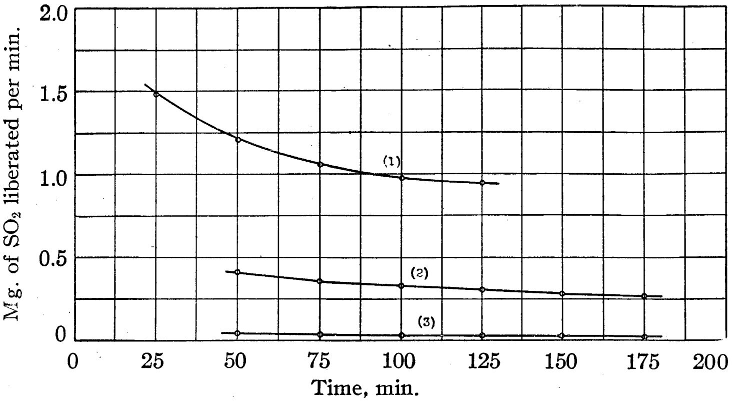

Fig. 4.—Comparison of degassing rates of: (1) non-aromatic fraction, (2) the $C_{16}H_{25}N$ naphthenic base and (3) quinoline acid sulfites.

oxide absorber containing 40% potassium hydroxide. Two absorbers, operating alternately at recorded intervals of time, are connected to the aeration unit through a two-way stopcock so that the rate of degassing can be followed without interruption. The absorbed sulfur dioxide is determined iodometrically. In a series of experiments involving three different bases, the rates of sulfur dioxide evolution from the aeration unit are deduced and plotted against time. At the inflection point of each curve, it is assumed, all of the *excess* sulfur dioxide—*and only the excess*—is removed, leaving behind only base acid sulfite. By shifting the time abscissa of the curve for each base so that the inflection points coincide, a composite set of curves follows whereby a comparison of the degassing rates is presented. Figure 3 shows the degassing rate of the $C_{16}H_{25}N$ naphthenic base. Figure 4 derived from Fig. 3, along with similar curves for quinoline and a complex non-aromatic fraction (b. p. 270–280°), denotes the comparative degassing rates of their acid sulfites.

Summary

Experience has demonstrated that, by following the old beaten track in processing coal tar bases, which are essentially of aromatic character, not much progress can be expected in isolation of the components of the far more complex straight-run petroleum base fractions.

In the present investigation, a new cyclic process of resolution is described which employs the reversible reaction

Sulfiting Degassing

$$\text{(A) Base} + SO_2 + H_2O \rightleftarrows \text{(B) Base}\cdot H_2SO_3$$

In (A), fractional acid extraction and in (B), fractional acid-sulfite dissociation are involved.

It was beyond the scope of the present investigation to effect quantitative separations of the known components of the complex mixture of the bases processed; on the contrary, the aim was to establish Fractional Sulfiting and Fractional Degassing as general procedures which can contribute to an extension of the chemistry of petroleum bases.

The Nitrogen Compounds in Petroleum Distillates. XIII. Isolation of Four Quinoline Homologs and Two Aromatic Bases of Probable Trinuclear Cyclic Structure[1]

By W. Nelson Axe[2] and J. R. Bailey

Introduction

The main objective of this investigation concerned the isolation of aromatics in the 300° range of kero bases. In refining the crude material, the following steps were involved: (1) fractional acid extraction followed by a rough distillation; (2) fractional distillation of the desired cuts from (1) after appropriate recombinations in the order of boiling points and refractive indices; (3) cumulative extraction[3] of fractions from (2) preceded by the usual recombinations; (4) fractional distillation of the aromatic bases which were concentrated as hydrochlorides in the aqueous layer in step 3.

Attempts to isolate individual components in fractions from step 4 around the 295° boiling range were rewarded by the recovery of two products in poor yield of the composition $C_{13}H_{15}N$ (I) and $C_{14}H_{17}N$ (II) through fractional precipitation and recrystallization of different salts. Further work on these compounds awaits the assembling of sufficient quantities for proof of structure.

Since the results reported above were disappointing, resort was had to degassing of acid sul-

fites. In the initial experiment on acid sulfites of aromatic fractions from cumulative extraction, the evolution of sulfur dioxide ceased abruptly when 90% of the original bases had layered out. An explanation of this observation was furnished by the discovery that, on prolonged degassing at different temperature levels, acid sulfites of aromatic bases may undergo oxidation to acid sulfates, provided aeration is employed to facilitate the removal of sulfur dioxide.[4]

From the base fractions obtained in the degassing experiment, a product of the composition $C_{14}H_{17}N$ (III) was isolated through its characteristic nitrate. The residual base fraction, obtained by sodium hydroxide precipitation of the acid sulfate solution, yielded a $C_{13}H_{15}N$ base (IV). This latter base was separated from the mixture as the characteristic acid sulfate. These bases are isomers of (II) and (I), respectively.

The structures of (III) and (IV) have been established conclusively through both degradation and synthesis. In accordance with the general observation that, in chromic acid oxidation of quinoline homologs, the stability of alkyls is in the progressive order of their positions of substitution from 1 to 8, inclusive,[5] the monocarboxylic acids from oxidation of (III) and (IV) proved to be 2,3-dimethylquinoline-8-carboxylic acid (V) and 2,3,-4-trimethylquinoline-8-carboxylic acid (VI), respectively.

Acid (V) proved identical with 2,3-dimethylquinoline-8-carboxylic acid, previously obtained in chromic acid oxidation of 2,3,8-trimethylquinoline[6] and 2,3-dimethyl-8-ethylquinoline.[7] Since this acid contains two carbons less than does base (III), it follows that the latter is a 2,3-dimethyl-8-propylquinoline. Accordingly, resort was had to synthesis to determine whether an *n*- or isopropyl was involved. The *n*-propyl isomer was prepared by a modification of Rhode's[8] synthesis of 2,3-dimethylquinoline through the action of concentrated hydrochloric acid on a mixture of *o*-amino-*n*-propylbenzene and tiglic aldehyde. The 2,3-dimethyl-8-*n*-propylquinoline, so obtained, proved identical with the kero base (III).

Decarboxylation of acid VI gave 2,3,4-trimethylquinoline, a base known to synthesis.[9] The position of the carboxyl at 8 was inferred from the fact that, among the six previously isolated quinoline homologs, none is substituted at positions 5, 6 or 7. The bases referred to include: 2,3-, 2,4-[10] and 2,8-dimethylquinoline,[11] 2,3,8-[6] and 2,4,8-trimethylquinoline,[3] 2,3-dimethyl-8-ethylquinoline.[7] The usual comparison of (IV) with a synthetic sample of 2,3,4,8-tetramethylquinoline[12] revealed the identity of the kero base.

Two transformer-oil bases of the composition $C_{15}H_{13}N$ and $C_{16}H_{15}N$ have been isolated. Obviously, they do not belong to the quinoline series, since the rather closely cut fraction of bases from which they were isolated possessed a refractive index of 1.6570 at 25°, indicating the presence of polynuclear types of a higher order. Furthermore, the empirical formulas correspond to a dimethyl and a trimethyl homolog of acridine or one of the three types of naphthoquinolines of the general formula $C_nH_{2n-17}N$, as compared with $C_nH_{2n-11}N$ for the quinoline series. Experimental evidence indicates that these provisionally assumed trinuclear types first occur in the 320° range of straight-run petroleum base fractions. Since acridine and its homologs have very high boiling points, it may be inferred that they are not represented, if at all, much below the 345° range.

Experimental

The Union Oil Company of California in processing 3000 barrels of kerosene Edeleanu extract obtained 3 barrels of bases. A supply of this crude material was partially refined in the Texas Laboratory by fractional acid extraction, followed by fractional distillation at reduced pressure.

The separate fractions, totalling 38.7 liters, which were obtained from the second distillation through recombinations in the order of boiling points and refractivities, were carried through cumulative extraction. Only the bases present as hydrochlorides in the water layer from this form of solvent extraction, and representing a relatively high concentration of aromatics, were used in this investigation. The so-called non-aromatic hydrochlorides which are segregated, in large part, in the chloroform layer have been reserved for future study. The yield of aromatic bases in this process is approximately 28% by volume. When it is considered that the average $n^{25}\text{D}$ value of the non-aromatics is not much above 1.5, while that of quinoline homologs approaches 1.6, the data in Table I emphasize the efficiency of this process.

---

[4] An experimental confirmation that the temperature of dissociation of base acid-sulfites rises progressively with their ionization constants has been established. When partial sulfite–sulfate conversion takes place, as in the present case, the bases of highest ionization constants are the ones involved. Proof of these conclusions will appear in a subsequent publication.

14	310	1.5559	1.5847	800

[a] Fractions 6 and 7 were combined prior to extraction.

Distillation data obtained on each of the fractions 1B to 7B, inclusive, showed a negligible variation in physical constants, indicating fractional distillation of the remaining fractions to be superfluous. In processing these fractions, bases (I) and (II) referred to in the introduction were isolated.

The individual fractions 8, 9, 10 and 11(B) dissolved in sulfurous acid were fractionally degassed through aeration. This procedure led to the isolation, in a favorable yield, of 2,3-dimethyl-8-*n*-propylquinoline (III) and 2,3,4,8-tetramethylquinoline (IV), neither of which was separated in applying the conventional methods hitherto employed in resolution of mixtures of bases. Table II is submitted as an example of the results obtained.

TABLE II

FRACTIONAL DEGASSING OF SULFITE SOLUTION OF FRACTION 9B (TABLE I)

Vol. 850 cc. (n^{25}D 1.5832)

Fraction	Temp., °C.	Fraction time, hrs.	Total time, hrs.	Vol., cc.	n^{25}D
1	10	6.5	6.5	135	1.5754
2	20	2.0	8.5	95	1.5754
3	20	2.0	10.5	82	1.5778
4	25	2.0	12.5	90	1.5808
5	25	18.0	30.5	160	1.5838
6	90	2.0	32.5	94	1.5889
7	90	2.0	34.5	Trace	...
8 Residue	..	..	..	164	1.5916

Fractions 1 through 7 comprise free bases which separated as a result of the dissociation of acid sulfites. The residual fraction, 8, did not degas due to oxidation of the original acid sulfites to acid sulfates.

Isolation of 2,3-Dimethyl-8-*n*-propylquinoline as the Nitrate.—To the cooled solution of each of the first seven fractions (Table II) dissolved in an equal volume of 1:1 ether–alcohol, nitric acid was added in slight excess (deduced from an assumed average base mol. wt. of 198). The precipitated nitrates after recrystallization gave the following yields: 22 g. (1), 16.5 g. (2), 8.5 g. (3) and 2.5 g. (4). Fractions 5, 6 and 7 gave negative results. This total yield of 49.5 g. came from fraction 9B (Table I). In processing fractions 8, 10 and 11(B) in a similar way, the amount of pure nitrate was increased to 112 g. This selective salt for the isolation of the dimethylpropylquinoline crystallizes from water containing a very small amount of nitric acid in slender rods melting at 169° with decomposition.

Anal. Calcd. for $C_{14}H_{17}N{\cdot}HNO_3$: C, 64.10; H, 6.91; N, 10.67. Found: C, 64.33; H, 6.93; N, 10.50.

Free Base.—The following constants were determined for the base prepared in the usual way from the pure nitrate or picrate: m. p. 14.5–15.5°; b. p. 299.5°; d^{20}_4 0.9996; n^{25}D 1.5778. It is insoluble in water and readily soluble in the common organic solvents. It is practically odorless.

Anal. Calcd. for $C_{14}H_{17}N$: C, 84.42; H, 8.54; N, 7.03. Found: C, 84.22; H, 8.58; N, 7.07.

Picrate.—This salt, which is difficultly soluble in the common solvents, crystallizes from glacial acetic acid in long lemon colored rectangular prisms which melt undecomposed at 198–199°.

Anal. Calcd. for $C_{20}H_{20}N_4O_7$: C, 56.07; H, 4.71; N, 13.08. Found: C, 55.83; H, 4.63; N, 13.14.

Acid Sulfate.—On addition of concentrated sulfuric acid to an alcohol–ether solution of the base, this salt precipitates and can be recrystallized from *t*-butyl alcohol in small rectangular prisms melting at 212–212.5°. It is readily soluble in water and ethyl alcohol.

Anal. Calcd. for $C_{14}H_{17}N{\cdot}H_2SO_4$: C, 56.56; H, 6.39; N, 4.71. Found: C, 56.20; H, 6.42; N, 4.97.

Hydrochloride.—This salt, prepared by passing hydrogen chloride into an ether solution of the base, crystallizes from acetone containing a trace of alcohol in microscopic rhombic prisms which, after drying in a vacuum desiccator, melt at 161–162°. It is readily soluble in water and alcohol.

Anal. Calcd. for $C_{14}H_{17}N{\cdot}HCl$: C, 71.31; H, 7.67; N, 5.93. Found: C, 71.32; H, 7.91; N, 6.19.

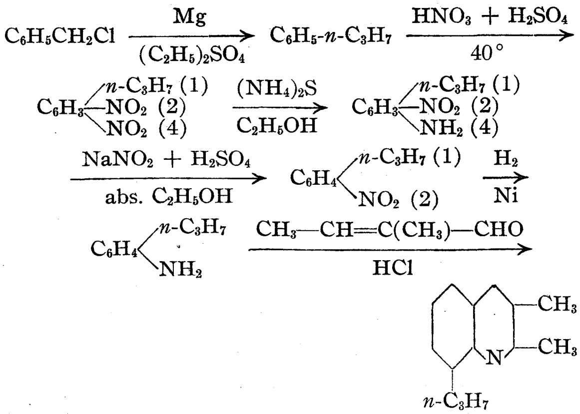
Zinc Chloride Salt.—For precipitation of this salt, an aqueous solution of zinc chloride is added to a molar amount of the base in dilute hydrochloric acid. Recrystallization from an alcohol–acetone mixture yields ill-defined microscopic crystals melting at 193–194°.

Anal. Calcd. for $C_{14}H_{17}N{\cdot}HCl{\cdot}ZnCl_2$: C, 45.19; H, 4.87; N, 3.91. Found: C, 45.09; H, 5.10; N, 3.89.

2,3-Dimethylquinoline-8-carboxylic Acid.—To a boiling solution of 5 g. of the base in 6 *N* sulfuric acid, is added, slowly, 15 g. of potassium dichromate in 23 g. of concentrated sulfuric acid diluted with 25 cc. of water. The reaction is complete in one hour. After neutralization of the sulfuric acid, the solution is extracted with chloroform. The crude product crystallizes from alcohol in needles melting at 201–202°: yield 1.75 g. or 27%. A mixture of this acid with an authentic sample of 2,3-dimethylquinoline-8-carboxylic acid showed no depression in melting point, thus confirming a propyl at position 8 of the original base. Decarboxylation of the acid through soda-lime distillation yielded the kero base 2,3-dimethylquinoline.

Anal. Calcd. for $C_{12}H_{11}O_2N$: C, 71.64; H, 5.47. Found: C, 71.43; H, 5.53.

Synthesis of 2,3-Dimethyl-8-*n*-propylquinoline.—In this synthesis the following series of reactions was involved



The *n*-propylbenzene was prepared according to the procedure of Gilman and Catlin.[13] The method described by Brady and Cunningham[14] was followed in the conversion of the hydrocarbon to *o*-nitro-*n*-propylbenzene. Reduction of the nitro compound to the corresponding amine was carried out in a high-pressure hydrogenator using a Raney nickel catalyst. Equimolecular proportions of *o*-amino-*n*-propylbenzene and tiglic aldehyde were heated with an excess of concentrated hydrochloric acid in accordance with Rhode's synthesis of 2,3-dimethylquinoline.[8]

Isolation of 2,3,4,8-Tetramethylquinoline through the Acid Sulfate.—The residual bases in Fraction 8 (Table II) were dissolved in a 1:1 alcohol–acetone solution. On the addition of concentrated sulfuric acid, a sticky mass separated which on recrystallization from water yielded a colorless crystalline product. From this salt was recovered 13 g. of pure base. The total over-all yield increased to 20.5 g. or approximately 4.5%, after fractions 8, 10 and 11 (Table I) had been processed as outlined for fraction 9 (Table II).

The acid sulfate crystallizes from alcohol in hexagonal prisms melting with decomposition at 298°.

Anal. Calcd. for $C_{13}H_{15}N \cdot H_2SO_4$: C, 55.10; H, 6.04; N, 4.94. Found: C, 54.88; H, 6.07; N, 4.87.

Free Base.—This base crystallizes from methyl alcohol in translucent, long, slender, rectangular prisms melting at 77–78°.

Anal. Calcd. for $C_{13}H_{15}N$: C, 84.32; H, 8.10; N, 7.56. Found: C, 84.41; H, 8.23; N, 7.55.

Picrate.—This salt crystallizes from glacial acetic acid in characteristic small, rectangular plates melting with decomposition at 240°. It is very difficultly soluble in other common solvents.

Anal. Calcd. for $C_{19}H_{18}N_4O_7$: C, 55.07; H, 4.35; N, 13.53. Found: C, 55.26; H, 4.48; N, 13.58.

Hydrochloride.—On addition of concentrated hydrochloric acid to an acetone solution of the base, the hydrochloride is precipitated. The salt crystallizes from an acetone–alcohol solution in ill-defined microscopic crystals melting with decomposition at 252–253°.

Anal. Calcd. for $C_{13}H_{15}N \cdot HCl$: C, 70.42; H, 7.27; N, 6.32. Found: C, 70.51; H, 7.46; N, 6.56.

Nitrate.—Concentrated nitric acid and a well-cooled alcoholic solution of the base yields a crystalline nitrate which after recrystallization from alcohol melts at 184.5° with decomposition.

Anal. Calcd. for $C_{13}H_{15}N \cdot HNO_3$: C, 62.89; H, 6.49; N, 11.29. Found: C, 63.10; H, 6.40; N, 11.30.

Zinc Chloride Salt.—The base in alcohol is treated with a molar proportion of hydrochloric acid and one-half mole of zinc chloride. The precipitated salt crystallizes from 95% alcohol in hexagonal prisms with dome-shaped end faces melting at 266–267°.

Anal. Calcd. for $(C_{13}H_{15}N \cdot HCl)_2 \cdot ZnCl_2$: C, 53.86; H, 5.56. Found: C, 53.89; H, 5.38.

Phthalone.—Molar amounts of the base and phthalic anhydride are heated for four hours at 200°, the melt is dissolved in glacial acetic acid and the phthalone is precipitated by dilution of the solution with water. Microscopic plates melting at 264° are obtained on recrystallization from alcohol.

Anal. Calcd. for $C_{21}H_{17}O_2N$: C, 79.97; H, 5.43; N, 4.43. Found: C, 79.81; H, 5.43; N, 4.40.

Chromic Acid Oxidation of the Base.—This experiment was carried out under conditions similar to those described for the oxidation of 2,3-dimethyl-8-*n*-propylquinoline. Here 5 g. of base, 8.5 g. of potassium dichromate and 12 g. of concentrated sulfuric acid diluted with 15 cc. of water were used. Four hours were required for the reaction; yield 0.8 g. of acid. After recrystallization from alcohol, the acid melted at 233.5–234°.

Anal. Calcd. for $C_{13}H_{13}O_2N$: C, 72.04; H, 6.11. Found: C, 72.35; H, 6.10.

Decarboxylation of the $C_{13}H_{13}O_2N$ Acid.—An intimate mixture of acid and soda-lime in the proportion of 1:4 was heated well above 360°. The base, extracted from the fusion residue with ether, formed a picrate melting at 220°. Comparison of this picrate with an authentic sample of 2,3,4-trimethylquinoline revealed an identity.

Synthesis of 2,3,4,8-Tetramethylquinoline.[12]—Synthesis of this base was effected by the Combes method.[15] Methylacetylacetone (0.7 mole) was condensed with *o*-toluidine (0.6 mole) in the presence of hydrochloric acid at water-bath temperature for eight hours. The base, isolated in the usual way, had the following physical constants after recrystallization from petroleum ether: m. p. 77–78°, b. p. 298–300°. The picrate melted at 240° and the acid sulfate melted with decomposition at 298°. Melting points of mixtures of the synthetic and kero base, as well as mixtures of the respective picrates, showed no depression, thus affording conclusive proof of structure.

Isolation of a $C_{15}H_{13}N$ Transformer-Oil Base.—To 54 g. of a fraction of bases (b. p. 340°, n^{25}_{D} 1.6570)[16] in an equal volume of glacial acetic acid, was added a hot acetic acid solution of 55 g. of picric acid. The reaction mixture was kept at ice-box temperature for twelve hours. The smeary picrates which separated were crystallized from

glacial acetic acid: yield 40 g., m. p. 178–183°. Two recrystallizations left 15 g. of picrates (m. p. 201–203°). Next, the crude viscous bases (n^{25}D 1.6096) liberated from the picrates were dissolved in a 1:1 alcohol–ether solution and a slight excess of concentrated sulfuric acid was added. The resulting acid sulfates after three recrystallizations from alcohol melted at 265–267° with decomposition. A base melting at 82–82.5° was liberated from the acid sulfate which after two recrystallizations from petroleum ether melted at 83.5–84°; yield of pure base, 0.7 g. The pure picrate of the base melted at 228.5–229.5°. From another fraction boiling at 340° (n^{25}D 1.6504), an additional quantity of the base was recovered, bringing the total yield up to 1.9 g.

Anal. of base. Calcd. for $C_{15}H_{13}N$: C, 86.95; H, 6.23; N, 6.76. Found: C, 86.97; H, 6.30; N, 7.00.

Anal. of picrate. Calcd. for $C_{21}H_{16}O_7N_4$: C, 57.79; H, 3.67; N, 12.84. Found: C, 58.10; H, 3.83; N, 12.97.

Isolation of a $C_{16}H_{15}N$ Transformer-Oil Base.—The bases, recovered from the residues after separation of the $C_{15}H_{13}N$ compound, were combined and processed through degassing of their sulfurous acid solution into 8 fractions of bases. To each fraction in alcohol was added a slight excess of concentrated nitric acid. Precipitates in fractions 5, 6, 7 and 8 followed immediately and appeared in very small amount in the first four fractions after seeding and prolonged stirring. The combined nitrates were recrystallized from water containing a trace of nitric acid. The base liberated from the salt melted at 86–87°. The melting point, 228–229°, of the picrate prepared from the base remained unchanged after recrystallization from glacial acetic acid.

The very slight solubility of the nitrate in water at 100°, which is approximately 1 part in 100, offers a selective method for the isolation of this base. This claim is emphasized by the isolation of only 0.6 g. of this substance, or 0.59%, calculated from the quantity of the complex mixture of bases processed.

The slight difference in melting points of this base and the $C_{15}H_{13}N$ compound, as well as the slight difference in melting points of the corresponding picrates, suggested an identity of the two bases. However, the melting point of a mixture of the two picrates showed a depression of 30°. Furthermore, the $C_{15}H_{13}N$ base possesses a pronounced sweet odor, whereas the $C_{16}H_{15}N$ base is odorless.

Anal. of base.[17] Calcd. for $C_{16}H_{15}N$: C, 86.84; H, 6.83; N, 6.32. Found: C, 87.86; H, 6.88; N, 6.60.

Anal. of picrate. Calcd. for $C_{22}H_{18}N_4O_7$: C, 58.66; H, 4.02; N, 12.44. Found: C, 58.62; H, 4.04; N, 12.46.

Summary

Fractional degassing of base acid sulfites as described in the preceding paper by Roberts and Bailey has been employed in isolation, from the 300° range of kero bases, of two quinoline homologs, 2,3-dimethyl-8-*n*-propylquinoline and 2,3,4,-8-tetramethylquinoline. The structures of these products have been established through degradation and synthesis.

Two other bases of undetermined structure of the compositions $C_{13}H_{15}N$ and $C_{14}H_{17}N$ were separated from bases boiling in the neighborhood of 295°.

Two high-boiling bases, $C_{15}H_{13}N$ and $C_{16}H_{15}N$, which are probably of the acridine or naphthoquinoline types, have been isolated from transformer-oil base fractions through employment of selective salts and fractional degassing of base acid sulfites.

---

[17] The determination of carbon in the free base is obviously in error, but lack of material prevented a duplicate analysis.

A System Correlating Molecular Structure of Organic Compounds with their Boiling Points. I. Aliphatic Boiling Point Numbers

BY CORLISS R. KINNEY

Several systems have been devised for correlating different physical properties of organic compounds with their molecular structure and two are particularly valuable tools in organic chemistry—molecular refraction and the parachor. Unfortunately, however, these methods give no information about certain types of isomerism and the parachor often involves considerable experimental difficulties. Consequently it would be most desirable to have available another method which correlated molecular structure with an easily determined physical property which would be sensitive to types of isomerism not shown by other methods. The boiling temperature of a compound is probably more dependent upon molecular structure, and more easily determined usually, than any other physical property; and yet no attempt has been made to devise a system for correlating the molecular structure of all types of organic compounds with their boiling points. Large numbers of expressions have been devised for correlating the boiling points of members of homologous series with the molecular weight or other similar property, but no general system has been made available for correlating all types of compounds. Such a system would be especially valuable for determining the structures of unknown substances, for calculating the boiling points of substances from their structure, and for studying the effect of one group upon another in the molecule.

At the boiling point of a substance the kinetic energy of the molecules in the liquid state equals the energy associated with the attractive forces tending to hold the molecules together plus the energy required to do the necessary work against the external pressure. Since the latter energy is constant at a given pressure for all types of molecules and since the molecular attractive forces are primarily dependent upon (1) the kind, (2) the number, and (3) the arrangement of the atoms in the molecule, the boiling point of the substance may also be considered to be primarily dependent upon the kind, number, and arrangement of the atoms in the molecule. The kind and number of the atoms in the molecule, *i. e.*, the molecular formula, may be determined by qualitative and quantitative analyses together with molecular weight estimations; consequently, the effect of the structure upon the boiling point of a compound may be studied in this way. The boiling point of a compound is affected by such factors as dipole moment, hydrogen bonds, association, etc.; but, since these effects are also dependent upon the kind, number and arrangement of the atoms in the molecule they will be accounted for to a large extent. The boiling point is, of course, greatly affected by the pressure; but, by using pressures at or near the normal pressure in the following considerations, that factor has been largely eliminated.

There is no known relationship between the boiling point of a compound and atomic values such as atomic weight, atomic volume, atomic refraction, and atomic parachor; consequently, it was necessary to choose numbers for the atoms and groups in molecules which may be used with boiling point data. It was also necessary to devise an expression for equating the two. The absolute boiling temperature of members of an homologous series of organic compounds may be expressed as a function of the molecular weight raised to a fractional power using Walker's[1] formula, $T = aM^b$, where T is the absolute boiling point, M the molecular weight, "a" a constant characteristic of each homologous series and of a different value for each series, and "b" another similar constant. The value of "b" does not vary greatly from a value of one-third for most series and it becomes apparent that boiling point data may be expressed as a function of the sum of the atomic values chosen for use with boiling points raised to the one-third power. These atomic values and the expression for equating them with boiling point data were obtained in the following way.

Practically all organic compounds may be considered to be derivatives of the normal paraffin hydrocarbons or of hydrogen. Consequently, the normal paraffin hydrocarbons and hydrogen were taken to be the basis of the system. Next, various values were assigned to carbon and hydrogen and the absolute boiling points of hydrogen and the normal paraffin hydrocarbons plotted against the cube root of the sum of the different atomic numbers assigned to carbon and hydrogen. In this way it was possible to choose those values of carbon and hydrogen which cause the boiling point of molecular hydrogen to coincide most closely with the straight line of the hydrocarbon plot, thus making it possible to compare derivatives of hydrogen and of the normal paraffin hydrocarbons. The best values of carbon and hydrogen are 0.8 and 1.0 unit, respectively, and may be called the atomic boiling point numbers (b. p. n.) for these atoms. Also the equation for the hydrogen–hydrocarbon plot may be used for correlating the boiling points of derivatives of hydrogen and the normal hydrocarbons with the boiling points of those substances themselves. Two forms of this equation are given below in which B. P. is the boiling point in degrees centigrade and B. P. N. (molecular boiling point number) is the sum of the individual atomic and group boiling point numbers expressing the structure of the molecule.

$$\text{B. P.} = 230.14\sqrt[3]{\text{B. P. N.}} - 543 \quad (1)$$

$$\text{Log B. P. N.} = 3(\log(\text{B. P.} + 543) - 2.3620) \quad (2)$$

The boiling point number (B. P. N.) of derivatives of hydrogen or of the normal hydrocarbons may be considered to be composed of two parts: that due to the hydrogen atom or the hydrocarbon residue and that due to the characteristic atom or group. The latter value may be determined readily as the difference between the boiling number for the hydrogen atom or the hydrocarbon residue and the molecular boiling point number

---

(1) Walker, *J. Chem. Soc.*, **65**, 193 (1894).

determined from the boiling point. For example, the branched chain hydrocarbons are considered to be alkyl derivatives of the normal hydrocarbons and the molecular boiling point number the sum of the atomic boiling point numbers for the hydrogen and carbon atoms in the normal chain plus the boiling point number which has been determined for the alkyl group. The boiling point number of the methyl group was determined from the following data, which demonstrates the method. The boiling point of 2-methylbutane is 28°, which gives an observed B. P. N. of 15.27. In the butane chain there are four carbon atoms which contribute 3.2 and nine hydrogens which contribute 9.0 units. The difference of 3.07 units is to be attributed to the side chain methyl group. As an approximation a value of 3.05 has been adopted as the b. p. n. of the side chain methyl group which gives a calculated B. P. N. of 15.25 and a boiling point of 27.75°. The b. p. n. of several of the alkyl groups together with a number of the characteristic groups present in aliphatic compounds have been determined and may be found in Table II. In Table I have been listed most of the paraffin hydrocarbons for which boiling points at atmospheric pressures have been recorded, the boiling point and the corresponding B. P. N., the calculated B. P. N., and the amount of the deviation from the calculated. Where the boiling point was recorded in the literature as a range of temperature the midpoint of the range has been taken as the boiling point. Many of the boiling points appearing in Table I were obtained at pressures considerably less than standard. This, of course, introduces quite a little error and undoubtedly accounts for, in part, the low boiling points recorded for many of the higher boiling compounds. Another source of inaccuracy is that introduced by the use of some boiling points that have been corrected and many that have not. In addition, the differences in technique in taking the boiling point must cause serious discrepancies. For example, compounds 43 and 44 in section B of Table I, 2,4,7-trimethyloctane

TABLE I

BOILING POINT NUMBERS FOR THE PARAFFIN HYDROCARBONS

and 2,6,7-trimethyloctane, have very similar structures and should have very similar boiling points; however, their recorded boiling points differ by nine degrees and, judging by their calculated boiling point numbers, both of the recorded boiling points are much too low. In spite of these difficulties in obtaining accurate boiling point data, the deviation is less than 5% in all cases except three and for two of these the boiling point was determined at 729 mm. Consequently, it appears quite likely that the general use of boiling point numbers as guide in obtaining boiling points would lead to more accurately determined and better standardized boiling points appearing in the literature. It is, of course, unfortunate that the boiling points of so few ethyl, propyl, and higher radical derivatives have been recorded at atmospheric pressure and it may be desirable later, as a consequence, to alter slightly the values assigned to these radicals when more boiling points have been recorded.

When two methyl groups are attached to the same carbon atom it would be expected, because of the steric effect, that the b. p. n. of the second methyl group would be less than the first. This is correct for the 2,2-dimethyl paraffins, such as 2,2-dimethylpropane (Table I, Sec. B, 2) and their derivatives, but does not apply to the 3,3-dimethyl derivatives such as 3,3-dimethylpentane (13), etc. The introduction of several methyl groups into the center of the carbon chain produces a marked exaltation of the boiling point. This is shown particularly by such compounds as 2,2,3,3-tetramethylbutane (7) or 2,3,3,4-tetramethylpentane (16). Young,[2] while studying the properties of 2,3-dimethylbutane (5) and 2,5-dimethylhexane (22), first noticed this behavior. The cause of this exaltation may be due to the relation of the structure of these molecules to the packing effect in the liquid state. Whether this is the cause or not, the new method of correlating boiling point data makes it possible to observe and study the various effects of structure upon the boiling point in a very striking manner. Since the maximum deviation from the calculated B. P. N. of these compounds is only about 5%, no corrective factor has been devised for the present, but for making more accurate calculations the effect of related groups upon the B. P. N. should be considered.

The introduction of other atoms or groups, in contrast with the introduction of alkyl groups, produces a very marked change in the b. p. n. depending upon the position (as well as the number) of the atoms or groups substituted into the molecule. In Table II various characteristic atoms and groups are listed giving the b. p. n. for the different positions that may be taken. For example, the values given for the b. p. n. of chlorine in the primary, secondary, and tertiary positions are 7.5, 6.5, and 6.0, respectively, and show the steric effect of the surrounding atoms in a striking manner. It is possible that the depression of the b. p. n. is due in part to a change in the dipole moment of such compounds, but insufficient data are available to make a decision. With molecular chlorine, hydrogen chloride, and methyl chloride data are available (Table III) and the change in b. p. n. corresponds to the change in dipole moment; however, the effect must be complicated by the steric effect in such a series.

TABLE III

Substance	B. p., °C.	Obsd. B. P. N.	B. p. n. of chlorine	Dipole moment $\times 10^{18}$
Chlorine	−33.7	10.48	5.24	0.0
Hydrogen chloride	−83.7	7.95	6.95	1.28
Methyl chloride	−23.7	11.49	7.69	1.86

The boiling point of a substance may be calculated from its structure in the following way provided, of course, that the b. p. n. of the various structural components are known. In Table IV the boiling points of the eight chloropentanes have been calculated and compared with the observed.

The agreement between the calculated and observed boiling points in Table IV is good with the exception of the last compound which belongs to the class of 2,2-dimethyl derivatives which, as pointed out above, show a marked depression of the boiling point. Furthermore, this compound shows the greatest depression of any examined thus far and the amount is usually less than half as much. If several tenths of a unit were subtracted to account for the behavior of the 2,2-dimethyl derivatives, the calculated boiling point would more closely approximate the observed value and this should be done in making more accurate calculations.

In calculating the structure of a substance such as an alkyl chloride from its boiling point, certain limitations are encountered. In the first place, there is no way to distinguish between those isomers in which the characteristic group is merely shifted along the carbon chain, *i. e.*, 2- or 3-chloropentane and 1- or 4-chloro-2-methylbutane which are listed in Table IV. In the second place the branched compounds have a second variable, *i. e.*, the position of the alkyl group. This requires that either the position of the alkyl group be known or that of the characteristic group. Since it is possible, usually, to determine the position of the characteristic group but not the position of the alkyl groups attached to the carbon chain, the new method becomes of especial value in determining the structure of hydrocarbon radi-

TABLE IV

	Substance	B. P. N. (calcd.)	B. p. (calcd.)	B. p. (obsd.)	B. P. N. (obsd.)
1	1-Chloropentane	4.0 + 11 + 7.5 = 22.5	106.7	108.35	22.67
2	2-Chloropentane	4.0 + 11 + 6.5 = 21.5	96.9	96.7	21.48
3	3-Chloropentane	4.0 + 11 + 6.5 = 21.5	96.9	97.3	21.54
4	1-Chloro-2-methylbutane	3.2 + 8 + 3.05 + 7.5 = 21.75	99.4	98.3	21.64
5	2-Chloro-2-methylbutane	3.2 + 8 + 3.05 + 6.0 = 20.25	84.3	86.0	20.41
6	3-Chloro-2-methylbutane	3.2 + 8 + 3.05 + 6.5 = 20.75	89.4	91.0	20.91
7	4-Chloro-2-methylbutane	3.2 + 8 + 3.05 + 7.5 = 21.75	99.4	99.6	21.77
8	1-Chloro-2,2-dimethylpropane	2.4 + 5 + 6.10 + 7.5 = 21.0	92.0	84.4	20.26

cals. This will be found of greatest value in the determination of the structure of hydrocarbons which have no characteristic group.

The data given in Table IV may be used in the following way to determine the nature of the hydrocarbon radical. Taking the observed boiling point of the first compound of 108.35° a B. P. N. (observed) of 22.67 is obtained. Knowing that the compound has a molecular formula of $C_5H_{11}Cl$ we may calculate the B. P. N. for the normal chloride, which always has the greatest B. P. N. by at least 0.75 unit. The calculated B. P. N. is 22.50, which tells us at once that the chloride boiling at 108.35° is *n*-pentyl chloride. The second compound boiling at 96.7° has a B. P. N. of 21.48, which is very nearly one unit less than the normal chloride, indicating that the compound is a secondary chloride with a straight chain. However, a side chain methyl group would lower the B. P. N. by 0.75 unit giving a B. P. N. of 21.75 which might be confused with the secondary chlorides when the boiling points were not carefully obtained. This difficulty is readily cleared up by determining whether compound 2 is a primary or secondary chloride. If it is shown to be a secondary chloride then it must be either 2- or 3-chloropentane and cannot have the branched chain structure. Compound 3 will, of course, yield the same results as 2. The fourth compound is a primary chloride and subtracting the value of the primary chlorine (7.5) from the observed B. P. N. of 21.64 there are 14.14 units to be attributed to the hydrocarbon radical. The normal pentyl chain has a value of 15.0, which indicates that compound 4 has a side chain methyl group which lowers the B. P. N. by 0.75 to the calculated value of 14.25. Again, there are two possible structures which satisfy these conditions, *i. e.*, 1-chloro-2-methylbutane and 4-chloro-2-methylbutane, compounds 4 and 7 in Table IV.

The fifth compound is a tertiary chloride and, subtracting 6.0 from the observed B. P. N. of 20.41, the boiling point number of the alkyl radical is found to be 14.41. This value, being approximately 0.75 unit less than the normal pentyl radical, indicates the presence of a branched chain methyl group and only 2-chloro-2-methylbutane fulfils the conditions. However, if the carbon chain were longer, it would not be possible to locate the particular carbon atom to which both the chlorine and methyl were attached. The sixth compound is a secondary chloride and the b. p. n. of the alkyl radical is again 14.41 and a derivative of isopentane. The only secondary chlorine derivative of isopentane is 3-chloro-2-methylbutane. The eighth compound is a primary chloride and the b. p. n. of the alkyl group 12.76. This value indicates that there are more than one branched chain methyl groups, in fact the depression of 2.24 units indicates the presence of three. However, that is impossible with five carbon atoms and using the rule that the 2,2-dimethyl derivatives have low boiling points, the compound may be identified as neopentyl chloride.

The b. p. n. for the various oxygen containing groups in aliphatic compounds are listed in Table II. The introduction of alkyl groups about the characteristic group lowers the b. p. n. more or less depending upon the group. The hydroxyl is affected the most, the depression being 2.0 units per alkyl group and the ketones the least where 0.5 is the observed value. The effect is probably due to the steric effect of the alkyl groups. In spite of the well-known irregularity of the alcohols, the maximum deviation from the calculated B. P. N., out of 53 alcohols examined, was 2.71 with 4-decanol while at least half of the alcohols showed a deviation of less than 1.0. The ethers behaved more regularly: the greatest variation observed being 0.72 with diisobutyl ether, while more than half deviated less than 0.2 from the calculated. Decanal, among the aldehydes, gave the greatest deviation with a value 1.31 too low. The majority of aldehydes showed a deviation of less than 0.6. Among the ketones 2-pentadecanone was too low by 1.9 while half of them deviated by 0.4 or less. The B. P. N. of decanoic acid was found to be farthest from the calculated and was 1.57 while half of the acids examined had deviations less than 0.4 unit. Among the esters methyl caprate was too low by 2.28 and half deviated by as much as 0.4 unit.

The amines, cyanides, and isocyanides have been studied among the aliphatic nitrogen compounds. The b. p. n.'s. for the various substitution products containing these characteristic groups may also be found in Table II. Using those values satisfactory results are obtained with the exception of tri-*n*-heptylamine for which a boiling point about 20° too low has been reported. This seems entirely out of line with the other tertiary amines and further investigation may show that a value nearer 350° is correct. The amine that gave the next widest variation from the calculated was di-(α-methylheptyl)-amine with 2.32. It also is high boiling and its boiling point may have been determined incorrectly. With at least half of the amines the deviation amounts to less than 0.4 unit. Among the alkyl cyanides decane nitrile gave the greatest variation of 1.42, while over half of them deviated less than 0.3. Out of ten isocyanides ethyl isocyanide deviated the most with 0.94 while half deviated 0.6 or less.

Other groups of compounds are being studied in the same way and a general survey of the field has been contemplated. The author will welcome data, suggestions, and criticism in the hope that the new method will become a particularly useful tool in organic chemistry and that many new relationships affecting the behavior of compounds will be the result. In developing the method the author is especially indebted to the late Professor E. P. Kohler and to Professors L. Pauling and H. Gilman for many valuable suggestions and encouragement.

Summary

A method has been devised for correlating the structure of organic compounds with their boiling point. Boiling point numbers for a variety of atoms, groups, and molecules have been obtained and the accuracy discussed. Methods for calculating the boiling point of a compound from its structure and the structure from the boiling point have been outlined. The combined effect of several groups in the molecule upon the boiling point has been discussed.

The Viscosities of Solutions of the Proteins of Horse Serum[1]

BY KATHLEEN R. FAHEY AND ARDA ALDEN GREEN

The viscosity of solutions of proteins is known to vary widely with the character of these solutes. Some, in sufficiently dilute solution, obey approximately the classical Einstein law relating viscosity and concentration. Thus Loeb,[2] in studying egg albumin, observed agreement with the Einstein equation; and Daniel and Cohn[3] noted that "the viscosity of such a protein as egg albumin is not very different from that of glycine when both solutes occupy the same volume fraction of solution. . . . Hemoglobin and serum albumin, whose molecules—according to Svedberg—are larger and not quite spherical, are, however, more viscous than demanded by the coefficient of Einstein's equation. None the less, hemoglobin like egg albumin obeys Poiseuille's law relating viscosity to pressure. A great many protein molecules are, however, highly asymmetrical in shape, and give rise both to anomalous viscosity and to double refraction of flow, in this respect resembling the long chain polymers studied by Staudinger and his collaborators."

The serum protein fractions as then separable were studied carefully by Harriette Chick[4] twenty-five years ago. She investigated their viscosities as affected by temperature and by concentrations of protein, salt and hydrogen ions. She reported, "In all cases, increase in protein concentration is accompanied by a disproportionately great in-

crease in the viscosity of the solution. The effect is greatest in case of euglobulin, solutions of which exhibit a high viscosity at a comparatively low protein content. It is least in case of serum albumin, which, for strengths of protein under about 10% behaves almost as a crystalloid. Pseudoglobulin is intermediate between the other two proteins in this respect."

Differences in viscosity of the various serum protein fractions are so great as to be determined readily, and are presumably of significance in regard to the size and shape of the molecules.

Three isoelectrically precipitable globulins, designated PI, PII and PIII, have been separated from normal horse serum.[5] Two of these, PI and PIII, have isoelectric points close to *p*H 5 and one, PII, close to *p*H 6. Since these globulin fractions differ in their method of preparation from those of Chick and other investigators, it was thought advisable to investigate their viscosities and also those of the remaining soluble serum proteins.

Experimental

The isoelectrically precipitable globulins PI, PII and PIII were prepared in the manner described in a previous communication.[5] In some instances the identical preparations were used. The essential characteristic of this method of separation of serum globulins is isoelectric precipitation in a very low concentration of salt.

The proteins precipitated from normal horse serum in solutions one-half saturated with ammonium sulfate were dialyzed against water. After dialysis dilute hydrochloric acid, approximately 0.01 *N*, was added cautiously until a precipitate formed, usually at *p*H 6.5. This precipitate was removed by centrifugation. It contained PIII as well as PII, for although the isoelectric point of PIII is close to *p*H 5, this fraction is nevertheless precipitated with PII at *p*H 6.5 because it is so very insoluble. These globulins were separated from each other by solution in acid and fractional reprecipitation with alkali. To the solution obtained after removal of PII and PIII dilute hydrochloric acid was added again until the *p*H was close to 5, and a certain amount of PI was isoelectrically precipitated. Dilution with water, further dialysis or reprecipitation with ammonium sulfate followed by dialysis brought down a further quantity of PI.

At least three or four solutions in alkali or acid and isoelectric reprecipitations were carried out on each fraction before the proteins were considered to approach homogeneity. The protein remaining in solution after all water insoluble proteins are removed by dialysis and electrodialysis from the total globulin fraction obtained by repeated precipitation with ammonium sulfate at one-half saturation was termed pseudoglobulin.

Since the euglobulins are insoluble at their isoelectric points, viscosities must be determined either in the presence of salt or at a reaction away from the isoelectric point. To obtain solutions in 0.5 *M* saline, precipitates were first dissolved in a small amount of sodium hydroxide; sodium chloride solution was then added, followed by an amount of hydrochloric acid equivalent to the amount of sodium hydroxide used to dissolve the precipitate. To prepare solutions in alkali, dialyzed suspensions of the precipitates in distilled water were treated with the minimum amounts of 0.1 *N* sodium hydroxide to bring the precipitates completely into solution. The resultant *p*H of the PIII solutions was 7.0 and 7.1, of the PII solution 8.0, and of the PI

[8] Earlier measurements from the Department of Physical Chemistry, Harvard Medical School,[3] hitherto unpublished in detail.

solution 6.5. The pseudoglobulin solution was electrodialyzed and its *p*H was 6.0. The amount of protein in solution was determined by heat coagulation at the isoelectric point; coagulated protein was washed on sintered glass filters till salt free and was dried at 110° to constant weight.

The viscosities were measured at 25 ± 0.1° in Ostwald viscosimeters. The densities were determined at the same temperature in a pycnometer of approximately 10 cc. volume. The relative viscosities reported are the average of at least three determinations. In calculating the relative viscosity the ratio of the time of flow of 0.5 *M* sodium chloride to water was taken as 1.015 and the density of 0.5 *M* sodium chloride and of water at 25° as 1.0173 and 0.99707, respectively. The data are recorded in Table I.

Discussion

For comparison with the existing data on the viscosities of serum proteins, the data are presented in Fig. 1, in which concentration of protein in grams per liter is plotted against the relative viscosity, η/η_0-1, where η is the viscosity of the solution and η_0 the viscosity of the solvent.

The viscosities of the serum proteins studied increase in the order albumin, pseudoglobulin, PI, PII and PIII. The pseudoglobulin and albumin values check satisfactorily with Chick's determinations,[4] and her curve for euglobulin, prepared by acidification of ten-fold diluted horse serum with acetic acid (to *p*H 5.4–6.0) lies between PI and PII.

Chick's data have been recalculated on a volume basis rather than as grams per 1000 grams. Under these circumstances curves for solutions obtained by addition of dilute sodium chloride or dilute alkali appear to be superimposable. Over the range studied our curves are also identical within the limit of error of these measurements whether the protein, PI or PII, was dissolved in 0.5 *M* sodium chloride at the isoelectric point or was in solution in dilute alkali.

Einstein,[9] in 1906, derived an equation for the viscosity of a suspension or solution of spherical particles

$$\eta/\eta_0 = (1 + 2.5\,\varphi) \qquad (1)$$

where φ is the volume fraction occupied by the particles (the solute), and η_0 the viscosity of the solvent at the same temperature. This equation is linear in φ and therefore in the concentration in grams per liter of solution if the partial specific volume of the solute is constant. It has been used by Daniel and Cohn[3] in describing the viscosities of a series of amino acids and related substances in dilute solution. They noted that

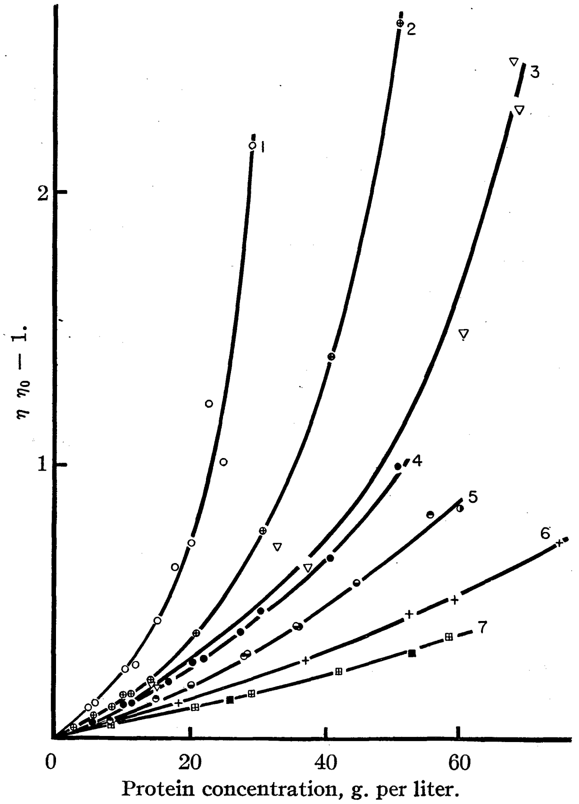

Fig. 1.—Viscosity of serum proteins: curve (1) serum globulin PIII ○; (2) PII ⊕; (3) euglobulin (Chick) ▽; (4) PI ●; (5) pseudoglobulin (this investigation ◓ ◒ and Chick ◑); (6) whole serum (Chick) +; (7) serum albumin (this investigation ⊞, Chick and Lubrzynska ■).

"measurements upon aliphatic amides, amino acids and peptides even up to viscosities more than three times that of water are given by the equation

$$(\eta/\eta_0 - 1) = 2.5\ K\varphi + (2.5\ K\varphi)^{2.8} \qquad (2)\text{''}$$

Although the viscosity curves of all proteins deviate in concentrated solutions from the linear relationship demanded by the Einstein equation, in sufficiently dilute solutions the linear relationship is approximated and the value of K may be estimated. The range over which viscosity is roughly linear with concentration is shown graphically for the serum proteins in Fig. 2. The values for K[10] are given in Table II together with

---

(9) A. Einstein, *Ann. Phys.*, **19**, 289 (1906); **34**, 591 (1917).

(10) The values of K adopted were obtained from determinations of relative viscosities of solutions of low protein concentration. Even over this range, however, K, calculated by means of equation 1, shows a drift with concentration. Estimated by extrapolation to infinite dilution on the basis of a plot of C against K, the following values of K were obtained and the corresponding values of s/d are also implied:

	Serum albumin	Pseudo-globulin	Serum globulins		
			PI	PII	PIII
K	2.6	4.5	4.6	7.0	10.0
s/d	8.0	11.8	12.0	15.5	19.0

Tobacco mosaic virus[18,19]	.73	35.0	...	...	36.9

values for some amino acids and related substances estimated by Daniel and Cohn. The values for the specific volume, V, have been calculated from values for concentration of protein and density in Table I and in Harriette Chick's data. The values calculated from the results of Chick are 0.725, 0.73 and 0.715 for serum albumin, euglobulin and pseudoglobulin, respectively. These are slightly smaller than the values 0.758 for serum albumin and 0.745 for serum globulin, containing both eu- and pseudoglobulin, estimated by Svedberg[13] on solutions which never exceeded 3%.

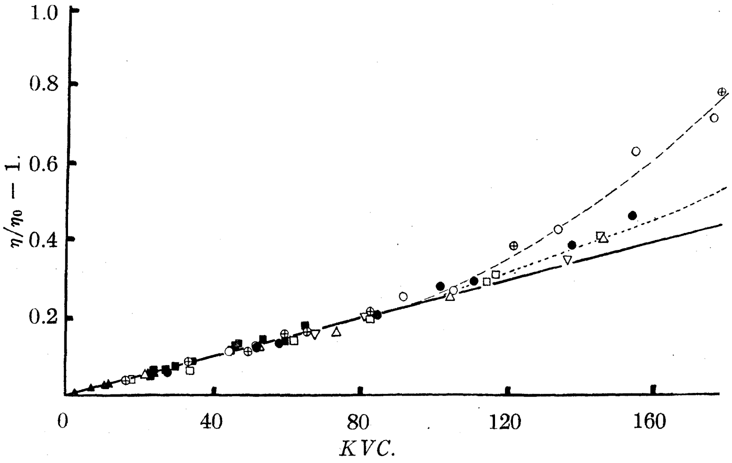

Fig. 2.—Viscosity of dilute solutions of proteins: PI ●; PII ⊕; PIII ○; pseudoglobulin □; serum albumin △; casein ▽ (Sackur[22]); hemoglobin ■ (Cohn and Prentiss[11]); and tobacco mosaic virus ▲ (Lauffer[18] Frampton and Neurath[19]).

In order to describe the deviations of viscosities from the linear relationship in the more concentrated solutions of protein, equation (2) may be modified further to give the following

$$\eta/\eta_0 - 1 = \left(\frac{2.5\ KVC}{1000}\right) + Y\left(\frac{2.5\ KVC}{1000}\right)^X \qquad (3)$$

The curves in Fig. 2 and the viscosity curves of Chick and collaborators up to $\eta/\eta_0 = 20$ given in Fig. 3 may be described in terms of the above equation using the values for K, X and Y reported in Table II.

The numerical value of K has been calculated from the linear relation in low concentration of protein. The more viscous is the protein the higher the value for K. The values for X for the serum proteins are approximately 4 and, therefore, greater than those for amino acids. The value for Y also tends to increase for the serum proteins and for the more viscous globulins, PII and PIII, is as high as 8.

The peculiarities of protein viscosity have been attributed to hydration of molecules,[4,14,15] to electrical interactions, and to shape of the molecules. W. Kuhn[16] has developed the following equation for the increase in viscosity of rod-like molecules

$$\eta/\eta_0 - 1 = 2.5\,\varphi + \frac{\varphi}{16}\left(\frac{s}{d}\right)^2 \qquad (4)$$

from which a definite relation between length, s, and width, d, of the molecule can be obtained assuming the length is much greater than the width. Guth[17] has presented a more general treatment of the problem in which the Kuhn equation is obtained as a limiting case for molecules which are ellipsoids of revolution. The relation between equation (4) and equation (1) may be expressed as follows

$$K = 1 + \frac{1}{40}\left(\frac{s}{d}\right)^2 \qquad (5)$$

The values for K adopted (Table II and footnote 10) lead to values of s/d varying from 1.7 for glycine to 26 for casein and 37 for tobacco mosaic virus.

A similar application of Kuhn's equation to the viscosity measurements on tobacco mosaic virus

---

[11] Cohn and Prentiss, *J. Gen. Physiol.*, **8**, 619 (1927).

[12] Loeb[2] found that the viscosity of egg albumin follows the simple Einstein equation where K is approximately 1.0. Further determinations on the viscosity of egg albumin will be reported later.

[13] Svedberg and Sjogren, THIS JOURNAL, **50**, 3319 (1928).

[14] M. Kunitz, *J. Gen. Physiol.*, **17**, 365 (1934).

[15] S. Arrhenius, *Medd. Vetenskapakad. Nobelinst.*, **3**, No. 13 (1916); *Biochem. J.*, **11**, 112 (1917).

[17] E. Guth, *Kolloid. Z.*, **74**, 147 (1936).

by Lauffer,[18] and Frampton and Neurath[19] results in an estimate of s/d as 35 to 36.8. Polson,[20] also, has calculated the relation of length to width of a number of proteins from viscosity measurements using the Kuhn equation in conjunction with the Arrhenius equation for estimating the viscosity increments at infinite dilution. His values of d/s for egg albumin and serum albumin are 0.142 and 0.123, respectively, which yield values of s/d of 7.05 and 8.13 of the same order of magnitude as those calculated above. On the same basis thyroglobulin and Octopus hemocyanin both have values of s/d of 10.

Staudinger[21] exhaustively studied long chained organic compounds of the paraffin series of exceptionally high viscosity and came to the conclusion that their specific viscosities depend on the length of the molecule. In the case of proteins and of acyclic amino acids and their esters with paraffin chains the situation is more complicated. The observed viscosity is higher than that calculated from chain length which he suggests is due to the numerous acid amide linkages.

Whatever the theoretical explanation of the viscosity behavior of protein solutions, it is of significance that these serum proteins vary in range of viscosity from that of the nearly spherical egg albumin molecule to that of the highly viscous casein molecule.[22] Whereas the globulin solutions of normal horse serum are largely homogeneous in the ultracentrifuge, and the titration curves differ definitely but only slightly,[5] the viscosities vary so widely as to be characteristic.

Conclusions

1. The viscosities of solutions of six protein fractions of normal horse serum have been measured and compared with those of other proteins.

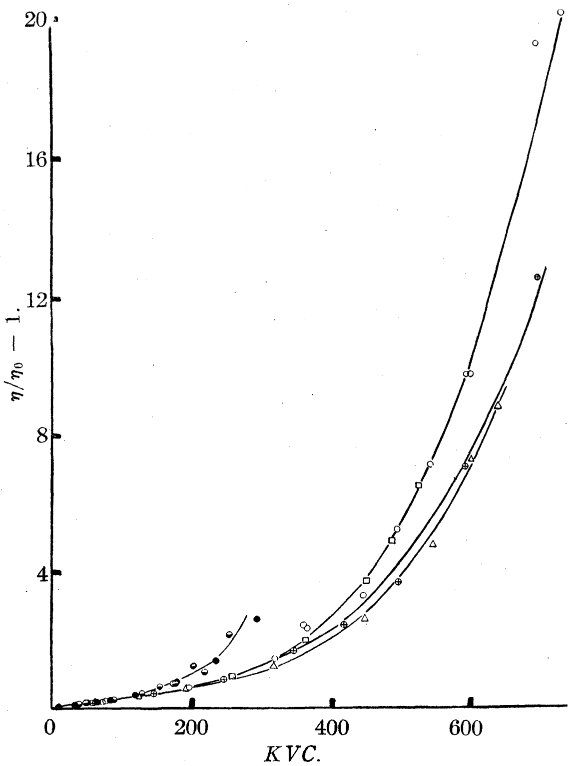

Fig. 3.—Viscosity of more concentrated protein solutions: euglobulin ○; pseudoglobulin ⊕; serum albumin □ and egg albumin △ calculated from Chick's data[4]; PII ●; and PIII ◒.

2. The viscosities of the solutions of three isoelectrically precipitable protein fractions, PI, PII and PIII increase in the order named, whereas that of pseudoglobulin is lower than any of these, and albumin is lowest of all.

3. The viscosity of concentrated protein solutions has been described by the equation

$$\eta/\eta_0 - 1 = \frac{2.5\,KVC}{1000} + Y\left(\frac{2.5\,KVC}{1000}\right)^X$$

4. The viscosities of the various serum proteins differ so greatly as to be essentially characteristic and perhaps are of significance in regard to the shape of the molecules.

The Photochemical Oxidation of Acetone*

BY F. O. RICE AND C. E. SCHILDKNECHT

(1) Introduction

In studying the photochemical decomposition of acetone, Damon and Daniels[1] observed that traces of oxygen produced an initial reaction much more rapid than the decomposition that occurred after all the oxygen was used up; this oxidation reaction was accompanied by a blue fluorescence and proceeded with a decrease in pressure. Damon and Daniels suggested that a chain reaction might be occurring but did not examine the products or investigate the oxidation reaction further. However, Fugassi,[1b] working in Daniels' laboratory, measured the quantum yield of the oxidation and concluded that if one molecule of oxygen reacts with one molecule of acetone, the quantum yield for the oxidation of acetone is the same as that for its decomposition. In contrast with our work, the experiments of Damon and Daniels and of Fugassi were performed with oxygen at partial pressures of less than 1% of that of the acetone.

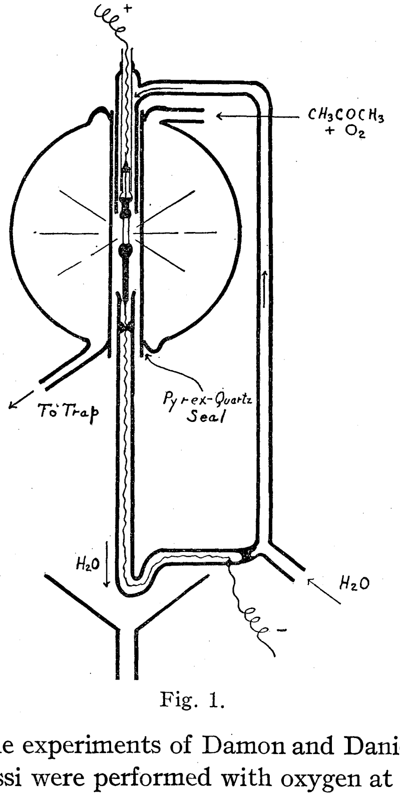

Fig. 1.

We have found that the oxidation occurs through a short chain and that the principal overall reaction may be expressed by the stoichiometric equation

$$CH_3COCH_3 + O_2 \longrightarrow CH_3COOH + HCHO$$

This is followed by a photochemical chain oxidation of the aldehyde according to the equation

$$HCHO + O_2 \longrightarrow H_2O + CO_2$$

These products are accompanied by various peroxides in smaller amount formed in secondary reactions.

The photochemical oxidations of formaldehyde and acetaldehyde have been studied by Carruthers and Norrish[2] and have been found to be short chains also. This is in marked contrast to the ordinary photodecomposition of these compounds, since the aldehyde decompositions are chains,[3] but the acetone decomposition is not a chain,[4] at least not at temperatures up to about 400°.

(2) Experimental

Various types of flowing systems were used in the work and one of them which was particularly satisfactory is shown in Fig. 1. Dry oxygen was bubbled through acetone at about 150 cc. per minute in a bubbler at 22° and gave a mixture containing about 25% of acetone. This was passed directly into the reaction vessel, a 1-liter Pyrex bulb containing a high pressure capillary quartz mercury arc of the type described by Daniels and Heidt.[5] The lamp was mounted in a quartz test-tube through which water was circulated; the temperature of the cooling water was kept at about 40° to prevent condensation of products on the walls of the tube. The lamps which we used had an output of from 0.05 to 0.2 einstein per hour between 2536 and 4350 Å. as measured by the uranyl sulfate–oxalic acid actinometer solution.[6] In the apparatus shown, a large part of the active light is absorbed and the photolysis presents a striking appearance by the condensation of droplets of products upon the walls of the jacket.

All experiments, including especially distillations, were performed behind shatter-proof glass because of the explosive nature of the peroxides formed. We had several explosions during the course of distillations but illumination of the pure acetone–oxygen mixture never resulted in an explosion. In one experiment we mixed hexane vapor with the acetone–oxygen mixture and observed that a

cloud formed during the course of the oxidation. After running for a few minutes, the mixture exploded, completely shattering the apparatus. The most difficult part of the work was the separation, identification and estimation of the products formed in the photoöxidation. The results of a typical run are shown in Table I.

TABLE I

21–22	50–54	75	3.0	Acetic acid[c]
23	30–35	13	0.5	Peroxide
24	35	13	.5	Peroxide[d]

[a] Contained some peroxide. [b] Contained some acetic acid. [c] Contained all the formaldehyde largely as paraformaldehyde. [d] Explosive white solid, m. p. ~30°.

The twenty-four fractions were obtained by distillation in a 30-cm. column with a rotating receiver and constant pressure control. Each fraction was weighed and a weighed portion of each was dissolved in water and used for quantitative estimations. The remainder was used for qualitative tests and preparation of derivatives.

Fractions (1) and (2) consisted of a gas with a sweetish, ethereal smell reminiscent of nitrous fumes but producing a stinging sensation in the nose when inhaled. The gas was soluble in water, did not give an aldehyde test and slowly liberated iodine from a potassium iodide solution acidified with acetic acid; it was very explosive. These properties and its boiling point indicate that it is dimethyl peroxide $CH_3–O–O–CH_3$.

Unreacted acetone was estimated by the iodoform method making a correction for the formaldehyde. Methanol was absent and acetaldehyde was present only in traces. Formaldehyde and its polymer were present in all the acetic acid fractions; the formaldehyde was identified as the 2,4-dinitrophenylhydrazone and was estimated volumetrically by reduction of copper.

Water was formed in the oxidation but was not estimated; free hydrogen was absent from the gases leaving the reaction vessel. There was a considerable amount of carbon dioxide formed which was estimated by absorption by Ascarite.

The last fractions, before distillation was completed, consisted of an oily residue; as this was heated to about 120° it turned reddish-brown and exploded with a bright flash of light demolishing the apparatus. Distillation at low pressure gave a white waxy solid, melting just above room temperature, which detonated violently if dropped on a hot-plate. It was sparingly soluble in water and reacted with acidified potassium iodide. This material was probably largely diacetyl peroxide which has already been reported by Carruthers and Norrish as a product of the photochemical oxidation of acetaldehyde. In Table II we summarize the analytical results for a typical run.

TABLE II

PHOTOCHEMICAL OXIDATION OF ACETONE

Conditions same as in Table I

Peroxide	.002	.07
Carbon monoxide	.002	.07
Water (not determined)	...	..

The quantum yield of the oxidation process had an average value of 0.3 as compared with the value 0.03 for the photochemical decomposition of acetone carried in a stream of carbon dioxide in the same flowing system. In one of these experiments a mercury–argon glow lamp was used as light source and the output of the lamp was determined in position in the reaction chamber just before and after each oxidation run by filling the jacket with actinometer solution. We assumed that the glow lamp emitted only light of wave length 2536 Å. (actually the figure is 86%) and from the extinction coefficient for acetone[7] and the dimensions of the irradiation jacket we calculated the quantum yields. In other experiments we used a capillary arc following the same method and made a graphical estimate of the distribution of energy in the spectrum of the lamp. The amount of acetone decomposed was found by titrating for acetic acid in the oxidation experiments and by estimating the carbon monoxide produced in the photodecomposition of pure acetone. The results obtained are shown in Table III.

The refractive index of the recovered acetone in the experiments in absence of oxygen was increased only very slightly (1.358 to 1.360) and no yellow color appeared on evaporation; a test for acetonylacetone was negative.

(3) Discussion of Quantum Fields

Our average value of 0.36 for the quantum yield of the oxidation process is near to Fugassi's[1b] value of 0.24, which is the number of molecules of oxygen reacting per quantum absorbed when the acetone is in very great excess. However, Damon and Daniels[1a] report a yield of 0.17 molecule per quantum for the decomposition in absence of oxy-

TABLE III

QUANTUM YIELD DETERMINATIONS FOR PURE ACETONE AND FOR ACETONE + OXYGEN

Temp. 80–100°. The light source was a mercury argon lamp in Expt. (1) and a high pressure capillary arc in all the others.

Expt.	Gas present	Length of run, hrs.	Output of lamp, einsteins/hr.	Light absorbed in run, einsteins	Moles product	Quantum yield
1	O_2	4.64	0.0011	0.00088	0.00034 CH_3COOH	0.39
8	O_2	2.75	.071	.025	.009 CH_3COOH	.36
9	O_2	2.16	.071	.0152	.0061 CH_3COOH	.40
11	O_2	1.50	.050	.0104	.003 CH_3COOH	.33
12	O_2	1.90	.050	.0123	.004 CH_3COOH	.33
1P	CO_2	1.00	.070	.0091	.0003 CO	.03

gen, in contrast with our value of 0.03; they found that the quantum efficiency was diminished by increasing the light intensity and by lowering the pressure of acetone. Since we used much higher light intensities and also a lower pressure of acetone, the difference may be due to different experimental conditions. Norrish, Crone and Saltmarsh[8] also obtained results substantially in agreement with Damon and Daniels, and reported values for the quantum yield of the decomposition process in the range 0.2 to 0.4.

There is a possibility of error in our results for the quantum yield of the decomposition process because we estimated the extent of decomposition by analyzing for carbon monoxide and Barak and Style[9] have shown that acetone partly decomposes photochemically into diacetyl below 60°. Unfortunately, while we tested for acetonylacetone, and examined the refractive index of the residual acetone, we did not make a direct test for diacetyl; however, it seems highly unlikely that 80–90% of the acetone decomposed would form diacetyl under our conditions, and this amount would be necessary to bring our result up to previous values.

(4) Mechanism of the Oxidation of Acetone.—The following scheme gives a satisfactory representation of the course of the reaction from the point of view of products formed as well as from the standpoint of certain rules concerning the course of elementary reactions.[10]

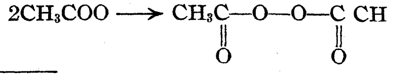
$$CH_3COCH_3 + h\nu \longrightarrow CO + 2CH_3 \qquad (1)$$

$$CH_3 + O_2 \longrightarrow CH_3{-}O{-}O \qquad (2)$$

$$CH_3O_2 \longrightarrow HCHO + OH \qquad (3)$$

$$OH + CH_3COCH_3 \longrightarrow H_2O + CH_3COCH_2 \qquad (4)$$

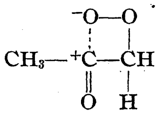
$$\left.\begin{array}{l} CH_3COCH_2 + O_2 \longrightarrow CH_3COCH_2{-}O{-}O \\ CH_3COCH_2O_2 \longrightarrow HCHO + CH_3COO \\ CH_3COO + CH_3COCH_3 \longrightarrow \\ \qquad CH_3COOH + CH_3COCH_2 \end{array}\right\}\text{Chain} \quad \begin{array}{l}(5)\\(6)\\ \\(7)\end{array}$$



$$2CH_3COO \longrightarrow \begin{array}{c}CH_3C\\ \|\\ O\end{array}{-}O{-}O{-}\begin{array}{c}C\\ \|\\ O\end{array}CH \qquad (8)$$

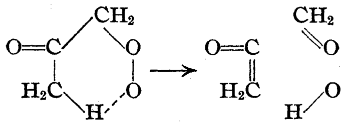
Since the oxidation occurs in the range 80–100° we have represented the primary step as a direct decomposition into carbon monoxide and methyl radicals since probably the acetyl radical is very unstable in this temperature range.[11] The reaction of methyl with oxygen (2) and the decomposition into formaldehyde and hydroxyl (3) as well as the reaction of hydroxyl with acetone (4) seem quite reasonable from the standpoint of the principle of least motion. Since the heavy fractions did not seem to contain any CH_3COOH, we have represented the radical $CH_3{-}O{-}O$ as decomposing, instead of attacking the acetone.

Presumably we can neglect any decomposition of the acetonyl radical into ketene and methyl because of the high activation energy of this process.[12] However, the decomposition of the acetonyl peroxide presents some difficulties: we may assume that there is an attraction between the positive carbon and negative oxygen as shown



$$\begin{array}{ccc} & {}^{-}O & {-}O \\ & \vdots & | \\ CH_3{-} & {}^{+}C & {-}CH \\ & \| & | \\ & O & H \end{array} \qquad (9)$$

followed by splitting off of formaldehyde, leaving an acetate radical or we may assume that the radical is chelated



(10)

and decomposes into formaldehyde, ketene and hydroxyl. The process represented by equation (6) is simpler than (10) and probably is to be preferred. Furthermore, if ketene was formed some of it probably would have escaped reaction with water formed in the chain and would have been detected by its characteristic odor. The considerable production of the solid explosive peroxide

[12] Rice and Herzfeld, THIS JOURNAL, **56**, 284 (1934).

(probably diacetyl peroxide) suggests that the main chain-terminating reaction is the combination of two acetate radicals.

It is of course possible that the attack of the hydroxyl radical on acetone may be represented by the equation

$$OH + CH_3COCH_3 \longrightarrow CH_3COOH + CH_3 \quad (11)$$

instead of (4), followed by equations (2) and (3). This would also represent correctly the chemical course of the decomposition, especially if we assume that reactions (4) to (8) occur to a small extent as side reactions producing diacetyl peroxide; however, we believe that equation (4) is to be preferred to equation (11).

Summary

1. The products of the photochemical oxidation of gaseous acetone at 100° with the full radiation from a mercury vapor lamp are acetic acid and formaldehyde; the formaldehyde is largely oxidized to carbon dioxide and water; there are smaller amounts of organic peroxides formed.

2. The quantum yield of the oxidation process has been found to be about 0.3, approximately ten times the quantum yield of the photochemical decomposition in presence of carbon dioxide in the same system.

The Oxide-coated Filament. The Relation between Thermionic Emission and the Content of Free Alkaline-earth Metal

BY C. H. PRESCOTT, JR., AND JAMES MORRISON

Introduction

The oxide-coated filament had its beginning in the sealing-wax era of vacuum technique. The obscure accident of its origin is not recorded, but all of our older physicists knew that an enhanced emission of electrons could be obtained by smearing sealing-wax on a platinum ribbon and burning it off in air. The first authentic study is recorded by Wehnelt,[1] who investigated the voltage-drop in a gas discharge tube with cathodes coated with various metallic oxides. Its further evolution and development to the status of a cathode in Western Electric vacuum tubes has been described by H. D. Arnold.[2] A comprehensive treatment of its history, the various modifications in current use, and divergent theories of its preparation and behavior has been given by Saul Dushman[3] in a treatise on "Thermionic Emission." A later review is given by J. H. deBoer.[4]

The present work is devoted to a quantitative determination of the relation between thermionic emission and the content of free alkaline earth metal. To this end we have employed a filament which is a platinum rhodium core coated with barium, strontium, and nickel carbonates. On heating in a reducing atmosphere this coating becomes a grossly homogeneous colloidal mixture of barium oxide, strontium oxide, and free nickel. After a thorough preliminary clean-up of the experimental tube, the requisite amounts of free alkaline-earth metal are generated by reaction with methane. The electrical measurements are summarized by the use of the Richardson equation for thermionic emission. Free alkaline earth metal has been determined by oxidation with carbon dioxide and analysis of the gaseous reaction products.

Acknowledgment is due to Mr. V. L. Ronci and his staff for their care in the assembly of the vacuum tubes used in these studies.

Experimental Procedure

The experimental tube used for these studies, as shown in Fig. 1, contains a filament whose core is a 0.0127-cm. wire of 80% platinum and 20% rhodium. The coating was applied by passing the core through a suspension of barium carbonate, barium nitrate, strontium carbonate, and basic nickelous carbonate in amyl acetate and pyroxylin. Three coats were applied after each of which the filament passed through an oven at 675° in an atmosphere of carbon dioxide. The coating vehicle largely evaporated and the fusion of barium nitrate gave the coating enough adherence to undergo the processes of assembly. The final coating is 0.0025 cm. thick to as close as we can determine.

The filament is mounted in the common axis of three cylindrical nickel plates. The central cylinder is the anode used in the measurements; the other two serve as guard rings to define a radial field about the segment of filament whose emission is measured. The filament core is scraped bare for 0.475 cm. from the welds, which just suffices to concentrate the end cooling in the bare segments. As a result the coated area runs at a uniform temperature, which is essential to ensure uniform activation and so give significance to the determination of free alkaline earth metal. Small holes (as shown in Fig. 1) are bored in the plates to permit temperature measurements of the filament which is held taut by a large molybdenum spring.

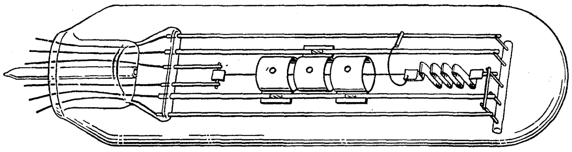

Fig. 1.—The experimental tube.

The physical dimensions of the filament and experimental tube are given in Table I.

Table I

Coated length	4.125 cm.
Plate length	0.9524 cm.
Filament core radius	.00635 cm.
Coating radius	.00889 cm.
Plate radius	.475 cm.
Coating area	.2305 sq. cm.
Emitting area	.0532 sq. cm.
Volume of bulb	245 cc.

With the exception of the filament, all metal parts, prior to assembly, were baked for four hours at 1200° in a stream of hydrogen, saturated with water at room temperature. This procedure was designed to burn out such impurities as carbon and sulfur. This treatment was found necessary in order to avoid spurious activation and large blanks in the determination of free alkaline earth metal.

We still encountered spurious activation by reaction of the oxides with carbonaceous residues from the coating bath. This necessitated a rigorous conditioning treatment. After the tube was baked out, and the plates outgassed by heating with induced high frequency current, the filament was glowed in successive samples of carbon dioxide. This treatment was continued until the carbon monoxide formed was reduced to about 0.05 cc. mm. (cubic centimeters at one millimeter pressure). The preliminary conditioning treatment is given in detail in Table II. Treatments are *in vacuo* except as specified.

Table II

1. Baked 60 min. at 400–425°
2. Glowed filament, 5 min. at 1000°
3. Glowed filament, 30 min. at 900° in 5 cc. mm. CO, 10 cc. mm. CO_2
4. Heated plates, 5 min. at 850°
5. Heated plates in 0.5 mm. H_2, 5 min. at 850°
6. Heated plates, 5 min. at 850°
7. Glowed filament in 10 cc. mm. CO_2, 30 min. at 900°
8. Baked 45 min. at 400°, measured rate of gas evolution to ensure substantial clean-up
9. Heated plates, 850°, measured rate of gas evolution
10. Glowed filament in 1–2 cc. mm. of CO_2, 30 min. at 900° and analyzed the gaseous products

The filament was activated by glowing for fifteen minutes at an uncorrected temperature of 900°, in a sample of methane. The methane was substantially decomposed, giving hydrogen and carbon monoxide, which indicate the chemical reaction

$$CH_4 + BaO = Ba + CO + 2H_2 \text{ or}$$
$$CH_4 + SrO = Sr + CO + 2H_2$$

Some of the active metal formed evaporated from the filament and reëvaporated from the plates, either during formation or in the subsequent stabilization treatment. Due to the "gettering" action of this evaporated metal, carrying down some of the gases, the reaction products were not quantitatively recovered for analysis.

Before taking electrical measurements it was necessary to denude the tube of gas and to permit diffusion to bring the filament coating into an equilibrium state. A liquid air trap was used to keep mercury vapor out of the tube during the measurements. This conditioning and stabilizing treatment is given in detail in Table III.

Table III

1. Heated plates, 3 min. at 800°
2. Baked 15 min. at 350°
3. Removed mercury vapor by use of liquid air, contd. bake for 15 min., fil. at 700° during last 5 min. of bake
4. Heated plates, 3 min. at 800°
5. Glowed filament, 15 min. at 900°
6. Glowed filament, 60 min. at 800°, 80 v. potential on plate

After the emission current at 800° and 80 v. had remained stable for a period of at least thirty minutes, the currents to the central plate were measured at a series of temperatures between 700 and 800°.

When the emission measurements were completed, the liquid air was removed, and the filament subjected to successive treatments in samples of carbon dioxide which were each collected for analysis. The total carbon monoxide found was taken as a measure of the free alkaline earth metal according to the reaction

$$CO_2 + Ba = BaO + CO$$

During this treatment a considerable proportion of the carbon dioxide was converted to barium and strontium carbonates. It should be noted, however, that the amounts were small as compared to the total amounts of barium and strontium oxides. These carbonates were subsequently decomposed and the carbon dioxide recovered, as the filament was glowed for approximately twenty minutes while the gases were pumped off for analysis.

Four tubes used in this study were each activated three times in methane and deactivated by treatments with carbon dioxide.

The Temperature Measurements

Temperatures were measured with an optical pyrometer of the disappearing filament type following in general a design by Forsythe.[5] This was calibrated from 700 to 1200° against a standard lamp obtained from the Bureau of Standards. A screen of Corning Pyrometer Red glass (effective wave length 0.66 μ) was used for temperatures above 800°. Below this temperature no screen was used, but no errors are introduced due to the predominantly red character of the light. The uncertainties in the temperature measurements are about 5°, which is within the limits of other errors in dealing with the oxide-coated filament.

Corrections were applied for a 90% transmission of the glass bulb and the emissive power of the filament which was approximately 64%. Since the sum of the emissive power and reflectivity is unity, we have been able to compute the emissive power from the diffuse reflectivity determined by a method analogous to that employed by Worthing.[6] Details of these measurements are described in another article.[7]

The experimental reflectivity (after the preliminary treatments) is approximately 36% both at room temperature and under operating conditions. There is little if any change due to activation, *i. e.*, formation of free alkaline earth metal. There is a gradual rise with time due to glowing at 900° which may be due to gradual sintering or slight loss of nickel. This introduces an uncertainty no greater than that already indicated in the temperature measurements.

The Measurements of Thermionic Emission

During emission measurements the tube was open to the vacuum pumps but protected from mercury vapor by a liquid air trap. After the filament was outgassed and stabilized, the thermionic emission was measured at a series of potentials from 0 to 100 v., and at several uncorrected temperatures ranging from 700 to 800° (corresponding to 998 to 1103°K. true temperature). Below 700° the filament could not be seen in the optical pyrometer, and above 800° the activity was unstable. At 900°, in particular, the activity rapidly dropped to a lower level, presumably characteristic of a dynamic steady state involving evaporation of active metal from the filament surface, but it recovered in a few minutes of aging at 800°. We thus were limited to a range of 100° in the region of normal operating temperatures. In this range, however, the measurements characteristic of a given state of the filament were entirely reproducible to within the limits of the temperature measurements.

Since the field within the collecting anode is strictly radial, the limiting case of temperature saturation where the current is limited by space-charge should follow the slope of the Langmuir space-charge equation.[8] This is a linear relation between the two-thirds power of the current and the applied voltage. Figures 2 and 3 show typical examples of the current–voltage relations, the two-thirds power of the current being plotted against the applied voltage. The theoretical slope is indicated by the broken line.

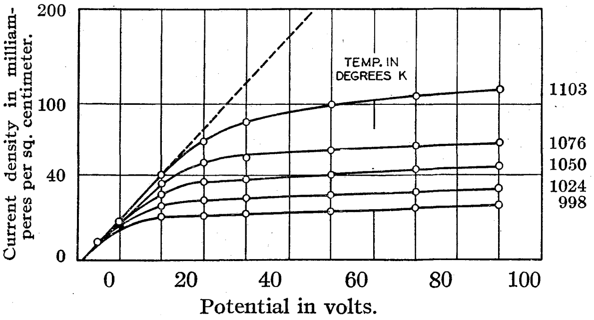

Fig. 2.—Tube A, state 4: two-thirds power of current density *vs.* applied potential.

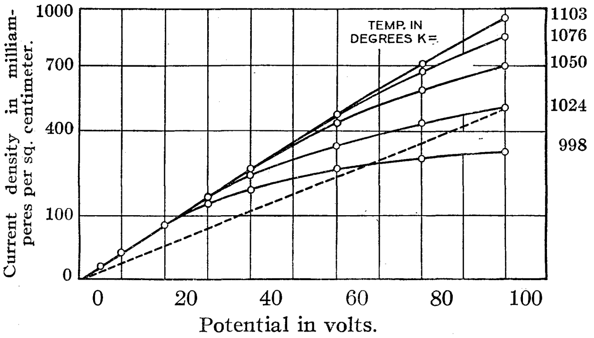

Fig. 3.—Tube C, state 3: two-thirds power of current density *vs.* applied potential.

We may note (as in Fig. 3) that, as the filaments become more active, the currents rise above the limiting values indicated by the Langmuir space-charge equation. Such an effect suggests such factors as gas ionization and spurious paths by which electrons could reach the anode. But these do not seem probable and should give curved relations and not the limiting straight lines found in all cases by experiment. We may note, however, that the theory is idealized in that it neglects the initial velocities of the electrons due to thermal agitation, and that the actual filament is rough in texture and may not conform to the theoretical conditions. It will require further work to elucidate this effect.

At higher potentials the space-charge is swept out and this region of the curves corresponds to

voltage saturation where the current is limited by the activity of the filament. In this case the emission conforms to the Richardson equation.[3]

$$i = AT^2e^{-\epsilon\phi/kT}$$

where A and $\epsilon\phi/k$ are empirical constants and ϕ (the thermionic work function) may be interpreted as the work required to remove an electron from the filament. Plotting log i − 2 log T, for the currents at 80 v., against the reciprocal temperature, as in Fig. 4, gives a family of straight lines, one corresponding to each activation state of the filaments studied. Four curves have been omitted which practically coincide with those shown in the high activity region. The deviations at higher temperatures for the more active states show the influence of space charge. With this exception the data may be summarized completely by two families of parallel straight lines, one for the active states and another for the inactive states following the preliminary clean-up. The two corresponding values of the work function are 1.37 and 1.64 v., respectively. The values of A would be given by the intercepts on the axis where $T = \infty$. These intercepts are, however, so far (on the graphs) from the region of observation that the different heights of the lines may be due in part to small changes in work function, and the absolute values of A as obtained by extrapolation would be doubtful. We have therefore taken as our measure of activity the currents corresponding to the ordinates of the lines at 1050°K. These are plotted in Fig. 6 against the content of free alkaline earth metal determined by analysis.

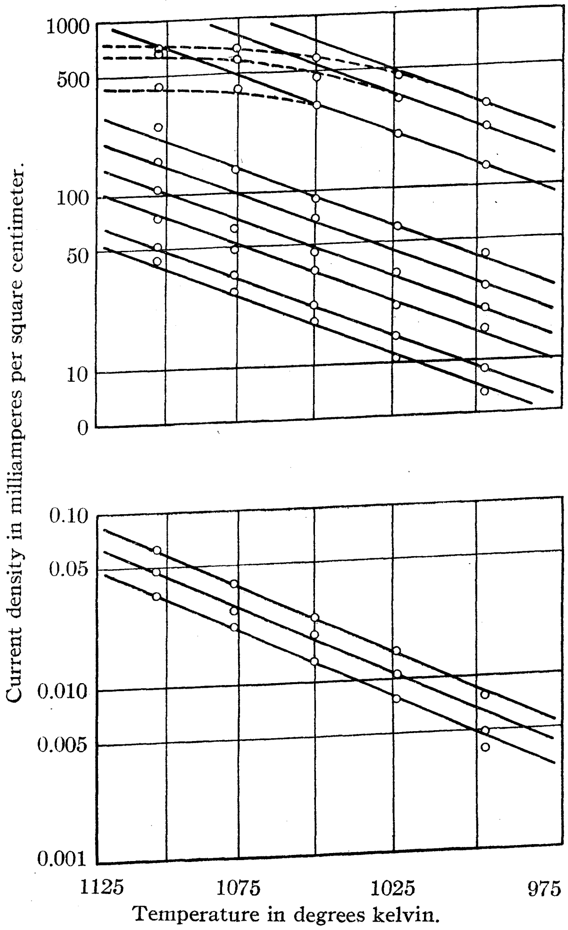

Fig. 4.—Current temperature relation for various active states. Log i/T^2 vs. $1/T$ according to the Richardson equation.

The Gas Analyses

The nucleus of the experimental methods is the equipment for gas analysis, a refinement of apparatus described by one of the authors.[9] The essential features are shown in Fig. 5. The gas for analysis is collected by a Toepler pump and measured in a capillary pipet, Fig. 5a, which operates in a fashion similar to a McLeod gage. The gas is then allowed to escape and is circulated through the absorption train. The gas is circulated by operation of the same Toepler pump and again collected for measurement. The reagents used in these analyses are copper oxide at 300°, magnesium perchlorate and soda

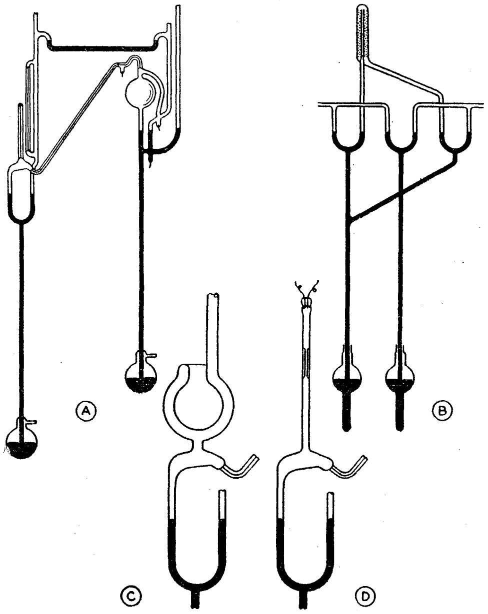

Fig. 5.—Details of the gas analysis apparatus.

---

[9] C. H. Prescott, Jr., This Journal, **50**, 3237 (1928).

lime. These may be switched in and out by mercury cut-offs as shown in Fig. 5b. Auxiliary equipment includes a platinum ribbon filament in a water-cooled tube, and the explosion pipet shown in Fig. 5d with which is associated another Toepler pump. Mixtures containing H_2O, CO_2, H_2, CO, and O_2 or CH_4 can be analyzed completely. The oxygen analysis by means of the platinum filament requires an excess of hydrogen or carbon monoxide. Methane cannot be exposed to the hot filament and consequently cannot be determined when oxygen is present. When oxygen is absent, methane, which is not affected by any of the reagents, is finally mixed with oxygen and exploded. With the tubes of reagents well outgassed the sensitivity of the apparatus is about 0.02 cc. mm. (cubic centimeters at a pressure of one millimeter of mercury). This is equivalent to 0.03 microgram of carbon monoxide, approximately the amount in one square centimeter of a monomolecular layer. The accuracy, which we definitely sacrificed to sensitivity, is about 2% except on the smallest samples.

The experimental tube and the liquid air trap are mounted as shown in Fig. 5c on a structure similar to the two pipets. Methane or carbon dioxide is pumped in by a third Toepler pump. During reaction the gas is entirely confined within the experimental tube, since the mercury is raised up into the stem of the tube completely filling the space of the liquid air trap. During thermionic measurements the mercury level is drawn down to permit liquid air to be placed in the trap and connection made to the high vacuum line.

The determination of free alkaline earth metal requires, in general, four or five successive treatments of thirty minutes in carbon dioxide at 900°, following each of which the gas is recovered for analysis. For the smaller amounts of active metal this has sufficed to reduce the carbon monoxide found to about 0.02 cc. mm., which appears to be a mean blank determination for the tube and analytical apparatus, and is close to the ultimate sensitivity of the method.

This blank raises a question as to a possible reaction between carbon dioxide and nickel

$$\mathrm{Ni} + \mathrm{CO_2} = \mathrm{NiO} + \mathrm{CO} \qquad K = p_{\mathrm{CO}}/p_{\mathrm{CO_2}}$$

The equilibrium constant may be computed from data on the reduction of nickel oxide by hydrogen[10] and the water gas reaction.[11] At 1209°K., the true temperature of the carbon dioxide treatments, this is 0.012. The lowest value of the CO–CO_2 ratio in our analyses is 0.017, while several of the low terminal ratios were twice the equilibrium value. Noting that the equilibrium is independent of total pressure, this indicates that no nickel could have reacted. We thus judge this residual carbon monoxide to be a spurious evolution, possibly not even coming from the filament.

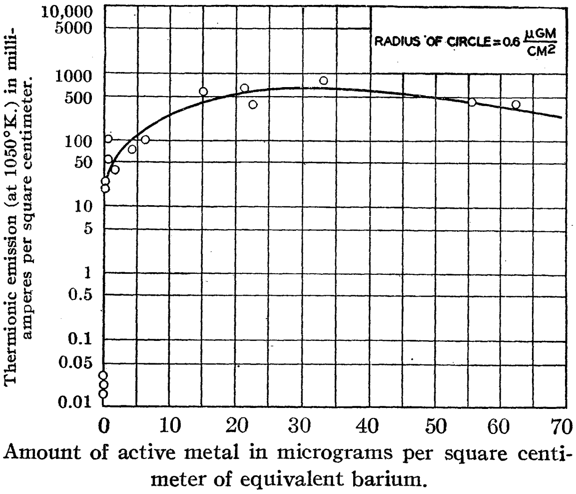

Fig. 6.—Thermionic emission *vs.* content of free alkaline earth metal.

In Table IV, following a summary of the corresponding thermionic data, we have shown the complete analytical results. Each tube is designated by a letter and each successive state of activity by a subscript. In estimating the total free alkaline earth metal for each state of activation, we have considered the results of those analyses prior to a value equal to or less than 0.02 cc. mm. subtracting 0.02 cc. mm. from each determination before summing. These are equivalent to the amounts of free alkaline earth metal shown as equivalent weights of barium.

In the fourth tube, used only for states with large amounts of active metal, the preliminary clean-up was abbreviated and the corresponding initial activity was ignored because of the uncertainty of its state. It was found that after active metal was once permitted to escape within the tube we could not reëstablish the low level of initial activity without cleaning up the whole tube again. Metal deposited on the plates redeposited on the filament when the plates were out-gassed prior to the activity measurements. Thus we have two active states B_3 and B_4 which

were obtained by reëvaporation of active metal and without use of methane. We should note, however, that this scattered free metal did not interfere with our analyses; the carbon dioxide would not react even with the active filament except at elevated temperatures. For the state B_4 we have no analysis since there was already indication that the amount of active metal was below the sensitivity of our apparatus. One further point, B_5, we have wished to include as corroborative of the other activities in its neighborhood. The tube was lost after the first analysis for this determination. But the course of successive analyses is so smooth that we have felt justified in estimating the total amount by comparison of the first analyses and interpolation between the total amounts for its neighbors.

Discussion

The results tabulated in Table IV are shown in Fig. 6 which expresses the correlation between thermionic activity (measured by the current density at 1050°K.) and the content of free alkaline earth metal. This latter is expressed as the equivalent micrograms of barium per square centimeter of superficial filament surface. The radius of the circles, 0.6 μ g./sq. cm., is equivalent to 0.02 cc. mm., the sensitivity of the gas analysis methods. The actual errors are somewhat larger, being the accumulations from several analyses each.

The lowest activity values, 20 microamperes per sq. cm., are still doubtless associated with free barium, formed by spurious activation, but an amount much less than our analytical limit of sensitivity. In the neighborhood of this limit, which corresponds to 0.6 μ g./sq. cm., the activity is 30 m. a. per sq. cm. The curve then rises to a value of 600 m. a. per sq. cm. which may be a maximum in the neighborhood of 30 μ g./sq. cm. But this maximum is not definitely established, and the most significant feature of the relation is its flatness from 15 to 60 μ g./sq. cm.

Taking a monomolecular film of barium as 0.14 μ g./sq. cm., the range 0.6-15-60 μ g./sq. cm.

is equivalent to 4-100-400 atomic layers upon the geometrical surface. Minute amounts of metal appear largely to saturate the active surfaces from which electrons are emitted. These may be the surfaces either of nickel or oxide particles. Further addition of active metal contributes little to thermionic activity, but provides a reservoir of active material.

Previous analyses of free alkaline earth metal in vacuum tubes are reported by Berdennikowa,[12] Clausing[4] (p. 348), and Fritz.[13] The water vapor method of Berdennikowa does not discriminate between active metal in the filament and elsewhere in the tube. The same criticism seems to apply to Clausing. Barium nitride formation and microanalysis, as employed by Fritz, appear selective but less sensitive. His results are equivalent to 5–15 micrograms of barium per tube.

The greater amounts found in our experiments we believe to indicate an increased retention, which may be adsorption upon or alloying with the finely divided nickel, and which may also be a factor in a very long useful life obtained with this type of coating. The contrary opinion, that barium is dissolved in barium oxide, has some support from the work of Schriel,[14] who reports a slight solubility, though no evidence for solution under vacuum conditions. From the overall composition, as shown in Table V, we conclude that the active metal is somehow dissolved, a conclusion further substantiated by the long time, upward of two hours, necessary to leach out the active metal in the carbon dioxide treatments.

TABLE V

Coating composition (referred to outside surface of coating)

SrO = 984 μ g./sq. cm.
BaO = 923 μ g./sq. cm.
Ni = 71.5 μ g./sq. cm.
Active metal = 0.6 – 65 μ g./sq. cm. as Ba

Summary

Using a filament coated with a colloidal mixture of barium oxide, strontium oxide, finely divided nickel, and free alkaline earth metal, we have investigated the quantitative relation between thermionic emission and the content of active metal. A high level of activity was found from 15 μ g./sq. cm. to 60 μ g./sq. cm. of equivalent Ba, with a slight apparent maximum at 30 μ g./sq. cm. where the thermionic current at 1050°K. is 600 m. a./sq. cm. The electron work function is 1.37 v.

The radiant emissive power at 0.66 μ is approximately 64%, independent of the content of active metal.

The free alkaline earth metal was determined by oxidation with carbon dioxide and analysis of the gaseous reaction products.

A Modified Method for the Preparation of Monochloropentamminocobaltic Chloride (Purpureocobaltic Chloride)

BY WALTER A. HYNES, LEO K. YANOWSKI AND MORRIS SHILLER

Monochloropentamminocobaltic chloride, or purpureocobaltic chloride, $[Co(NH_3)_5Cl]Cl_2$, is one of the earliest and best-known of the cobaltammines. During the course of work on the application of such complexes to the microscopic detection of anions,[1] it became necessary to prepare relatively large amounts of this substance in a pure state.

Purpureocobaltic chloride has been prepared and its constitution studied by numerous investigators[2] since its initial synthesis in 1851. These workers used air or pure oxygen as chief oxidants and cobaltous carbonate as the usual source of cobalt.

The chief objections to the older method of preparation are the length of time required for the preparation of the substance, the low yield of pure substance obtained and the impurity of the final product. The low yield and relative impurity of the final product obtained by the usual method are due to the presence of hexammines and other cobaltammines, only removable by repeated recrystallizations or by precipitation from cold

aqueous solutions by acid, followed by separate washings with alcohol and ether.[3]

To obtain approximately 10 g. of *pure* purpureo chloride by the older method required an average of about forty hours due to time required for aeration, evaporations and extractions, whereas by our method we can obtain an average of 35 g. of pure salt in not more than five hours.

Experimental

Forty grams of coarsely ground crystalline cobaltous chloride, $CoCl_2 \cdot 6H_2O$, is added to a mixture of 50 ml. of water, 100 ml. of concentrated (28%) ammonium hydroxide and 100 g. of solid ammonium chloride in a flat porcelain dish. Twenty-five ml. of 30% hydrogen peroxide is added to this mixture with continuous stirring. The dish is then heated on the steam-bath for one hour. The paste obtained at this point is treated with 500 ml. of 3 *N* hydrochloric acid and heated, with continuous stirring, over the free flame to not more than 60°. The mass is filtered and washed with approximately 150 ml. of 2 *N* hydrochloric acid. The residue is suspended in 1500 ml. of 1.2 *N* ammonium hydroxide and heated to not more than 60° with continuous stirring, when all the purpureo chloride will be dissolved. This liquid is filtered immediately, the filtrate transferred to a 3000-ml. beaker, placed on the water-bath, and 1500 ml. of concentrated hydrochloric acid added in three 500-ml. portions at fifteen-minute intervals, stirring during each addition, and the heating continued for thirty minutes after the last addition, a total time of one hour. The liquid is filtered while still warm and the residue first washed thoroughly with 2 *N* hydrochloric acid, then with 95% alcohol until there are no further traces of hydrochloric acid in the washings and finally with four to five 25-ml. portions of ether. The residue is then dried for one hour in an oven previously raised to 60°. The yield at this point averages 34 g., equivalent to 85% of the theoretical value. The salt requires no further purification for use as a microscopic reagent or in the preparation of other compounds.

The material was analyzed for nitrogen by both micro Dumas and macro Kjeldahl, for cobalt by semi-micro determination as sulfate, and for total chlorine by the micro Pregl method,[4] and the following values were obtained.

	Nitrogen			
	Dumas	Kjeldahl	Cobalt	Chlorine
Calculated	27.96		23.53	42.47
Found	27.99	27.91	23.62	42.56
	28.04	27.89	23.62	42.59

Although several investigators have employed hydrogen peroxide as an oxidant in preparing cobaltic compounds,[5] none has specified that this substance may be used as the oxidant in preparing the purpureo chloride.

A single 1500-ml. volume of 1.2 *N* ammonium hydroxide, about one-half that used in the ordinary method, was employed as solvent to avoid numerous extractions. Heating in ammoniacal solution at 60° hastens conversion of the purpureo to the aquo salt, this temperature being quite safe, as shown by Lamb and Marden.[6] The converse transformation to the purpureo is well known, but it was deemed advisable to add the acid slowly with stirring to prevent any possible occlusion of roseo chloride by the purpureo salt.

We have noticed that the thoroughly dried purpureo chloride is non-hygroscopic, while a sample which had not been oven-dried tended to gain weight on exposure to air.

Acknowledgment is made to the Works Progress Administration for the City of New York for assistance rendered under Project No. 465-97-3-120.

Summary

1. Purpureocobaltic chloride has been prepared from $CoCl_2 \cdot 6H_2O$ using hydrogen peroxide as oxidant in the presence of ammonium chloride.

2. The product is obtained in much better yield and in a much shorter time than is required by the ordinary method.

The Action of Carbon Dioxide and of Carbon Monoxide on Manganese

BY A. N. CAMPBELL AND E. A. BROWN

In the course of experimental work in this Laboratory, Mr. T. H. Martin had occasion to use carbon dioxide in scavenging apparatus containing heated metallic manganese. He found that the issuing gas was inflammable and recognized it to be carbon monoxide, the only source of which could be reduction of the carbon dioxide by the metallic manganese. Accordingly, a systematic investigation of this reaction was undertaken by the present authors.

A search of the literature revealed the following. Guntz[1] prepared metallic manganese by distilling off the mercury from a mercury amalgam, produced by electrolysis. It is important to notice that the manganese so obtained was pyrophoric, or at least had a very small particle size. He heated this manganese to 400° in a current of carbon monoxide. The manganese burned with sufficient liberation of heat to raise the mass to white heat. The carbon monoxide was absorbed so rapidly as to cause a partial vacuum in the apparatus, no carbon dioxide being formed. Guntz gives the equation

$$\mathrm{Mn} + \mathrm{CO} = \mathrm{MnO} + \mathrm{C} + 34{,}500\ \mathrm{cal.}^{2}$$

He then tried the reaction with carbon dioxide, using the same procedure, and observed the same results, in accordance with the equation

$$2\mathrm{Mn} + \mathrm{CO_2} = 2\mathrm{MnO} + \mathrm{C}$$

Nishibori[3] heated pure manganous oxide with carbon monoxide at 780°. The analysis of the gas phase gave the equilibrium proportions: $\mathrm{CO} = 93.5\%$, $\mathrm{CO_2} = 6.5\%$. Presumably the equilibrium here is

$$\mathrm{CO} + \mathrm{MnO} \rightleftarrows \mathrm{Mn} + \mathrm{CO_2}$$

Lorenz and Heusler,[4] working at low temperatures in the vicinity of 350°, made observations in agreement with those of Guntz. Insofar as their manganese was highly impure, containing 7% carbon, further detail seems inappropriate. In connection with our own observations, however, it should be mentioned that they heated the manganese in a stream of carbon dioxide, and on opening the apparatus the front end of the boat in which the manganese was heated was found to have been eaten away and a brownish manganese glass formed.

Charpy[5] has studied the reaction with carbon monoxide at 1000°, employing metallurgical products, metallic manganese and rich ferromanganese. The solid products consisted of a mixture of manganese monoxide and carbon. Heller[6] found that manganese begins to react with carbon monoxide at 330°, at 350° the reaction is fast, and at 410° very fast.

Both the reactions under consideration are heterogeneous, but they differ fundamentally from the frequently studied catalytic type, where the solid phase remains unchanged throughout. We may, however, accept the view that reaction is preceded by adsorption of the gas on the solid surface. If the adsorption is slight, the velocity measurements comply with the formula for a unimolecular reaction. When the saturation limit is approached, on the other hand, the rate of reaction is apparently independent of the concentration or pressure of the gas, until the concentration of the gas has decreased considerably. Such reactions are said to be of zero order.[7]

In the cases under consideration here, the matter is complicated by a further factor. When carbon dioxide, or carbon monoxide, reacts with metallic manganese, MnO is known to be formed. This must accumulate in an ever thickening layer around the manganese particle, and through this layer all carbon dioxide, or carbon monoxide, subsequently reacting with the manganese, must diffuse. In addition, where carbon monoxide is a product of the reaction, it must diffuse out through it. The velocity measurements give the resultant speed of three processes going on simultaneously: (1) adsorption, (2) diffusion, (3) reaction. If one process is slower than the others, its speed will be the effective speed of the three, no matter how great the velocity of the others. Diffusion may be slower, but can never be faster, than adsorption, for adsorption supplies the diffusing

molecules. Similarly, reaction may be slower, but never faster than diffusion. If, in the cases under discussion, the slow process is that of diffusion, Fick's law of diffusion shows that the velocity measurements should comply with the formula of a unimolecular reaction, but we are faced with the further complication that Fick's law requires a diffusion layer of constant thickness, whereas here the layer of MnO is constantly increasing; the relative effect of increasing thickness would be greatest at first, subsequently decreasing with the thickness of the layer. Failure to comply with the unimolecular relationship will not therefore constitute evidence that diffusion is not the slow process. Furthermore, in the case of the carbon dioxide reaction, the carbon monoxide generated must diffuse out through the oxide layer, and this will have a retarding effect on the inward diffusion of carbon dioxide. It is evident from all this that any interpretation of the velocity measurements will be complicated, but certain predictions can be made. When the manganese is fresh, the oxide layer will be so thin that diffusion will produce no appreciable retardation. Accordingly, velocity measurements will give the resultant speed of adsorption and reaction together, and curves obtained by plotting composition of the gas phase against time will be similar to those for catalytic changes. When the manganese is old, and the layer of oxide thick, the increment in thickness as the reaction goes on will hardly affect the rate of diffusion. Then Fick's law will give the rate of diffusion of carbon dioxide through the layer quite accurately. This rate will be slower than the rate of reaction, which will therefore appear to be unimolecular.

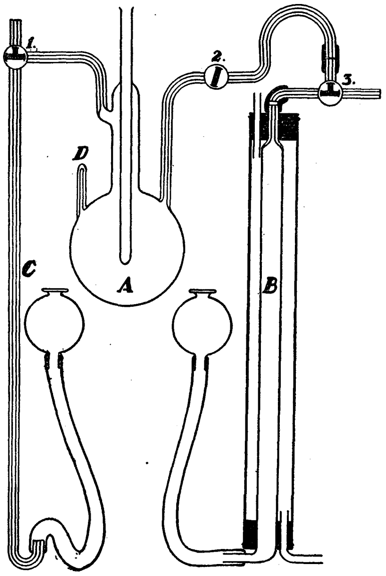

Fig. 1.

Experimental

Figure 1 is a diagram of the apparatus. The reaction chamber, A, was built from a Pyrex distilling flask of roughly 550 cc. total capacity. For temperature measurement inside this chamber an iron–constantan junction was used, the thermocouple leads running down the long tube in the neck of the flask. For measuring pressure an open manometer, C, was used, connected to the flask through the three-way cock 1; the manometer was read with a cathetometer. The free outlet of stopcock 1 led to a Hyvac pump. B is the gas buret for measuring samples taken for analysis; it was water-jacketed. The flask was filled with carbon dioxide through cock 3. After filling, the gas analysis pipets were connected to 3. An electric furnace was constructed such that flask A could be immersed completely in it, leaving only capillary tubing at uncontrolled temperature (about 0.3% of total volume). Temperatures were measured with a Leeds and Northrup potentiometer indicator, having an accuracy of 1 to 2 °F. As a check on the factory calibration, the cooling curves of pure zinc and of pure lead were taken with the instrument.

The side-arm D has the function of permitting additions of fresh manganese, without dismantling the apparatus. Carbon dioxide was prepared from limestone and hydrochloric acid and purified by passage through silver nitrate solution, calcium chloride, and phosphorus pentoxide. Carbon monoxide was prepared from sulfuric acid and sodium formate, and purified by passage through concentrated sulfuric acid, potassium hydroxide solution, calcium chloride, and phosphorus pentoxide.

The gas buret contained mercury, by lowering the level of which, samples of the gas phase could be removed and measured. The measured sample was then displaced through 3 to the gas pipets. That carbon monoxide is the sole gaseous product of the reaction was first determined by combustion with oxygen in a slow-combustion pipet. After this had been demonstrated, subsequent analyses were performed simply by determining the carbon dioxide with a potassium hydroxide pipet and obtaining carbon monoxide by difference.

Pyrophoric manganese was not used. The metal was obtained from the Johnson, Matthey Company of Toronto in the form of a powder and had the analysis: Mn, 96.84%; Fe, 1.74%; Si, 0.61%; C, 0.12%. The manganese was not in truly pulverized form but was very finely crushed and apparently had been screened to a uniform size after crushing. The mean diameter of the particles was 0.096 mm., but there were many particles much larger (> 0.16 mm.).

To determine whether or not the reaction represented by the equation

$$CO_2 + Mn = MnO + CO$$

was the sole one taking place, the flask was loaded with manganese and carbon dioxide, and its temperature gradually raised. Temperature and pressure were recorded every five minutes. Departure from Gay-Lussac law behavior began near 350° and became marked at 600°. Evidently, then, carbon dioxide is converted not only to carbon monoxide, but to a non-gaseous substance as well, for if the reaction were simply that formulated above, there would be no departure from Gay-Lussac law behavior.

That carbon monoxide is formed is beyond doubt. After one hour of heating at 600°, during which time the pressure fell over 400 mm., a sample of the gas contained only 1.0% carbon dioxide. Judging by the pressure drop, about 250 cc., at normal pressure, of gas remained. As previously mentioned, in similar preliminary experiments the carbon monoxide was determined directly by slow combustion, and it was found to correspond to 100% conversion.

After the completion of the preliminary experiments, systematic work was commenced at 600°, but owing to the frequent collapse of the flask under vacuum at this temperature, it was possible to bring only two runs to completion. The method of procedure followed throughout was to evacuate the flask, raise it to the required temperature, then fill it with the appropriate gas. The two successful runs gave the following results

Run	Duration, hr.	% CO_2 unchanged	Approximate initial press., mm.	Final press., mm.
2	1	0.0	831	646
3	0.5	0.0	869	727

The ratio of the change in pressure to the initial pressure gives the proportion of the whole going in the side reaction. This was 20.5% for run 2, and 16.3% for run 3. Since there was complete conversion to carbon monoxide in both cases, it appears to follow that the side reaction is slow compared to the main reaction, but that this deduction is not entirely justified will be seen in the sequel.

An experiment was now carried out at 500°, using 10.0021 g. manganese and 556 cc. carbon dioxide. At the end of two hours the pressure had dropped from 760 to 734 mm. and therefore the fraction of the whole being removed by the side reaction was 3.4%. The gas analysis at the end of the run showed no carbon dioxide remaining, which means that in two hours at 500°, with fresh manganese, the conversion of dioxide to monoxide is complete.

A series of runs was now undertaken in a somewhat different manner. Samples of the gas phase were withdrawn from time to time for analysis, and the whole experiment continued uninterruptedly until complete conversion was attained. Occasionally a run was carried out with carbon monoxide as starting gas, in an attempt to reach the equilibrium, if any, from the other side. Six experiments were carried out at 500°, and six at 400°, pressure readings being taken throughout, for the purpose of following the side reaction. Fresh metallic manganese was not used for each run, but a fresh charge occasionally was added to what was already present. Unimolecular "constants" were calculated for periods between consecutive analyses, and also for the period between the start and each analysis, the values being referred by calculation to a standard charge of 10 g. manganese.

The results showed that the relative speed of the side reaction is still less at 400 than at 500°. From the pressure drop, the fractions of the charge going to the side reaction are calculated as 7.3% in one and one-half hours at 500° and 4.0% in the same period at 400°. The unimolecular "constants" are by no means constant throughout any run. This can be seen from the plot of composition–time, where the curves appear to be much straighter than is required for unimolecular behavior. Figure 2 shows the composition–time curves for three runs. In each of these fresh manganese had been added recently. Runs A and B were at 500°, and run C at 400°. The curves show very well the greater speed at the higher temperature. Run B was faster than A, because the quantity of manganese was larger.

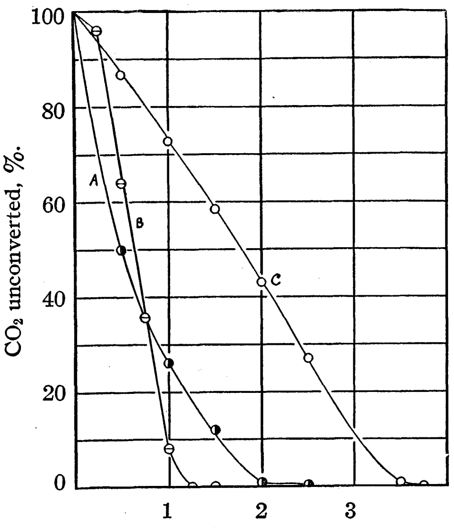

Fig. 2.—Conversion of CO_2 to CO in presence of manganese.

The form of the curves is similar to that of a zero order reaction. The long straight section shows a constant rate of conversion, indicating that adsorption of carbon dioxide is great. When conversion is nearly complete, the rate falls off because there is not enough carbon dioxide left in the gas phase to maintain the concentrated adsorption film.

When the manganese had been used for previous runs, its age began to have a retarding effect on the reaction rate. The "constants" showed this, being less numerically, with increasing use of the manganese. They did, however, show an approach to constancy with increasing use. This approach to constancy with age of the manganese was predicted in the introduction on the basis of diffusion.

In the runs that were followed right through, the final state was always one of complete conversion of carbon dioxide to the monoxide, so it was concluded that there was no appreciable equilibrium. As a check on this, two runs were carried out with carbon monoxide as the starting gas, one run for four hours at 500° and one for nineteen hours at 400°. In neither case was any carbon dioxide generated. Therefore, there is no appreciable equilibrium at 400 or 500°.

A number of runs in the neighborhood of 300° were vitiated from the following cause. A fresh supply of manganese had been obtained from Merck. This came in the form of a solid lump which was pulverized in a rock crusher. During the pulverizing, the manganese took fire for a moment. Subsequent examination showed it to contain manganese dioxide. In all attempts to use this powder it was characterized by extreme sluggishness of reaction. Apparently, then, the presence of a relatively small quantity of dioxide in the manganese insulates it more or less completely from being attacked by carbon dioxide. Fortunately there still remained some of the original manganese which was used in three experiments at 350°. These experiments showed that the reaction goes to completion at 350°.

To study the falling off in the rate of conversion with age of the manganese charge, an extended run was carried out at 500°. The reaction flask was cleaned out and 5.000 g. of fresh manganese introduced. The flask was then filled with carbon dioxide at 500° and the run continued until conversion to monoxide was just complete. The flask was then evacuated immediately and refilled with carbon dioxide. This process was repeated three times. The slowing down is illustrated by the curves of Fig. 3. Here composition is plotted against the logarithm of time, to shorten the diagram. The curves show progressively slower reaction rate with age of the manganese. When plotted against time and not log time, curve 1 has a straight portion like a zero order curve. The others curve at first and then flatten out to a line that is not far from horizontal for 3 and 4, and which approaches 0% CO_2 far out on the time axis. These curves come closer together with age of manganese, as the layer of oxide on the manganese particles becomes thicker. This increasing proximity of the curves for successive runs shows that a uniform rate of reaction is being approached, as was predicted in the introduction. Unimolecular "constants" were calculated for 3 and 4. The figures bear out what is evident from the curves, that the rate of reaction is not yet the same for successive runs. Were the manganese to be exhausted before the layer became sufficiently thick, this stage would never be reached. Comparatively coarse manganese would be more likely to give this effect.

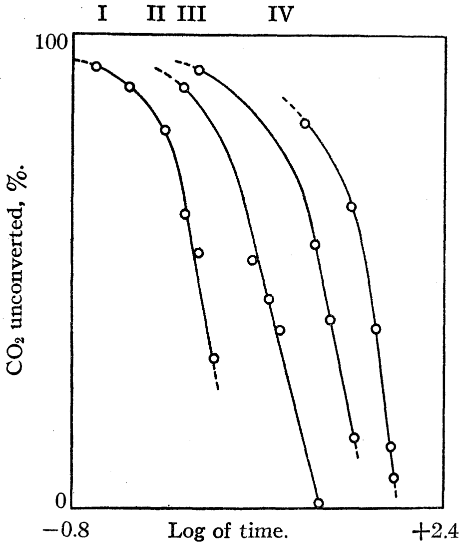

Fig. 3.—The effect of continuous use on the velocity of conversion.

Reaction between Manganese and Carbon Monoxide.—It was thought that this reaction would only attain measurable velocity above 600° and therefore a fresh apparatus was constructed. This consisted of a silica reaction flask connected to a hard glass manometer by a ground joint. The flask was embedded in a furnace capable of giving 800°. The capacity of the flask was 155 cc. and it was charged with 10 g. of manganese. The procedure was otherwise as before, except that no analysis was necessary, the course of the reaction being very simply followed by the drop in pressure.

For this work, the first consignment of manganese having been almost entirely exhausted and the second unsuitable, a third consignment was obtained from the Johnson, Matthey Co. Its analysis was much the same: Mn, 97.22%; Fe, 1.70%; Si, 0.55%; C, 0.11%, but the particle size was found to be much smaller. The average particle diameter was found to be 0.032 mm., as against 0.096 mm. for the manganese used in the earlier experiments.

Experiments were carried out at 600 and 500°. The results showed the reaction, which has been styled the "side reaction," to be unexpectedly rapid. This is undoubtedly due, at least in part, to the finer particle size. Considering consecutive experiments in which the same manganese was used, the speed of the reaction falls off rapidly with use, that is, with increasing thickness of the manganous oxide layer. The data do not comply with the requirements of a first order reaction. The reaction rate is much slower at 500 than at 600°.

An experiment was now carried out with the temperature rising from cold, to determine the temperature at which reaction became appreciable. On plotting pressure against temperature, it was seen that the reaction became rapid between 460 and 470°.

Because of the unexpected rapidity of the carbon monoxide reaction, a run was carried out at 600°, using the original coarser manganese. As was expected, the rate was much slower. Experiments were also carried out at 500°, using the coarser manganese. The velocity was less, although fresh manganese was used.

At all temperatures there is complete decomposition of the carbon monoxide by the manganese. The retarding effect of age is greater with the coarse manganese than with the fine, as would be expected.

The question now arose of whether, using the fine manganese, the same results, qualitatively at least, could be obtained, in respect of the conversion of carbon dioxide to carbon monoxide by manganese. For example, one of the early experiments gave complete conversion of carbon dioxide in two and one-half hours, using a fresh charge of 10 g. of coarse manganese at 500°. The experiment was therefore repeated at the same temperature, using the finer manganese. Pressures were read from time to time, and, after two and one-quarter hours, a sample of the gas phase was drawn off and analyzed for carbon dioxide. Conversion was practically complete and the pressure drop in two hours was 500 mm., whereas in the corresponding experiment with coarse manganese the drop in pressure was only about 40 mm. in the same time. This shows very clearly how the fineness of subdivision favors the reaction with carbon monoxide.

Presumably, if manganese is left in contact with either carbon dioxide or carbon monoxide, for a sufficient length of time, at a temperature of 500° or higher, complete decomposition of the gaseous phase to give manganous oxide and carbon, with production of zero pressure, will result. To test this point, an experiment was carried out at 600°, using carbon dioxide, and 10 g. of fresh fine manganese. Zero pressure was attained in thirty minutes.

Finally an experiment was carried out at 400°, using a carbon monoxide filling and 10 g. of the finer manganese. After two hours there was no change in pressure, indicating zero reaction velocity. It should, however, be mentioned that the manganese had been used in three previous experiments. At all events, the reaction velocity of the carbon monoxide reaction is very small at 400°. This is by no means the case with the carbon dioxide reaction.

As general conclusions to the latter part of this work, we would stress the effect of particle size. With pyrophoric manganese, at temperatures of 500° and above, it is possible that no carbon monoxide would be obtained from carbon dioxide by the action of manganese.

The Solid Phase

2.0364 grams of metallic manganese was heated in a stream of pure dry carbon dioxide in a porcelain boat contained in a wide silica tube, in an electric furnace at 600°. The charge was heated for five one-hour periods, at the end of each of which it was cooled in a stream of carbon dioxide and weighed. By the end of the fifth period the increase in weight was constant at 34.7% of original weight. The increase required for Mn–MnO is 29.2%.

The solid remaining had the characteristic dark green color of manganous oxide. An analysis of the solid product was then carried out. This gave the following figures: total Mn, 76.8%; free Mn, 4.87%; MnO_2, 1.1%; Mn as MnO_2, 0.7%; O_2 as MnO_2, 0.4%.

$$\text{Mn as MnO} = \text{Total Mn} - (\text{Mn as } MnO_2) - (\text{free Mn}) = 71.23\%$$

O_2 required for MnO	21.1%
Carbon	1.45%
	99.75%

No other oxide contains O_2 and Mn in proportions to fit the analysis. It is apparent that carbon dioxide converts metallic manganese to manganese monoxide. The reaction is therefore

$$Mn + CO_2 = CO + MnO$$

The analysis shows an increase in the amount of carbon over that of the original manganese, which contained only 0.12% carbon. This increase can be explained by the side reaction

$$CO + Mn = MnO + C$$

When the tube was removed from the furnace the section where the boat had been was found to have a frosted appearance inside as if the silica had been acted on. This is of interest as Lorenz and Heusler[4] concluded that manganese was volatile in carbon monoxide at white heat and was deposited as a dust on the interior of the tube. It seems to us more likely that a volatile and very unstable carbonyl is formed.

For study of the reaction between carbon monoxide and manganese a similar apparatus was used, except that the carbon monoxide was stagnant and a manometer was introduced to indicate absorption.

A charge of 3.0015 g. of manganese was heated for five days at 700°, then for a short period at 870°, after which there was no further indication of a drop in pressure. When the cooled furnace was opened, it was found that the interior of the silica tube was covered here and there with a greenish black deposit, while adhering to the porcelain boat was a pink deposit, which rendered weighing useless. This is further evidence supporting the contention of Lorenz and Heusler that manganese is volatile in carbon monoxide. The charge in the boat, in addition to possessing the characteristic greenish color of manganese monoxide, contained shining crystalline granules, presumably graphite. When the silica tube was removed from the furnace, it broke in two where the boat had been. This was apparently due to the silica having been attacked, for a pink layer fully 2.5 mm. thick now constituted most of the wall of the tube: only a thin shell of unchanged silica remained. The pink material was crystalline and is perhaps manganese metasilicate, $MnO{\cdot}SiO_2$. The mineral rhodonite has this composition and is pink in color. Either manganese is volatile in carbon monoxide, as claimed by Lorenz and Heusler, or it reacts with it so violently as to be almost explosively dispersed. This latter alternative does not seem likely, as no signs of excessive activity were observed in the experiments.

Total carbon in the product was determined by direct combustion, and free carbon by treatment with 50% hydrochloric acid and burning the residual carbon. Both determinations gave the same result, indicating that all the carbon is free, and not existing as carbide. The results of the analysis were:

Free carbon (= total carbon) = 14.3%
Total Mn = 66.0%
O_2 by difference = 19.7%

This corresponds to C = 14.3%; MnO = 85.7%. The reaction

$$Mn + CO = MnO + C$$

requires a percentage composition of C, 14.5%; MnO, 85.5%.

Discussion

By the use of non-pyrophoric manganese, the reaction of carbon dioxide with metallic manganese has been shown to take place in two stages, viz.,

$$CO_2 + Mn = MnO + CO \text{ (first stage)}$$
$$CO + Mn = MnO + C \text{ (second stage)}$$

The net result: $CO_2 + 2\,Mn = 2\,MnO + C$.

Lorenz and Heusler, as well as Guntz, were aware of these reactions, but did not recognize them to be stages of one reaction. Guntz used pyrophoric manganese, and the reaction was so fast that he failed to observe the first stage, and from his results formulated an equation identical with that obtained by uniting the first and second stages, as above. Lorenz and Heusler used manganese that contained so much carbon that it corresponded to the formula Mn_3C, so that it cannot be claimed that their results represented the action of metallic manganese on carbon dioxide and carbon monoxide. They did, however, observe the conversion of carbon dioxide to carbon monoxide. They also observed, as did Guntz, that manganese monoxide and carbon are formed when carbon monoxide is used.

This work has established that the only products are those indicated by the equations. It also appears that metallic manganese is volatile in carbon monoxide. This can only mean that manganese unites with carbon monoxide to form a volatile compound, presumably a carbonyl, which is almost immediately decomposed. Lorenz and Heusler stated that a carbonyl is not formed, by which they mean a carbonyl having some degree of stability. Their spectroscopic examination of the gas issuing from their apparatus showed manganese to be absent, and this proves that, if carbonyl is formed, it must be extremely unstable.

The speed of reaction depends not only on the temperature, but on the age and quantity of the manganese. With fresh manganese, reaction is fast between 500 and 600°. It is slower at 400°, and extremely slow at temperatures approaching 300°. The carbon dioxide reaction is of the zero order type, when the manganese is fresh, as shown by the curves of Fig. 2. When the layer of manganese monoxide becomes of appreciable thickness, the rate of conversion is no longer dependent on adsorption, but on the rate of diffusion through the layer. Hence, when the manganese monoxide layer becomes very thick, the reaction appears to be of the first order.

Nishibori found an equilibrium between carbon dioxide and carbon monoxide at 780°, in the presence of manganese monoxide. At the lower temperatures at which the present experiments were carried out, no such equilibrium exists. Conversion of carbon dioxide to carbon monoxide was always complete, except in experiments near 300°, where the reaction is so slow that a false equilibrium seemed to exist. It is not possible, therefore, to calculate the heat of reaction from the van't Hoff isochore. The heats of reaction can, however, be calculated from the known heats of formation, whence we obtain

$$\begin{aligned} CO_2 + Mn &= MnO + CO + 22{,}800 \text{ cal.} \\ CO + Mn &= MnO + C + 64{,}400 \text{ cal.} \\ CO_2 + 2Mn &= 2MnO + C + 87{,}200 \text{ cal.} \end{aligned}$$

These figures show that both forward reactions are exothermic and hence the back reaction is favored by raising the temperature. Nishibori obtained 6.5% carbon dioxide at 780°, while our work shows that there is no equilibrium at 600°. Somewhere between these two limits of temperature, appreciable equilibrium sets in.

Summary

It has been shown that the reaction previously formulated

$$2Mn + CO_2 = 2MnO + C$$

really consists of two consecutive stages

$$Mn + CO_2 = MnO + CO \qquad (a)$$

and

$$Mn + CO = MnO + C \qquad (b)$$

At temperatures of 400° and less reaction (a) predominates almost exclusively. At temperatures higher than 400°, the velocity of reaction (b) increases very rapidly, and, using pyrophoric manganese, this probably would result in the complete removal of the carbon monoxide formed by (a), at least above 500°.

The velocities of both reactions are principally conditioned by the rate of diffusion through the manganous oxide layer. Apparently, manganous oxide is more pervious to carbon dioxide than to carbon monoxide.

Both reactions are exothermic but no indication of a back reaction was detected up to 600°.

Isotonic Solutions. I. The Chemical Potential of Water in Aqueous Solutions of Sodium Chloride, Potassium Chloride, Sulfuric Acid, Sucrose, Urea and Glycerol at 25°[1]

BY GEORGE SCATCHARD, W. J. HAMER[2] AND S. E. WOOD

Sinclair and Robinson[3] have developed the isotonic or isopiestic method[4] so that it is more precise than any of the direct methods of measuring the chemical potential (or activity) of the solvent in which the temperature of measurement does not vary with the concentration. We have modified their method to give a still greater precision. We believe that our error is not greater than 0.1% of ϕ, the osmotic coefficient when the total molality, νm, is greater than one molal, and not greater than 0.001 in $\phi\nu m$ for smaller concentrations.

In order to determine the chemical potential of the solvent, or any related quantity, from isotonic measurements, however, it is necessary to know it as a function of the composition for one solute. On the other hand, the method gives a way of comparing the measurements with different solutes. We have, therefore, made such measurements on aqueous solutions of sodium chloride, potassium chloride, sulfuric acid, sucrose, urea and glycerol at 25° with a triple objective: to determine to what degree of precision we can extend the method, to obtain as accurate a standard as possible, and to make a comparison between the values of the chemical potential of water determined by a variety of the most accurate methods.

To understand the reasons for our modifications it is necessary to consider the attainment of equilibrium in some detail. The isotonic method is beautifully simple. A weighed amount of a solution of known composition is placed in a tared cup; a set of such cups are allowed to come to equilibrium through the vapor phase, and each cup is weighed again. Any change in weight must be due to a gain or loss of solvent. We compare six solutions simultaneously, but the discussion of the factors which must be taken into account is clearer if we consider but two. In our apparatus each solution weighs about a gram; each cup has a volume of about 15 cc. and the volume of the whole vapor space is about 300 cc. We may suppose that the solvent is water, that the solutions are about one molal in total solutes, that the initial concentration ratio is 1.01, and that we wish to reduce it to 1.001. This will require the distillation of about 0.05 g. of water from one cup to the other. At 25° the vapor pressure of water is about 25 mm., and that of a molal solution, about 0.5 mm. less. At the start the two vapor pressures differ by 0.005 mm. or 0.02%; at the end they should differ by 0.0005 mm. or 0.002%. The 0.05 g. of water would occupy about 2000 cc. as saturated vapor. Any air would doubtless be pumped from the cup losing water, and probably much of the air in the outer volume would be concentrated in the cup gaining water. However, the hydrostatic pressure of water vapor plus air is always equal throughout the vapor space. If the partial pressure of air in the cup gaining water exceeds 0.0005 mm. near the end of the reaction, the reaction will cease until the air diffuses out. Even smaller amounts of air will slow up the reaction considerably.

The final vapor pressure difference of 0.0005 mm. corresponds to a temperature difference of about 0.00035°. If the temperature fluctuates so that the solution with the lower vapor pressure is hotter than the other by more than this amount, the distillation will tend to go in the wrong direction. Moreover, the adiabatic distillation of 0.3×10^{-6} g. of water between one gram samples is sufficient to cause this temperature difference. This is only six millionths of the water which has to be distilled. It is a simple matter to calculate the effect upon each of these quantities of changes in the initial concentrations or concentration dif-

[4] "Isotonic" was introduced by Hugo de Vries, who first used an isotonic method in 1882, to define solutions in equilibrium with respect to transfer of the solvent. "Isopiestic" was substituted by Bousefield in 1918 because he considered "isotonic" bound up with theories which he did not like. However, "isotonic" has the advantage of historical priority and the more important one that it stresses equilibrium, which is the important relation, while "isopiestic" overemphasizes the equality of pressure, which is no more important than the equality of several other properties.

ferences, the desired accuracy and the size of the sample.

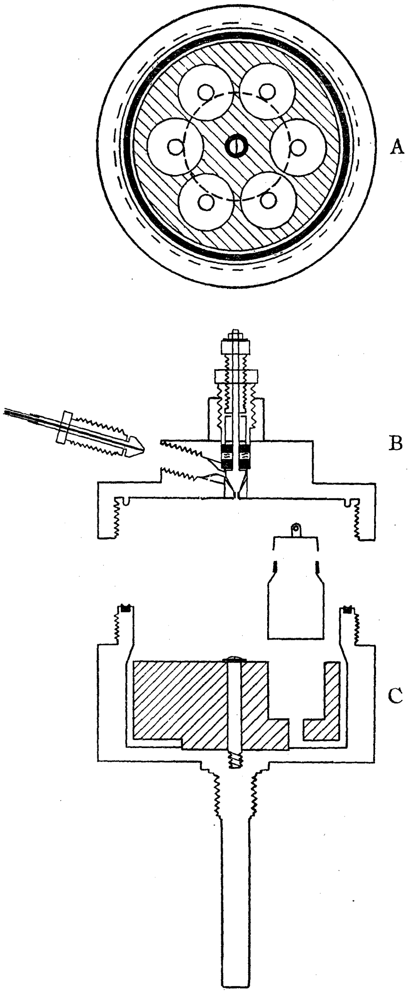

Fig. 1.—Apparatus. The left-hand side of the vertical section of the copper block is taken perpendicular to the other side.

Therefore, the essentials of the apparatus and procedure are: good heat conduction from one cup to another, a good thermal buffer to prevent fluctuations of temperature, efficient stirring to assure mixing and heat conduction without heating, evacuation adequate to remove the air, small samples to reduce the amount of distillation necessary and tight cups to permit accurate weighings. Sinclair[3a] discusses fully the heat and temperature effect, but states that thorough evacuation is unnecessary. His apparatus is as efficient as ours for the heat conduction, but we believe that our modifications give improvements in the other respects. To save space we will omit a detailed comparison and merely describe our apparatus and procedure.[5] The apparatus is illustrated in Fig. 1. The six cups are of platinum and are shaped like milk cans. Each is a cylinder 3.5 cm. high and 2.5 cm. in diameter. The top is constricted to 1.8 cm., and a nickel ring, 0.5 cm. high, is silver-soldered to the outside of the constriction. The outside of this ring is carefully ground with a 3° taper to fit a nickel lid. The bottom and lower 2 cm. of the side wall of the cup are lined with platinum gauze to increase the surface and aid the stirring and heat conduction.

The six cups fit snugly in cylindrical holes arranged symmetrically in a gold-plated copper block, 9.5 cm. in diameter and 3.5 cm. deep. This block fits into a stainless steel vessel of 12.5 cm. outside diameter and 7.5 cm. high. The cover screws on against a lead gasket and has a conical valve through which the vessel is evacuated. The male fitting for the evacuating tube is replaced by a dummy while the vessel is in the thermostat. This vessel fits on a table in the thermostat which rotates around an axis inclined at 45°. Each cup rotates about its own axis also inclined at 45°, as it revolves around the central axis.

The copper block weighs 1.6 kg. and the steel of the vessel weighs 4.6 kg. The only contact between them is over a circular area 5 cm. in diameter at the center of the bottom. They should give an effective thermal buffer. The fact that the thermostat oil must circulate around the lead counterweight and the massive steel rotating table just before it reaches the vessel increases the buffer action so that short-time temperature fluctuations must be much smaller in the vessel than in the recording thermometer. Slow changes of temperature of moderate magnitude are not troublesome.

The oil thermostat bath and thyratron regulator are similar to those described by Beattie[6] except that the plate circuit of the thyratron is connected directly to the main a. c. line instead of to the transformer, and that a mercury regulator in the bath is inserted in the galvanometer circuit to protect the galvanometer if the bath cools. This regulator maintains its temperature constant within 0.001° over an interval of a few hours and within 0.005° over a twenty-four hour period.

The composition of the most concentrated sulfuric acid solution in each series was determined

---

(5) Certain of these modifications which were adopted by us in 1935 and used in this work have been previously reported by C. M. Mason, THIS JOURNAL, **60**, 1638 (1938).

(6) J. A. Beattie, *Proc. Am. Acad. Arts Sci.*, **69**, 389 (1934).

by a weight titration of sodium carbonate with methyl orange as indicator. All other solutions were made up by weight. All weights were corrected to vacuum. For solutions in which the total concentration, νm,[7] was greater than 0.4, about 1 g. of solution was weighed into each of the six cups. For more dilute solutions about 0.5 g. was used. For solutions in which νm was greater than one, six drops of water was placed at the bottom of the vessel so that their evaporation might sweep out the air from below the copper block and might reduce the evaporation from the cups. To control the evacuation and prevent splattering the vessel was not connected directly to the vacuum line but to a bulb of about the same volume as the vessel itself. The bulb could be connected to an oil pump or to the vessel. The latter connection was always made so that the passage of gas was very slow. After the pressure had reached the vapor pressure of water, the vessel was evacuated ten times more. For solutions in which νm was less than one, 20 cc. of the sodium chloride solution was put directly into the steel vessel. When the vessel tipped, this rose around the lower cups and gave better thermal contact between them and the copper block. Since it also made necessary washing and drying the cups before they were weighed, this procedure was used only for the more dilute solutions for which it was needed. The vessel was evacuated as for the more concentrated solutions and, after three hours' rotation in the thermostat, it was evacuated ten times more and then replaced in the bath.

Solutions with νm greater than one were rotated in the bath for twenty-four hours; those with νm less than 0.6 were rotated seventy-two hours, and the intermediate solutions were rotated forty-eight hours. The vessel was then removed from the bath, dry air was allowed to enter, the top was removed and the lids were placed on the cups as soon as possible, which was usually less than half a minute after the opening of the vessel. In most of the runs each cup contained a different solute. For runs 7, 9, 11, 13, 15, 17, 19 and 21, the cups were returned to the vessel after the previous run, so that each of these depended upon the same initial weighings as the previous run.

The success with which equilibrium is attained in concentrated solutions is illustrated by two preliminary experiments which are not included in our final results. The first shows how closely equilibrium is attained even when the amount of water distilled is large. The initial concentrations of urea and of sulfuric acid were adjusted so poorly that the urea lost 0.58 of its 0.92 g. of water and the sulfuric acid gained about the same amount. In spite of this huge change, the largest difference from the equilibrium value is only four-tenths of one per cent. The initial, final and equilibrium concentrations are

	Initial	Final	Equilibrium
NaCl	3.237	2.670	2.671
KCl	2.693	2.931	2.926
H_2SO_4	3.510	2.111	2.114
Sucrose	3.592	3.985	3.982
Urea	2.382	6.429	6.427
α-Met. gluc.	4.063	4.509	4.523

The other experiment illustrates the reproducibility of the equilibrium concentrations because the drops of water added before evacuating in the second of two runs with the same solutes compensated so exactly for the loss during evacuation that the average loss was only 0.05 mg., and the concentrations are almost the same for the two runs. We list the concentrations before the first run, the equilibrium concentrations after each run and the milligrams gained during the second run.

	Initial concn.	Equilibrium concn. First	Equilibrium concn. Second	Second gain, mg.
NaCl	1.5730	1.5483	1.5479	+0.25
KCl	1.6585	1.6432	1.6429	+ .17
H_2SO_4	1.3391	1.3081	1.3080	+ .03
Sucrose	2.4177	2.4186	2.4188	− .04
Urea	3.2026	3.2920	3.2925	− .15
α-Met. gluc.	2.5716	2.6083	2.6082	+ .03

The discrepancy between the two determinations of ϕ for any solute from ϕ for any other is measured in parts per thousand by the difference between the corresponding entries in the last column. The maximum discrepancy is 0.04% and the average is only 0.02%.

The isotonic method was also adapted to the simultaneous measurement of solubility and the chemical potential of water from the saturated solution. A stock solution was made up which was almost saturated. In one or two of the cups an unweighed quantity of this solution was added to about a gram of the solid. The other cups each contained a weighed quantity of the same solution or of a comparison solution. At equilibrium the concentration of the solution without excess solid must be the same as that in the solu-

---

(7) ν is the number of particles from one molecule of solute, and m is the concentration in moles per kg. of water.

tion directly in equilibrium with the solid phase. So the solubility may be determined conveniently without any need of separating from the solid phase. The composition of the comparison solutions gives at the same time the potential of the solvent. This method is particularly convenient for cases of high solubility varying rapidly with the temperature, and with viscous saturated solutions. The solubility of each solid used was determined in this way. These measurements were made with cups without the nickel rings and with light platinum covers which leaked enough at this stage so that it was necessary to make two weighings and extrapolate back to the time of closing.

The equilibrium concentrations as moles per kilogram of water are given in Table I for the 32 runs which are used in the computations. About a hundred other runs were made and not used. A few were discarded because of obvious spattering, or leakage with the old platinum covers, or insufficient purification of one of the materials. However, most of these runs were made in developing the technique, particularly with dilute solutions. In some of the more concentrated solutions two cups contained the same initial solution. Both final values are given in the table, and their agreement gives another check on the accuracy of the method. The saturated solutions are indicated in the table.

TABLE I

ISOTONIC CONCENTRATIONS AT 25°

[a] Saturated solution. [b] Compared with the standard through urea.

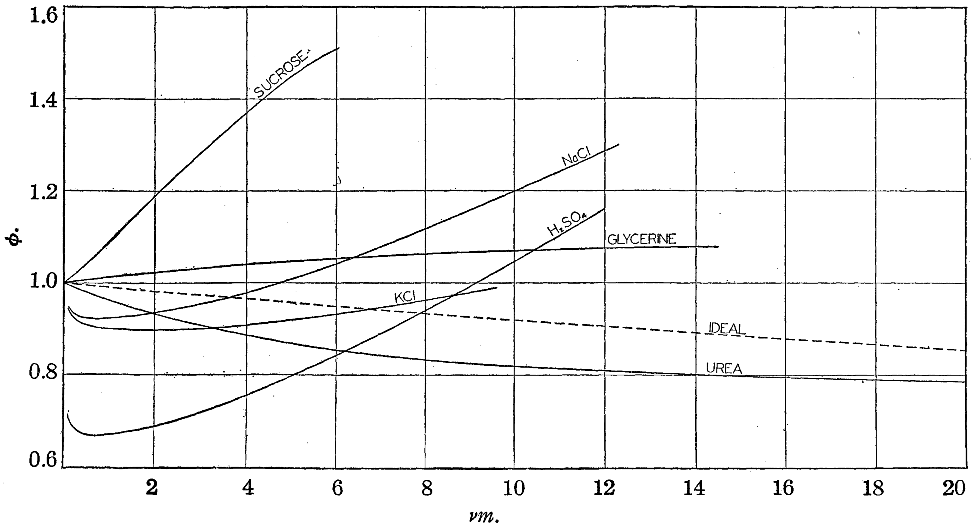

Fig. 2.—Osmotic coefficients.

A convenient way of comparing the results is in terms of the osmotic coefficient, ϕ

$$\phi = (\mu_{00} - \mu_0)/w_0RT\nu m = -(\ln a_0)/w_0\nu m \quad (1)$$

in which μ_{00} is the chemical potential of the pure solvent, μ_0 is the potential of the solvent in the solution, w_0 is one thousandth of the molecular weight of the solvent, R and T have their usual significance, ν and m have been defined above, and a_0 is the activity of the solvent. In Fig. 2 our values of ϕ are plotted against νm. The curve labeled ideal is $[\ln(1 + w_0\nu m)]/w_0\nu m$ and is the osmotic coefficient of an ideal solution, for which the activity of the solvent is equal to its mole fraction. For solutions which are isotonic, $(\mu_{00} - \mu_0)$ is the same in each solution, and therefore $\nu m\phi$ is also the same. In this diagram the isotonic lines are rectangular hyperbolas with the equations $\phi = k/\nu m$. For some purposes it is convenient to plot ϕ against $\nu m\phi$ so that the isotonic lines are all perpendicular.

In determining the best standard curve from measurements on several substances, it is convenient to assume a curve for one substance as standard and to compute each value for another solution from this curve and the concentrations of the standard and of the other solution. Then the standard curve is altered as often as necessary to give the best fit for all the measurements. We have chosen sodium chloride as the standard since it was used in almost every run; it is easily purified, and its curve is much simpler than that of sulfuric acid which is the only other substance used in all the most concentrated solutions.

The scale of Fig. 2 is much too small for comparison of our smooth curves with the experimental results. We have therefore plotted the deviation function $\Delta\phi$ which is defined for each solute under the corresponding figure. The last term for the electrolytes is the Debye–Hückel square root correction in very dilute solutions and becomes very nearly constant in more concentrated solutions.[8] The constants in the other terms are empirical. The graphs for the individual solutes all have the same scale of ordinates in which each division is 1%.

Sodium Chloride (Fig. 3).—An analytical reagent was dissolved in conductivity water and precipitated by hydrogen chloride gas. The precipitate was dried at 300° and then at room temperature by passing through the finely powdered material in a Gooch crucible a current of air which had been dried by calcium chloride. The solubility of 6.144 M may be compared with 6.145 M of the "I. C. T." (vol. IV, p. 235).

The vapor pressures of sodium chloride solutions have been measured at 25° by Frazer and S. S. Negus,[9] and by Pearce and F. Fordemwalt,[10] and at 20° by Frazer and W. R. Norris.[9] The latter were corrected to 25° through the use of the heat of dilution measurements of Gulbransen and Robinson[11] and of Lipsett, Johnson and Maass.[12] Osmotic coefficients at 25° were calculated from the freezing point measurements of Scatchard and Prentiss[13] and the first of these heat measurements. The treatment of dilute solutions will be discussed elsewhere. The os-

motic coefficients were also calculated from Harned's measurements of the electromotive force of cells with sodium amalgam and silver chloride electrodes[14] with the use of activity coefficients up to 0.1 *M* determined by Brown and MacInnes[15] from cells with transference and the transference numbers. Since sodium chloride was chosen as our standard, no experimental points appear in Fig. 3 for our own measurements. The freezing point values agree with the standard curve almost exactly. Below one molal the vapor pressure measurements scatter too widely to be of use. At higher concentrations those of Pearce and Fordemwalt check the curve within their fluctuations from any smooth curve. Those of Frazer and Negus agree even better except for the last two points which were measured in two steps. The measurements at 20° give values about 1% high. The electromotive force measurements agree with the standard up to 0.1 *M*; they yield osmotic coefficients lower than the standard below 1 *M* and higher above that concentration, with a maximum deviation of almost 1%.

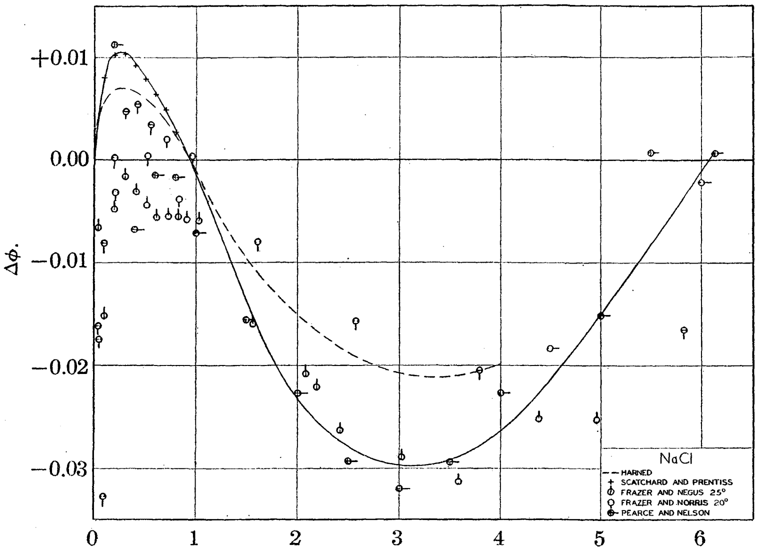

Fig. 3.—Sodium chloride deviations: $\Delta\phi = \phi - 1 - 0.07m + 1.165[1 + \sqrt{m} - 1/(1 + \sqrt{m}) - 2 \ln (1 + \sqrt{m})]/m$.

Potassium Chloride (Fig. 4).—An analytical reagent was crystallized three times from conductivity water and dried at 300° and then in a current of dry air as described for sodium chloride. The solubility of 4.804 *M* may be compared with 4.81 *M* ± 0.5% of the "I. C. T." (vol. IV, p. 239). The vapor pressure measurements of Pearce and Snow[16] are much less consistent than those from the same laboratory with sodium chloride, and the average deviation is almost one per cent. and negative. The measurements of Lovelace, Frazer and Sease[17] at 20°, computed to 25° with the use of the heat of dilution measurements of Lange and his collaborators,[18] are about 1% higher than the standard curve. The electromotive force measurements of Harned and Cook,[19,14] yield high values of the osmotic coefficient throughout the range of their measurements. The measurements of Shedlovsky and MacInnes[20] with cells with transference combined with transference numbers lead to very exact agreement up to half molal. We did not integrate their results further because the measurements are sparse and there seems to be some question of the accuracy of their measurement at 0.5 *M*. Figure 4 shows how precisely the standard curve for potassium chloride is fixed by the isotonic measurements once the curve for sodium chloride is determined.

We may also compare our measurements with Robinson and Sinclair's measurements of the isotonic ratios of sodium chloride to potassium chloride.[5b] For concentrations above one molal their ratio of sodium chloride concentration to potassium chloride concentration averages 0.1% smaller than ours. This difference is smaller than the fluctuations of their results or the accuracy they claim. Below one molal, where our fluctuations are also larger, their ratio is about 0.1% larger than ours.

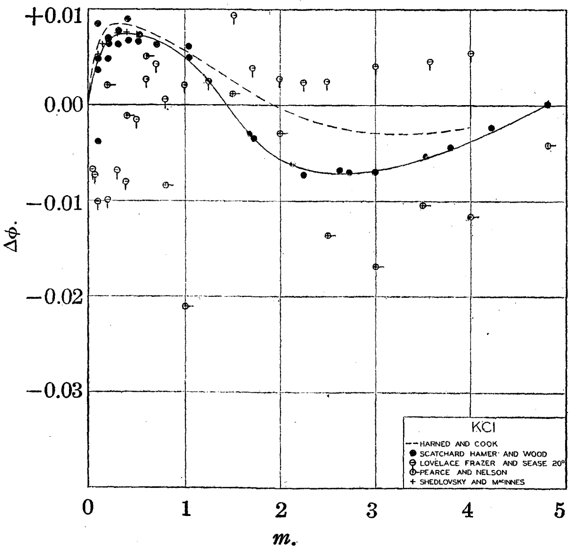

Fig. 4.—Potassium chloride deviations: $\Delta\phi = \phi - 1 - 0.026m + 1.165[1 + \sqrt{m} - 1/(1 + \sqrt{m}) - 2 \ln (1 + \sqrt{m})]/m$.

Sulfuric Acid (Fig. 5).—Chemically pure sulfuric acid was distilled very slowly in an all-glass still into conductivity water to give a solution of density 1.8. The vapor

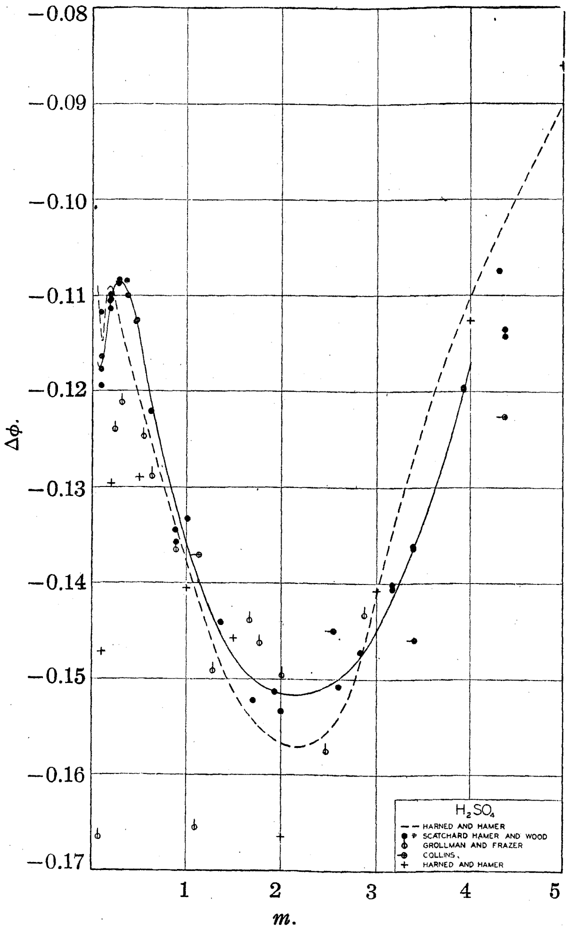

Fig. 5.—Sulfuric acid deviations: $\Delta\phi = \phi - 1 - 0.13m + 2.330[1 + \sqrt{3m} - 1/(1 + \sqrt{3m}) - 2 \ln (1 + \sqrt{3m})]/3m$.

pressure measurements of Grollman and Frazer[21] scatter about our standard curve with a small average difference. Those of Collins[22] lie slightly above it below 3 *M* and below it above 3 *M*. Harned and Hamer's measurements[23] of the cells

$$H_2,\ H_2SO_4\ (m),\ PbSO_4,\ PbO_2,\ Pt \qquad (I)$$

and

$$H_2,\ H_2SO_4\ (m),\ Hg_2SO_4,\ Hg \qquad (II)$$

may be combined to give

$$E_{I} + E_{II} - E_{I_0} - E_{II_0} = (RT/F) \ln a_0 \qquad (2)$$

However, 0.01 mv. corresponds to 1% at 1 *M* and to 0.1% at 5 *M*. The largest deviation from our standard curve corresponds to 0.03 mv. at 2 *M*. The values of ϕ determined by integration from the chemical potential of the acid measured by one of these cells singly lie below our standard curve below about 3 *M*, and above at higher concentrations, with a maximum deviation of about 0.5%. The integrated deviation curve has a minimum at about 0.1 *M*, and a maximum at about 0.2 *M* which cannot be avoided without attributing to the experiments an error much larger than appears probable. We have drawn our standard curve with a similar maximum and minimum to correspond to our measurements although these measurements are probably not precise enough to establish independently that there is such an irregularity.

Sucrose (Fig. 6).—From a nearly saturated cane sugar solution prepared by percolation the sucrose was precipitated by adding ethyl alcohol at 0°. It was dried over calcium chloride and then in a current of dried air as described for sodium chloride. To avoid errors due to hydrolysis no solution of sucrose was used which had been in contact with water more than a week. Our solubility of 6.053 *M* corresponds to 67.44% sucrose, which may be compared with the 67.89% of "I. C. T." (vol. II, p. 344). We have not found the measurements of osmotic pressure to be accurate enough for our purposes. The vapor pressures of sucrose solutions have been measured at 25° by Frazer and L. C. Beard,[9] at 20° by Frazer and H. K. Parker,[9] and at 0° and 30° by Berkeley, Hartley and Burton.[24] We have interpolated these last measurements linearly in $1/T$, which corresponds to a heat of dilution independent of the temperature, and have used the same temperature coefficient to calculate ϕ at 25° from the measurements of Frazer and Parker. Above two molal the measurements of Frazer and his collaborators are in good agreement with our standard curve. Those of Berkeley and collaborators are about 1.5% higher.

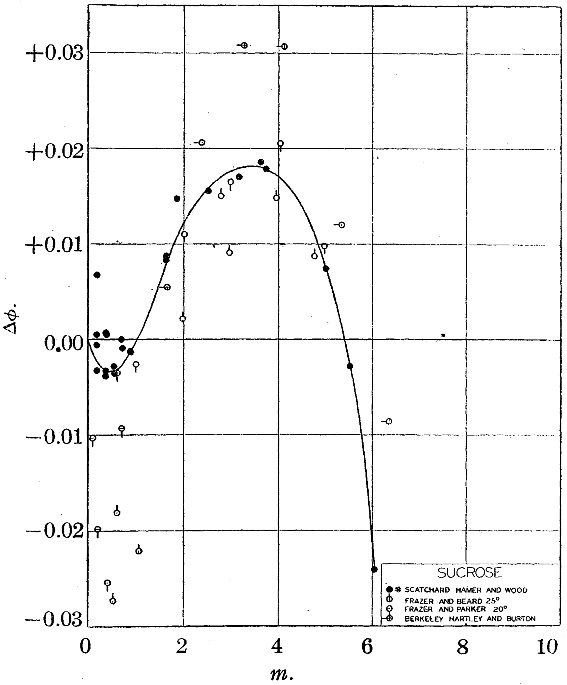

Fig. 6.—Sucrose deviations: $\Delta\phi = \phi - 1 - 0.088m$.

Urea (Fig. 7).—Synthetic urea was crystallized from conductivity water and then from ethyl alcohol, both without heating above 60°. It was dried over calcium chlo-

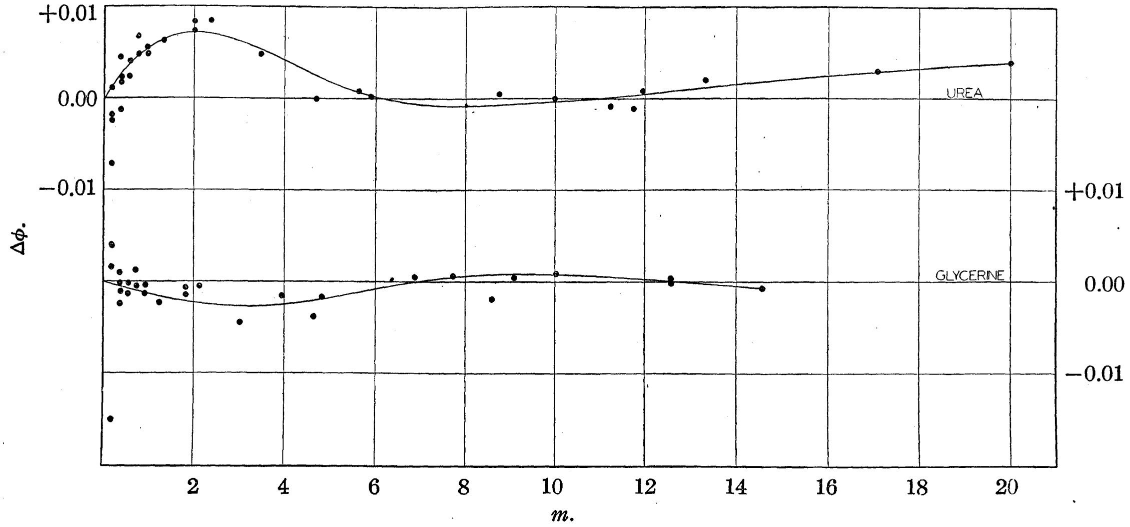

Fig. 7.—Urea and glycerol deviations: Urea, $\Delta\phi = \phi - 1 + 00.05m/(1 + 0.179m)$; Glycerol, $\Delta\phi = \phi - 1 - 0.016m/(1 + 0.1333m)$.

ride and then in a current of dry air as described for sodium chloride. To avoid errors due to hydrolysis or to rearrangement to ammonium cyanate, no urea was used which had been in contact with water more than a week. A study of 0.01, 0.1 and 1.0 *M* urea solutions showed that at room temperature it requires a month for the conductance of a urea solution to reach 0.1% of that of a sodium chloride solution of the same molality. The solubility of 20.007 *M* was confirmed by two determinations in each of which four cups contained urea solutions. These gave an average of 20.006 with an average deviation of 0.006. This checks the measurements of Pinck and Kelly[25] as closely as they can be interpolated to 25°. Values of 17, 18 and 19 *M* are also found in the literature. The vapor pressures of urea solutions have been measured at 25° by Lewis and Burrows.[26] We confirm their statement that a saturated solution is nearly ideal, but find that their measurements are otherwise not sufficiently accurate for our purposes. Urea was included in our study in the hope that the deviations from ideality would be so much smaller in dilute solutions that a simple interpolation would be justified. Figures 2 and 7 show that the difference from ideality does not decrease rapidly with decreasing concentration until the solutions are quite dilute and that the deviations from our analytical function are little, if any, simpler than for the other substances.

The measurements of Chadwell and Politi[27] yield values of ϕ at the freezing point which are very slightly higher than ours at 25° in dilute solutions but decrease more nearly linearly to 0.7646 at 8.083 *M* (the eutectic) where the value at 25° is 0.8333. This difference would correspond to a partial heat content of water 0.65 cal./mole more positive than that of pure water if this heat content difference were independent of the temperature. However, the heat capacity measurements of Gucker and Ayres[28] show that this difference is becoming more positive with decreasing temperature, and is changing more rapidly the lower the temperature. This variation together with the decrease of freezing point with increasing concentration may explain the fact that the average value of $(\mathrm{d}\phi/\mathrm{d}T)/m$ between the freezing point and 25° appears to increase rapidly with increasing concentration although ϕ/m decreases slightly. However, the value of $(\mathrm{d}\phi/\mathrm{d}T)/m$ at 8.08 molal is only about half as large as the value calculated for concentrations below one molal from Naudé's heat of dilution measurements at 18°.[29]

Glycerol (Fig. 7).—To 300 cc. of C. P. glycerol was added 25 cc. of concentrated hydrochloric acid and the mixture was heated on the water-bath for twelve hours. It was then distilled *in vacuo* and the middle portion collected and stored in small glass containers in which it was protected from the atmosphere. The vapor pressures of aqueous glycerol solutions have been measured by Drucker and Moles.[30] Their results correspond to our curve for sucrose much more closely than they do to our results for glycerol. This means a discrepancy of 40–50% in ϕ at 5 and 11 *M*. Glycerol, like urea, was chosen in the hope that the deviations from ideality would be small enough to justify a simple interpolation. The deviations of our smooth standard curve from the analytical expression are never greater than 0.3% so that our hopes appear to be realized. However, glycerol is a hygroscopic liquid and therefore it is not a convenient standard.

α-Methyl Glucoside.—Berkeley, Hartley and Burton[24] also measured the vapor pressures of aqueous solutions of α-methyl glucoside at 0 and at 30°. Therefore this substance was used in some of the preliminary runs. Eastman "Eastman Grade" product was crystallized once from synthetic methyl alcohol, and dried in a current of air as described for sodium chloride. The melting point was raised thereby from 157.5 to 164.0°. Since the small sample could not be purified further and since the vapor pressure measurements appeared to be less useful than

those with sucrose, glycerol was substituted in the later runs. Our measurements may be represented approximately by $\Phi = 1 + 0.0785m/(1 + 0.163m)$, and a solubility of 5.55 *M*.

Table II contains the osmotic coefficients and one plus the logarithms of the activity coefficients at rounded molalities. The one is added to the logarithms of the activity coefficients to avoid negative values and to make this column, like that for ϕ, approach unity at zero concentration. We do not consider our measurements at low concentrations sufficiently accurate for the extrapolation of the activity coefficients of the electrolytes to zero concentration. We have therefore accepted the value for sodium chloride at 0.2 *M* from heat of dilution and freezing point measurements,[13,11] the value for potassium chloride at 0.1 *M* of Shedlovsky and MacInnes,[20] and the value for sulfuric acid at 0.2 *M* of Harned and Hamer.[23] The differences at other concentrations correspond, of course, to the differences in osmotic coefficients discussed above.

Robinson and Sinclair[3b] and Robinson in his later papers based their standard largely on the electromotive force measurements of Harned with potassium chloride[14] and it corresponds very closely to the dotted curve we have drawn from these measurements, agreeing with our standard within 0.1% up to 1 *M* and giving a maximum deviation of 0.66% at 3 *M*. Smith and Smith[31] use as standards sucrose solutions, for which they use the equation $\phi = 1 + 0.095m + 0.0013m^2$ up to 3 *M* based on the vapor pressure measurements of Berkeley, Hartley and Burton[24] and measurements of osmotic pressure. Above 0.5 *M* their values are about 0.8% higher than our standard. Our measurements permit the comparison of sixteen of the most precise series of measurements of the chemical potential of water in aqueous solutions made with four different solutes in six laboratories by six distinct methods. Although any choice of the best curve through such a mass of data must involve some subjective judgment, we believe that the uncertainty in our curve is not more than 0.2%. With the osmotic coefficient

in Table II any one of the five solutes may be used as standard.

Summary

A modification for precision work of the isotonic apparatus and method of Sinclair and Robinson is described.

The isotonic concentrations at 25° of aqueous solutions of sodium chloride, potassium chloride, sulfuric acid, sucrose, urea and glycerol have been determined from 0.1 M sodium chloride to the saturated solution or to a saturated solution of sodium chloride.

The solubilities in water at 25° of sodium chloride, potassium chloride, sucrose and urea have been determined in the same apparatus by a new and convenient method.

The most precise determinations of the chemical potential of water in solutions of non-volatile solutes have been compared critically by means of these isotonic measurements, and a standard curve for the osmotic coefficients of each substance has been based on all the measurements with any of these substances.

Transference Numbers of Lanthanum Chloride at 25° by the Moving Boundary Method

BY L. G. LONGSWORTH AND D. A. MACINNES

Introduction

In recent publications from this Laboratory Brown and MacInnes[1] and Shedlovsky and MacInnes[2] have shown that transference numbers, and electromotive forces of concentration cells, may be used in determining activity coefficients of salt solutions. The salts studied in this manner have been the chlorides of hydrogen, sodium, potassium and calcium. The results were found to be in close accord with the Debye–Hückel theory. In addition transference numbers are of utility in interpreting the results of conductance measurements according to the recent developments of the interionic attraction theory. The extension of the studies to solutions of lanthanum chloride appeared to be of interest. Since this salt is of a highly unsymmetric valence type, the data obtained should afford a severe test of the interionic attraction theory in relation to both activity coefficients and conductances. This paper describes the determination of the transference numbers of lanthanum chloride by the moving boundary method and gives data on these numbers at 25° in the concentration range 0.0075 to 0.5 normal.

Description of the Apparatus

Of the apparatus used in determining transference numbers by the moving boundary method the cell was the same as that used in recent investigations in this Laboratory and has been described fully.[3] The constant current device has, however, been much simplified, as shown in Fig. 1. In this figure a portion, B, of the storage battery, A-B, furnishing current to the moving boundary cell, C, is shunted by a potential divider, the point of contact, T, being shifted by winding resistance wire from one of the insulated cylinders, DD′, to the other. In series with this and the cell C is a decade resistance box, R, with the range 10 to 11,110 ohms, which is shunted by the galvanometer, G, and the Hulett cell, X, which is, essentially, a heavy-duty Weston unsaturated standard cell. The needle of the galvanometer carries a vane, V, of aluminum foil which serves to intercept the light to the photo-tube, PJ 23. The photoelectric current operates a thyratron, FG 57, whose plate circuit includes the electromagnet E which controls the addition of potential by the divider, DD′, by drawing the pulley P_1 against the constantly rotating disk F. On release the pulley P_2 causes an adjustment in the reverse direction. For use with continuously increasing resistance, as in the present case, P_2 may be removed.

In operation the resistance R is set at such a value that a drop of 1.0189 v., the potential of the Hulett cell, results from the passage of the current. The advantages of this arrangement over that previously described[3] are: (1) a thyratron has replaced a vacuum tube and two mechanical relays and (2) a Hulett cell and a resistance box have replaced a Weston standard cell, standard resistances, potentiometer and storage battery. The precision and convenience of the apparatus have been increased since it is no longer necessary to adjust the potentiometer current at intervals during a transference number determination. As a matter of fact, the device will operate for an indefinitely long period with an accuracy of 0.01% or better.

The frequency control of the local a. c. power supply is

now of sufficient precision to warrant replacement of our original timing device by a counter driven by a synchronous motor.

Preparation of the Solutions

Lanthanum chloride from two sources was used in this investigation. Preliminary treatment of both samples included precipitation with recrystallized oxalic acid, ignition to the oxide, solution in distilled hydrochloric acid and precipitation as $LaCl_3 \cdot 7H_2O$ with hydrogen chloride gas at 0°. One sample was obtained from a German source and the second was prepared for us under the direction of Professor B. S. Hopkins of the University of Illinois. Spectroscopic examination and conductance measurements showed that the two samples were practically identical. Spectroscopic comparison with a cerium-free sample kindly given us by Professor G. Jones of Harvard and with samples to which known amounts of cerium had been added indicated that our material contained less than 0.03% of cerium and was free of other impurities. Since cerium has nearly the same mobility and equivalent weight as lanthanum the presence of this amount of cerium in our salt has no appreciable effect on either the transference or the conductance measurements. We are indebted to Dr. G. I. Lavin of these Laboratories for the spectrographic analysis of our material.

Several methods of preparing lanthanum chloride for weighing were used and the results are summarized in Table I. As much of the water of hydration as possible was removed at a low temperature in a vacuum desiccator, using "Drierite" and continuous pumping. The temperature of this desiccation is given in the first column of the table. The sample, either pure or mixed with ammonium chloride, was then placed in a Richards "bottling" apparatus and heated to a high temperature in a stream of dry hydrogen chloride gas. The treatment given the material is recorded in the second column of Table I. As is indicated in the third column, a minute trace of insoluble material, presumably the basic chloride, invariably remained when the *fused* salt was dissolved in water. Fusion with ammonium chloride, in the process of which the ammonium salt sublimes and is carried away by the stream of hydrogen chloride gas, did not prevent the formation of this basic chloride. When, however, the salt was heated to 600° the resulting solution was clear.[4] The agreement between the conductances of the various preparations as given in the last column of Table I indicates, barring improbable compensation, that the insoluble residue in the fused material and the residual water in that heated to 600° amount to less than 0.01%, which is the limit of error of the conductance measurements.

TABLE I

PREPARATION OF STOCK SOLUTIONS OF LANTHANUM CHLORIDE

Temp. of vacuum desiccation, °C.	Treatment in HCl atmosphere	Basic chloride residue	Equiv. conductance, $\Lambda_{0.1}$
140	Rapid fusion	Large	. . .

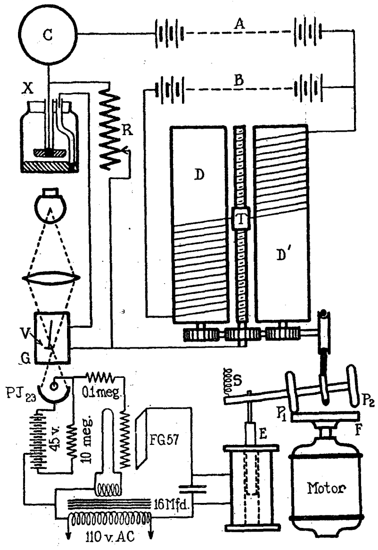

Fig. 1.

Lithium Chloride was prepared by dissolving, in hydrochloric acid, lithium carbonate that had been recrystallized from boiling water. This salt proved to be an excellent cation indicator for solutions of lanthanum chloride over the entire range of concentration studied.

Lanthanum bromate was prepared by the addition of an excess of solid silver bromate to a concentrated solution of lanthanum chloride. The trace of silver ion remaining in the solution of lanthanum bromate does not interfere with the use of this solution as anion indicator since the cation constituents migrate away from the boundary. Although the bromate ion is but slightly slower than the chloride ion it was found that satisfactory boundaries between solutions of their lanthanum salts could be obtained at 0.2 and 0.5 normal. Lanthanum bromate was used therefore to obtain confirmation of the results with lithium chloride as indicator.

Anion boundaries with lanthanum acetate were also tried but excessive heating in the indicator solution caused mixing at the boundary. Moreover, this salt appears to be appreciably hydrolyzed.

Experimental Results

The experimental results are given in Table II in which concentrations are expressed in equivalents per liter of solution at 25°. Values of the transference number obtained in individual determinations are recorded under "$T_{\pm}$ observed" and their average under "$T_{\pm}$ mean." These values are subject to two small corrections: for the conductivity of the solvent (1.5×10^{-6} mho), and for the volume changes in the closed side of the moving boundary cell, both of which are discussed in detail by MacInnes and Longsworth.[3] The

volume change for both the anion and cation boundaries is

$$\Delta V = \frac{1}{3} T_+ \bar{V}_{\text{LaCl}_3} + V_{\text{Ag}} - V_{\text{AgCl}}$$

in which $\bar{V}_{\text{LaCl}_3} = 0.01615 + 0.01733 \sqrt{\text{molality}}$, $V_{\text{Ag}} = 0.0103$ and $V_{\text{AgCl}} = 0.0258$, all at 25°. These corrections are given in the fourth and fifth lines of Table II and the corrected transference numbers in the sixth line. The conductances of all solutions were measured on the bridge described by Shedlovsky[5] and are recorded in the last line of the table. A value of 0.012856[6] for the specific conductance of 0.1 demal potassium chloride was used in the determination of cell constants.

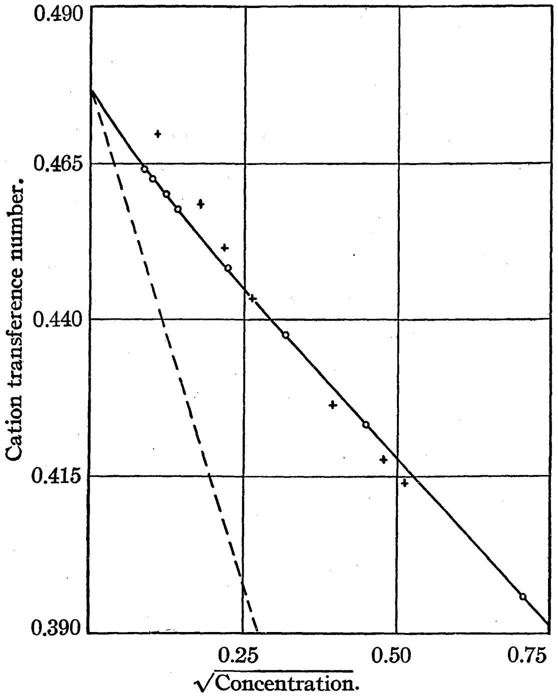

Fig. 2.

Discussion of the Results

In Fig. 2 the transference data for lanthanum chloride are plotted as ordinates against the square root of the concentration as abscissas. The values recently obtained with the Hittorf method by Jones and Prendergast[7] are indicated by the crosses while our results are plotted as circles. The differences between the results by the two methods, reaching a maximum of 0.007 for the most dilute solutions, are larger than those found in similar comparisons for lithium[8] and potassium chlorides[9] and are certainly outside the limit of error of the moving boundary measurements. That the Hittorf values for dilute solutions are not consistent with the results for other salts, and with Kohlrausch's law of independent ion mobilities, have already been pointed out by Hartley and Donaldson.[10] A test of the accuracy of our measurements is afforded by independent observation of both anion and cation boundaries with the same solution. The sum of the transference numbers thus obtained should be 1.0000. Thus from the data of Table II, $T_+ + T_- = 0.9999$ at 0.2 normal and 1.0008 at 0.5 normal. It may be noted that the conductances of Table II are in excellent agreement with the values published by Jones and Bickford.[4]

The smooth curve drawn through our data has been extrapolated to the value of 0.4768. This limiting cation transference number is based on the values of 76.34 and 145.9 for the limiting conductances of the chloride ion[11] and lanthanum chloride,[12] respectively. The dashed line in Fig. 2 is the limiting slope

$$\left(\frac{dT_+}{d\sqrt{C}}\right)_{C \to 0} = \frac{(z_+ + z_-)T_+^0 - z_+}{\Lambda_0} \beta \sqrt{z_+ + z_-} \quad (1)$$

derived by Longsworth[13] from the Onsager theory.[14] As in the case of calcium chloride the

experimental curve of transference numbers for lanthanum chloride apparently merges with the limiting slope only at extreme dilutions. Assuming that the salt conductances have been extrapolated correctly, we are confronted with the anomaly that these conductances appear to obey the Onsager equations to somewhat higher concentrations than do the transference numbers, although the latter are merely ratios of ionic conductances. No satisfactory explanation for this anomaly has been advanced. A similar anomaly involving the activity coefficients will be discussed in a forthcoming paper from this Laboratory.[15]

In Fig. 3 we have plotted, as ordinates, the chloride ion conductances, $\lambda_{Cl} = T_{Cl}^{MCl}\,\Lambda$, of lanthanum, calcium[13,16] and sodium chlorides[8,17] against the square root of the concentration as abscissas. The smooth curves through the experimental points are extrapolated to the limiting conductance of the chloride ion, 76.34, and the straight lines through this point are the limiting slopes given by the following Onsager equations

$$\left.\begin{aligned} \lambda_{Cl}^{NaCl} &= 76.34 - 47.2\sqrt{C} \\ \lambda_{Cl}^{CaCl_2} &= 76.34 - 74.0\sqrt{C} \\ \lambda_{Cl}^{LaCl_3} &= 76.34 - 99.1\sqrt{C} \end{aligned}\right\} \qquad (2)$$

The conductance of the chloride ion associated with a univalent cation exhibits the normal positive deviation from the limiting slope with increasing concentration. When associated with a divalent cation, however, the deviations in dilute solutions appear to be negative and still more pronounced negative deviations occur when the co-ion is trivalent as in lanthanum chloride. These negative deviations, due to the anomalous behavior of the transference numbers discussed in the preceding paragraph, do not appear to be indicative of intermediate ion formation since the salt conductances are normal.

The curves of Fig. 3 also serve to illustrate the large deviations from additivity of ion conductances when the valence of the co-ion is altered. In our study of the chloride ion conductance in solutions of uni-univalent chlorides, it was observed that this conductance was additive at concentrations below about 0.02 normal and depended only slightly upon the specific nature of the co-ion at higher concentrations. The magnitude of this dependence is indicated in Fig. 3 by the vertical line through each point for λ_{Cl}^{NaCl}. These lines were drawn to include, at each concentration, the values of λ_{Cl} for hydrogen, potassium and lithium chlorides. Marked deviations from additivity occur, however, when the valence of the co-ion is increased, as is shown by the divergence of the three curves of the figure.

Sherrill and Noyes[18] have assumed for the purpose of computation that ion conductances are additive at equal ionic strengths. This is equivalent to extending the concentration scale for a bi-univalent salt by the factor 1.5 and that for a tri-univalent salt by 2. Alteration of the concentration scales by these factors is, however, insufficient to bring the curves of Fig. 3 into coincidence. Although not strictly applicable at the concentrations for which transference data are available, the Onsager theory explains, qualitatively, this valence effect. Thus reference to equation (2) indicates that $\lambda_{Cl}^{CaCl_2}$ should equal λ_{Cl}^{NaCl} when $C_{NaCl} = (74.0/47.2)^2\, C_{CaCl_2} = 2.45C_{CaCl_2}$. The corresponding factor for C_{LaCl_3} is 4.40. Even these factors are not large enough. The ones actually required are 3.3 for calcium chloride and 10 for lanthanum chloride. Thus the open circles and crosses of the upper curve of Fig. 3 are, respectively, the observed values of $\lambda_{Cl}^{LaCl_3}$ and $\lambda_{Cl}^{CaCl_2}$ plotted on such adjusted concentration scales. The transposed points fall on the λ_{Cl}^{NaCl} curve with deviations of the same order as is observed among univalent chlorides, *i. e.*, deviations attributable to properties of the co-ion other than its valence. Although only those

points on the two lower curves for which $\lambda_{Cl} > 62$ can be thus transposed, computations with the available data indicate that the curves may be thus superposed to higher concentrations.

Summary

Measurements of the transference numbers at 25° of aqueous solutions of lanthanum chloride by the method of moving boundaries have been made. The chloride ion conductances of these solutions have been compared with similar measurements of solutions of calcium chloride and sodium chloride. From this comparison an empirical rule for the effect of the valence of the co-ion on the chloride ion conductance has been obtained.

The Electrolytic Conductivity of Zinc Sulfate and Copper Sulfate in Water at 25°[1]

BY BENTON BROOKS OWEN AND ROBERT W. GURRY[2]

Within the last decade the conductivities of a large number of electrolytes have been precisely redetermined at 25°. Most of these modern measurements have been confined to 1–1 and 2–1 valence types because they conform to the requirements of the inter-ionic attraction theory at experimentally accessible dilutions, and may therefore be readily extrapolated. The 3–1 electrolyte lanthanum chloride can possibly be satisfactorily extrapolated along the Onsager[3] slope, but no 2–2 electrolyte has yet been found amenable to this simple treatment. The extrapolation of the conductivities of zinc and copper sulfates is of particular interest because of the complications introduced by relatively large departures from the limiting slope and partial hydrolysis of the ions.

In the present research we have carefully measured the specific conductivity and *p*H of dilute solutions of these salts at 25°, and made what we believe to be adequate solvent and hydrolysis corrections. The results have been extrapolated by a number of methods fulfilling the requirements of the inter-ionic attraction theory, and which lead to essentially the same values of Λ_0. Zinc and copper sulfates are particularly well suited for this type of investigation because they can be highly purified, and their hydrolysis corrections are not too great to be estimated with sufficient accuracy. Furthermore, the supplementary thermodynamic and conductance data required in our calculations are available for these salts, and for the sulfate and hydrosulfate ions.

Materials and Technique

Merck reagent grade zinc sulfate heptahydrate was recrystallized twice from a mixture of highly purified methanol and water, and then twice from conductivity water. The last crystallization was accomplished by partial evaporation of the water at room temperatures with the necessary precautions against contamination by dust.

Merck reagent grade copper sulfate pentahydrate was recrystallized four times from conductivity water. The purified salt was crushed in an agate mortar and dried over a mixture of the penta- and trihydrates.

Stock solutions, 0.1 and 0.5 *m*, were prepared by weight and checked by gravimetric analysis. Vacuum corrections were applied throughout. Samples of the zinc sulfate solutions were evaporated at 95° and the salt dehydrated at 300° and weighed as $ZnSO_4$. The copper was determined electrolytically, with the last traces precipitated as sulfide and weighed as oxide. All duplicate analyses checked within 0.02% from the means.

The Dike[4] bridge was operated by a vacuum tube oscillator at 1000 cycles. It was calibrated against Bureau of Standard resistors with a d. c. source and a sensitive galvanometer. All measurements reported were made without shunts, and were reproducible to 0.002%.

The temperature was adjusted to 25 ± 0.005° with a platinum resistance thermometer certified by the Bureau of Standards, and thermoregulation within 0.005° was maintained during the course of the measurements.

The cells were the type B[5] generally employed in this Laboratory. The electrodes were lightly platinized. Cell constants were determined several times during the course of the measurements with 0.1 demal potassium chloride according to Jones and Bradshaw.[6] The cell constants, *l/a*, were 4.5221 for cell III and 3.7260 for cell IV. The specific conductivity of the water employed was usually less than 2×10^{-7} mho.

The *p*H values required for the solvent and hydrolysis corrections were obtained colorimetrically by the use of LaMotte indicator standards in the zinc sulfate solutions, and electrometrically with glass electrodes[7] in the copper

sulfate solutions. The results were plotted on a large scale against $\sqrt{C}$ for interpolation at the required concentions. The pH at even values of $\sqrt{C}$ are recorded in Table III. The acidity of dilute zinc sulfate solutions has been studied recently by Kolthoff and Kameda[8] by both colorimetric and electrometric methods. Their pH values are about 0.1 unit lower than ours, but in view of the sensitivity of these unbuffered solutions to acid and basic impurities, this concordance seems satisfactory.

Experimental Results

The experimental data are recorded in Tables I and II as specific conductivities, κ, at the concentrations, C, in moles per liter of solution. The specific conductivity of the solvent, κ_0, and the cell constant, l/a, employed in each run are given at the bottom of the columns of data to which they apply.

Although the specific conductivities are known to within 0.01%, the calculated equivalent conductivities are less accurate because of the uncertainties in the solvent and hydrolysis corrections. The maximum values of these combined corrections are about 0.2 and 0.8 conductance units in the zinc and copper solutions, respectively.

The solvent conductance was assumed to be due to hydrogen and hydroxyl ions from the ionization of the water, and a constant residual specific conductance, δ, due to unknown impurities. The latter was estimated by subtracting the specific conductance of pure water, 0.546×10^{-7}, from the measured solvent conductance, κ_0. Then. as the pH of the water was altered by hydrolysis of the salt being studied, the correction for solvent conductance becomes

$$1000\,\Delta\kappa_1 = \lambda_H C_H + \lambda_{OH} C_{OH} + 1000\delta \qquad (1)$$

For this correction we used $\lambda_H = 350$ and $\lambda_{OH} = 200$. The concentrations, C_H and C_{OH}, were determined from the pH values given in Table III. The equivalent conductance corrected for solvent is then given by

$$\Lambda_1 = \frac{1000\kappa}{2C} - \frac{1000\,\Delta\kappa_1}{2C} \qquad (2)$$

The variation of pH with total salt concentration is due to hydrolysis of the bivalent ions, and can be expressed as follows

$$Zn^{++} + H_2O \rightleftharpoons Zn(OH)^+ + H^+$$

and

$$SO_4^{=} + H_2O \rightleftharpoons HSO_4^- + OH^-$$

The formation of H_2SO_4 and $Zn(OH)_2$, or more complex ions, was assumed to be negligible in dilute solutions.

Since we are concerned with obtaining the conductance due to Zn^{++} and $SO_4^{=}$ ions only, it is necessary to correct the apparent equivalent conductivity, Λ_1, for the decrease due to replacement of a small fraction of the bivalent ions by the monovalent complex ions $Zn(OH)^+$ and HSO_4^-. The correction to be added is

$$1000\,\Delta\kappa_2 = C_{ZnOH^+}(2\lambda_{Zn^{++}} - \lambda_{ZnOH^+}) + C_{HSO_4^-}(2\lambda_{SO_4^=} - \lambda_{HSO_4^-}) \qquad (3)$$

Accordingly the desired equivalent conductance of (unhydrolyzed) zinc sulfate is given by

$$\Lambda = \Lambda_1 + \frac{1000\,\Delta\kappa_2}{2C} \qquad (4)$$

The equivalent conductances of the ions were taken as 79.8 and 50 for $SO_4^{=}$ and HSO_4^-; 53.5 and 32.1 for Zn^{++} and $ZnOH^+$; and 52.0 and 31.2 for Cu^{++} and $CuOH^+$. According to our final results $\lambda_{Cu^{++}}$ should have been nearer 54, but it would be useless to revise the corrections on this basis because λ for $ZnOH^+$ and $CuOH^+$ were merely assumed to be 0.6 of the values of the corresponding divalent ions by analogy with the

---

(8) Kolthoff and Kameda, THIS JOURNAL, 53, 832 (1931).

findings of Chandler[9] and Jeffery and Vogel[10] in dealing with organic acids.

The complex univalent ion concentrations were estimated as follows. The HSO_4^- concentration was calculated from the measured *p*H and the stoichiometric $SO_4^=$ concentration, using 0.012 as the ionization constant[11] of the hydrosulfate ion, and disregarding activity coefficients. The $ZnOH^+$ (or $CuOH^+$) concentration was then found by adding the difference $C_{H^+} - C_{OH^-}$ to the HSO_4^- ion concentration, since the $ZnOH^+$ (or $CuOH^+$) and HSO_4^- concentrations would be equal at exact neutrality.

The final equivalent conductances corrected by equation (4) were interpolated graphically at even values of $\sqrt{C}$, and recorded in Table III. For this purpose we used a very large scale plot of Λ *vs.* $\sqrt{C}$ with a stiff spline, and also several plots of deviation functions of the type $[\Lambda + A\sqrt{C} - BC]$ *vs.* $\sqrt{C}$ to expose errors in curve fitting. The discordance between the values read from two curves was never greater than 0.02 conductance unit, and since this is probably the order of the uncertainty in the combined corrections used in calculating Λ, these smoothed values will be used in the extrapolations to follow.

Extrapolations and Discussion

In the extrapolation of activity coefficient data for bi-bivalent electrolytes the initial departures from the limiting slope may be taken into account by the inclusion of higher terms[12,13] in the Debye–Hückel equation, or by the introduction of a dissociation constant to allow for the effect of relatively stable ion-pairs upon the ionic distribution.[14,15] In the absence of a numerical development of the higher terms for the Onsager equation, the modern extrapolation of bi-bivalent conductance data has always involved the concept of incomplete dissociation.

There are two techniques available for evaluating the dissociation constant, K. Onsager[16] and Davies[17] estimate K at each concentration. Fuoss and Kraus[18] determine it graphically from the slope of a suitable extrapolation function. This procedure has been greatly simplified by Fuoss,[19] and recently extended to higher concentrations by Shedlovsky.[20] All of these methods are based upon some assumption regarding the conductance, Λ_i, of the hypothetical completely ionized electrolyte. It may be assumed to obey the limiting law at the lowest experimental concentrations, or approach it asymptotically according to some arbitrary empirical function. In the extrapolation of our data we have used the limiting law and most of the empirical extensions employed for this purpose. Although all extrapolations give values of Λ_0 agreeing within 0.6 conductance unit, the apparent variation in K is over 20%, being very sensitive to the manner in which Λ_i is assumed to approach the limiting law.

In Fig. 1 we have illustrated the extrapolations which we consider most satisfactory. The open circles represent the smoothed results of Table III plotted to conform to the Fuoss[19] function

$$\Lambda/F_{(z)} = \Lambda_0 - (C\vartheta^2 y^2_{\pm})\Lambda_0/K \qquad (5)$$

and the dots are calculated according to the modification

$$\Lambda S_{(z)} = \Lambda_0 - (C\vartheta^2 y^2_{\pm})\Lambda_0/K \qquad (6)$$

proposed by Shedlovsky.[20] Equation (5) assumes the limiting law, and equation (6) allows for

slight positive deviations from the limiting law by multiplying the slope by the factor Λ/Λ_0 which rapidly approaches unity at high dilutions. In both of these equations $Z = (\alpha\Lambda_0 + \beta)\Lambda_0^{-3/2}\sqrt{C}$, ϑ is the degree of dissociation, and $y_{\pm}$ is the mean ionic activity coefficient. The function

$$F_{(Z)} = 1 - Z(1 - Z(1 - \ldots)^{-1/2})^{-1/2})^{-1/2} \qquad (7)$$

is tabulated by Fuoss,[19] and the corresponding function of Shedlovsky[20] is given by

$$S_{(Z)} = 1 + Z + \frac{Z^2}{2} + \frac{Z^3}{8} - \ldots \qquad (8)$$

In the calculation of Z, we have used $\Lambda_0 = 132.8$ for zinc sulfate, $\Lambda_0 = 133.6$ for copper sulfate, and the theoretical values $\alpha = 1.8215$ and $\beta = 239.40$. It was not necessary to calculate the value of ϑ ($\vartheta = \Lambda/\Lambda_0 F_{(Z)} = \Lambda S_{(Z)}/\Lambda_0$) because accurate values of the stoichiometrical activity coefficient, $y_{\text{stoi.}} = \vartheta y_{\pm}$, are available[21–23] for zinc sulfate, and the values for copper sulfate are known[24] to be very similar. In the calculation of $y_{\text{stoi.}}$ at the concentrations required for our purposes, we used the extended terms[12] and an "a" value of 3.64 Å.[22]

Inspection of Fig. 1. shows that the plots according to equation (6) are more nearly linear than those based on equation (5), but they both lead to the same values of Λ_0. The limiting slopes approached by the more linear plots were used in the estimation of K. The results of the extrapolations are $\Lambda_0 = 132.8$, $K = 0.0049$ for zinc sulfate, and $\Lambda_0 = 133.6$, $K = 0.0043$ for copper sulfate. Davies[17] reported $K = 0.0045$ for both salts at 18°.

To illustrate the dependence of K upon the type of conductance function, the same values of $y_{\text{stoi.}}$ used above, and the equation

$$\Lambda_i = \Lambda_0 - (\alpha\Lambda_0 + \beta)\sqrt{C\vartheta} + BC\vartheta \qquad (9)$$

lead to $\Lambda_0 = 132.9$ and $K = 0.0047$ for zinc sulfate when B is 2350. In making this calculation, $\vartheta = \Lambda/\Lambda_i$, and Λ_0 and B are adjusted by trial to yield a constant value of K. In this particular case K showed a total variation of only 0.6% between 0.005 and 0.01 molal. A variation of four or five times this figure would seem permissible in such a determination, and it is interesting to note that within these limits we can obtain values of K as low as 0.0044, and Λ_0 as high as 133.3 for zinc sulfate by means of equation (9).

The Bjerrum equation[14] permits an independent estimate of K from activity coefficient data alone. The substitution of $a = 3.64$ Å. in this equation, with proper attention to valence, leads to $K = 0.0030$ at 25°. The discordance between this value and those derived above from conductivities is not so serious as might appear on first sight, because of the very loose physical sense in which K is defined. Even the difference between the values obtained by equations (6) and (9) shows that K for zinc sulfate is more arbitrary than that for a weak electrolyte such as acetic acid, and leads one to suspect that its present status is more of the nature of an adjustable mathematical parameter than a definite physical entity.[25]

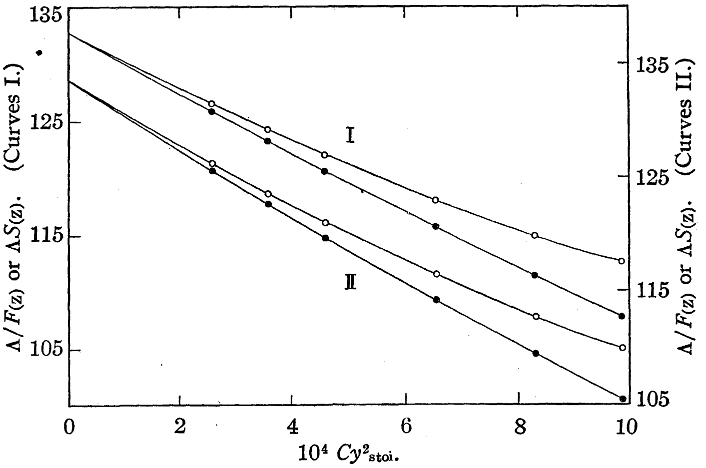

Fig. 1.—Determination of Λ_0 and K for $ZnSO_4$ (Curves I) and $CuSO_4$ (Curves II) at 25°.

In comparing the results of our extrapolations with those available in the literature we find considerable discordance. O'Connor[26] obtained $\Lambda_0 = 142$ for copper sulfate from data extending down to 0.000025 mole per liter, but reports no experimental details. We attempted to extend our measurements to 0.000087 mole per liter with the use of 30,000 ohm shunt, but have not included them in our tabulations because the shunt introduces an error of the order of ± 0.1% in κ and we feel that the pH measurements and solvent corrections are unreliable at such dilutions. It may be significant, however, that our points at $c \simeq 0.000087$ would cause the plots in Fig. 1. to curve

abruptly upward and increase the intercepts by about one conductance unit.

No recent direct determination of Λ_0 at 25° for zinc sulfate has come to our attention, but Courrell, Hamilton and Butler[27] published data which, according to their observed slopes, would lead to $\Lambda_0 \simeq 125.9$ for zinc chloride or $\lambda_0 \simeq 49.6$ for the zinc ion. Using $\lambda_0 = 79.6$ for the sulfate ion, derived from Shedlovsky's value of Λ_0 for sodium sulfate quoted by Longsworth,[28] our values of λ_0 for the zinc and copper ions would be 53.1 and 53.9, respectively.

Summary

The specific conductivities and *p*H values of dilute zinc and copper sulfate solutions were measured at 25°. The results were corrected for hydrolysis, and the equivalent conductances of the hypothetical unhydrolyzed salts reported at even values of $\sqrt{C}$.

The limiting equivalent conductances and "ionization constants" of the salts were estimated by several procedures based upon the interionic attraction theory and the law of mass action. The dependence of the results upon the nature of the extrapolation function was discussed, and $\Lambda_0 = 132.8$, $K = 0.0049$ for zinc sulfate, and $\Lambda_0 = 133.6$, $K = 0.0043$ for copper sulfate were proposed as the most reliable values.

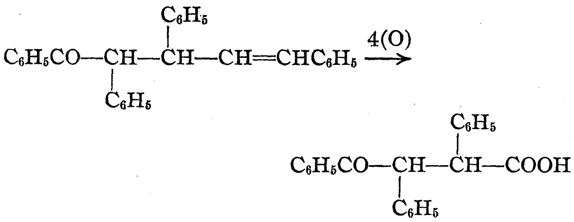
[CONTRIBUTION FROM THE SANDERS LABORATORY OF CHEMISTRY, VASSAR COLLEGE, AND THE SCHOOL OF CHEMISTRY OF THE UNIVERSITY OF MINNESOTA]

α,β-Diphenyl-β-benzoylpropionic Acid

BY H. MARJORIE CRAWFORD

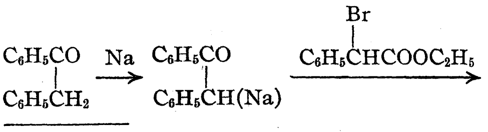
α,β-Diphenyl-β-benzoylpropionic acid has been prepared by Reimer and Reynolds[1] by the oxidation of α,β-diphenyl-γ-benzalbutyrophenone



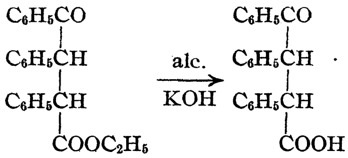
$$C_6H_5CO-\underset{C_6H_5}{CH}-\overset{C_6H_5}{CH}-CH=CHC_6H_5 \xrightarrow{4(O)} C_6H_5CO-\underset{C_6H_5}{CH}-\overset{C_6H_5}{CH}-COOH$$

They reported that the acid melted at 211–212° and crystallized from alcohol with one molecule of alcohol of crystallization. They also prepared the methyl ester which melted at 159°.

A simpler method of preparation was sought to obtain considerable quantities of the acid for use in connection with some other work. The following procedure* was adopted

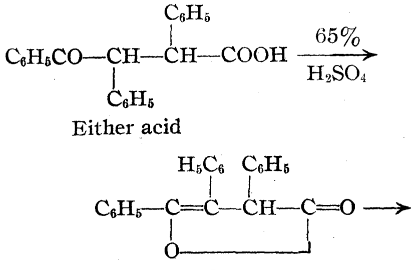


$$\begin{matrix} C_6H_5CO \\ | \\ C_6H_5CH_2 \end{matrix} \xrightarrow{Na} \begin{matrix} C_6H_5CO \\ | \\ C_6H_5CH(Na) \end{matrix} \xrightarrow{C_6H_5\overset{Br}{C}HCOOC_2H_5}$$



$$\begin{matrix} C_6H_5CO \\ | \\ C_6H_5CH \\ | \\ C_6H_5CH \\ | \\ COOC_2H_5 \end{matrix} \xrightarrow[KOH]{alc.} \begin{matrix} C_6H_5CO \\ | \\ C_6H_5CH \\ | \\ C_6H_5CH \\ | \\ COOH \end{matrix}$$

Analyses and neutralization equivalent ensured the identity of the product, but it consisted of a mixture of the two racemic modifications of the acid, one melting at 201–202° and the other melting at 211–212°. The high melting isomer yields the 159° methyl ester reported by Reimer and Reynolds. The low melting form was formed in much larger quantities. Treatment of either acid with 65% sulfuric acid gave a lactone which must have the double bond in the β,γ-position since it can be hydrolyzed to give a mixture of both acids



$$C_6H_5CO-\underset{C_6H_5}{CH}-\overset{C_6H_5}{CH}-COOH \xrightarrow[H_2SO_4]{65\%}$$

Either acid

$$C_6H_5-C=\overset{H_5C_6}{C}-\overset{C_6H_5}{CH}-C=O \longrightarrow \quad (\text{ring: } C_6H_5-C \text{ and } C=O \text{ joined through } O)$$

Lactone

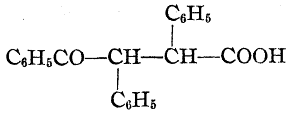
*** This method of preparation of the acid and other preparations and analytical results marked with an asterisk formed part of the thesis submitted by Brunhilde Reich as partial fulfilment of the requirements for the degree of Master of Arts at Vassar College.**



$$C_6H_5CO{-}\underset{C_6H_5}{CH}{-}\overset{C_6H_5}{CH}{-}COOH$$

Both acids

Rearrangement to the conjugated α,β-unsaturated lactone apparently does not occur in this case, for, if it did, hydrolysis should lead to one new racemic unsaturated hydroxy acid.

Experimental

Desoxybenzoin was prepared in 80% yields from benzoin, using the method of Ballard and Dehn.[2]

Ethyl α-bromophenylacetate was prepared in 85% yields from 136 g. (1 mole) of phenylacetic acid, 240 g. of bromine, 8 g. of red phosphorus and 100 cc. of absolute alcohol. The yield was reduced to 72% when double quantities were used.

α,β-Diphenyl-β-benzoylpropionic Acid.—After trying several methods of making the sodium derivative of desoxybenzoin, the following procedure* was adopted and gave the acid mixture in about 40% yields. Sodium powder, 2.3 g. (0.1 mole), in dry ether was treated with 19.6 g. (0.1 mole) of desoxybenzoin in a 200-cc. flask fitted with a condenser and guard tube. The mixture was warmed on the steam-bath until the sodium had practically all disappeared. This usually required about an hour and the solution became clear orange in color. Ethyl α-bromophenylacetate, 20 g. (just under 0.1 mole), was added slowly through the condenser and the heating continued for one and one-half hours. Most of the ether was then evaporated and replaced by alcohol. The mixture was then heated on the steam-bath for two hours with 85 cc. of 15% potassium hydroxide, diluted with water and filtered from unchanged desoxybenzoin and didesyl. Acidifying the filtrate with hydrochloric acid precipitated the keto acids. Several runs were made on double quantities without changing the yield. The acids from several runs were combined for recrystallization.

The low melting acid was formed in much larger quantities, and separated first from the ethyl alcohol solution of the two. Later both forms separated at the same time, but, when crystallization was carried out slowly, they were so different in appearance that the two kinds of crystals could be separated by hand. Further recrystallization of the two acids from alcohol gave pure compounds melting at 201–202° and 211–212°. The low melting acid differed from the high melting one in crystallizing from alcohol without alcohol of crystallization. Both acids are very soluble in chloroform, and acetone, soluble in alcohol, ethyl acetate, ether and benzene, and insoluble in ligroin and water. Ethyl alcohol or acetone and water were the best solvents for recrystallization. The 201° compound formed clusters of stout needles and the 211° compound separated in a mass of very fine needles.

Anal. Calcd. for $C_{22}H_{18}O_3$ (330): C, 79.98; H, 5.49. Found: C, 79.76; H, 5.67; neut. eq., 324.*

Attempts* to prepare the oxime and phenylhydrazone of the keto acids were unsuccessful.

Esters of α,β-Diphenyl-β-benzoylpropionic Acid.—Both ethyl esters could be separated from the original reaction mixture, but it was more satisfactory to prepare the esters from the pure acids by esterifying with the appropriate alcohol and a small quantity of concd. sulfuric acid. The corresponding esters of the two acids did not differ much in solubility. Both methyl esters were very soluble in acetone and chloroform, soluble in benzene and methyl alcohol and only very slightly soluble in ether, ethyl acetate and ligroin. The ethyl esters were very soluble in chloroform, benzene, acetone and ethyl acetate, soluble in ether and ethyl alcohol and insoluble in ligroin.

The methyl ester of the 211° acid melted at 158.5–159° as described by Reimer and Reynolds,[1] and was recrystallized from a mixture of methyl alcohol and acetone.

The methyl ester of the 201° acid was recrystallized from methyl alcohol and melted at 147–148°.

Anal. Calcd. for $C_{23}H_{20}O_3$: C, 80.21; H, 5.85. Found: C, 80.33; H, 6.0.

The ethyl ester of the 211° acid was recrystallized from ethyl alcohol and melted at 138–139°.

Anal. Calcd. for $C_{24}H_{22}O_3$: C, 80.40; H, 6.19. Found: C, 80.35; H, 6.32.

The ethyl ester of the 201° acid was recrystallized from ethyl alcohol and melted at 147.5–148°.

Anal. Calcd. for $C_{24}H_{22}O_3$ (358.7): C, 80.40; H, 6.19. Found: C, 80.44; H, 6.20; mol. wt.,* 352, 349.

Lactone.—When either of the acids was stirred and heated on the steam-bath with 65% sulfuric acid for several hours, the lactone, m. p. 124–125°, resulted.*. It was very soluble in chloroform and ethyl acetate, soluble in alcohol, ether and benzene and insoluble in ligroin.

Anal. Calcd. for $C_{22}H_{16}O_2$ (312.7): C, 84.59; H, 5.16. Found: C, 84.68; H, 5.26; mol. wt.,* 318, 313.

Two grams of the lactone was heated under reflux for one hour with 25 cc. of alcohol and 2 g. of potassium hydroxide. The solution was then cooled, diluted with water and acidified with hydrochloric acid. The resulting acid mixture was recrystallized from ethyl alcohol and both acids were recovered, the 201° compound in much larger quantities.

The author wishes to thank the University of Minnesota for the courtesy shown her as an Honorary Fellow of the University while on leave from Vassar College in the spring of 1938.

Summary

1. A new method of preparing α,β-diphenyl-β-benzoylpropionic acid is reported.

2. The two racemic forms of the acid and their methyl and ethyl esters are described.

3. The dehydration of either acid leads to the formation of a lactone.

NOTES

A Criterion for the Mechanism of the Reactions of Alkyl Halides with Hydroxylic Solvents. Reactions of Benzhydryl Chloride

By Leslie C. Bateman, Edward D. Hughes and Christopher K. Ingold

The two types of mechanism which we have postulated[1] for aliphatic substitutions, one involving bimolecular replacement in a single stage and the other preliminary ionic fission, have been discussed recently.[2] The point of interest is the ionization mechanism, which we term unimolecular and Hammett polymolecular; and although in the sequel we use our own label, we strongly agree with the purpose of Hammett's, which is to emphasize the role of the solvent. We ourselves have done this in discussions,[1c,3] pointing out, for instance, that only through solvation is the activation energy of an ionic fission reduced to accessible values.

In a number of well-established unimolecular substitutions the entrant group comes, not from the solvent, but from a reagent present in small and controllable concentration.[4] For these the observed reaction order determines the mechanism. In other substitutions, for instance, the hydrolysis and alcoholysis of alkyl halides in hydroxylic solvents, the reaction order is no longer diagnostic, and other, less direct, methods must be employed. Several have been suggested,[4] but we need here to refer only to one particular method.

This has been illustrated with respect to the simultaneous hydrolysis and alcoholysis of *t*-butyl chloride in aqueous alcohol. The total first order reaction was first investigated by Hughes,[5] who found that the rate was unaffected by hydroxonium and hydroxide ions, but was much increased with increasing water content of the solvent. He concluded that the reaction was unimolecular. Olson and Halford[2b] examined the applicability of an equation, in constructing which they assumed the reaction to be bimolecular. The formula is

$$\text{Rate} = (k_a p_a + k_w p_w) p_{\text{RCl}}$$

where the k's are rate constants, the p's partial vapor pressures, and the subscripts refer to alcohol, water and *t*-butyl chloride; and it may be used either to calculate the total rate, or, from the partial rates $k_a p_a p_{\text{RCl}}$ and $k_w p_w p_{\text{RCl}}$, to deduce the composition of the product (ROEt + ROH). Having computed k_a and k_w from observed total rates, the authors showed that their formula gave an accurate description of the variation of total rate with solvent composition, and concluded on this account that the reaction was indeed bimolecular. Then we pointed out[3] that the success with which the formula represents the total rate owes nothing to the assumed mechanism, the essential postulate, the participation of solvent in the transition state, being true for all reactions in solution, including the unimolecular process. We also noted, however, that the product compositions should be calculable with a corresponding success only if the reaction is bimolecular, for in that case the product is formed in the rate-measured reaction, so that its composition is fixed by measured rate constants, whereas in unimolecular substitution the product arises subsequently to the rate-measured stage, so that its composition cannot in principle be deduced from measured constants. An application of this criterion to the reactions of *t*-butyl chloride showed that they were not bimolecular as had been claimed, and we concluded that they were unimolecular in agreement with Hughes.

The main object of this note is to point to the analogy of a second reaction of an alkyl halide with a solvent, in which a similar criterion has been applied, with results pointing again to the unimolecular interpretation. This is the reaction of benzhydryl chloride with aqueous ethanol. Like the reaction of *t*-butyl chloride, its first order rate is unaffected by hydroxonium and hydroxide ions, but is much increased with increasing water content of the solvent. Total rates have been measured by Ward, by Norris and Morton, by Kny-Jones and Ward,[6] and by Farinacci and

[6] (a) Ward, *ibid.*, 2285 (1927); (b) Norris and Morton, This Journal, **50**, 1795 (1928); (c) Kny-Jones and Ward, *ibid.*, **57**, 2394 (1935).

Hammett,[2a] and product compositions by the last-named authors. This was before Olson and Halford's vapor pressure theory had become available, but Farinacci and Hammett noted that a bimolecular mechanism, interpreted with the aid of a concentration mass law, could not bring rates and product compositions into harmony, for when added water increased the reaction rate it did so chiefly, not by diverting the formation of benzhydryl ethyl ether into that of benzhydrol, but by accelerating the production of benzhydryl ethyl ether. Such a "catalytic" effect is, however, expected on the basis of the unimolecular mechanism.

Olson and Halford show, with respect to the example studied by them, that, whereas the vapor pressure formula exactly accounts for the variation of rate with solvent composition, a corresponding concentration formula fails completely. We have therefore considered the question of whether Farinacci and Hammett's inference is likely to be changed if this calculation is carried from the concentration basis of the assumed equation

$$\text{Rate} = (k'_{\text{a}}c_{\text{a}} + k'_{\text{w}}c_{\text{w}})c_{\text{RCl}}$$

to the vapor pressure basis of Olson and Halford's theory. We conclude that it could not be changed. The transformation cannot, as a matter of fact, be effected completely, because the partial vapor pressures of benzhydryl chloride are unknown and would be difficult to determine accurately. We can, however, convert to the new basis the treatment of the solvent components, and, assuming an approximate invariance in the Henry's law constants of benzhydryl chloride over the relevant range of solvent compositions, test for the effect of the incompleteness of our procedure by reference to the observed total rates. For this range, the representation of the total rates is in fact so good that we have the same empirical justification as Olson and Halford for proceeding to predict the separate parts of the total rate, or, what is equivalent, the product compositions; and this is the prediction that really distinguishes the bimolecular and unimolecular mechanisms. In view of the relatively low water concentrations used, we are not surprised to find that the predicted values differ relatively little from Farinacci and Hammett's, and that therefore, as the table indicates, they show correspondingly pronounced divergences from the experimental values. Bearing in mind also the more completely investigated case of *t*-butyl chloride, it cannot be doubted that Farinacci and Hammett's conclusions stand, *i. e.*, that the vapor pressure theory could not bring the hydrolysis and alcoholysis of benzhydryl chloride into harmony with the bimolecular mechanism.

REACTION OF BENZHYDRYL CHLORIDE WITH AQUEOUS ETHANOL AT 25°

H_2O Moles/l.	k (10^{-5} min.$^{-1}$) Found	k (10^{-5} min.$^{-1}$) Calcd.	Moles % ROH Found (F. and H.)	Moles % ROH Calcd.	Moles % ROH Calcd. (F. and H.)
0.000	343	..	..	0.0	0.0
.600	474	482	1.8	31.5	27.7
1.320	634	652	11.8	51.5	46.0
1.579	691	..	..	55.1	..

We take the opportunity to refer to four points raised by Hammett[2a,7] with reference to the detailed interpretation of the unimolecular mechanism, as the relevant experimental material is, and will be, considerably scattered. The first, relating to the incompleteness of racemization, is dealt with in papers[8] which were unavailable when he wrote. The second was that dissolved negative ions had not been found to participate in homogeneous solvolytic reactions. But they do participate if their concentration is adequate in relation to that of the reactive constituent of the solvent; thus chloroacetate ions form *t*-butyl chloroacetate without increasing the reaction rate in the hydrolysis of *t*-butyl chloride in moist formic acid, and chloride ions retard the hydrolysis of benzhydryl chlorides in moist acetone. The third point was that solvolytic reactions apparently require high concentrations of hydroxylic solvents, water having failed to react with α-phenylethyl chloride in moist acetone though it accelerated the total reaction in moist acetic acid. However, we regard the difference as one of degree, depending on the ionizing properties of the solvent as a whole, and can show that hydrolyses which are slow in moist acetone are rapid in equally moist sulfur dioxide, though sulfur dioxide, like acetone, is non-hydroxylic. Fourthly, the example of sulfur dioxide illustrates how poor an index to ionizing power is the dielectric constant, doubtless because of its very indirect connection with the short-range forces determining solvation. These, however, are points of detail: as to essentials we endorse Hammett's statement[7] that his views and ours are in harmony.

Summary.—Of the bimolecular and unimolecular mechanisms of aliphatic substitution,

---

(7) Steigman and Hammett, *ibid.*, **59**, 2536 (1937).

(8) Hughes, Ingold and others, *J. Chem. Soc.*, 1196 *et seq.* (1937).

the former alone yields the product in a reaction stage whose rate can be measured; and therefore a comparison of rates and product compositions in competing reactions, such as those of an alkyl halide in aqueous alcohol, affords a criterion of mechanism. Such a criterion was applied by Farinacci and Hammett to the reactions of benzhydryl chloride but Olson and Halford have made proposals to change the quantitative basis of such comparisons. We consider whether Farinacci and Hammett's rejection of the bimolecular mechanism stands in the light of this work, which we have more fully examined with respect to the reactions of *t*-butyl chloride; and we conclude that it does stand. Thus the hydrolyses of *t*-butyl chloride and benzhydryl chloride are mutually confirmatory examples in which the application of the criterion mentioned favors the unimolecular mechanism, some details concerning which are discussed.

A New Method for the Preparation of 3,5-Cholestadiene

BY KENZO HATTORI

The various methods for the preparation of the so-called cholesterilene have been discussed recently by H. E. Stavely and W. Bergmann.[1] These authors also prepared 3,5-cholestadiene (I) by the Wolf–Kishner reduction of the semicarbazone of the 7-ketocholesterilene (II). Since this procedure involves prolonged heating at 180–200°, the possibility of a rearrangement of the double bonds is not excluded. In order to eliminate such possibility, 3,5-cholestadiene was prepared by the treatment of pseudocholestene dibromide (III) with silver nitrate in pyridine solution at room temperature.[2] The diene obtained by this reaction seems to be identical with the 3,5-cholestadiene described by Stavely and Bergmann.

Nine-tenths of a gram of pseudocholestene dibromide was dissolved in 20 cc. of pyridine containing 18% of silver nitrate. The reaction mixture was kept in the dark at room temperature for one month. The solution was then diluted with water, acidified with sulfuric acid and extracted with ether. The residue obtained on evaporation of the ether extract was recrystallized from a mixture of alcohol and ether. The diene crystallizes in needles, m. p. 79–80°, $[\alpha]^{15}D$ $-68.7°$.

Anal. Calcd. for $C_{27}H_{44}$: C, 87.96; H, 12.04%. Found: C, 88.3; H, 11.7%.

The diene gave a positive reaction with Rosenheim's reagent and with antimony trichloride. Mixed with a sample of cholesterilene, prepared from cholesterol,[3] m. p. 79°, $[\alpha]^{15}D$ $-76.0°$, it gave no depression of the melting point.

Identification of Methylisopropylcarbinol in Sharples Diethylcarbinol

BY FRANK A. KARNATZ AND FRANK C. WHITMORE

In connection with another research,[1] an attempt was made to obtain pure 3-pentanol by a series of careful fractional distillations of a sample of commercial diethylcarbinol supplied by the Sharples Solvents Corporation. It was noted that even after many fractionations the material of almost constant refractive index boiled over a range of 4°. Since the refractive index of methylisopropylcarbinol is very near that of 3-pentanol ($n^{20}D$ 1.4095 and 1.4100, respectively), the lower boiling portion of the sample was carefully refractionated by parts in an efficient column. In this way a fraction was obtained, b. p. 111.5° (732 mm.), $n^{20}D$ 1.4096, which gave the α-naphthylurethan of methylisopropylcarbinol,[2] m. p. and mixed m. p. 108–110°.

The identification of this alcohol, which had not been found in the hydrolysis products of the chloropentanes by previous investigators,[3] is of considerable theoretical interest. It demonstrates that the hydrolysis of 3-chloro-2-methylbutane to the alcohol does not involve complete rearrangement. The conversion of the alcohol to the chloride even under the mildest conditions gives the rearranged product, 2-chloro-2-methylbutane.[4] Both these conversions are being studied further to determine the relative amounts of rearranged and non-rearranged products from each.

The Stability of Dry Potassium Ferrocyanide

BY ROBERT B. LOFTFIELD[1] AND ELIJAH SWIFT, JR.

In the course of a previous investigation,[2] it was noticed that sometimes dry potassium ferrocyanide undergoes a slight decomposition. Since this salt is one of the few quadrivalent salts that is sufficiently stable to be useful in precise electrochemical investigations[3] where the effect of ionic charge on the properties of solutions is being studied, it seemed of some importance to determine the conditions under which decomposition takes place.

Mallinckrodt reagent grade potassium ferrocyanide was precipitated from saturated solution at 0° by adding an equal volume of cold 95% alcohol. The crystals were allowed to grow for several hours and then were centrifuged and washed with cold 95% alcohol. This process was repeated and the salt was dried by sucking off the excess alcohol with a water pump. After standing in a clear glass bottle exposed to the ordinary laboratory light for over a year, no change in color could be observed by comparison with freshly prepared salt, and no odor of hydrogen cyanide was perceptible in the bottle.

The salt was dehydrated as in previous investigations[3] in order to get a sample whose exact composition would be known. About 0.5 g. of the salt was placed in a platinum boat in a Richards bottling apparatus and a slow stream of nitrogen was allowed to flow over the sample while heating to 90°. The nitrogen was removed with a water pump and the tube flushed out several times with nitrogen and finally left evacuated for one to two hours while the temperature was maintained at 90–100°. The tube was then filled with nitrogen and the salt cooled in a slow stream of the gas. This method of preparing the salt was found by Jones and Jelen[3a] to give material of constant weight.

Fabris[4] has stated that there is a considerable loss of cyanide[5] when this salt is heated above 50° in air. To check this statement, samples of salt were heated to 100° for three hours in a slow stream of air, the effluent gas being passed through a solution of sodium hydroxide. The Prussian blue test applied to this solution was negative, showing that less than 0.01% of the salt was lost as cyanide in this process. Negative tests for cyanide were also obtained when samples of salt were heated in a slow current of nitrogen, using the Prussian blue test and the specific ferric thiocyanate test.[6] It seems evident that this salt may be dehydrated safely at 100°, although decomposition will take place at higher temperatures.[7]

After the dehydrated salt had come to room temperature, half of the boat was covered with platinum foil and the salts exposed to illumination. After two hours of illumination with a "Pointalite" bulb and forty hours' illumination with a 200-watt tungsten bulb 15–20 cm. above the surface, no change in the color of the salt was observed. The tube was then flushed out several times with dry oxygen and the process repeated. After about forty hours of exposure a slight change in the color of the salt was observed, and after seventy-two hours there was a decided greenish-blue color on the surface of the salt. This color was much less pronounced underneath the foil where the light could reach the salt only indirectly; while another sample kept in dry oxygen in the dark for seventy-two hours failed to show any color change whatever. Presumably the reaction involves the formation of Prussian blue, but the amount of material formed was too minute to be analyzed readily, and it was not thought worth while to investigate this reaction further. The test was repeated by placing a fresh sample in dry oxygen in direct sunlight, and the same result was observed after one or two hours' exposure. A control sample of the hydrated salt showed no reaction whatsoever under any of the above conditions.

Another sample of the anhydrous salt was placed in an atmosphere of moist oxygen and exposed to illumination. No reaction was observed, probably because the salt picked up moisture and went into the more stable hydrated form before any appreciable photochemical reaction could take place.

To determine whether the anhydrous salt is deliquescent, a sample was placed in a container saturated with water vapor at room temperature (30°). The salt quickly picked up even more than the three moles of water normally present and deliquesced to a sticky mass. Microscopic examination of the dehydrated salt showed that the crystals are practically intact after dehydration, since there is no change in the gross form and the smallest crystals appear quite as clear as before dehydration. Larger, clear crystals become translucent after dehydration, due to their breaking up into smaller units, but they also retain the same shape, and do not break up into an amorphous white powder.[8] It is probable that the dehydrated material will go back to the same photochemically stable trihydrate on exposure to moisture.

On the basis of this investigation, we believe that potassium ferrocyanide is sufficiently stable to be used in precise investigations if the following conditions are observed:

1. The salt must not be dehydrated at temperatures greater than 100°.
2. The dehydrated salt must be kept out of contact with moisture before and during weighing, but not necessarily after.
3. The dehydrated salt must be kept in the dark to prevent decomposition.

Changes in the Physical Properties of Regenerated Cellulose by Liquid Ammonia

BY RICHARD G. ROBERTS

During the dialysis of proteins and hormones contained in bags made from regenerated cellulose film and placed in liquid ammonia, it was observed that the bags changed in size and in flexibility. Therefore, a series of comparative tests on some of the physical properties of the film and ammonia-treated film was made. The film used in these tests was du Pont Cellophane number 600.

The film was cut into strips of convenient size and placed in a Dewar flask. Liquid ammonia, previously dried over metallic sodium, was added to immerse the film sample completely. The film was not previously dried by us. The Dewar flask was tightly stoppered, and attached to a mercury seal. The liquid ammonia boiled off in about twenty-four hours, and any excess ammonia gas was removed by a vacuum pump.

Physical properties showing an increase:	
Tear strength (Elmendorf test)	200.0%
Tensile strength	70.6%
Thickness (flat micrometer)	152.4%
Weight (per unit area)	27.3%
Physical properties showing a decrease:	
Length (with grain)	8.3%
Width (cross grain)	17.8%
Area	24.7%

Ratios: Increase of tear strength to decrease in area, approximately 8 to 1. Increase of tensile strength to decrease in area, approximately 3 to 1.

It has been shown that bags made from regenerated cellulose film may be used conveniently for dialyzing experiments in liquid ammonia, although some space must be allowed for shrinkage.

The author wishes to thank Montgomery Ward and Company, Chicago, Illinois, for the use of apparatus in their testing laboratory.

The Specificity of the Fermentation Test for Vitamin B_1

BY ALFRED S. SCHULTZ, LAWRENCE ATKIN AND CHARLES N. FREY

The fermentation method for the determination of vitamin B_1[1–3] has been in successful operation for some time. The effect of 2-methyl-5-ethoxymethyl-6-aminopyrimidine has been described.[2] We have assayed a wide variety of substances such as non-autoclaved yeast, rice polish, vitamin pills and concentrates, solutions of crystalline vitamin, and milk, and no evidence of the interfering substance has been found. In an investigation on the metabolism of vitamin B_1,[4,5] we found reason to believe that a portion of the fermentation stimulating effect of urine is not due to vitamin B_1. While this did not appear to alter the significance of the results, it was thought very desirable to find a method for differentiating between the intact vitamin molecule and any possible breakdown product. A way of doing this has been found in the differential oxidation of the vitamin B_1 in the presence of the aminopyrimidine.

Alkaline ferricyanide in the cold will readily oxidize the vitamin to thiochrome. Preliminary experiments with a sample of thiochrome obtained from Merck and Company showed it to be inactive in the fermentation reaction. The aminopyrimidine is more resistant to oxidation and it is a simple matter to oxidize B_1 preferentially when present in addition to aminopyrimidine. A solution containing 8 gamma of the aminopyrimidine and 8 gamma of thiamin hydrochloride in a volume of 35 ml. was treated with 2.5 ml. of 1% $K_3Fe(CN)_6$ and 2.5 ml. of 50% NaOH. After standing at room temperature for five minutes the solution was neutralized with dilute sulfuric acid and made to 100 ml. A 25-ml. aliquot of this was tested in the usual manner by gas test. It gave a stimulation which corresponded exactly to 2 gamma of the aminopyrimidine (*i. e.*, the B_1 was destroyed). Parallel experiments showed that the neutralized oxidizing solution was without influence on controls with either thiamin hydrochloride or aminopyrimidine.

COMMUNICATIONS TO THE EDITOR

CRYSTALLINE COPPER-PROTEIN POSSESSING TYROSINASE ACTIVITY

Sir:

A crystalline material has been obtained from the aqueous extract from the wild mushroom, *Lactarius piperatus,* which may be phenol oxidase, or closely related to it. The crystals were six-sided plates and undoubtedly belonged to the hexagonal system. They were insoluble in water, dilute acids and salt solutions, but soluble in an aqueous solution of secondary sodium phosphate. Analysis showed a copper content of 0.25 and 13.6% nitrogen. Their phosphate solution was active in promoting the aerobic oxidation of *p*-cresol and catechol.

The procedure followed in obtaining the crystals can be described briefly as follows. The aqueous extract of the ground mushrooms was precipitated with 0.6 saturated ammonium sulfate, redissolved in water, the latter made 0.2 saturated with ammonium sulfate and the precipitate discarded. The filtrate obtained in the last operation was reprecipitated with 0.6 saturated ammonium sulfate, the precipitate formed redissolved in water and the solution treated with three volumes of cold acetone. The precipitate thus obtained was dissolved in water and treated with alumina. The liquid separated from the alumina contained about 50% of the active oxidase. This liquid was treated with boneblack and after filtering the filtrate was again precipitated with 0.6 saturated ammonium sulfate. The precipitate from the last operation was taken up in water and had an activity of 7000 units per cc. when determined according to the Graubard and Nelson method as modified by Adams and Nelson [THIS JOURNAL, **60,** 2472 (1938)]. When this liquid was gradually acidified by acetic acid, changing the *p*H from 6.5 to 5, and allowed to stand in the ice box, crystals separated.

TETRAMETHYLPLATINUM AND HEXAMETHYLDIPLATINUM

Sir:

Tetramethylplatinum has been prepared in 46% yield from trimethylplatinum iodide and methylsodium. It is the most soluble organoplatinum compound so far prepared, being readily soluble in the cold in benzene, acetone, ether and petroleum ether (b. p. 60–68°). The compound crystallizes from petroleum ether as large hexagonal crystals which decompose but do not melt at elevated temperatures. *Anal.* Pt, 76.84; C, 18.32; H, 4.31. We have found that the compound is one of several by-products of the Pope and Peachey [*J. Chem. Soc.,* **95,** 571 (1909)] reaction for the preparation of trimethylplatinum iodide from platinic chloride and methylmagnesium iodide. Hydrogen chloride converts tetramethylplatinum to trimethylplatinum chloride. *Anal.* Pt, 70.20; Cl, 13.10.

Hexamethyldiplatinum has been synthesized in 60% yield by heating trimethylplatinum iodide with powdered potassium in dry benzene. *Anal.* Pt, 81.13; C, 14.55; H, 3.92. The compound is very soluble in benzene, acetone and ether, but only slightly soluble in cold petroleum ether. It is best crystallized from a benzene–petroleum ether solution. Molecular weight determinations show that hexamethyldiplatinum is not dissociated at the freezing point of benzene [mol. wt.: calcd., 480.4; found, 482]. Iodine in ether converts the compound to the known trimethylplatinum iodide.

These two organoplatinum compounds are interesting because they demonstrate for the first time that true organoplatinum compounds not having acid radicals can be prepared. A detailed account of these and other organoplatinum compounds will be published shortly.

THE IDENTIFICATION OF METHYLCHAVICOL IN AMERICAN GUM SPIRITS OF TURPENTINE

Sir:

Recent investigations have shown that gum spirits of turpentine of slash and longleaf pine contain about 95% of pinenes [Dupont, *Ann. chim.*, [10] **1**, 184 (1924); Aschan, "Naftenföreningar, Terpener och Kamferarter," Helsingfors, 289 (1926); Palkin, Technical Bulletin 596, U. S. Department of Agriculture (1932)]. We have been able to obtain physical and chemical evidence, including the fact that homoanisic acid is obtained on oxidation, that the fractions boiling above those of the pinenes contain considerable amounts of methylchavicol (4-methoxyallylbenzene).

This was shown by the isolation of methylchavicol from turpentine by the method described by Balbiano [*Ber.*, **42**, 1504 (1909)], for the separation of methylchavicol from anethole. Seventy-five grams of a fraction, b. p. 88–95° at 10 mm., obtained by fractionation of steam-distilled residues of spirits of turpentine was dissolved in 400 cc. of ether and shaken for one hour with a solution of 81 g. of mercuric acetate dissolved in 350 cc. of water. After separating the ether, the aqueous solution was heated for ten hours at 70–80° with 70 g. of sodium hydroxide and 80 g. of granulated zinc. The mixture was then distilled with steam, the distillate extracted with ether and the ether solution dried and distilled, leaving 8 g. of methylchavicol, the main fraction of which boiled at 213–215°; $d^{25}{}_{25}$ 0.9600; $n^{22}{}_{D}$ 1.51372. Physical constants recorded in the literature are: b. p. 214–215° [Klages, *Ber.*, **32**, 1439 (1899); d^{21} 0.9645; n_D 1.5236; (Beilstein, "Handbuch der organischen Chemie," fourth edition, **6**, 571 (1923)]. Ten grams of this product was oxidized at room temperature with 630 cc. of 4% potassium permanganate solution. After removal of manganese dioxide, the filtrate was evaporated to about one-third of its original volume and acidified with hydrochloric acid. The precipitated anisic acid was recrystallized from water and melted at 184–185° (corr.); yield, 2.5 g. Calcd. for $C_8H_8O_3$: C, 63.18; H, 5.30. Found: C, 63.32; H, 5.46. The acid did not lower the melting point in the mixed melting point test with an authentic sample of this material.

The aqueous filtrate from which the anisic acid had been removed was evaporated to a small volume, extracted with ether and dried. The ether was distilled and about 0.3 g. of a substance, apparently homoanisic acid, was obtained. It was recrystallized from water and melted at 85.5–86.5°. Homoanisic acid melts at 85–86° [Pschorr, Wolfes and Buckow, *Ber.*, **33**, 172 (1900)]. Calcd. for $C_9H_{10}O_3$: C, 65.04; H, 6.07. Found: C, 65.30; H, 6.54.

We assume that the difference in odor between highly purified turpentine and American gum spirits of turpentine can be partly attributed to the presence of phenol ethers.

RECEIVED OCTOBER 28, 1938

PANTOTHENIC ACID AS A GROWTH FACTOR FOR THE DIPHTHERIA BACILLUS

Sir:

It has been shown in experiments already presented elsewhere that β-alanine and nicotinic acid are essential for the growth of certain strains of the diphtheria bacillus [Mueller, *Proc. Am. Exptl. Biol. Med.*, **36**, 706 (1937)]. β-Alanine has long been known to be a constituent of meat extract both in the free form and also combined with histidine in the compound carnosine, in which form it has also been shown to be available to the diphtheria bacillus [Mueller, *J. Biol. Chem.*, **123**, 421 (1938)]. In a personal communication, we have recently learned from Dr. R. J. Williams that pantothenic acid [Williams, *et. al.*, THIS JOURNAL, **55**, 2912 (1933); **60**, 2719 (1938)] also yields β-alanine upon hydrolysis. Dr. Williams suggests, further, that β-alanine may be effective in producing growth with *C. Diphtheriae* only insofar as it serves as a building stone for the production of pantothenic acid, which may be the material actually required by the organism, and he has supplied us with specimens of pantothenic acid and calcium pantothenate in varying degrees of purity. With this material we have been able to test out this theory and to show that it well may be correct.

Using a control medium containing the products of complete acid hydrolysis of casein, lactic, pimelic and nicotinic acids and inorganic salts, but completely deficient in β-alanine, a series of media has been prepared in which increasing quantities of β-alanine were added to one set, pantothenic acid or calcium pantothenate to a second and the latter substance hydrolyzed by autoclaving with normal hydrochloric acid for thirty minutes at 15 lb. (1 atm.) to a third. The various media were autoclaved (*p*H 7.6) for ten minutes at 10 lb. (0.67 atm.) pressure. After inoculation with the strain of the diphtheria bacillus (Allen), and incubation for three days at 35°, the resulting bacterial growth was centrifuged down, washed and the bacterial nitrogen determined by a method already described, as a measure of bacterial growth [Mueller, *J. Bact.*, **29**, 383 (1935)]. The table shows the results obtained: A = β-alanine; B = Ca pantothenate (about 50%) stated to yield 16% β-alanine on hydrolysis; C = solution B after acid hydrolysis.

[a] Heavy growth.

This and other similar experiments uniformly show a smooth, gradual increase in growth with the addition of pantothenic acid, whereas with β-alanine there is no definite increase over controls until a concentration of from about 2.5 γ per 10 cc. is used. At this point, initiation of growth is slow and irregular, possibly dependent on the size of the inoculum, (platinum loop of pellicle). At levels of 5, 10 and 20 γ concentration of β-alanine or its equivalent of panthothenic acid, growth is heavy and the amounts produced by the two materials are very nearly the same. Hydrolysis of pantothenic acid yields a solution with the properties of β-alanine, *i. e.*, no effect until the concentration of the latter in the hydrolytic products reaches 2.5 γ/10 cc. medium, whereas doubling this concentration regularly leads to heavy growth.

These facts tend to support the view that β-alanine must first be built up into some more complex material before it may be directly utilized by *C. Diphtheriae*, whereas with pantothenic acid no such preliminary synthesis is required.

It is interesting and significant that Snell, Brown and Peterson [THIS JOURNAL, **60**, 2825 (1938)] have shown recently that both pantothenic acid and nicotinic acid are apparently essential factors for growth of certain strains of the lactic acid bacteria. These organisms, unlike the diphtheria bacillus, seem to be unable to effect the synthesis of pantothenic acid from β-alanine, requiring the presence of the more complex material for satisfactory growth.

PRESSURE–AREA RELATIONS FOR MONOMOLECULAR FILMS OF TRI-*p*-CRESYL PHOSPHATE AND RELATED COMPOUNDS

Sir:

Interesting differences in surface activity have been observed in a study of phosphorus-organic compounds closely related in structure. Monomolecular film properties of the three isomers of tricresyl phosphate (ortho, meta and para) are practically identical but quite unlike those of either tri-*p*-cresyl phosphite or tri-*p*-cresyl thiophosphate.

Pressure–area relations have been studied on a modified Cenco film-balance apparatus, using general techniques similar to those described by N. K. Adam[1] and Harkins, Ries and Carman.[2,3] The volatile solvent used for the Eastman compounds was twice-distilled benzene. Films were spread on distilled water.

Tri-*p*-cresyl phosphate forms well-behaved, compressible films, whereas the corresponding phosphite and thiophosphate show extremely poor film-forming properties. Films of the phosphite and thiophosphate require compression far beyond the minimum film area for monomolecular

(3) Harkins, Carman and Ries, *J. Chem. Phys.*, **3**, 692 (1935).

thickness before an appreciable rise in pressure is observed. For example, at a pressure of only 1 dyne per cm., the tri-*p*-cresyl thiophosphate film thickness (62.9 Å.) is over five times as great as the maximum monomolecular thickness (11.6 Å.) of tri-*p*-cresyl phosphate.

An interesting correlation between polar group structure and film properties is apparent when we consider the schematic diagrams in Fig. 1.

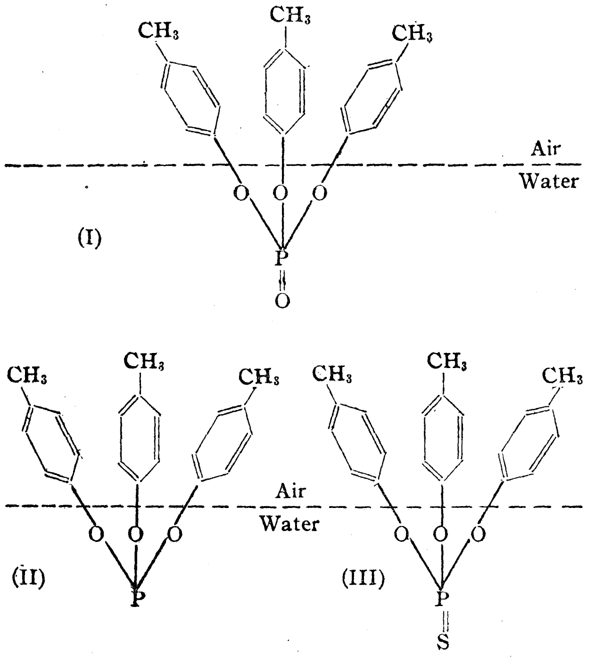

Fig. 1.—Schematic diagrams of molecular orientation at an air–water interface: (I) tri-*p*-cresyl phosphate; (II) tri-*p*-cresyl phosphite; (III) tri-*p*-cresyl thiophosphate. At expanded areas the rings are probably drawn close to the water.

The two poor film-forming compounds (II and III) differ from the tri-*p*-cresyl phosphate (I) in that they lack the P=O group. We must, therefore tentatively conclude that the important contribution to the polarity of the molecule is made by the P=O group as indicated by the superior film properties of tri-*p*-cresyl phosphate.

The most important pressure–area characteristics of a typical tri-*p*-cresyl phosphate film (27.9°) may be briefly summarized. The molecular area values at film pressures of zero (extrapolated), 5 and 8.76 dynes per cm. (the maximum) are, respectively, 99.4, 69.3 and 46.5 sq. Å. Using a density of 1.1284 g. per cc. the film thickness values at the same pressures are, respectively, 5.42, 7.78 and 11.6 Å. Partial overlapping of the molecules may perhaps account for the small areas in the final stages of the compression. The compressibility at $f = 0$, $[(a_0 - a_1)/a_0]/(f_1 - f_0)$ is 0.0607.

The above-mentioned compounds with each of the three rings attached directly to the polar group are much more compressible than the polycyclic compounds in which only one ring is attached to the principal polar group.[4] The molecular configurations of the latter type permit an approach toward vertical orientation and allow closer packing. It has been shown that films of horizontally oriented long chain molecules (polymers of ω-hydroxydecanoic acid) are much more compressible than those of vertically oriented molecules.[3] This present work indicates that perhaps the same general relationship applies to ring systems. The film compressibilities of a number of multiple ring compounds which are capable of vertical orientation range from one-sixth to about one-eighteenth that of tri-*p*-cresyl phosphate. In both types of orientation the films formed by ring compounds are, in general, more compressible than those composed of straight chain molecules. An increase in maximum film pressure with increasing vertical length of the ring system is also noted.

---

[4] Pressure–area relations for such a series of three-ring and five-ring compounds have been investigated and the data tabulated.[2,5]

THE REDUCTION OF α-HALOGENATED KETONES: THE SYNTHESIS OF *dl*-PSEUDOEPHEDRINE

Sir:

The great advantage of aluminum isopropylate in the reduction of aldehydes and ketones lies in its specificity for the carbonyl group, side reactions such as condensation and the like being either absent or negligible. Lund [*Ber.*, **70,** 1520 (1937)] has shown this with certain ketones with primary bromine in the α-position. This reduction without removal of the α-halogen has now been tested with α-bromo ketones which have β-hydrogen available for a loss of halogen acid. The results with open chain ketones containing secondary α-bromine show that removal of bromine, and reduction to the bromohydrin, occur in about equal amounts. Thus α-bromopropiophenone with aluminum isopropylate forms the bromohydrin in about 35% yield (b. p. 73–75° (0.1 mm.)), which in turn with methylamine yields a mixture of isomeric hydroxyamines, one of which is *dl*-pseudoephedrine, m. p. 116.5–117.0°; the hydrochloride, m. p. 162–163° (over-all yield from the bromo ketone, 10%). This was identified by comparison with an authentic sample, m. p. 116.5–117.2°, mixed m. p. 116.5–117.0°, prepared from *dl*-ephedrine kindly supplied by Dr. E. H. Volwiler, Abbott Laboratories, Chicago, Illinois, and by Dr. R. H. Manske, the Canadian National Research Council, Ottawa. Contrary to expectations, no *dl*-ephedrine was found.

Cyclic secondary α-bromo ketones, and open chain tertiary α-bromo ketones, such as 2 bromocholestanone, and α-bromoisobutyrophenone, respectively, yield products almost entirely free of bromine. This work is being continued with other types of halogenated ketones.

NEW BOOKS

Tabellen und Vorschriften zur quantitativen Analyse. Gravimetrie, Elektroanalyse, Probierkunde der Edelmetalle und Gasanalyse. (Tables and Directions for Quantitative Analysis, Gravimetric, Electroanalysis, Assay of the Noble Metals, and Gas Analysis.) By W. D. TREADWELL, Professor in the United Technical Institute in Zurich. Verlagsbuchhandlung Franz Deuticke, Helferstorferstrasse 4, Wien, Germany, 1938. xii + 284 pp. 126 figs. 17.5 × 25 cm. Price, RM. 9.

The author states in the preface that his object is to present in the shortest possible form a selection of proved methods of analysis in order to make it possible for the analyst already acquainted with the fundamentals to do his work more easily. The reviewer cannot imagine any publication in which could be found more information concerning analytical chemistry contained in less than 300 pages. Here is evidence showing extreme energy on the part of the author in collecting valuable data concerning, and proved directions for determining, more than the usual list of cations and anions. It also shows his skill in collating such material in a very logical manner. About 275 references to original literature are given.

In the interest of economy of space the author has collected in one chapter the description of the common operations of quantitative technique, and such descriptions are almost completely omitted in the individual processes discussed throughout the book.

This book might be divided into eight parts. The first forty-one pages deal with general methods of quantitative analysis and include directions for carrying out all the common operations of analysis. This discussion is more complete, however, than is usually found in textbooks of quantitative analysis. In addition to the usual directions included here, such as those for weighing, calibration of weights, precipitations, filtration, drying, etc., are to be found desirable directions for such procedures as the determination of specific weight, ashing of organic substances, separation by extraction and distillation, and the preparation and testing of reagents.

From page 47 to page 96 are to be found directions for the determination of a very wide selection of cations. Besides all the common metals for which methods are given, one finds directions for the determination of many of the less familiar ones, such as scandium, cerium, yttrium, gallium, indium and the platinum metals. In this section, it is worthwhile to note that the author has seen fit to give methods of quantitative separation of cations which commonly occur together. It is interesting to see that considerable reference is made to the use of organic reagents as precipitants for many cations.

From page 97 to page 130 is a section on electroanalysis including theory, directions for the determination of eighteen separate metals by electrolysis, and methods of separating eleven of these from other ions likely to be present.

There follows from page 131 to page 142 a section on the assay of the noble metals. Here the principle of cupellation is discussed and methods are given for the estimation of all the noble metals usually determined by this method.

From page 142 to page 170 are to be found excellent directions for the separation and determination of all the common and some of the less common anions. The reviewer feels that this section alone would be sufficient to make it advisable to include this book in his library.

Pages 170 to 194 are devoted to distillation methods of separation and analysis. Here again are found worthwhile discussions not usually included in reference books of quantitative analysis.

The next section, pages 194 to 202, is devoted to elementary analysis which includes the determination of carbon, hydrogen, nitrogen, the halogens and sulfur. Both macro and micro methods are given.

The final section of the book, page 203 to page 259, is devoted to gas analysis. Not only the more common gases, but many of the less common, such as ethylene oxide, iron pentacarbonyl, nickel tetracarbonyl and butadiene, are included in the methods given. A page devoted to the determination of dust in gases shows the diversity of the subject matter covered.

The book is concluded with tables of gravimetric factors and logarithms.

The reviewer was well pleased with the editing and printing of the book. The binding of the reviewer's copy was poor.

Those who have a good fundamental training in analytical chemistry will welcome this book as being a good place to go to get information concerning methods. It is primarily a book for analytical chemists rather than for chemical analysts. It is one that should find its place in every reference library and on the desk of every analytical chemist.

CHESTER M. ALTER

Annual Review of Biochemistry. Vol. VII. By JAMES MURRAY LUCK, Editor, and CARL R. NOLLER, Associate Editor, Stanford University. Annual Reviews, Inc., Stanford University P. O., California, 1938. ix + 571 pp. 16 × 23 cm. Price, $5.00.

A new group of authors compiled volume seven of this series, including English, German, Swiss, Danish and Australian, as well as American contributors. Subjects covered in one or more of the preceding volumes, and the authors of each include: Biological Oxidations and Reductions, by L. Michaelis and C. V. Smythe; The Chemistry of the Carbohydrates and the Glycosides, by E. F. Armstrong; The Chemistry of the Acyclic Constituents of Natural Fats and Oils, by G. S. Jamieson; The Chemistry of Amino Acids and Proteins, by M. Bergmann and C. Niemann; The Chemistry and Metabolism of the Compounds of Phosphorus, by K. Lohmann; Carbohydrate Metabolism, by H. E. Himwich; Fat Metabolism, by F. Verzár; Metabolism of Amino Acids and Proteins, by H. A. Krebs; The Metabolism of Creatine and Creatinine, by K. Thomas; The Hormones, by O. Wintersteiner and P. E. Smith; Nutrition, by H. H. Mitchell; The Biochemistry of Muscle, by E. Lundsgaard; Liver and Bile, by A. C. Ivy and L. A. Crandall, Jr.; Animal Pigments, by R. Lemberg; The Terpenes, Saponins, and Closely Related Compounds, by W. A. Jacobs and R. C. Elderfield; The Chemistry of Bacteria, by W. H. Peterson and M. J. Johnson; Growth Regulators in the Higher Plants, by P. Boysen Jensen.

The vitamin chapter of the earlier volumes was divided in volume seven into three sections as follows: The Vitamin B group, by R. A. Peters and J. R. O'Brien; Vitamin C (Ascorbic acid, Cevitamic acid), by R. A. Peters and H. W. Davenport; the Fat-soluble Vitamins, by J. C. Drummond. The discussion of enzymes was narrowed down this year to The Chemistry of the Crystalline Enzymes, prepared by J. H. Northrop and R. M. Herriott. Pepsin, trypsin and chymotrypsin, carboxypeptidase, papain and a number of redox enzymes are covered in this review. Two wholly new topics, *viz.*, Acid–Base Metabolism, by J. Sendroy, Jr., and Organic Insecticides, by F. B. LaForge and L. N. Markwood are also reviewed in the current volume.

As heretofore, this review is a veritable mine of useful information respecting contemporary biochemical progress. One senses that each contributor has made a real effort to select carefully the useful material in his field, and present it in an adequate manner. The editors have made a careful selection of contributors, and have arranged and indexed the volume in a form which facilitates its use.

C. H. BAILEY

The Standardization of Volumetric Solutions. By R. B. BRADSTREET, B.S., formerly Analytical Chemist, U. S. Rubber Products Co. Chemical Publishing Company of New York, Inc., 148 Lafayette St., New York, N. Y., 1938. v + 126 pp. 14 × 21 cm. Price, $3.00.

The Solution of Problems in Quantitative Analysis. By SAUL B. ARENSON, Professor of Inorganic Chemistry, University of Cincinnati. Edwards Brothers, Inc., Ann Arbor, Mich., 1938. iv + 41 pp. 21.5 × 27.5 cm. Price, $0.35.

Bradstreet's book on Volumetric Solutions begins with a brief survey of definitions, standard substances, possible sources of error, calibration of apparatus, and choice of indicators, and then offers a collection of standardization methods for many of the more common quantitative analytical reagents: hydrochloric and sulfuric acids, sodium, potassium, barium and ammonium hydroxides, thiocyanate, silver nitrate, potassium ferrocyanide, iodine, sodium thiosulfate, permanganate, dichromate, ferrous salts, arsenious oxide, potassium iodate, ceric sulfate, Wijs and Hanus solutions, Chloramine T, hypochlorites, titanous salts and various indicators (with appendix tables). For each reagent there is given a brief discussion of its advantages and shortcomings, procedure for preparing the solution, and the various accepted standardization methods. The critical discussion is brief, well documented and in most cases reasonably complete and modern. Mechanically the little book is well made but is a good example of the evils of low-cost production (without the usual argument of low purchase price), being plate-printed from not too well arranged typewritten copy, which is liberally punctuated with errors (Faulk for Foulk, Yound for Young, Hammet for Hammett, as well as plain spelling and typing errors), and inconsistent and unorthodox abbreviations.

In the second title, Professor Arenson attacks a very real problem, and in chapters entitled: Computations, Gravimetric Analysis, Normal Solutions of Acids and Bases, Normal Solutions in Oxidation and Reduction, Precipitation Titrations, he gives, in conversational conference style, discussions of methods, illustrative examples and numerous problems in each of the five groups listed. Although the scope of the work and the treatment of topics are, in general, less complete as compared with Wilkinson's text [THIS JOURNAL, **60**, 1516 (1938)], this neatly lithoprinted book will be of considerable help to students wrestling with Quantitative Analysis calculations.

ALLEN D. BLISS

About Petroleum. By J. G. CROWTHER. Oxford University Press, 114 Fifth Avenue, New York, N. Y., 1938. xiv + 181 pp. Illustrated. 14 × 22.5 cm. Price, $2.25.

This is a very carefully written little book. It is something of a relief to find that, as Mr. Crowther has demonstrated, it is possible to write about petroleum without borrowing the showmanship of the promoter, the hyperbole of the high pressure salesman, or the moronic sensationalism of the tabloids.

It may seem deadly serious to some readers, but at any rate it is packed with information, which to the reviewer appears to be authentic and well selected. In such a small book restricted to technical and scientific information it is not surprising that there are many terse statements which merely whet the reader's appetite for more. In view of the political occurrences in Europe in September, 1938, it is of interest to note the following statements by Mr. Crowther:

"Large countries such as the United States are being integrated into units by the swift communications of air transport. The attitude of Englishmen toward other nations, and their conception of the role of England among the nations, are changing swiftly since London came within half an hour's journey of other lands."—And, "the importance of oil to industries and military forces, has given petroleum great political significance. The desire for oil is now one of the more important of the motives which guide the diplomatic and military policies of modern nations."

"About Petroleum" is well worth reading by teachers of chemistry and engineering as well as business men as showing the extent to which science of the most diverse branches has permeated and become vital to the modern petroleum industry. The research man in so-called pure science will note with satisfaction the following:

"The solution of the wider problems of the petroleum industry does not depend merely on the advance of the science of petroleum, but on the advance of pure science itself. The industry will have to inspire, for its own ultimate benefit, the creation of new branches of pure science."

B. T. BROOKS

Library Guide for the Chemist. By BYRON A. SOULE, Sc.D., Assistant Professor of Analytical Chemistry, University of Michigan. McGraw-Hill Book Company, Inc., 330 West 42d Street, New York, N. Y., 1938. xiii + 302 pp. 14.5 × 21.5 cm. Price, $2.75.

Here is a book for students written by a teacher who realizes the special value of including among things learned in college a knowledge of where and how to look for further information as needed. A good deal of information is given about "where" but the emphasis is on "how," on which emphasis is needed. The text is primarily a "guide to the use of keys and summaries."

The early chapters reveal the general trend in the development of chemical literature. After chapters on the arrangement of a library and on card catalogs, the investigators themselves are considered (biography), then their original reports (journals), next the initial summaries of their articles (abstracts), then the periodic digests (annual reviews), followed by surveys of smaller divisions within a field (monographs) and finally by synopses as assembled in large compendiums (encyclopedias). Then specialized reference books and tables of constants, "the last step in condensation," are classified as inorganic, organic, analytical and physical and considered in this order. Finally the patent literature, government publications and the writing of reports are discussed.

The book is filled with interesting tables compiled in a manner which should be effective for students. These are often not complete but the book does not pretend to be a complete catalog of source material. The tables on yearbooks and on monograph series are good examples.

The inclusion of an early chapter on biography was a happy thought, for chemical literature is largely a record of the achievements of earnest investigators, many of them great men, and such a beginning should help to inspire student interest. There is great value in becoming acquainted with the masters.

Another pleasing feature of this book is the author's practice of including at the beginnings of chapters pertinent "sayings" of others. These lend an authoritative kind of emphasis and seem appropriate in a book on literature even though it be scientific literature.

The author has a knack of writing short, simple definitions, such as "An abstract is essentially an annotated reference." Any lack of precision is remedied by surrounding discussion.

"Experiments have settings." The author's discussion of this fact reveals a good comprehension of the limitations of words and combinations of words in records as well as of the limitations of those who use words in making the records. This understanding adds much value to Doctor Soule's discussion of indexes and their use. This portion of the book could well be expanded, however, for an understanding of the characteristics of indexes and of their use is of primary importance in literature searching. The book would gain in value if its own index provided a better example. It is a pretty good index as indexes go but it has too many of the characteristics of word indexing as opposed to subject indexing. For example, there is a group of alphabetically arranged entries under the heading "Patent" and then a little farther on a similar group under the heading "Patents," the only difference apparently being that the singular word was used part of the time in the text and the plural part of the time. There is some scattering, as an entry "Government publications" in the G's and a separate entry "Publications, foreign government" in the P's, entries under "Periodicals" and a separate entry "Journal appraisal," etc. The inclusion of word-for-word book titles in the index has largely been responsible for such a scattering as that indicated by the following index entries:

Analytical chemistry, conductometric
Conductometric analysis
Electrometric analysis
Quantitative analysis, electrolytic methods
Electrolytic analysis
Potentiometric analysis
Potentiometric titration

Perhaps the use of italic letters for book-title entries, if they are not to be grouped under headings designating subjects, would improve the situation. The use of more cross references would be helpful.

Patents are discussed at length, both as to their legal aspects and as to their role as scientific literature. Directions for making patent searches are also given. These are particularly thorough chapters.

Your reviewer finds himself wondering a little whether he has a touch of Jehovah complex when it comes to things American or the author has a modicum of complex of the bovine variety so that the grass looks a little greener to him on the other side of the fence—or ocean. Perhaps neither is true.

Your reviewer yields to no man when it comes to the making of curious mistakes (other kinds, too) and so hesitates to refer to one in a book which seems to be quite free from mistakes but cannot resist mentioning that the journal he edits is referred to by Doctor Soule as a "*bi*-monthly appearing on the tenth and twentieth."

The first sentence in this book's preface is: "The literature of chemistry is probably more adequately classified, more thoroughly indexed, and more consistent in terminology than that of any other science." Even so the searching of chemical literature is a complex and difficult matter. None can afford to neglect to learn where and how to look and Doctor Soule's book should prove to be very useful indeed in helping students to learn this art. Doctor Soule has done a good job.

E. J. CRANE

(I) **Le Rapport entre la Spectroscopie et les Réactions initiées par la Lumière.** (Spectroscopy and Photochemical Reactions.) By W. ALBERT NOYES, JR. (II) **The Determination of the Mechanism of Photochemical Reactions.** By PHILIP A. LEIGHTON. (III) **The Photochemistry of the Halogens.** By GERHARD K. ROLLEFSON. Hermann et Cie., Éditeurs, 6 Rue de la Sorbonne, Paris, France, 1937–1938. 45 pp. 72 pp. 53 pp. 16.5 × 25.5 cm.

These three booklets, published under the direction of the first-named author, outline the present status of the subject. The first discusses typical primary photochemical processes from the standpoint of the spectral characteristics of photolytes. With a minimum of mathematics it achieves an exposition of modern theory which is at once sound and clear. The next deals with secondary reactions evoked by atoms, free radicals and excited molecules resulting from primary acts. Ammonia and hydrazine, halogens reacting upon the ethylenic linkage, oxygen and ozone, are critically discussed to illustrate the possibilities of kinetic reasoning as well as the pitfalls involved. The third supplies a coherent interpretation of the chief photochemical reactions of the halogens, including the author's extensive work upon them.

Pending the expected appearance of two, more comprehensive, books on the subject, these contributions are of very real value to French and American readers alike.

GEORGE S. FORBES

The Metabolism of Living Tissues. By ERIC HOLMES, M.A., M.D., Fellow and Tutor of Downing College and University Lecturer in Biochemistry. Cambridge University Press: The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1937. xi + 235 pp. 13 × 19 cm. Price, $2.25.

Sir Frederick Hopkins in a foreword to this book points out that its "primary aim...is to provide an adequate survey of all that is most significant in our present knowledge of the dynamic side of biochemistry. Its author has had a wide experience as a teacher of the subject, and writes with a full understanding of the needs of the student. In my opinion he here supplies a need which is real."

"The Metabolism of Living Tissues" cuts across the boundary sometimes set up between physiology and biochemistry. The tools of modern biochemical research are described in general terms. Three early chapters are devoted to enzymes, oxidations and oxidation–reduction potential, while two of the concluding chapters are concerned with hormones and vitamins. Other chapters deal with metabolic processes in the liver, in the kidney, in voluntary and cardiac muscles and in the nervous system.

The lucid explanation of the dependence of intermediary carbohydrate metabolism on coördinated functions of liver, muscles, adrenals, pancreas and pituitary should prove useful to students of physiology. Placing the emphasis on living tissues rather than on dead materials should stimulate the interest of students of biochemistry. It is among the books recommended for undergraduates in biochemical sciences at Harvard.

It is devised for the young student rather than for the research worker. There is a detailed subject index but no references to literature are given; hardly half a dozen biochemists are named, and two of these names, Hagedorn and Jensen, are spelled incorrectly. Otherwise there are almost no typographical errors.

DAVID B. DILL

Experiments in Organic Chemistry. By LUCIUS JUNIUS DESHA, Professor of Chemistry, and LARKIN HUNDLEY FARINHOLT, Associate Professor of Chemistry, Washington and Lee University. McGraw-Hill Book Company, Inc., 330 West 42d Street, New York, N. Y., 1938. xi + 233 pp. 24 figs. 14.5 × 21 cm. Price, $1.75.

As the authors state in their preface, "The purpose of this manual is to provide a program of laboratory work closely correlated with Desha's textbook *Organic Chemistry*. It is justified by the distinctive order of presentation adopted in that text. . . ." This consists of a parallel study of aliphatic and aromatic compounds, which is especially advantageous for a laboratory course. The manual contains almost no descriptive material, but specific references to the textbook head each experiment. The result is a concise set of directions for most of the syntheses commonly included in a beginning laboratory course and for an unusually large number of small scale tests. Among these the experiments entitled "General Methods of Forming Double Bonds," "Rearrangements" and "Tautomerism" seem new and especially interesting. There is no introductory chapter on manipulation, but each operation is described in the first experiment in which it is used.

Throughout the book emphasis is placed on the identification of organic compounds; a final chapter (23 pages) describes the standard procedure and refers the student to the small scale tests of the earlier parts. These include the preparation of most of the derivatives commonly used. It has recently been recognized that such material can be profitably included in a beginning laboratory course. However, in this manual so much emphasis is placed upon identification that the synthetic side of the subject is somewhat overshadowed. This is apparent not in omission of synthetic material, but in the absence of all descriptive matter and study questions which would serve to orient a particular compound, emphasize the side reactions in its preparation and present the limitations of the general reaction being studied. References to a textbook written primarily from a theoretical viewpoint do not throw much light on this practical aspect of the problem. This constitutes the principal shortcoming of an otherwise well planned and well written book.

THOMAS L. JACOBS

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by R. J. MEYER. Eighth edition. System-Number 63, **Ruthenium.** Issued by the Deutsche Chemische Gesellschaft. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 35, Germany, 1938. 124 pp. 17 × 25 cm. Price, RM. 16.50.

The publishers of the Gmelin Handbook state that this volume on Ruthenium constitutes the first installment of the complete Monograph on the platinum group metals, and that subsequent installments will follow in rapid succession. This is certainly welcome news to the inorganic chemist, as several decades have passed since the appearance of the corresponding volume in the last edition of the Gmelin Handbook. The "system number" of ruthenium (63) is not exceeded by those of any other elements except the members of the platinum group, so that practically all the compounds of ruthenium, with their chemical elements, are included in this volume.

ARTHUR B. LAMB

A Manual of Radioactivity. By GEORGE HEVESY, Copenhagen, and F. A. PANETH, London. Second edition, completely revised and enlarged. Translated by Robert W. Lawson, Sheffield. Oxford University Press, 114 Fifth Avenue, New York, N. Y., 1938. xvi + 306 pp. 54 figs. 16 × 24 cm. Price, $5.50.

Much has happened in the field of nuclear chemistry since the appearance of the first English edition of this book in 1926 (THIS JOURNAL, **49,** 305 (1927)). This is reflected in the excellent revision and expansion of the present second edition.

It is not only the subject matter in this field which has been enriched by the discovery of artificial radioactivity and of two new fundamental particles, but the entire philosophy of elements has undergone a remarkable revolution. A theory of nuclear stability and disintegration has been perfected. The new artificially radioactive elements are already more numerous than all of those previously known in the three natural families. Several new types of disintegration have been found among the new elements.

All of this, however, fits into the framework of the periodic system and the displacement law as it existed since 1913 and to which one of the authors made substantial contributions.

Four entire new chapters have been added and enough other new material to increase the total length from two hundred and fifty to four hundred pages. Nevertheless, the book has retained its character of a very readable and useful manual of radioactivity.

Some literature references have been added at the end of chapters, which is a very acceptable innovation, but still falls short of the value derived from complete literature references. The historical survey at the end has been retained and brought up to date. The more recent progress in all of the important fields is recorded. The tables of isotopes—radioactive and stable—and of the artificial radioactive elements and their properties are excellent.

S. C. LIND

Lehrbuch der Pharmakologie, Toxikologie und Arzneiverordnung. (Textbook of Pharmacology, Toxicology and Prescription Writing.) By Dr. med. EMIL STARKENSTEIN, Professor in the Dutch University in Prague. Verlag Franz Deuticke, Helferstorferstrasse 4, Wien I, Germany, 1938. xi + 758 pp. Illustrated. 17.5 × 25.5 cm. Price, RM. 20; bound, RM. 23.

This textbook is intended for medical students studying pharmacology. After a brief introduction in which the topics of general pharmacology, general toxicology and the place of pharmacology in practical therapeutics are discussed, the so-called special pharmacology is taken up and treated on the basis of physiological systems more or less in accordance with the scheme first used by Gottlieb and Meyer in their well-known textbook. The treatment of the various topics appears to be quite satisfactory and to take in account recent advances; a more complete account is given of the chemistry of the digitalis glucosides than is found in current textbooks and the sections on the hormones and vitamins are particularly good. No references are given, which detracts in many ways from the value of the book. The book will not appeal to American students, and will serve only as a textbook for a limited group.

E. K. MARSHALL, JR.

Inorganic Colloid Chemistry. Volume III. The Colloidal Salts. By HARRY BOYER WEISER, Professor of Chemistry at The Rice Institute. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1938. viii + 473 pp. 74 figs. 15.5 × 24 cm. Price, $6.00.

Weiser's three volumes constitute the readiest and most modern and complete reference works to the information extant with regard to the various inorganic colloids. They are so clearly and pleasantly written, and so well and thoroughly documented, that any of them serve as a text, although necessarily incomplete, from which to gather the theories and applications of colloid science arising from the materials studied. Many important theories are discussed for their own sake. Interesting accounts are also given of many technical materials, such as plaster of Paris, inorganic pigments, halides in photography, soil colloids, base exchanging silicate gels, and cements. "The first portion of each section is concerned with a critical survey of the conditions of formation and the general characteristics of the individual salts in the colloidal state; and the second portion, with the principles underlying their applications." It is to be hoped that as the subject advances we may look forward to further revisions of the three volumes.

Throughout the text divergences of opinion are quoted. In many cases the reader must ask why no investigator has established the facts in question which would be decisive. Presumably the answer lies in the enormous extent of the field compared with the number of available workers in any part of it. Students will note the many opportunities thus afforded for further useful research.

Professor Weiser has rendered an important service in compiling and discussing the information so far obtained with regard to all inorganic substances, elements (Vol. I), oxides and hydroxides (Vol. II), and now in the present Vol. III all remaining inorganic compounds in the colloid condition.

J. W. MCBAIN

Les Classiques de la Découverte Scientifique. Gauthier-Villars, Éditeur, 55 Quai des Grands-Augustins, Paris VI^e, France, 1938. 13.5 × 19 cm. Les Métaux Légers: Aluminium, Glucinium, Magnésium, Métaux Alcalins Mémoires de Henri Sainte-Claire Deville, Heroult, Bussy, Gay-Lussac, Thénard. Préface par LÉON GUILLET. xix + 166 pp. La Dissolution. Mémoires de Lavoisier, Gay-Lussac, Loewel, Gernez, Lescoeur, Raoult. Préface par HENRY LE CHATELIER. xvii + 148 pp. Détermination des Poids Moléculaires. Mémoires de Avogadro, Ampère, Raoult, van't Hoff, D. Berthelot. Avant-propos par R. LESPIEAU. xvii + 165 pp. Halogènes et Composés Oxygénés du Chlore. Mémoires de Scheele, Berthollet, Gay-Lussac et Thénard, Davy, Balard, Courtois, Moissan, Millon. Avant-propos par A. DAMIENS. xiv + 147 pp. Price, each, 21 francs.

The great majority of chemists read only the current or recent literature; unlike their literary brethren they know the classics of their field only by repute or in the abstracts found in textbooks. This series of Famous Scientific Papers makes accessible quite a few historically important papers collected into handy sized volumes each dealing with a broad topic. The Académie des Sciences has done the chemical world a real service by supporting this collection, which is planned to include 15 volumes. Some of these have already been reviewed in the JOURNAL.

Unlike the Alembic Club Reprints or the Ostwald's Klassiker no translations were specially prepared for these volumes, only such material was used as was already available in French. Consequently few non-Gallic writers are included and the impression is gained that this project is, in part, an attempt to glorify the achievements of the French chemists. Some of the volumes give a rather complete coverage, others contain obvious gaps. Nonetheless these collected essays are extremely interesting and valuable; many little known facts can be gleaned from their pages. Students and teachers will profit from reading these records of fundamental discoveries related by master chemists.

Each volume has a good preface by a competent authority; full page likenesses of most of the writers are given along with brief biographical sketches. The printing is nicely done on fairly good stock, the covers are paper. These economies are reflected in the extremely modest price. It would be a boon if an American or English publisher could put out comparable volumes at this price level.

RALPH E. OESPER

Molecular Beams. By R. G. J. FRASER, Ph.D., Imperial Chemical Industries, Limited. Chemical Publishing Company of New York, Inc., 148 Lafayette Street, New York, N. Y., 1938. ix + 70 pp. 22 figs. 10.5 × 17.5 cm. Price, $1.25.

In this monograph the author reviews briefly the most significant work published in this field since the appearance in 1931 of his longer monograph on Molecular Rays for the Cambridge Series of Physical Chemistry. The present booklet is, however, not merely a report of new work; it is a highly condensed outline of the entire field with a description "in something like adequate detail of its more fruitful areas only."

The chapter headings are "Molecular Beams," "Gas Kinetics," "Magnetic Moments," and "Electric Moments." The most important extension beyond the 1931 treatment occurs in the third chapter, in which the notable contributions of I. I. Rabi and co-workers, and those of O. Stern and collaborators, are reviewed under the sub-title "Nuclear Spins and Magnetic Moments." The author's own recent contribution to the molecular ray study of free radicals receives brief notice in the first chapter, and his contribution to the study of molecular scattering by the method of crossed beams is set forth in the second chapter. There are approximately sixty references to the literature of date more recent than 1931.

As to the presentation, the author's aim would seem to be at preciseness of statement together with utmost economy of words; and his style approaches to the happy state referred to in the dedicatory note: namely, that of being (like the molecular ray itself) "unidirectional and collision-free."

T. E. PHIPPS

Dipole Moments. Their Measurement and Application in Chemistry. By R. J. W. LE FEVRE, D.Sc., Ph.D., F.I.C., Lecturer in Chemistry, University College, London. Chemical Publishing Company of New York, Inc., 148 Lafayette Street, New York, N. Y., 1938. v + 110 pp. 28 figs. 10.5 × 17.5 cm. Price, $1.50.

Two books on dipole moments now appear after a period of several years during which only reviews in journals or chapters in larger works have been devoted to the subject in English. Actually, the present small volume has no greater content than might be expected of a chapter in a treatise, but, without attempting completeness, it deals with the major methods and problems of the subject. It presents the fundamentals of the theory of dielectrics and the methods by which the dipole moment is calculated. A general outline of the experimental methods for obtaining the data necessary for the calculation of the moment includes a detailed account of the method of dielectric constant measurement used by the author. An excellent summary of the various attempts to treat the solvent effect in dipole moment measurements is followed by the longest chapter of the book, which describes classical examples of the solution of structural problems through dipole moments and discusses the relation of moment values to various recent questions of molecular structure. The book closes with brief chapters on "Intramolecular Rotation and Flexibility of Molecules" and "Some Anomalous Dipole Moments" and a table of moment values selected for the most part from the appendix to the "Transactions of the Faraday Society," Volume 30, 1934.

The presentation of the material is smooth, clear and authoritative and should prove admirable for a senior, a graduate student, or an older chemist wishing to find out something about dipole moments. The investigator directly concerned with the determination or interpretation of moments will probably find, by the slight exertion of reading an easily readable book, useful comments or references to recent literature which may have escaped his attention, but cannot expect an exhaustive treatment of any particular topic, as reference is made to only a fraction of the dipole moment papers in the literature. Frequently, only the work done in England on a particular problem is mentioned when it is sufficient to show the argument and, not unnaturally, the problems investigated in England are emphasized. It is rather surprising to an American reader to note the seemingly scrupulous care with which use of the word "resonance" and mention of Pauling's work in this field are avoided. Although there is mention of "canonical structures," "mesomerism" appears to replace the phenomenon of "resonance." One should not, however, attempt a detailed criticism of so brief a book, for within the limitations imposed by its small size, it may be regarded as extremely successful.

CHARLES P. SMYTH

Crystal Chemistry. By CHARLES W. STILLWELL, Ph.D., Research Chemist, Dennison Manufacturing Company. McGraw-Hill Book Company, Inc., 330 West 42nd Street, New York, N. Y., 1938. x + 431 pp. 72 figs. 14.5 × 21 cm. Price, $4.50.

The study of crystalline substances has today reached such large proportions that it is coming to be treated in several independent parts: for example, first the concepts and language of crystal geometry; second, the several techniques for its study and their practical applications; third, the compilation of the geometrical constants of known crystals; fourth, analysis of these results, their bearing on the general subject of the atomic structure of matter, and their correlation with physical and chemical properties. In the absence of single volumes or treatises which cover all of these divisions, books like the present one, which belongs in the fourth category mentioned, are to be welcomed.

This book, like Hassel's book of the same name (reviewed in THIS JOURNAL, **57**, 964 (1935)), interprets the results of crystal structure studies for chemistry students. It is intended as a text or as a point of departure for a more thorough study of the field, and may be expected to prove useful in modernizing courses in inorganic chemistry.

The volume begins with a discussion of the sizes of atoms and ions, and how they vary with environment in crystals. There follow two valuable chapters, one on the structures and properties of the elements, with a treatment of the metallic state, the other on the nature of alloys. In the next three chapters on the structures and properties of binary and ternary compounds, the subject of ionic and covalent bonds is taken up. The principles thus outlined are applied in the following chapters on silicates, including a discussion of inorganic glasses; on Werner compounds; on isomorphism, mixed crystals and polymorphism; and on organic crystals. The two concluding chapters on natural and synthetic fibers are of technical as well as general interest.

As illustrating what is in the book, on p. 330 there is an interesting rationalization of the composition of dental enamel; on p. 390 the mechanism of the permanent wave is explained. Throughout the book is much of the fertile work of V. M. Goldschmidt, which is otherwise quite inaccessible.

As illustrating what is not in the book, on p. 178 it is not indicated that CsCl has the NaCl structure at high temperatures, nor that the potassium halides have the CsCl structure at high pressures. From the lack of mention of silicate glass fibers in the last chapters one might conclude, contrary to common sense, that they are not fibers at all because they lack the internal structure of the fibers included in the discussion. There is much on the thermodynamic and mechanical properties of crystals, but nothing on their optical properties.

The style is generally stimulating, sometimes obscure. The index is rather brief. The format is the excellent one of the International Chemical Series.

ADDITIONS AND CORRECTIONS

Notice to Readers.—For the convenience of those who wish to cut out the corrections and attach them to the margins of the articles corrected, they have been printed upon one side of the page only.

1933, Vol. 55

M. S. Kharasch and F. R. Mayo. The Peroxide Effect in the Addition of Reagents to Unsaturated Compounds. I. The Addition of Hydrogen Bromide to Allyl Bromide.

Page 2485. In Fig. 2, percentage by volume (rather than mole fraction) of allyl bromide should have been plotted against the index of refraction of mixtures. Had this been done, deviations of the curves from straight lines would have been insignificant.

Page 2487. In experiment 217 of Table XV, aqueous potassium dichromate was used as color filter.

Page 2488. In line 3, insert "this" between "and" and "dibromide."

Page 2492. In line 7 from the bottom of the page, XVIIIC should be XVIII-C.—M. S. Kharasch.

1935, Vol. 57

Leo A. Flexser, Louis P. Hammett and Andrew Dingwall. Determination of Ionization by Ultraviolet Spectrophotometry.

Page 2106. In Table I the seventh item in the second column should read "1250" instead of "1350," and the corresponding item in the last column "4.09" instead of "3.92." The average pK should be "4.18 ± 0.09" instead of "4.16 ± 0.11."—Louis P. Hammett.

1937, Vol. 59

William G. Young, Zene Jasaitis and Leo Levanas. Investigations on the Stereoisomerism of Unsaturated Compounds. III. The Preparation of the *cis* and *trans* 4-Octenes.

Page 406. In column 2, lines 3 and 7, for "20–20.5°," read "120–120.5°." Also in line 7 for "62.9 mm." read "62.9°."—William G. Young.

Russell Bliss Akin and Marston Taylor Bogert. The Synthesis of 1,4-Dimethyl-6,7-methylenedioxyphenanthrene and of Certain Substituted 9,10-Dimethyl-1,2,-5,6-dibenzanthracenes.

Page 1567. In column 1, line 10, for "(2.94 g.)" read "(29.4 g.)."—Marston T. Bogert.

Arthur A. Vernon. The Vapor Pressure and Dissociation of Tungsten Hexachloride in the Gas Phase.

Pages 1832–1833. The author writes: "Dr. J. A. M. van Liempt of the N. V. Phillips Gloeilampenfabrieken, Eindhoven, Holland, has called my attention to the fact that an error was made in determining the equation of the straight line plot of log p against $1/T$ from the data given in my article. The corrected equation is

$$\log p = 13.652 - \frac{5276}{T}$$

but the heat of vaporization remains unchanged since it was determined from the slope of the line from the graph."—Arthur A. Vernon.

Nicholas T. Farinacci and Louis P. Hammett. Water Catalysis in Alcoholysis of Benzhydryl Chloride.

Page 2543. In column 1, line 3 from the end, for "$k_1 + k_2$" read "$k_1 + k_2c_w$." In Table I, the items in the last column should be "0.0, 27.7, 46.0."—Louis P. Hammett.

1938, Vol. 60

Herbert N. McCoy. Biography of Julius Stieglitz.

Page 15 (*Obit.*). In column 1, line 30, omit the words "popular" and "("aspirin")."—Herbert N. McCoy.

J. Allen Wheat, II, and A. W. Browne. The Chlorinates. II. Temperature–Concentration Equilibria in the System Alpha-Carbon Tetrachloride–Chlorine. The Carbon Perchlorides.

Page 372. In column 1, line 9 from the end, for "2-$(CCl_4)_2 \cdot Cl_2$" read "$(CCl_4)_2 \cdot Cl_2$."

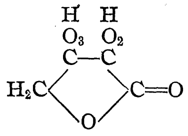
F. F. Blicke and E. L. Cataline. Tertiary Arsines and Arsine Oxides.

Page 422. In Table II, in the column of compound names, "Oxide" should be inserted as a heading between lines 7 and 8.—F. F. Blicke.

W. D. Kumler. The Dissociation Constants of Some Enols Related to *l*-Ascorbic Acid. Tetronic Acid, α-Chlorotetronic Acid, α-Bromotetronic Acid, α-Iodotetronic Acid, α-Hydroxytetronic Acid and Ethyl α-Iodoacetoacetate.

Page 861. In footnote (1a), the next to the last word should be "lactone" instead of "lactose."

In column 2, the structural formula numbering should be as indicated:



W. D. Kumler.

A. H. Blatt. The Alkylation of Oxymethylene Desoxybenzoin.

Page 1165. In column 2, line 22, for "esterification" read "etherification."—A. H. Blatt.

George Scatchard and C. L. Raymond. Vapor–Liquid Equilibrium. II. Chloroform–Ethanol Mixtures at 35, 45 and 55°.

Page 1278. The temperatures are in error due to an error in the calibration of the potentiometer. The mixtures were studied at 34.97_0, 44.97_9 and 54.97_6°. To replace Table I, the vapor pressures of the components may be represented by the following equations for the common logarithm of the pressure in mm. of mercury, which were determined by least squares ($T = 273.16 + t$)

Ethanol, 35–75°: (S. D., 1.6×10^{-4}) $\log p = 7.80335 - 1343.010/T - 136050/T^2$

Chloroform, 35–60°: (S. D., 6.5×10^{-4}) $\log p = 6.24266 - 674.551/T - 150306/T^2$

The average deviation of our published results from these equations is −0.1%; so the comparison with the measurements of others is scarcely affected. These equations yield as normal boiling points 78.30_6° for ethanol and 61.20_4° for chloroform.—GEORGE SCATCHARD.

John R. Durland and Homer Adkins. Hydrophenanthrenes.

Page 1502. In column 2 the second and third formulas should be:
