Hindered Rotation of the Methyl Groups in Propane. The Heat Capacity, Vapor Pressure, Heats of Fusion and Vaporization of Propane. Entropy and Density of the Gas

BY J. D. KEMP* AND CLARK J. EGAN

Evidence proving the existence of a high potential barrier which hinders the rotation of the methyl groups about the single carbon–carbon bond in ethane[1–3] has made apparent the need for more experimental data on the hindering potentials in similar molecules. Accordingly, the entropy of propane gas has been obtained experimentally from calorimetric data with the aid of the third law of thermodynamics, and has also been calculated as a function of the height of the potential barrier by means of spectroscopic and molecular structure data. The contributions of a hindered rotator to the entropy, energy, and heat capacity have been given by Pitzer.[4] The height of the potential barrier was determined as that necessary to bring the spectroscopic entropy value into agreement with the experimental entropy value.

Purification of Propane.—C. P. propane, of 99.9% purity, from the Ohio Chemical Company, was bubbled through 12 *N* sodium hydroxide and 36 *N* sulfuric acid. It was then passed through a tube containing phosphorus pentoxide and condensed in a previously evacuated bulb. The liquid was subjected to two successive fractionations in a vacuum-jacketed fractionating column, the middle 30% being retained each time. From the course of the heat capacity curve just below the melting point, the amount of liquid-soluble solid-insoluble impurity was estimated to be less than 0.001 mole per cent. The method of making this calculation has been described previously.[5] A less accurate value of 0.002 mole per cent. impurity was calculated from the change of the melting point in heating from 5 to 20% melted.

Apparatus and Measurement of Amount. The Density of Propane at 1 Atmosphere and 298.10°K.—The calorimetric apparatus and procedure have been described previously.[6,7] Gold Calorimeter IV was used for the investigation. The volume of the propane was determined by means of the 5-liter measuring bulb described by Giauque and Johnston.[8]

A gas density determination was made after each of the three heats of vaporization. The volumetrically measured propane was condensed and weighed in a glass bulb containing pentane, which reduced the vapor pressure of the propane. The molal volume of propane, V, at T near 298°K. and P near 1 atm. was found to be

$$V = \frac{82.06T}{P} - 401 \pm 7 \text{ cc.} \qquad (1)$$

This gives 1.8325 ± 0.0007 g./liter for the density of propane gas at 298.10°K. and 1 atm.

Vapor Pressure.—The procedure used in the measurements of vapor pressure has been described previously.[6] The observations have been represented by the equation

liquid propane, 166 to 231°K., (0°C. = 273.10°K.)

$$\log_{10}P_{(\text{Int. cm. Hg})} = -(1325.358/T) + 9.64920 - 0.0118950T + 0.000013420T^2 \qquad (2)$$

A summary of the measurements is presented in Table I. The calculated and observed values are compared in columns 3 and 4. Temperatures have been given to 0.001° because of the high relative accuracy. The absolute temperatures may be in error by several hundredths of a degree. Column 5 contains values of the rate of change of pressure with temperature calculated from equation (2).

Entropy of actual gas at boiling point	60.29 ± 0.1
Correction for gas imperfection	0.16
Entropy of ideal gas at 1 atm. and 231.04 °K.	60.45 cal./deg. per mole

The correction for gas imperfection was obtained from the expression[7]

$$S_{\text{ideal}} - S_{\text{actual}} = (27RT_c^3P)/32T^3P_c$$

The values of the critical pressure and temperature were taken as T_c = 369.9°K. P_c = 42.01 atm.[16]

Magnitude of the Potential Barrier.—Although it would be more logical to evaluate the entropy due to the two degrees of freedom concerned with the internal rotation of the methyl groups and thereby estimate the magnitude of the potential barrier, it is more convenient to calculate an entropy value with the assumption of free internal rotation and evaluate $S_{\text{free}} - S_{\text{experimental}}$. With this quantity and a table of $S_{\text{free}} - S_{\text{hindered}}$ as a function of the potential barrier, the magnitude of the barrier may be obtained.

The values of the natural constants used were those given in the "International Critical Tables." The following data from the electron diffraction measurements of Bauer[17] were used to calculate the rotational contribution to the entropy.

$$\text{C–C} = 1.50_3 \pm 0.02\ \text{Å}.$$
$$\text{C–H} = 1.08_1 \pm 0.02\ \text{Å}.$$
$$\text{C–C–C} = 114^\circ 12'$$

The remaining H–C–H angles were assumed to be tetrahedral, namely, 109°28′. Kassel[18] has derived the partition function for freely rotating propane. The expression for the rotational entropy

$$S_{\text{free rotation}} = R/2 \ln (I_x - 2K \sin^2\alpha)(I_y - 2K \cos^2\alpha)(I_z)(K)^2 + 5/2\, R \ln T - R \ln \sigma + 447.599$$

may be separated into the usual expression

$$S_{\text{external rotation}} = R/2 \ln I_xI_yI_z + 3/2\, R \ln T - R \ln 2 + 267.649$$

plus

$$S_{\text{free internal rotation}} = R/2 \ln(I_r)^2 + R \ln T - R \ln 9 + 179.950$$

where the reduced moment

$$(I_r)^2 = (K)^2 \left(1 - \frac{2K \sin^2\alpha}{I_x}\right)\left(1 - \frac{2K \cos^2\alpha}{I_y}\right)$$

K = moment of inertia of a methyl group. α = one-half of the C–C–C angle. I_z = moment of inertia about the axis through the center of gravity and perpendicular to the carbon plane. I_y = moment of inertia about the axis which bisects the C–C–C angle in the carbon plane. I_x = moment of inertia about the axis through the center of gravity and perpendicular to both y and z axes.

From the above data the moments of inertia times 10^{40} g. cm.^{2} were found to be I_x = 26.9; I_y = 96.8; I_z = 108.2; K = 5.18; I_r^2 = 18.93. The symmetry number σ was taken equal to 18.

Kohlrausch and Köppl[19] have summarized the Raman data on propane. They have also included the results of Bartholomé[20] on the infrared spectrum of propane. The three vibrations of the carbon skeleton have been identified at 373, 867 and 1053 cm.$^{-1}$. For the calculation of the vibrational contribution to the entropy, the remaining frequencies were estimated as follows: seven at 950 cm.$^{-1}$, seven at 1440 cm.$^{-1}$ and eight at 3000 cm.$^{-1}$.[21]

The sum of the translational, rotational and vibrational entropies of freely rotating propane was calculated to be 63.85 ± 0.25 cal./deg. per mole at one atmosphere at the boiling point, 231.04°K. The disagreement of this value with the experimental value, 60.45 ± 0.10 cal./deg. per mole, indicates that the rotation of the methyl groups in propane is hindered rather than free. Although lack of equilibrium in the crystal at low temperatures has caused discrepancies in the experimental and spectroscopic entropy values of several molecules, the reasons for this lack of equilibrium are known and such an explanation for the disagreement in the case of propane as in the cases of ethane,[1] tetramethylmethane[22] and methylamine[23] seems very improbable. Pitzer,[21] by interpolating the values of the barriers present in similar molecules, has predicted a hindering potential of 3400 cal./mole for propane.

The difference, $S_{\text{free}} - S_{\text{experimental}}$, was found to be 3.40 ± 0.3 cal./deg. per mole at the boiling point. This amount of entropy corresponds to a

barrier of 3300 ± 400 cal./mole,[24] which is in excellent agreement with the predicted value mentioned above. The entropy at 298.10°K. has been calculated to be 64.7 ± 0.3 cal./deg. per mole from molecular and spectroscopic data, the experimental value of the potential barrier and the experimental value of the entropy at the boiling point. This value at 298.10°K. is the entropy to be used in thermodynamic calculations.

In these calculations the nuclear spin entropy, $8 R \ln 2 = 11.015$ cal./deg. per mole, has been neglected. Table IX contains a summary of the calculations.

Entropy of propane with a potential barrier of 3300 cal./mole (nuclear spin entropy not included)		64.7 ± 0.3

Summary

The heat capacity of condensed propane has been measured from 15°K. to the boiling point. The melting point was found to be 85.45 ± 0.05°K., the boiling point 231.04 ± 0.05°K., the heat of fusion 842.2 ± 0.8 cal./mole and the heat of vaporization 4487 ± 4 cal./mole.

Vapor pressure measurements have been made on liquid propane and the results have been represented by the equation (liquid propane, 166 to 231°K. (0°C. = 273.10°K.))

$$\log_{10} P_{(\text{Int. cm. Hg})} = -(1325.358/T) + 9.64920 - 0.0118950T + 0.000013420T^2$$

The density of propane gas at 298.10°K. and one atmosphere was found to be 1.8325 ± 0.0007 g./liter.

At one atmosphere at the boiling point the experimental entropy of propane (ideal gas) was evaluated as 60.45 ± 0.10 cal./deg. per mole.

The entropy of propane calculated with the assumption of free internal rotation minus the experimental entropy, $S_{\text{free}} - S_{\text{experimental}}$ (at the boiling point), was found to be 3.40 ± 0.3 cal./deg. per mole, which corresponds to a potential barrier of 3300 ± 400 cal./mole hindering the internal rotation of the methyl groups.

The entropy of propane (ideal gas, with a 3300 cal./mole barrier) at one atmosphere and 298.10°K. was found to be 64.7 ± 0.3 cal./deg. per mole (nuclear spin entropy not included). This is the entropy value to be used in thermodynamic calculations.

Vapor Pressure Studies. I. Evidence for the Validity of Raoult's Law. The Systems Benzene–Diphenyl, Benzene–Benzyl Benzoate, Ethyl Acetate–Benzyl Benzoate

BY H. H. GILMANN[1] AND PAUL GROSS

Attention recently has been drawn[2] to the paucity of direct experimental evidence which is available in support of Raoult's law. In view of its importance for modern solution theory and because of the difficulty of giving a general theoretical foundation to the law, the desirability[3] of adding to this evidence has been emphasized.

In connection with a study of the stability of addition compounds in non-aqueous systems as indicated by partial pressure determinations, partial pressure data were also obtained for certain binary systems consisting of a volatile and a non-volatile component. Some of these cases furnish evidence bearing on the validity of Raoult's law.

The systems in question are benzene–diphenyl, benzene–benzyl benzoate and ethyl acetate–benzyl benzoate. Benzyl benzoate boils at 324°

[2] Guggenheim, *Trans. Faraday Soc.*, **33**, 161 (1937).

[3] Hildebrand, THIS JOURNAL, **59**, 794 (1937).

According to Rechenberg[4] it has a vapor pressure of 4.5 mm. at 156°. By means of a log p *vs.* $1/T$ plot the data given by Rechenberg above 156° were extrapolated to 95°, the highest temperature investigated here. The vapor pressure found thus was 0.3 mm. Since the partial pressure of the benzyl benzoate from the solutions could be no greater than this, its contribution to the total vapor pressure would be negligibly small. The measurement of the total vapor pressure of the systems containing benzyl benzoate would therefore be a direct determination of the partial pressure of the volatile component, benzene or ethyl acetate. A test of Raoult's law with systems of this type has the definite advantage that it involves fewer assumptions than earlier tests such as that of Zawidski with systems involving two volatile components. These necessitated the assumption of the validity of the gas laws and of Dalton's law of partial pressures in order to calculate the partial vapor pressures from the composition of the liquid condensate of the vapor phase which had been determined analytically.

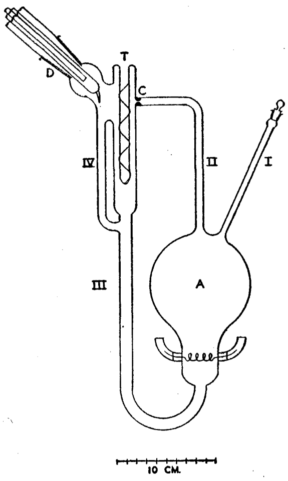

Fig. 1.

The same considerations apply to the system benzene–diphenyl in the range of temperatures between 50 and 80°. Here the partial pressure of the benzene can be placed equal to the total pressure of the solution with but negligible error. At the highest temperatures measured, 90–95°, the vapor pressure of the diphenyl is no longer negligible. However, even in these cases an estimate of the contribution that the partial pressure of its vapor makes to the total indicates that it is of the same magnitude as the experimental error. These cases will be considered in detail later.

Apparatus and Method

The total vapor pressures were determined by an ebulliometric method using a modification of the apparatus of Swietoslawski.[5] The principle of this is based on the earlier apparatus of Cottrell and need not be reviewed here. The precise boiling point elevation measurements of Washburn and Reade[6] and the extensive tests of his own apparatus by Swietoslawski[7] show that this method gives true values for the vapor–solution equilibrium and that it is capable of great precision. Our experience confirms this. The apparatus is shown in Fig. 1. The large bulb A (600 cc.) is filled through the stoppered side-tube I with a solution of known composition to a point just below the end of tube II. The solution is boiled by the platinum heating coil and also, if necessary, by external heating by means of gas micro burners heating the lower portion of A. A stream of mixed vapor and bubbles rises in II and is ejected through the constriction C onto the thermocouple well T. The volatile component is condensed in an efficient inner jacket condenser attached to D so designed as to have a minimum hold-up of returning condensate. The latter is by-passed through tube IV to prevent cooling of the vapor equilibrium chamber surrounding T. The return tube III is brought into the bottom to promote mixing and circulation. This and the heating coil which prevents bumping at low pressures are modifications in Swietoslawski's original design.

A pressure control system, containing a large thermally insulated reservoir of 30-liter capacity to minimize pressure variations, was attached to the upper end of the condenser. Pressures were read with a baromanometer similar in design to that of Germann[8] employing tubes of 13-mm. i. d. and with an electric device for setting the zero position in the arm connected to the pressure system. The scale was ruled on a strip of plate glass on a Geneva Society dividing engine and checked with a cathetometer. Pressures could be read to 0.2–0.3 mm. Atmospheric pressure readings taken at intervals with the baromanometer were compared with those of a "Greene Precision Barometer" which had a 0.75-inch (1.9-cm.) diameter mercury column and were found to be in agreement within the precision of the readings on the baromanometer. All pressures are corrected to sea level at 34° latitude and 0°.

Temperatures were determined by means of a 24-junction copper–constantan thermocouple designed according to the recommendations of White.[9] This was calibrated by the Bureau of Standards at six temperatures, the cold junctions being at zero. The Bureau's certificate furnished a four constant equation to represent the dependence of e. m. f. on temperature. A three constant equation of the type recommended by Adams[10] was found to fit their calibration data somewhat better and was therefore used. The hot junctions of the thermocouple were placed in the glass well T and covered with "Nujol" to about 1 cm. depth to ensure good thermal transfer from the walls of the well. E. m. f.'s were read with a Leeds and Northrup calibrated Type K potentiometer.

As an over-all check on the pressure and temperature readings the boiling temperatures of redistilled water under five different pressures from 352.6 to 751.8 mm. were determined and found to agree within 0.01° with those given in "International Critical Tables" in all but one case which differed by 0.02°. The vapor pressures of benzene from 40 to 80° and those of ethyl acetate from 40

to 90° were determined. Since these compounds were carefully purified and the data in the literature, especially for ethyl acetate, show some disagreement it seems worth while to record our observed values here. Table I gives the values for benzene and Table II those for ethyl acetate.

TABLE I

t	p, mm.
36.73	157.8
40.90	188.5
45.13	223.9
50.19	272.1
55.09	326.7
60.63	389.9
64.89	461.2
69.67	544.7
74.98	646.0
79.78	753.0

TABLE II

t	p, mm.
39.46	183.7
53.35	324.1
67.96	557.1
77.04	758.6
83.01	919.8
87.58	1061.4

Large scale smoothed curves of the values in Tables I and II were drawn and the values for each even ten-degree interval found. These values are listed in the columns headed 100% in Tables V and VI. These were compared with the best values in the literature listed in "International Critical Tables." The benzene values agreed within 1 mm. with those of Young at 40, 50 and 60° and with those of Smith and Menzies at 65, 70 and 80°. The ethyl acetate values agreed within 1 mm. with those of Rechenberg[11] at 40, 60, 70, 80 and 90° but differed by 2.2 mm. at 50°, 3.4 mm. at 60°, and 2.0 mm. at 80° from those in "International Critical Tables." At 60 and 90° the difference from the latter values was less than 1 mm.

In view of the purity of our substances and the comparisons cited for water, benzene and ethyl acetate we estimate that in the determination of the vapor pressures of pure substances the method will probably not result in errors greater than 0.03° in temperature, and 1.5 mm. in the pressure values. The errors in the case of the solutions will be discussed later.

Materials

Benzene.—A good grade was purified as follows: (a) shaken with concentrated sulfuric acid until no coloration was perceptible, (b) washed with water, then with 25% sodium hydroxide solution and then with water, (c) shaken with mercury, (d) washed with water and then dried over calcium chloride and phosphorus pentoxide, (e) distilled in a large Dufton column and the fraction distilling between 80.15 and 80.17° was then (f) fractionally recrystallized, that with melting point 5.42–5.46° being stored over sodium for use.

Diphenyl.—This was recrystallized twice from absolute alcohol, dried, and then distilled twice under about 7 mm. pressure at 112°. The product so obtained had a melting point of 68.95°.

Ethyl Acetate.—Eastman Kodak Company best grade was distilled and the fraction between 77.00 and 77.18° was dried over phosphorus pentoxide for three weeks. It was then distilled in the Dufton column, the large fraction distilling between 77.14 and 77.16° being used.

Benzyl Benzoate.—This was fractionally distilled under reduced pressure. Attempts at distillation at ordinary pressure as recommended by Berkeley[12] resulted in slight cracking and so were abandoned. The melting point of each fraction was determined and the best fractions redistilled. The best fractions from this redistillation melted from 19.10 to 19.20° and these were used.

Data

Samples of the actual data obtained are given in Tables III and IV. These values of the pressure at different temperatures for each solution of fixed composition were plotted and a smooth curve drawn through the points. From this the pressures at 10° intervals were found and these are tabulated in Tables V, VI and VII under the corresponding compositions in mole per cent. In the row immediately below each value of the mole per cent. (N) is tabulated the value of the quantity 100 Δ defined by the equation

$$\Delta = (p/p_0) - N$$

Here p is the observed pressure at the mole per cent. in question and p_0 is the vapor pressure of the pure volatile component at the temperature concerned, as listed in the row marked 100 mole per cent. Δ is the difference between the mole fraction computed from Raoult's law and the actual composition of the solution and is a measure of the deviations from the law. These deviations are averaged for constant temperature in the last row at the bottom and for constant composition in the last column at the right of each table.

Before discussing the significance of the data a closer evaluation of the possible errors of the

method as a whole in the case of the solutions is desirable. Further errors in addition to those previously evaluated as inherent in the pressure and temperature measurements, are of two sorts. The first involves the assumption that the contribution to the observed pressure of the partial pressure of the benzyl benzoate or diphenyl is negligible. This is clearly the case for benzyl benzoate whose vapor pressure is below 0.5 mm. even at 95°. The case of diphenyl requires further consideration. The only vapor pressure data at low temperatures for diphenyl available in the literature are those quoted by Montillon, Rohrbach and Badger[13] for temperatures above 69.2°. From a smoothed curve through these values the following vapor pressures were found: 0.56 mm. at 70°, 1.3 mm. at 80°, 2.5 mm. at 90° and 3.3 mm. at 95°. These figures measure the es-

caping tendency of the pure diphenyl. Since the maximum concentration in the solutions is only 30 mole % diphenyl its escaping tendency will be materially lower in all cases. To attempt to estimate the actual partial pressures would beg the question at hand so that we will use the above figures to estimate the error due to the volatility of the diphenyl, realizing that they represent an extreme and improbable upper limit. At 50, 60, 70, and 80° this greatest possible contribution to the total pressure would be of the same order or less than the other errors in the method already discussed. At 90 and 95° the total pressure could be 0.4% greater than the partial pressure of benzene for the 30 mole per cent. diphenyl solution. These values could result in errors in the calculated mole per cent. of benzene from 0.2 to 0.3% at 90 and 95°. These estimates apply only to the highest diphenyl concentration at these temperatures. For all lower concentrations at these temperatures these greatest possible errors due to this cause would be materially smaller. Again it must be emphasized that these figures are based on the improbable premise that the partial pressure of diphenyl is the same from its 30 mole per cent. solution in benzene as its vapor pressure as a pure liquid.

The second type of errors are those due to the possible errors in the composition of the solution phase. The errors in weighing the components of a given solution were much less than one per mille and due precautions were taken that no serious loss of the volatile component occurred on transfer to the ebulliometer. This was weighed at the beginning and end of each run and only inappreciable losses in weight were found, indicating that the condenser was effectively stopping loss of the volatile component. Any possible error due to the segregation of a small, more or less constant fraction of the volatile component as it drained down from the condenser was minimized by the large volume of solution employed. The fact that reasonable differences in the rate of heating did not affect the boiling temperatures also indicated that any error due to such fractional condensation was small.

An over-all check on the reliability of the method was obtained by making two sets of duplicate runs with solutions of identical composition in which different pressures and temperatures were employed in each case. A sample of one pair of these runs is given in Tables III and IV together with the values of the pressures found independently from the smoothed curves for each run, for each 5° interval. The average discrepancy in the pressure readings for these two sets of duplicate runs was 1.0 mm. with one difference as great as 3 mm. These estimates indicate that the average error in terms of the pressures for these systems would be less than 2 mm. and that occasional errors of 3 mm. might occur. The presence of these errors could affect the values of p/p_0 by 1% or less on the average at the low pressures and by approximately 0.5 to 0.7% at the higher pressures. This might result in values of 100 Δ of these orders independent of any real deviation from Raoult's law. Furthermore, a very few values of 100 Δ of twice this amount might be expected. Examination of Tables V and VI indicates that the values of 100 Δ are on the whole less than these error limits would indicate. Therefore these two systems obey Raoult's law within the limits of error over the temperature and concentration ranges measured.

The deviations in the system ethyl acetate–benzyl benzoate as shown in Table VII are from two to three times greater than this experimental error and are all positive indicating a real, though small, positive deviation from Raoult's law in this system.

Discussion

Two assumptions are necessary for the derivation of Raoult's law on simple statistical grounds:[14] first, that the two molecular species have closely similar molecular fields and second, that they have the same size. In the system benzene–diphenyl the first of these conditions is fulfilled but not the second. Since benzyl benzoate contains the carbonyl and ether groups, both of which are polar and should have a different field than that of benzene, it might appear that neither of the conditions are fulfilled in the benzene–benzyl benzoate system. It is probable, however, that the major portion of the contacts with neighboring benzene molecules will be made by the phenyl rings and that these will shield the ester group and will to a large extent determine the character of the external molecular field of the molecule. Its field should thus be similar to that of the benzene.

The present measurements taken in conjunction with the solubility determinations of War-

---

[14] Hildebrand, THIS JOURNAL, **59**, 795 (1937).

ner, Scheib and Svirbely[15] and the freezing point determinations of Washburn and Reade[16] indicate that the system benzene–diphenyl approximates fairly closely to the ideal over a large range of temperature. Furthermore, determinations of the lowering of the freezing point of benzene by benzyl benzoate made by Kendall and Booge[17] indicate that the system benzene–benzyl benzoate remains approximately ideal at considerably lower temperatures than those of the present measurements.

The system ethyl acetate–benzyl benzoate shows small but definite positive deviations from Raoult's law which persist substantially unchanged over a considerable temperature range. Two factors appear to be of importance in this case. In the first place contacts will be largely between the alkyl groups of the ethyl acetate and the phenyl groups of the benzyl benzoate. It is probable that the fields of these would be dissimilar as the solubility[14] of diphenyl in heptane deviates greatly from the ideal. Second, the shielding of the polar ester group in ethyl acetate is less complete than in benzyl benzoate. It is probable that this group accounts for an appreciable portion of the attractive forces between ethyl acetate molecules themselves. When these are surrounded in part by benzyl benzoate molecules it would seem probable that the separation between the polar ester groups in the two molecules of unlike size would be greater and their mutual attractions smaller. As a consequence the ethyl acetate molecules would show a higher escaping tendency.

If this analysis of the situation in these systems is correct it would indicate that differences in the volume of the components of a system are of secondary importance as determining its deviation from Raoult's law in comparison with differences in the effective molecular fields. The effective fields will be those of the component atoms or groups in the molecules which are most frequently in contact.

Summary

The total vapor pressures of the systems benzene–diphenyl, benzene–benzyl benzoate and ethyl acetate–benzyl benzoate have been determined from 50 to 95° over limited ranges of concentration. The bearing of these measurements on the validity of Raoult's law as applied to these systems is discussed. The benzene–diphenyl and benzene–benzyl benzoate systems follow Raoult's law within the limits of the experimental error. The ethyl acetate–benzyl benzoate system shows deviations several times larger than the experimental error, indicating a slight, but real, positive deviation from Raoult's law.

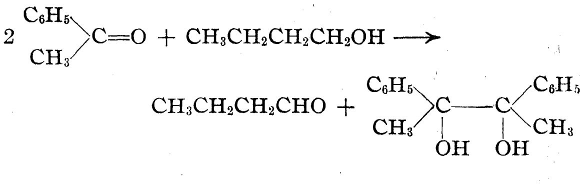
Photochemical Interaction between Ketones and Alcohols

BY CH. WEIZMANN, ERNST BERGMANN AND YEHUDA HIRSHBERG

Ciamician and Silber[1] were the first ones to observe that ketones and (primary or secondary) alcohols, under the influence of light, may undergo a process of mutual oxidation and reduction. But although the amount of available experimental material is not small,[2] the elementary photochemical processes, apparently, have not yet been elucidated. In connection with other experiments which will be referred to later on, we have started an investigation of the questions concerned, primarily of the reaction products in some typical cases

Acetophenone and butanol on irradiation with the mercury arc give the pinacol of the former substance, butanol being dehydrogenated to form butyraldehyde according to the scheme



$$2\,(C_6H_5)(CH_3)C{=}O + CH_3CH_2CH_2CH_2OH \longrightarrow CH_3CH_2CH_2CHO + (C_6H_5)(CH_3)C(OH){-}C(OH)(C_6H_5)(CH_3)$$

Fifty per cent. of the theoretical amount of the aldehyde could be traced by titration according

to Wagner.[3] It is interesting to note that both the diastereomerides of the pinacol, but to quite a different extent, are contained in surprisingly large yields in the solid product which is formed; their separation could be effected by fractional crystallization from light petroleum (b. p. 80–100°).

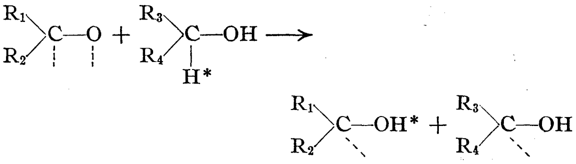
Acetophenone and cyclohexanol on irradiation gave the diastereoisomerides of acetophenonepinacol and cyclohexanone. Here, the cyclohexanone was determined in the mixture with excess cyclohexanol by Girard's reagent (trimethylammonium chloride acethydrazide)[4] which converts the ketone into a water-soluble, easily decomposable derivative. The amount of cyclohexanone found was as high as 80% of the theoretical yield.

In an analogous way acetophenone reacts with phenylmethylcarbinol to give the same mixture of pinacols. All these interactions parallel the known reaction between acetophenone and ethyl or isopropyl alcohol. In the same way, pinacol has been obtained from acetone and isopropyl alcohol.[2a]

The system cyclohexanone–cyclohexanol gives cyclohexanone pinacol only in poor yield. This substance[5] could not be obtained in an analytically pure state, but its identity has been proved by conversion into dicyclohexenyl.[6] Obviously, one cannot yet decide whether the above system is relatively inert or a complete exchange of two hydrogen atoms takes place, which would give again the original mixture of reactants.

Finally, the pair acetone–butanol was irradiated. Three substances have been isolated in pure state: two isomeric forms of *sym*-dipropylglycol, $C_3H_7CHOHCHOHC_3H_7$ (one liquid, one solid) as half-oxidation products of butyl alcohol and the trimeric form of butyraldehyde. In addition butyraldehyde and isopropanol were found in the first fractions of the reaction product. The question as to whether part of the acetone was converted into pinacol could not be decided, since no pure fraction consistent with its properties has been isolated. The balance of the concerned oxidation and reduction processes gave satisfactory results.

The characteristic feature of all these reactions is the reducing power of hydrogen H* on the carbon atom of a (primary or secondary) alcoholic group, $-CH^*OH$. That the hydrogen of the hydroxyl group itself is relatively insignificant may be concluded from the fact that ethers behave similarly toward ketones.[7] The primary step, however, in all these cases is most probably not the loosening of this hydrogen atom. This may be deduced from the following consideration. If irradiation would cause the loosening or dissociation of the C–H* bond—which is even for thermodynamical reasons highly improbable—then irradiation of an optically active secondary carbinol like phenylmethylcarbinol should lead to racemization, free radicals of the $C_6H_5CHCH_3$ type being configurationally unstable.[8] There is no change in rotation to be observed on irradiation of the optically active carbinol, but if a mixture of acetophenone and the carbinol is irradiated, the mixture of the epimeric acetophenone pinacols is found inactive, although one of them could have been formed in active state.[9] We therefore come to the conclusion that the first step in the irradiation of the above-discussed mixtures is the activation of the carbonyl compound, *e. g.*, leading to a diradical form.[10] This form reacts with the carbinol, splitting the C–H* bond and giving two radicals



which subsequently stabilize by symmetrical or unsymmetrical dimerization or by a second oxidation–reduction process. It is not easy to foresee which stabilization reaction will actually occur in a given case; here the relative stability of the intermediate radicals will play an important part.

It may well be that hemiacetal formation which takes place between carbonyl and hydroxyl compounds plays also a certain role in the course of the photocondensation, but it cannot be essential, since, according to the investigations of K. L.

Wolf and Herold,[11] some of our pairs of compounds are unable to form hemiacetals.

The photochemical mobilization of the hydrogen in an alcoholic group is of interest with regard to the mechanism of ergosterol irradiation. At variance with the assumption of Spring[12] that this important reaction involves primarily epimerization at C_3, Windaus and Dimroth[13] were able to demonstrate that the secondary hydroxyl group at C_3 is actually not influenced by irradiation, while in the presence of eosin, which acts as hydrogen "acceptor," the well-known conversion of ergosterol into ergopinacol occurs.[13b,14] This reaction, undoubtedly, is rather complex in nature but here too, the primary step appears to be the loosening of the H* atom in the secondary alcoholic group in the presence of the activated "acceptor" molecule.

Experimental Part

Acetophenone and Butanol.—The irradiation product was fractionated. In the first fraction (b. p. 110–120°) butyraldehyde has been determined, as described above. The main part of this fraction was unchanged butyl alcohol: 0.74 g. was heated with 1.93 g. of *p*-nitrophthalic anhydride and 5 cc. of toluene for twelve hours on the water-bath. The solid product was collected and recrystallized from 20% acetic acid: leaflets, m. p. 146°, which were identified by mixed melting point as butyl hydrogen *p*-nitrophthalate.

The second fraction (b. p. 80–110° at 20 mm.) consisted of acetophenone, the third one (b. p. 205–210° at 25 mm.) was a viscous oil, which crystallized immediately on trituration with light petroleum (b. p. 40–60°). The solid product on recrystallization from light petroleum (b. p. 80–100°) gave first prisms, m. p. 123°, which were identified as acetophenone pinacol[15] by mixed melting point and analysis. The mother liquor was treated with petroleum ether, and the precipitate (m. p. 85–95°) recrystallized from petroleum ether (m. p. 80–100°); diamond-shaped crystals, m. p. 122–123°. This substance was again identified as isomeric acetophenone pinacol[16] by mixed m. p. and analysis.

Cyclohexanone and Cyclohexanol.—After removal of cyclohexanone and cyclohexanol, a viscous residue was obtained, boiling at 130–131° (20 mm.), 90° (0.04 mm.). It was identified by analysis and conversion into dicyclohexenyl.[6]

Anal. Calcd. for $C_{12}H_{22}O_2$: C, 72.7; H, 11.0. Found: C, 72.5, 72.4; H, 10.2, 10.5.

Acetone and Isopropanol.—The pinacol formed distilled at 60–65° (2 mm.) and was identified as its crystalline hydrate, m. p. 50°.[17]

Acetone and Butanol.—The reaction product was divided into five fractions: (a) b. p. 50–70° (760 mm.) acetone. (b) b. p. 78–80° (760 mm.). This fraction contained 29.1% isopropanol, as found after oxidation with chromic acid by Messinger's method for the determination of acetone,[18] which would not be present in this fraction, and 45% butyraldehyde. (c) b. p. 95–120° (760 mm.). This fraction was mainly butyl alcohol, but still contained 2.7% isopropanol. (d) b. p. 110–115° (25 mm.). Liquid *sym*-di-*n*-propyl-glycol. *Anal.* Calcd. for $C_8H_{18}O_2$: C, 65.7; H, 12.3. Found: C, 65.2; H, 12.3. (e) b. p. 140–150° (25 mm.). This fraction immediately separated crystals, which could be isolated by trituration with ice-cold petroleum ether (b. p. 40–60°). From the same solvent leaflets, m. p. 121°, with some sublimation, were obtained. Analysis showed that this substance was a solid isomer of the foregoing one. *Anal.* Calcd. for $C_8H_{18}O_2$: C, 65.7; H, 12.3. Found: C, 65.0; H, 12.3.

The mother liquor of the crystals was again distilled *in vacuo*, the first portion being rejected as containing some more of the above crystals. The fraction b. p. 95° (0.3 mm.), $n^{11.5}D$ 1.4640, was analytically identified as *p*-butyraldehyde. *Anal.* Calcd. for $(C_4H_8O)_3$: C, 66.7; H, 11.1. Found: C, 66.4; H, 11.1.

Experiments with Optically Active Phenylmethylcarbinol.—An equimolecular mixture of phenylmethylcarbinol ($[\alpha]_D$ +23.6°) and acetophenone (2 g. of each) was irradiated for about two hundred hours with a small mercury arc lamp and the mixture gradually turned yellow. Fractionation gave a mixture of the unchanged reactants (1.2 g.; b. p. 40–60° at 0.04 mm.) and a residue which crystallized on trituration with light petroleum (2.57 g.) and could be identified by the method of fractional crystallization indicated above[1] as mixture of the two acetophenone pinacols. While this mixture was optically inactive, the rotation of the liquid fraction amounted to α_D 9.05°. Under the assumption that this liquid product was still an equimolecular mixture of acetophenone and phenylmethylcarbinol, the specific rotation of the latter substance would be $[\alpha]_D$ +18.1°.

Irradiation of pure phenylmethylcarbinol for about two hundred hours failed to produce an appreciable decrease in rotation (19.2 ⟶ 18.6°), only a slight yellowish discoloration taking place.

Summary

The irradiation of the following pairs of compounds has been studied: acetophenone–butanol, acetophenone–cyclohexanol, acetophenone–phenylmethylcarbinol, cyclohexanone–cyclohexanol, acetone–butanol.

Optically active phenylmethylcarbinol is not racemized by ultraviolet light, but in the presence of acetophenone an optically inactive product is formed.

An activated ketone molecule reacts with the

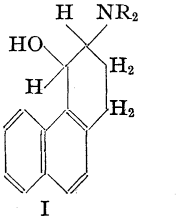
Studies in the Phenanthrene Series. XVII. Amino Alcohols Derived from 9-Hydroxy-1,2,3,4-tetrahydrophenanthrene[1]

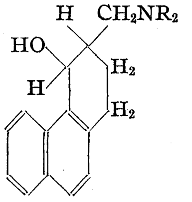
BY ALFRED BURGER

Some of the amino alcohols of types I and II derived from 1,2,3,4-tetrahydrophenanthrene[2] have been found to possess relatively favorable pharmacological properties.[3]

The 1,2,3,4-tetrahydroisoquinolino derivative of type I, for example, approaches codeine and pseudocodeine in analgesic action. The corresponding derivative of type II is weaker in analgesic effect, but does not exhibit any convulsant and emetic action. In morphine, the phenolic hydroxyl group is undoubtedly an important factor influencing the high analgesic effect of this alkaloid,[4] and therefore it appeared desirable to synthesize amino alcohols of types I and II carrying a phenolic hydroxyl group in one of the aromatic nuclei. The synthesis of the first group of amino alcohols with these structural features was planned as shown.

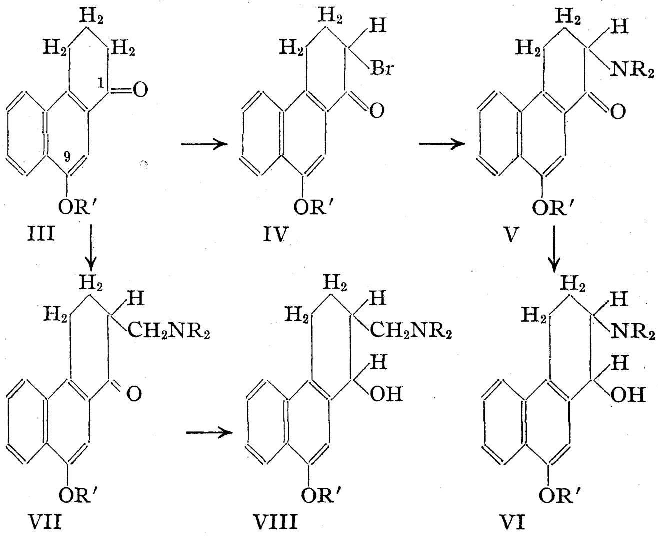


I



II

The starting materials for these syntheses, III (R′ = H, CH$_3$, CH$_3$CO) are relatively easily accessible.[5]



The preparation of IV (R′ = H, CH$_3$) did not offer any difficulties; only monobromo compounds were obtained. Attempts to exchange the bromine atom in IV (R′ = H) with secondary amines were without success. With R′ = CH$_3$, however, the reaction resulted in the expected amino ketones in yields that varied according to the secondary amine used. With piperidine the corresponding amino ketone V (R$_2$ = C$_5$H$_{10}$) was obtained in a yield of about 60%, while 1-hydroxy-9-methoxyphenanthrene appeared as a by-product. When diethylamine was used the amino ketone was formed in yields of about 30%; in this instance the formation of 1-hydroxy-9-methoxyphenanthrene by loss of hydrogen bromide and subsequent aromatization seems to be a main reaction, perhaps accompanied by the simultaneous formation of III.[6]

Unfortunately, catalytic hydrogenation under various experimental conditions did not furnish the corresponding amino alcohols VI, since the hydrogen absorption would not stop at this stage.

[6] Compare footnotes 5 and 6 of Ref. 2a.

An excess of one to four moles of hydrogen was absorbed, and it was impossible to isolate any homogeneous reaction products.

The amino ketones of type VII were obtained by the Mannich method[7] in yields varying from 20–70%, depending on the nature of NR_2 and R′ (CH_3 or CH_3CO). Catalytic hydrogenation yielded the corresponding amino alcohols VIII. In each case only one of the two possible diastereoisomeric forms was obtained.

Further experiments that should lead to isomeric phenolic amino alcohols of types VI and VIII are in progress.

Experimental Part

Derivatives of 1-Keto-9-hydroxy-1,2,3,4-tetrahydrophenanthrene.—The reduction of β-[1-(4-methoxynaphthoyl)]-propionic acid[8] was carried out by the technique of Martin.[9] Five per cent. of glacial acetic acid by volume was added to the reaction mixture.[10] Commercial mossy zinc proved to be superior to other grades. The properties of the γ-[1-(4-methoxynaphthyl)]-butyric acid, obtained in a yield of 50%, agreed with those described by Martin[9] and by Kon and Ruzicka.[5]

It was hoped that the yield of the butyric acid derivative could be improved by reducing the methyl ester of β-[1-(4-methoxynaphthoyl)]-propionic acid catalytically. This ester was prepared from the acid with diazomethane in ether solution, or by the action of dimethyl sulfate in sodium hydroxide solution. It was recrystallized from dilute methanol, giving colorless needles, m. p. 42–43°.

Anal. Calcd. for $C_{16}H_{17}O_4$: C, 70.29; H, 6.28. Found: C, 70.46; H, 5.96.

In alcoholic solution, using a 16% palladium–charcoal catalyst, this ester absorbed more than two moles of hydrogen very slowly. Forty per cent. of the starting material was recovered unchanged, and the remaining acid, obtained by saponification of the mother liquors, was oily.

Hydrogen under high pressure at 100° in the presence of a chromite catalyst did not attack the ester in four hours. In other experiments (156, 185 and 210° for six hours, respectively) a mixture was obtained that melted from 104–108°. Repeated crystallization from methanol raised the m. p. to 120–122°. This substance appears in colorless leaflets, but is not entirely pure. Its behavior in alkaline solution and its analyses indicate that it represents a methoxytetrahydronaphthyl-γ-butyrolactone. No further efforts in this direction were made.

1 - Keto - 9 - acetoxy - 1, 2, 3, 4 - tetrahydrophenanthrene.—Ten grams of 1-keto-9-hydroxy-1,2,3,4-tetrahydrophenanthrene[5] was allowed to react with acetic anhydride (15 ml.) in pyridine solution (30 ml.) for forty-eight hours. Large crystals separated and were filtered. The mother liquor was evaporated in a vacuum, and the residue was combined with the crystals. The product was purified by distillation in a high vacuum, and recrystallization.

1 - Keto - 2 - bromo - 9 - methoxy - 1,2,3,4 - tetrahydrophenanthrene.—Ten grams of 1-keto-9-methoxy-1,2,3,4-tetrahydrophenanthrene was dissolved in 250 ml. of absolute ether, and 2.4 ml. of bromine was added. Two milliliters of a saturated ethereal solution of hydrogen chloride was added to initiate decoloration which was complete after about five minutes. The bromo ketone crystallized out, was filtered, washed with methanol and water, and purified by crystallization.

1 - Keto - 2 - diethylamino - 9 - methoxy - 1,2,3,4 - tetrahydrophenanthrene.—Eight grams of 1-keto-2-bromo-9-methoxy-1,2,3,4-tetrahydrophenanthrene was boiled under reflux with 20 g. of diethylamine in 80 ml. of benzene for five hours. A crystalline precipitate separated out after some time. Water was added to the reaction mixture, and the free diethylamino ketone was obtained by the addition of alkali to the aqueous solution. The crude diethylamino ketone melted at 90–95°. It was converted to the hydrochloride in acetone solution. From the benzene layer, 1-hydroxy-9-methoxyphenanthrene was obtained as described below.

1 - Hydroxy - 9 - methoxyphenanthrene.—The benzene layer (see above) was evaporated in a vacuum, and the residue was boiled with a 5% methyl alcoholic potassium hydroxide solution for ten minutes. The solvent was evaporated in a vacuum, the residue was dissolved in water and the filtered solution was acidified. The 1-hydroxy-9-methoxyphenanthrene precipitated as an oil which soon solidified (1.9 g.). It was purified by distillation in an oil-pump vacuum and crystallization from benzene–petroleum ether. Colorless needles were obtained, m. p. 131–132°.

Anal. Calcd. for $C_{15}H_{12}O_2$: C, 80.32; H, 5.40. Found: C, 80.76; H, 5.66.

1-Acetoxy-9-methoxyphenanthrene.—One and nine-tenths grams of 1-hydroxy-9-methoxyphenanthrene was boiled with 30 ml. of acetic anhydride and 2 g. of anhydrous sodium acetate for three hours. The mixture was decomposed with water, and the acetylation product was purified by distillation at 5 mm. pressure and crystallization from alcohol; fine, colorless needles, m. p. 154.5–155.5°; yield 2 g.

Anal. Calcd. for $C_{17}H_{14}O_3$: C, 76.66; H, 5.30. Found: C, 76.52; H, 5.04.

Attempts to oxidize this compound to 1-acetoxy-9,10-phenanthrenequinone failed.

1,9-Dihydroxyphenanthrene.—One part of 1-acetoxy-9-methoxyphenanthrene was boiled under reflux with twenty parts of a mixture of 48% hydrobromic acid and glacial acetic acid (1:1) for one hour. The reaction mixture was poured into water, and a pink crystalline precipitate separated out. It was dissolved in cold dilute potassium hydroxide solution which contained some sodium sulfite. The dihydroxy compound obtained by acidification was purified by distillation in a high vacuum and recrystallization from benzene. The compound was obtained as light brown plates which sinter at 181° and melt at 184–185° (evac. tube).

[a] Bromination of 1-keto-9-hydroxy-1,2,3,4-tetrahydrophenanthrene was carried out as in the case of no. 2. A mixture of chloroform and ether (5:1) was used as a solvent. The bromo compound turned dark at 190°, the light color returned at 210° and the sample did not melt below 330°. [b] Prepared analogously to no. 4. The free piperidino ketone, prepared from the hydrochloride, was recrystallized from methanol: brown needles which darken rapidly in air, m. p. 112–113°. Also in this case, 1-hydroxy-9-methoxyphenanthrene was obtained as a by-product in the preparation of the piperidino ketone. [c] Prepared from the free base with ethereal perchloric acid. [d] After drying at 100° in a high vacuum. [e] Prepared from no. 12 with dilute ammonium hydroxide solution. [f] Prepared by making the acid mother liquors of the crude no. 15 alkaline with sodium bicarbonate solution and extraction into ether. The pure substance melted at 195–196° (decomp.) in an open tube. Methylation with diazomethane in alcohol–ether solution yielded the methyl ether, m. p. 129–131°, identical (mixed m. p.) with no. 8. [g] One part of no. 13 was heated with 3 parts of an 8% methyl alcoholic potassium hydroxide solution for a few minutes, the solution was diluted with water and acidified with hydrochloric acid. The tarry hydrochloride precipitated out. It was separated from the mother liquor by decanting, and it crystallized on treatment with acetone. [h] The mother liquors from the preparation of this salt contained dark basic and non-basic by-products of elevated m. p.

Anal. Calcd. for $C_{14}H_{10}O_2$: C, 79.97; H, 4.80. Found: C, 80.13; H, 5.08.

1,9-Diacetoxyphenanthrene.—A sample of 1,9-dihydroxyphenanthrene was allowed to react with acetic anhydride in pyridine solution overnight. The diacetoxy compound was purified by distillation in the vacuum of an oil pump and crystallization from dilute alcohol, resulting in fine, colorless needles, m. p. 154–155°.

Anal. Calcd. for $C_{18}H_{14}O_4$: C, 73.44; H, 4.80. Found: C, 72.87; H, 4.80.

1,9-Dimethoxyphenanthrene.—One and six-tenths milliliters of dimethyl sulfate was added dropwise to a mixture of 0.3 g. of 1-hydroxy-9-methoxyphenanthrene, 1.45 ml. of 60% potassium hydroxide solution and 10 ml. of acetone, with vigorous stirring in the course of ten minutes.[11] After another ten minutes, the dimethoxy compound was precipitated with water and purified by distillation in an oil-pump vacuum and crystallization from methanol; colorless oblong plates resulted, m. p. 113–114°. The yield was nearly quantitative.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.63; H, 5.93. Found: C, 80.68; H, 6.38.

Preparation of Amino Ketones by the Mannich Reaction.—One mole of 1-keto-9-methoxy- or 1-keto-9-acetoxy-1,2,3,4-tetrahydrophenanthrene was boiled with 1.2 to 1.4 moles of the hydrochloride of the respective secondary amine and 3 moles of para-formaldehyde in 4 to 7 parts of isoamyl alcohol for four to five minutes. The hydrochlorides of the amino ketones precipitated as oils on addition of ether. These oily salts either solidified and could be filtered out, or, as in the case of the easily soluble diethylamino derivatives, they were extracted into water. The amino ketones were liberated and purified by crystallization or by conversion to a crystalline salt. The hydrochlorides of the less soluble amino ketones often can be separated from some unchanged hydrochloride of the respective secondary amine by their insolubility in cold water. Washing with acetone frequently removes colored impurities.

Preparation of Amino Alcohols.—The hydrochlorides of the amino ketones were hydrogenated, using a platinum oxide catalyst in methanol solution. One mole of hydrogen was absorbed in two to sixteen hours. The catalyst was filtered, and the solution concentrated in a vacuum. The hydrochlorides of the amino alcohols crystallized directly from the solution, or after addition of ether, and were purified by recrystallization.

The acetyl derivatives of the amino alcohols were obtained by allowing the free alkamines or their hydrochlorides to react with acetic anhydride in pyridine solution overnight. The solutions were then evaporated in a vacuum and the acetyl derivatives were converted into the hydrochlorides in the usual way.

Oxime of 1-Keto-9-methoxy-1,2,3,4-tetrahydrophenanthrene.—Ten grams of 1-keto-9-methoxy-1,2,3,4-tetrahydrophenanthrene, 6 g. of hydroxylamine hydrochloride, and 7.5 g. of barium carbonate in 170 ml. of alcohol were boiled for four hours. The barium salts were filtered from the hot solution, and the oxime was allowed to crystallize from the filtrate; yield, 9.7 g. of shining needles (from alcohol), m. p. 174–175°.

Anal. Calcd. for $C_{15}H_{15}NO_2$: N, 5.81. Found: N, 6.08.

1 - Amino - 9 - methoxy - 1, 2, 3, 4 - tetrahydrophenanthrene.—A solution of 9.5 g. of the oxime of 1-keto-9-methoxy-1,2,3,4-tetrahydrophenanthrene in 500 ml. of moist ether was allowed to react with 30 g. of aluminum amalgam for forty-eight hours. The mixture was filtered and the aluminum sludge was washed repeatedly with warm ether. The ethereal solution was extracted with dilute hydrochloric acid. An insoluble yellow hydrochloride (5.8 g.) precipitated and was filtered off. The clear aqueous solution was made alkaline, the oily amine was extracted into ether, and converted to the hydrochloride (1.1 g.) in the customary way. It was recrystallized from methanol as colorless needles, m. p. 291° (dec., evac. tube).

Anal. Calcd. for $C_{15}H_{18}ClNO$: C, 68.28; H, 6.88; N, 5.31. Found: C, 68.42; H, 7.39; N, 5.33.

The insoluble hydrochloride could be recrystallized from 400 parts of alcohol. It appeared as a poorly crystalline material that turned yellow on drying.

Summary

The synthesis of several tertiary 1-hydroxy-2-aminomethyl - 1, 2, 3, 4 - tetrahydrophenanthrenes, carrying in position 9 a phenolic hydroxyl, a methoxy or acetoxy group, is described. A number of derivatives of 1,9-dihydroxyphenanthrene were obtained from 1-hydroxy-9-methoxyphenanthrene, which is formed in a side reaction in the exchange of the bromine atom of 1-keto-2-bromo-9-methoxy-1,2,3,4-tetrahydrophenanthrene with secondary amines.

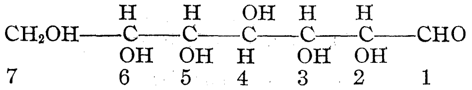
A Suggestion for Naming the Higher Carbon Sugars[1]

By C. S. Hudson

When the initial syntheses by Emil Fischer of higher carbon aldoses in the heptose, octose and nonose series were in progress it became necessary to name the new sugars by some general plan. He named them (1) according to the hexose from which they were made (D-gluco, D-manno, D-gala, etc.) and (2) according to the number of carbon atoms in the sugar chain (heptose, octose, nonose); such is the historical origin of the names D-glucoheptose, D-galaoctose, etc.[2] Since the cyanohydrin synthesis yields two D-glucoheptoses from D-glucose, it was necessary for Fischer to distinguish between them, which he did later[3] by the provisional symbols α and β, given empirically in the order of isolation. Subsequently Philippe[4] synthesized several more of the higher carbon sugars obtainable from D-glucose and found it necessary in the octose and higher series to expand the α and β naming; in consequence certain sugars today are designated D-α,α,α- and D-α,α-β-glucononose; indeed theory predicts eight as the number of aldononoses obtainable from D-glucose and by present usage they are to be distinguished by the eight possible arrangements of α and β in a three-membered term. Fischer[5] also distinguished the two forms of methyl-D-glucoside (now known to be the pyranosides[6]) by the designations α and β, assigned empirically, and today this latter use has become universal for the ring forms of the sugars and their derivatives because in a large number of cases the designations have been correlated with the stereostructures according to the plan of nomenclature that the writer proposed in 1909.[7] It can hardly be questioned that the provisional naming of higher carbon sugars by the symbols α and β and combinations of them, given empirically, should at some stage of progress be replaced by a plan that names these sugars according to their configurations. This could not be done by Fischer nor by Philippe, because only two of the configurations were then known in full (the two D-glucoheptoses). Later the configurations of the two D-mannoheptoses, the two D-galaheptoses and two of the D-mannooctoses were established by Peirce,[8] and those of the two D-guloheptoses by LaForge.[9] The discovery of several independent rules of rotation correlating direction of rotation with configuration has supplied a simple way of learning the configurations of the remaining higher carbon sugars, and these methods have been applied to D-gulomethylose[10] and to two of the D-glucooctoses[11] and D-galaoctoses[12]; thus today we know the configurations of fourteen of the higher carbon aldoses (and two of the higher carbon aldomethyloses) and possess simplified methods for determining the configurations of all the others. Would it not be well therefore to introduce some new plan for naming higher carbon sugars of known configuration by which the name of the sugar will indicate its configuration with the minimum burden upon the memory? One might give configurational definition to the terms α and β, which would be the least possible change from the present names, but this would continue the present very confusing use of these symbols in two senses in the same name, for example, α-D-α-glucoheptose. The writer has been using for about twelve years in unpublished notes a system which avoids this confusion and, as some colleagues have looked upon it with favor, it is here published.

Consider the sugar that is now known as D-α-glucoheptose.



$$\begin{array}{lcccccc} & \mathrm{H} & \mathrm{H} & \mathrm{OH} & \mathrm{H} & \mathrm{H} & \\ \mathrm{CH_2OH}— & \mathrm{C}— & \mathrm{C}— & \mathrm{C}— & \mathrm{C}— & \mathrm{C}— & \mathrm{CHO} \\ & \mathrm{OH} & \mathrm{OH} & \mathrm{H} & \mathrm{OH} & \mathrm{OH} & \\ 7 & 6 & 5 & 4 & 3 & 2 & 1 \end{array}$$

D-α-Glucoheptose (D-Gluco-D-gulo-heptose)

It is made from D-glucose and its asymmetric carbon atoms 6, 5, 4 and 3, reading from the left, have the configuration that is carried over from D-glucose. Now read the configurations of carbon atoms 2, 3, 4 and 5 from the right; they are

the same as in D-gulose. This is more than a formal analogy because it is known from many examples that the higher carbon sugars have properties closely resembling those of the hexoses of like configuration for carbon atoms 2, 3, 4 and 5. It is suggested therefore that the sugar be named D-gluco-D-gulo-heptose. This name defines the configuration unequivocally, indicates that the sugar is made from D-glucose and reminds one that it may be expected to resemble D-gulose in properties.[13] Although the prefix gulo- does not require the D-symbol, since the D-gluco term is not compatible with an L-gulo term in a heptose, octose or nonose, it seems preferable to retain it because of its plain expression of the fact that the heptose resembles D- rather than L-gulose. Most of the higher carbon sugars of known configuration are listed below with the designation of the proposed new name, following the system just described.

The names of derivatives are readily formed in the usual way, for example: D-gala-L-gala-octitol, octopyranoside, octonic and octaric acids, octal, octosazone, etc.

In Fischer's era rhamnose and fucose were designated substituted pentoses (substitution of methyl for a hydrogen atom directly attached to

---

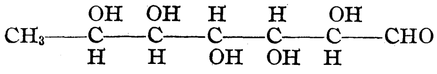
[13] I considered years ago the name D-glycero-D-gulo-heptose as an alternative for D-gluco-D-gulo-heptose, but discarded it in favor of the name that specifically indicates the hexose from which the higher carbon sugar is prepared.

[14] The D-guloheptoses were named by their discoverer (LaForge[9]) α and β as here written; LaForge proved their configurations by showing that D-α-guloheptitol is identical with D-β-galaheptitol. Isbell [*J. Research Nat. Bur. Standards*, **19**, 639 (1937)] recently has proposed reversal of the symbols in a plan which gives configurational definition to α and β; the disadvantage of this plan already has been mentioned.

[15] This configuration follows from the observation by George Peirce[8] that the sodium salt of D-manno-L-manno-octaric acid is optically inactive, but obviously it needs substantiation. The corresponding D-manno-L-manno-octitol was crystallized by Fischer and Passmore [*Ber.*, **23**, 2226 (1890)] but there is no mention of a rotatory measurement; the substance is probably inactive in accordance with the above provisional configuration of the sugar. We expect to be able to present data soon that will permit decision regarding the formula.

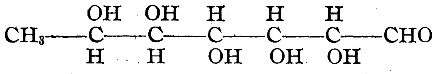
the carbon atom of the terminal group CH_2OH), a usage which persists in the class name methylpentose; the practice is now becoming general to consider them as 6-desoxyhexoses, under the class name methylose,[16] with an appropriate prefix to designate the configuration. Thus natural rhamnose is L-mannomethylose and natural fucose is L-galamethylose (or L-galactomethylose, if one chooses to use the full prefix). By combining this plan of nomenclature with that which is suggested in this article, the two 7-desoxyheptoses whose configuration is known may be given the following systematic names.

METHYLO-HEPTOSES[17] (OR 7-DESOXYHEPTOSES)



$$CH_3-\underset{H}{\overset{OH}{C}}-\underset{H}{\overset{OH}{C}}-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{OH}{C}}-CHO$$

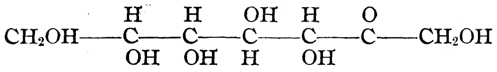
(α-L-Rhamnohexose of Fischer)
L-Manno-L-gala-methylo-heptose



$$CH_3-\underset{H}{\overset{OH}{C}}-\underset{H}{\overset{OH}{C}}-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-CHO$$

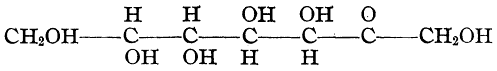
(β-L-Rhamnohexose of Fischer)
L-Manno-L-talo-methylo-heptose

The 2-ketoheptoses need to carry the name of the appropriate hexose only; the five known ketoheptoses are the following



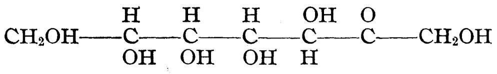
$$CH_2OH-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{OH}{C}}-\underset{OH}{\overset{H}{C}}-\overset{O}{C}-CH_2OH$$

D-Glucoheptulose[18]
(Its mirror image is L-Glucoheptulose)[19]



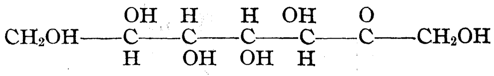
$$CH_2OH-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{OH}{C}}-\underset{H}{\overset{OH}{C}}-\overset{O}{C}-CH_2OH$$

D-Mannoheptulose
(Originally named D-Mannoketoheptose)[20]



$$CH_2OH-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{OH}{C}}-\overset{O}{C}-CH_2OH$$

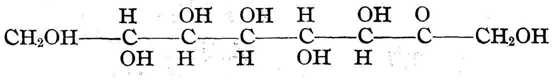
D-Altroheptulose[21]
(Originally named Sedoheptose)[22]



$$CH_2OH-\underset{H}{\overset{OH}{C}}-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{OH}{C}}-\overset{O}{C}-CH_2OH$$

L-Galaheptulose[23]
(Originally named Perseulose)[24]

Beginning with the 2-keto-octoses, of which none are now known, prefixes of two hexoses would be required, leading for example to the unequivocal name D-gala-L-gluco-octulose for a ketose of the configuration



$$CH_2OH-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{OH}{C}}-\underset{H}{\overset{OH}{C}}-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{OH}{C}}-\overset{O}{C}-CH_2OH$$

In designating the α- and β-forms of ring derivatives (*e. g.*, the methyl glycosides) it seems to the writer advisable to follow the simplest rule that is adequate, which is to name the more dextrorotatory member of a pair in the D-sugar series as α (or, in full, α-D-); its enantiomorph is an α-L-form, which represents the more levorotatory member of a pair in the L-sugar series. I made this suggestion in 1909 and it has been generally adopted, but there recently has come from Isbell[25] the proposal to modify it and to reverse the α-β- naming in the arabinose and fructose series, and in a recent article Schlubach and Graefe[26] question the naming of a certain new methyl sorboside as an α-L-form because it closely resembles in certain peculiarities a β-D-methylfructoside. The recent experimental work of Jackson and Hudson[27] in correlating the configurations of carbon atom 1 in many of the aldohexopyranosides, aldopentopyranosides and an aldopentofuranoside furnishes proof of stereostructures which confirm in all cases the nomenclature that I originally proposed. The system of naming α- and β-methyl glycosides, etc., is best understood if one writes the skeleton stereostructures for the rings. The pyranoid forms are derived from the structures (I) and (II), as proved by Jackson and Hudson.

---

(16) Votoček, *Bull. soc. chim.*, **43**, 18 (1928).

(17) The order methylo-heptose seems preferable to heptomethylose because, as pointed out in an analogous case by Freudenberg and Raschig [*Ber.*, **62**, 376 (1929)], hepto-methylosazone is an ambiguous name since it can apply to either the phenylosazone of a hepto-methylose or the methyl phenylosazone of a heptose; methylo-heptosazone is not ambiguous. To overcome the objection raised by Freudenberg and Raschig in the case of the name altro-methylose, it may be well to use altro-methylohexose instead. Rhamnose would then be L-manno-methylohexose and its osazone would be L-manno-methylo-hexosazone. The ambiguity could also be avoided by naming osazones with two words (*e. g.*, altromethylose osazone), as is in fact often done, especially with osazones from substituted phenylhydrazines.

(18) Austin, This Journal, **52**, 2106 (1930).

(19) Bertrand and Nitzberg, *Compt. rend.*, **186**, 925, 1172 (1928).

(20) LaForge, *J. Biol. Chem.*, **28**, 511 (1917).

(21) Ettel, *Collection Czechoslov. Chem. Communications*, **4**, 504, 513 (1932).

(22) LaForge and Hudson, *J. Biol. Chem.*, **30**, 61 (1917).

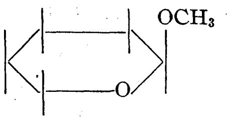
(23) This configuration for perseulose was made highly probable by LaForge;[20] definitive proof has been established recently by Raymond M. Hann and the writer and it will be published shortly.

(24) Bertrand, *Compt. rend.*, **147**, 201 (1908); **149**, 225 (1909).

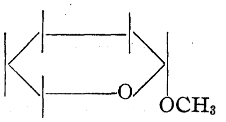
(25) Isbell, *J. Chem. Ed.*, **12**, 96 (1935); *J. Research Nat. Bur. Standards*, **18**, 505 (1937). Isbell appears to have considered only the pyranoid ring forms; if his plan were adopted it would require that in aldohexoses having *cis-trans* configuration for the hydroxyl groups on carbon atoms 4 and 5 (galactose, talose, gulose and idose) a pyranoside would be named α in the D series if it is the more dextrorotatory member of a pair, but a furanoside that is the more dextrorotatory member of its pair would have to be named a β-D-form, which seems objectionable; with septanosides and with tetrofuranosides it is not clear how one would name them by Isbell's plan. I warn against the confusion that must ultimately result if Isbell's modification of my simple, generally applicable rule is followed.

(26) Schlubach and Graefe, *Ann.*, **532**, 211 (1937).

(27) Jackson and Hudson, This Journal, **59**, 994 (1937).

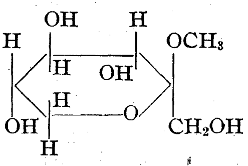


(I) $\left.\begin{matrix}\alpha\text{-D-}\\ \beta\text{-L-}\end{matrix}\right\}$ Methyl glycosides
(C_1 is dextrorotatory)

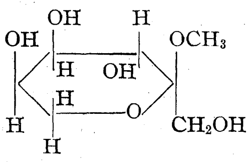


(II) $\left.\begin{matrix}\beta\text{-D-}\\ \alpha\text{-L-}\end{matrix}\right\}$ Methyl glycosides
(C_1 is levorotatory)

These skeleton structures permit one to write the stereo pyranoid formulas for any given case from the name of the substance; formula (I) pertains to α-D- and β-L-forms, where C_1 is dextrorotatory, and formula (II) to β-D- and α-L-forms, where C_1 is levorotatory. Thus the formulas for the methyl pyranosides of L-sorbose and D-fructose that were discussed by Schlubach and Graefe[26] take the forms (III) and (IV)

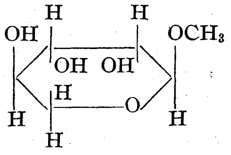


(III) β-Methyl-L-sorbopyranoside

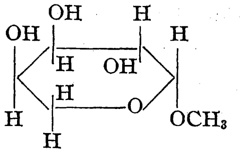


(IV) α-Methyl-D-fructopyranoside

and their close stereo similarity is apparent; their only difference is in respect to the configuration of their carbon atom 5, and it is to be concluded that their common peculiar behavior is independent of the stereo form of this particular carbon atom. The following is an interesting case in this connection. In acid methyl alcoholic solution D-lyxose finally reaches equilibrium when its α-methyl pyranoside is the predominating substance; under like conditions D-arabinose forms its β-methyl pyranoside principally; the stereo formulas (V) and (VI) show that the stereo form of carbon atom 3 for these substances has a great influence upon the stability of the grouping on carbon atom 1. The same influence from carbon atom 3 is noticed in the configurations of the more stable forms of the acetohalogen sugars and the fully acetylated forms, of ring configuration.

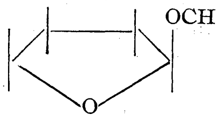


(V) α-Methyl-D-lyxopyranoside

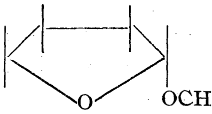


(VI) β-Methyl-D-arabinopyranoside

The skeleton formulas for the furanoid ring are (VII) and (VIII), as proved by Jackson and Hudson.

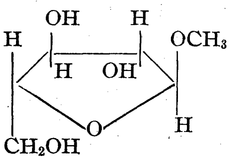


(VII) $\left.\begin{matrix}\alpha\text{-D-}\\ \beta\text{-L-}\end{matrix}\right\}$ Methyl glycosides
(C_1 is dextrorotatory)

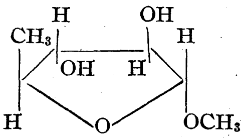


(VIII) $\left.\begin{matrix}\beta\text{-D-}\\ \alpha\text{-L-}\end{matrix}\right\}$ Methyl glycosides
(C_1 is levorotatory)

The known[28] α-methyl-D-arabinofuranoside is written as (IX) and the known[29] α-methyl-D-arabinomethylopentoside as (X); it is seen that closely approach mirror-image forms, which accounts for their opposite signs and near magnitudes of rotation.



(IX) α-Methyl-D-arabinofuranoside ($[\alpha]_D$ + 123)



(X) α-Methyl-L-arabinomethylopentoside ($[\alpha]_D$ −129)

Lastly, the skeleton formulas for the septanoid ring glycosides, etc., obviously are to be written in similar conventional form; detailed examples may be omitted.

---

Summary

It is proposed to abandon the use of the symbols α and β as parts of the actual names of the higher carbon sugars and to designate these by the abbreviated names of two hexoses, one of which indicates the hexose that is used in the synthesis and the other of which shows the hexose that the new sugar resembles in its ring configurations. Examples are shown for the proposed names and for the use of the symbols α and β in designating the stereostructures of the pyranoid, furanoid and septanoid ring forms.

WASHINGTON, D. C. RECEIVED MARCH 3, 1938

[CONTRIBUTION NO. 239, DEPARTMENT OF CHEMISTRY, KANSAS STATE COLLEGE]

The Reaction of Kojic Acid with Aldehydes[1,2]

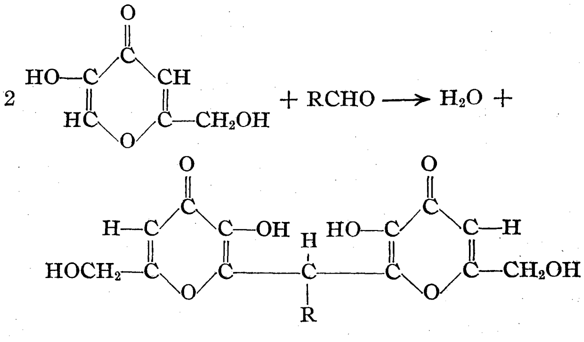
BY H. N. BARHAM AND G. NATHAN REED

Kojic acid, 2-hydroxymethyl-5-hydroxy-γ-pyrone, was first obtained by Saito[3] in a culture of *Aspergillus oryzae* grown upon steamed rice. Since then it has been found to be produced when different species of *Aspergilli* are grown upon a variety of organic substances.[4] The acid used in this research was produced in the laboratories of Kansas State College by the growth of *Aspergillus flavus* upon a glucose medium.

While investigating the properties of kojic acid it was observed that a solid reaction product was obtained readily with formaldehyde. This reaction was extended to other aldehydes until a series of solid derivatives was obtained which included derivatives from all of the normal, saturated, aliphatic aldehydes up to heptaldehyde, as well as acrolein, benzaldehyde, hydrocinnamaldehyde, cinnamaldehyde, and α-furfuraldehyde.

An investigation of these derivatives was made in order to establish their constitution. The molar quantities involved in their preparation, together with other quantitative data, indicated that the products were formed by the elimination of one molecule of water from two molecules of kojic acid and one molecule of aldehyde. The aldehyde products gave red colorations with ferric chloride, could be titrated with standard alkali and formed insoluble copper salts which contained the calculated per cent. of copper. Upon treating with thionyl chloride, chloro compounds were formed which could be produced also by the reaction of the corresponding aldehydes with 2-chloromethyl-5-hydroxy-γ-pyrone (obtained from kojic acid with thionyl chloride). Acetate esters were prepared and when hydrolyzed gave acetyl values corresponding to four hydroxyl groups per molecule. Attempts to hydrolyze the aldehyde products with dilute acid or alkali were unsuccessful. When the aldehyde products were treated with phenyldiazonium chloride and the resulting mixture neutralized with alkali, colored compounds were produced which appeared to be unstable diazonium salts of the phenolic hydroxyls. Under similar conditions, kojic acid coupled with phenyldiazonium chloride to form a stable dye.

It was concluded, therefore, that these aldehyde products were formed according to the equation



Experimental Data

Reagents.—The crude kojic acid obtained by concentrating the fermentation liquor was recrystallized twice from water, using Norite in the first recrystallization to decolorize the solution. The final purification was accomplished by chilling hot alcoholic solutions with rapid stirring. Prepared in this manner, the acid was obtained as fine, light cream-colored needles of m. p. 152–153°.

The formaldehyde used was a U. S. P. formalin solution. The other aldehydes were Eastman preparations.

(4) A critical review of the literature upon kojic acid was made by Barham and Smits, *Trans. Kansas Acad. Sci.*, **37**, 91–113 (1934).

Preparation of the Aldehyde Products.—Although in the preliminary study slightly better yields were obtained from the use of two mols of kojic acid for each mol of aldehyde, in the actual preparation equimolar proportions were used because the products obtained in this way were easier to purify. A typical reaction mixture contained 10 g. of kojic acid and an equivalent amount of aldehyde dissolved in 100 cc. of ethyl alcohol. One cc. of concentrated ammonium hydroxide was added as a catalyst. The reaction mixture was refluxed one hour and then placed in an electric air-oven at 60–65° for from two to forty-eight hours depending upon the aldehyde used. By attaching a long glass tube to the reaction flask and passing this through the vent in the top of the oven, evaporation was prevented and the heating could be continued as long as required. Following this period in the oven, the reaction mixture was poured into a crystallizing dish and concentrated by surface evaporation. The solid material which formed was removed by filtration, washed with a little alcohol, and dried in a desiccator under reduced pressure.

The reaction of kojic acid and the aldehydes was always accompanied by the formation of resinous material. The quantity produced was influenced decidedly by the solvent, the catalyst, and the temperatures employed. Formaldehyde and kojic acid gave good yields with water as the solvent if no ammonium hydroxide was added, but in the presence of this catalyst resin formation was dominant. The remaining aldehydes did not react in water solutions. Likewise, the crystalline products were not formed when alcoholic solutions were used without ammonium hydroxide. On the other hand, using alcoholic solutions and ammonium hydroxide, the presence of any appreciable concentration of water favored the formation of these resins. Furthermore, the quantity of this resinous material was increased by lengthening the period of heating, especially at the boiling point of the alcoholic solutions. The particular conditions described above were selected in order to reduce to a minimum the amount of these resinous substances in the crude products.

The lower aldehydes reacted readily. Among the higher aliphatic aldehydes, the rate of reaction was influenced by the length and character of the carbon chain—those with an even number of carbon atoms reacted more easily than those with an odd number. The yields were good in most instances. Benzaldehyde reacted readily, giving good yields. Hydrocinnamaldehyde was somewhat slower in action while cinnamaldehyde reacted very slowly. Furfuraldehyde reacted readily but gave only fair yields. Acrolein reacted with extreme difficulty and the yields were very poor.

Purification of the Products.—The crude reaction products were purified by extraction with boiling chloroform or by recrystallization from alcohol. In the latter case, the alcoholic solutions were chilled in a freezing bath of salt and ice while stirring vigorously to prevent supersaturation. Repeated extractions or recrystallizations were necessary to eliminate the greater portion of the contaminating resinous substances but it is believed that traces still remained in spite of continued effort to remove them.

Physical Properties of the Products.—The purified products are light cream-colored, powdery solids. They are practically insoluble in cold water, while their solubility in hot water decreases rapidly as the molecular weight increases. All are somewhat soluble in alcohol with a pronounced tendency to give supersaturated solutions. They are slightly soluble in methyl alcohol and acetone, much less soluble in chloroform, and apparently insoluble in ether, ligroin, benzene, toluene, and carbon tetrachloride. They are soluble in alkali but insoluble in acids. The melting points of the products are given in Table I.

TABLE I

MELTING POINTS OF PRODUCTS

Aldehyde used	M. p., °C. (corr.)
Formaldehyde	248.3–249
Acetaldehyde	211.2–212
Propionaldehyde	217.5–218
Butyraldehyde	192.4–193
Valeraldehyde	185.6–187.2
Capraldehyde	144–147
Heptaldehyde	152.6–153.6
Benzaldehyde	242.4, dec.
Hydrocinnamaldehyde	182–183.5
Cinnamaldehyde	175–176
α-Furfuraldehyde	210–211
Acrolein	About 250[a]

[a] Yield too small to purify and determine m. p. carefully.

Combustion Analysis.—The combustion analyses of the aldehyde products are given in Table II. The calculated values are for a product formed by two mols of kojic acid and one mol of aldehyde with the loss of one mol of water.

TABLE II

ANALYTICAL RESULTS BY COMBUSTION

Aldehyde product	Carbon, % Calcd.	Carbon, % Found		Hydrogen, % Calcd.	Hydrogen, % Found	
Formaldehyde	52.70	52.78	52.85	4.05	4.42	4.22
Acetaldehyde	54.19	54.28	54.16	4.51	4.80	4.67
Propionaldehyde	55.55	55.71	55.28	4.94	5.11	5.02
Butyraldehyde	56.81	56.99	56.92	5.33	5.61	5.61
Valeraldehyde	57.95	58.01	57.98	5.68	5.81	5.94
Heptaldehyde	59.99	60.12	60.82	6.32	6.58	6.69
Benzaldehyde	61.31	61.96	61.35	4.30	4.52	4.43
Hydrocinnamaldehyde	63.00	62.50	62.31	5.00	5.06	5.05
α-Furfuraldehyde	56.35	55.99	56.01	3.87	4.08	4.04

Chemical Properties of the Products.—The aldehyde products gave a red coloration with ferric chloride. The intensity of the color produced decreased as the molecular weight increased, as would be expected from the solubilities. The products reacted readily with alkali and it is believed that they could be titrated with 0.1 N sodium hydroxide if an indicator were used which changed color at a pH of about 12. When the products were dissolved in standard alkali, back titrated with acid until neutral to phenolphthalein, and treated with an excess of copper acetate, insoluble copper salts were precipitated. These salts were analyzed for copper by igniting to copper oxide. The results given in Table III are for 1-g. samples of the aldehyde products and the calculated values are for products containing two phenolic hydroxyls and resulting from the reaction of two mols of kojic acid with one mol of aldehyde through the loss of one mol of water.

TABLE III

COPPER CONTENT

Product	Copper, % Calcd.	Copper, % Found
Formaldehyde	17.785	17.690
Acetaldehyde	17.115	17.084
Propionaldehyde	16.494	16.675
Butyraldehyde	15.916	16.090
Heptaldehyde	14.403	14.370
Benzaldehyde[a]	14.668	16.550

[a] Copper precipitate brownish in color and obviously contained some reduced copper.

The kojic acid–aldehyde products reacted readily with thionyl chloride. The unchanged thionyl chloride was removed from the reaction mixture with petroleum ether and the derivatives recrystallized from water. These derivatives did not show the presence of ionizable halogen but a sodium fusion revealed the presence of organic halogen. The chloro compound prepared in this manner from the butyraldehyde product melted at 180–184°. When 2-chloromethyl-5-hydroxy-γ-pyrone (prepared from kojic acid through the action of thionyl chloride) was treated with butyraldehyde, using the procedure outlined in the preparation of the aldehyde products, a product was obtained which melted at 183–185°. Apparently the same compound was prepared by these two reactions.

The acetates of the aldehyde products were prepared by treating with an excess of acetic anhydride and a few drops of concentrated sulfuric acid. If these mixtures were allowed to stand for twelve hours at room temperature, dark red solutions were formed. Upon decomposing the excess of acetic anhydride with water and evaporating the solutions before a fan, resinous products were obtained. The repeated extraction of these resinous products with water gave white solids which were purified by recrystallizing from ethyl alcohol or ethyl acetate. If the original reaction mixtures were treated with a large excess of ether, the acetates were precipitated immediately as crystalline solids. The melting points of the acetates were: from formaldehyde product, 105–107°; from acetaldehyde product, 134–136°; and from benzaldehyde product, 166–168°.

The acetates of the aldehyde products were hydrolyzed quantitatively by dissolving a weighed sample in a known quantity of standard alkali (an excess was always used), brought to colorless toward phenolphthalein with standard hydrochloric acid, and back titrated to full red with standard alkali. The net quantity of alkali used was determined by difference. The amount of alkali required for the liberated aldehyde product was determined by a blank. When this value was subtracted from the net quantity of alkali used, the difference was taken as a measure of the acetic acid produced upon hydrolysis. The values obtained for 1-g. samples of the acetates are given in Table IV and compared with the theoretical amounts of acetic acid calculated for diacetate and tetraacetate derivatives.

TABLE IV

HYDROLYSIS OF ACETATE ESTERS

Acetate prepared from	Total titration	No. of acetate groups	Required for nuclear OH	CH_3COOH by difference	Calcd.
Formaldehyde	123.8	2	46.1	77.7	56.62
product		4	37.7	86.1	86.70
Acetaldehyde	123.2	2	41.0	82.2	50.76
product		4	33.8	89.4	83.70
Benzaldehyde	117.0	2	41.2	75.8	43.86
product		4	34.8	82.2	74.1

A sample of the acetaldehyde product was dissolved in glacial acetic acid. The addition of an excess of ether to this solution precipitated a solid which, after recrystallizing from alcohol, required 49.50 cc. of 0.1 *N* sodium hydroxide to titrate a 1-g. sample to the full color of phenolphthalein. Since 50.80 cc. of 0.1 *N* sodium hydroxide was required to titrate a 1-g. sample of the original acetaldehyde product, it is evident that an oxonium salt was not formed by the aldehyde product.

The aldehyde products were not hydrolyzed either by refluxing for nineteen hours with dilute sulfuric acid or by stirring for forty-eight hours with 0.1 *N* sodium hydroxide.

Kojic acid did not react with benzal chloride in alcoholic solution. However, when the method of Friedel and Crafts was employed, using freshly distilled nitrobenzene as a solvent, a free evolution of hydrogen chloride was observed. After heating for two hours at 100–150° the reaction mixture was poured into an excess of water and the solid which precipitated removed by filtration. This solid was extracted repeatedly with ether and finally with alcohol. Evaporation of the alcohol gave a small amount of material which melted at 250–256° with decomposition; this compares favorably with the melting point of the crude benzaldehyde product.

When kojic acid was dissolved in alkali, cooled to 0–5°, treated with phenyldiazonium chloride, and the mixture made alkaline, a dark red solid was precipitated. This substance was stable. It could be dried and kept exposed to the air for an indefinite period of time. No apparent decomposition occurred when it was treated with moderately strong acid. When the same procedure was used with the aldehyde products, red and brown solids were obtained. However, these solids were unstable and turned dark upon drying in air. Apparently a gas was liberated during this decomposition. A freshly prepared sample of the colored compound obtained from the acetaldehyde product was suspended in cold, dilute (2:1) hydrochloric acid. After standing for a half hour at 0–5° the solution was filtered and the filtrate placed in a solution of "H-acid" (1-amino-8-naphthol-3,6-disulfonic acid). When this mixture was made alkaline an intense red color was produced which appeared to be identical with the color formed when "H-acid" was treated with phenyldiazonium chloride. The residue from the acid treatment melted at 188–198° and when mixed with an equal amount of acetaldehyde product the melting point rose to 201–210°. From these results, the colored compounds were assumed to be diazonium salts of the phenolic hydroxyls and not the products of true coupling reactions.

Discussion of Results

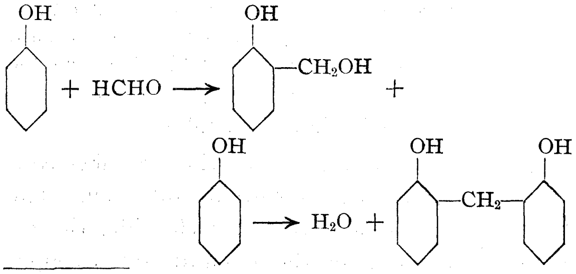
The qualitative analysis of the products consistently gave negative results for nitrogen. The production of color with ferric chloride, the reaction with alkali, and the precipitation of copper salts all indicate that the phenolic hydroxyls in position 5 are also present in the aldehyde products. Since these products do not hydrolyze readily they probably are not acetals. Further, the reaction with thionyl chloride points to the presence of the hydroxymethyl groups in the aldehyde products. These conclusions are all fully confirmed by the formation of tetraacetate esters.

This leaves position 6 as the most probable point of attack. It is known that when the Friedel and Crafts reaction is used with aromatic phenols, the hydrogen in the para position is replaced. However, when the para position is blocked, the reaction may occur at the ortho positions. If it is assumed that the hydroxymethyl group of kojic acid is para to the phenolic hydroxyl, then the only available point of attack is at position 6.

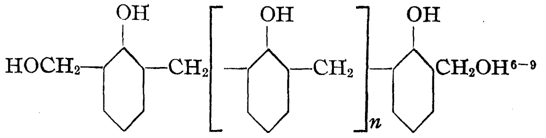
Further confirmation is given by the formation of the diazonium salts. Sidgwick[5] explains the coupling reaction of diazonium salts with phenols as forming a diazonium salt of the phenol which later rearranges by the diazo group passing to the para or ortho position. These diazonium salts of the phenol group are unstable, decomposing easily to give nitrogen, and when treated with dilute acids the original compounds are formed. Since both of these properties were observed in the products which were formed by the aldehyde products reacting with phenyldiazonium chloride, it may be assumed that diazonium salts of the phenolic hydroxyl groups were formed. If the aldehyde has attacked position 6, then all possible positions for the rearrangement of these phenolic salts are blocked and the true coupling reactions cannot proceed beyond this initial step.

It is concluded, therefore, that the aldehyde products may be represented by the general formula previously given.

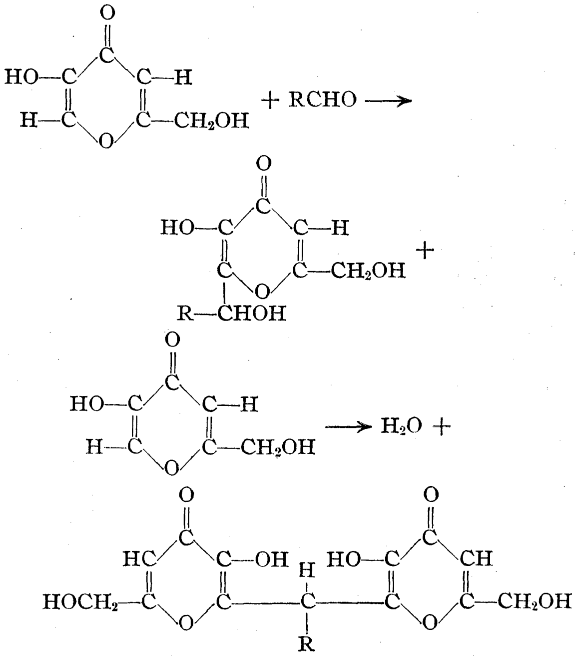
A study of the reaction of aromatic phenols with aldehydes to form resins of the Bakelite type reveals that the mechanism of reaction is probably



and that this reaction continues until a compound is formed which may be represented by



In the case of para substituted phenols, *i. e.*, *p*-cresol, the reaction occurs only at the ortho positions. Assuming that kojic acid reacts as a para substituted phenol, the analogous reaction would be



From this point of view, these aldehyde products may correspond to the compounds which appear in the early stages of phenolic resin formation. The reaction, however, stops at this stage because the ortho and para positions in both rings are blocked. That resins may be formed under certain conditions has already been mentioned under the preparation and purification. We believe that these resinous substances are produced either by molecules of kojic acid condensing from the hydroxymethyl group of one molecule to position 6 of a second molecule and so on, or by the aldehyde products condensing with unchanged kojic acid by a similar mechanism. Further investigation of this field is planned.

Conclusions

1. We have shown that kojic acid reacts with aldehydes to form solid derivatives. A series of these products has been prepared using all of the normal, saturated, aliphatic aldehydes up to heptaldehyde, in addition to acrolein, benzaldehyde, hydrocinnamaldehyde, cinnamaldehyde, and α-furfuraldehyde.
2. The probable formula for these products is given.
3. A possible mechanism of reaction is suggested based upon the present theory of resin formation by aromatic phenols and aldehydes.

On the Mechanism of the Catechol–Tyrosinase Reaction

BY HARRY WAGREICH AND J. M. NELSON

Catechol has been used widely as a substrate in the study of oxidases, partly because the aerobic oxidation of this substance is catalyzed by a great many enzymes of this class. Robinson and McCance[1] showed that two atoms of oxygen are consumed in the complete oxidation of catechol, although only one atom is required, stoichiometrically, for the formation of *o*-benzoquinone, the normal product of primary oxidation. The reaction therefore is not a simple one, and a further complication arises from the fact that *o*-benzoquinone is very fugitive in aqueous solutions, especially in the presence of unoxidized catechol, as shown by Dawson and Nelson.[2]

Regarding the mechanism of the oxidation, Onslow,[3] Richter,[4] Platt and Wormall[5] and others favor the idea that hydrogen peroxide is one product of the reaction, which would account for the oxygen consumption

$$C_6H_4(OH)_2 + O_2 \longrightarrow C_6H_4O_2 + H_2O_2$$

On the other hand, Raper[6] suggests that one atom of oxygen converts catechol into *o*-benzoquinone and that this is oxidized further by the second atom consumed. To gain further insight into the problem, it seemed of interest to extend the observations of Dawson and Nelson by following the amount of oxygen consumed.

The apparatus shown in Fig. 1 was used to measure the amount of quinone formed when one atom of oxygen per mole of catechol had been consumed. The vessel was charged with 1250 cc. of 0.02 *M* phosphate–citrate buffer (*p*H 6.2) containing 100 mg. of catechol, and 500 units of tyrosinase preparation[7] (about 15 cc.) was placed in one of the side bulbs (F). The stirrer was started and, when the solutions in the vessel and

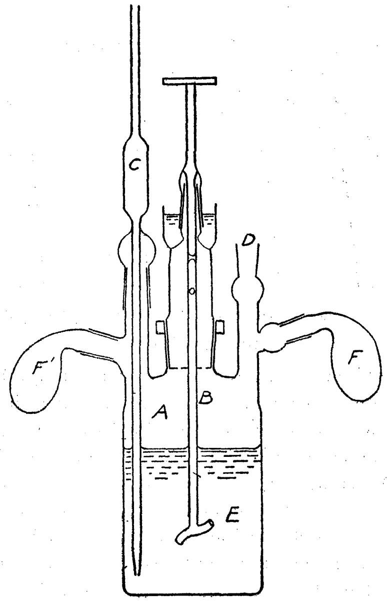

Fig. 1.—A modified form of the apparatus described by Reinders and Vles [*Rec. trav. chim.*, **44**, 1 (1925)]. A represents a heavy 2-liter glass reaction vessel, into which a pump-stirrer B was inserted. At the upper end of the stirrer was a water seal such as described by Rosenthal, Lorch and Hammett [THIS JOURNAL, **59**, 1795 (1937)]. The pipet C permitted the withdrawal of samples from the reaction solution. Tube D was connected to a manometer similar to that described by Reinders and Vles. Bulbs F and F′ were used for introducing the enzyme. The vessel A was fitted into a metal frame so as to be held in position in the thermostat.

side bulb had reached the temperature of the thermostat (25°), the bulb F was turned in order to introduce the enzyme into the reaction mixture. After five minutes the oxygen absorbed corresponded to one atom of oxygen per mole of catechol, and at this point 25 cc. of the solution was withdrawn by means of the pipet C and the quinone determined by the method of Dawson and Nelson. The amount of quinone corresponded to 98% of the catechol oxidized. This observation confirms Raper's view that only one atom of oxygen is utilized in the formation of *o*-benzoquinone. The second atom, therefore, must be involved either in the further oxidation of *o*-benzoquinone or in the oxidation of a product of its decomposition.

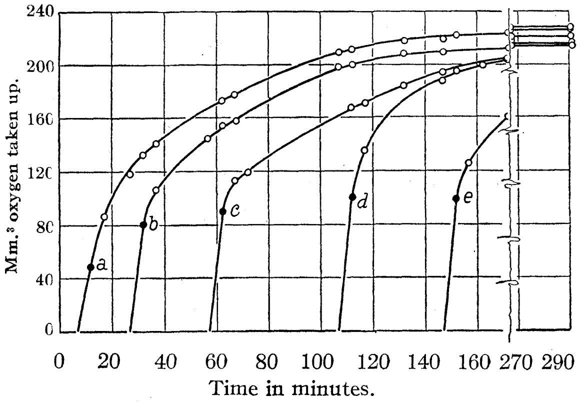

Fig. 2.—Showing the increase in rate of uptake of the second atom of oxygen, with increasing lengths of time elapsing before the enzyme was added to the disappearing *o*-benzoquinone contained in the reaction vessels of the Barcroft–Warburg apparatus. Reaction mixture the same for each curve: 4 cc. of *M* acetate–acetic acid buffer, *p*H 5, 2 cc. catechol solution (2 mg. of catechol); 2 cc. of a solution containing an amount of ceric ammonium sulfate equivalent to oxidizing 2 mg. catechol to *o*-benzoquinone. One cc. of a tyrosinase preparation (3 units) was placed in the side bulb of each reaction vessel, and the enzyme introduced into the reaction mixture at the times indicated on the abscissa axis. Temperature was 25°.

Raper and co-workers[8] found in their excellent study of the enzymatic oxidation of tyrosine to melanin that oxygen was taken up at three different stages in the course of the oxidation, and that the uptake of the last atom of oxygen was independent of the enzyme. To learn whether the uptake of the second atom of oxygen in the oxidation of catechol is catalyzed by tyrosinase the procedure described was followed. To be sure that the first stage was complete, the catechol was first oxidized to *o*-benzoquinone by an equivalent amount of ceric sulfate at *p*H 4.4 (or potassium ferricyanide in the case of more alkaline solutions, *p*H 7.7).[2,9] Since no determination of quinone was necessary, it was more convenient to use the Barcroft–Warburg respirometer method for measuring the amount of oxygen taken up.[10] The results showed that no oxygen uptake occurred in the absence of tyrosinase. When the enzyme was added to the reaction mixture 115 mm.^{3} of oxygen (1.1 atoms) was consumed at *p*H 4.5 in sixty minutes and at *p*H 7.7 in thirty minutes.

That the substance oxidized by the second atom of oxygen is not *o*-benzoquinone, as proposed by Raper, but some compound formed as the quinone disappears (possibly reformed catechol as discussed more fully in the subsequent part of the paper), is suggested by data shown graphically in Figs. 2 and 3. The data shown in Fig. 2 were obtained by placing a series of aqueous solutions containing a given quantity of catechol, freshly oxidized by an equivalent amount of ceric sulfate to *o*-benzoquinone, in the reaction flasks of a Barcroft–Warburg apparatus. After varying periods of time, as indicated on the abscissa scale in the figure, constant amounts of a tyrosinase preparation were added from the side-arms of the respective reaction flasks containing the gradually changing *o*-benzoquinone. The points marked a, b, c, d, and e on the curves correspond to the amount of oxygen taken up during the first five minutes after the addition of the enzyme. It will be observed upon examining the curves that this amount increased with the length of time elapsing before the enzyme was added (to about one hundred minutes). In other words, as the unstable *o*-benzoquinone disappears a new substance seems to be formed which is oxidized by the tyrosinase. The observed increase in the rate of oxygen uptake is due to the gradual increase in the concentration of this new substance with the length of time elapsing before the addition of the enzyme. The lack of further increase in the rate of oxidation occurring when the length of time elapsing before the addition of the enzyme exceeds one hundred minutes suggests an equilibrium being reached between the disappearing *o*-benzoquinone and the new oxidizable substance. This suggestion falls in line with the observation of Dawson and Nel-

son, who found that *o*-benzoquinone (judging from the liberation of iodine when a portion of the solution was added to acidified potassium iodide solution) did not entirely disappear even after the elapse of considerable time. The same idea is suggested by the curve in Fig. 3 representing the disappearance of *o*-benzoquinone with time, and discussed more fully below.

To obtain, if possible, some idea concerning the quantitative relationship between the amount of *o*-benzoquinone which had disappeared in a given time and the amount of the new oxidizable compound formed, the following experiment was undertaken. A solution consisting of 1030 cc. of water, 200 cc. of *M* sodium acetate–acetic acid buffer (*p*H of final solution 4.8), and 1.1499 g. of ceric ammonium sulfate, was placed in the reaction vessel of the apparatus described in Fig. 1. After the solution had attained the temperature of the thermostat, 100 mg. of catechol dissolved in 25 cc. of water was added, and it was assumed that the catechol was oxidized immediately to *o*-benzoquinone. After thirty-four minutes a 25-cc. portion of the reaction solution was withdrawn and its quinone content was found to have decreased to 10%, based upon the amount of catechol used. To compare this with the amount of the new oxidizable substance formed, 15 cc. of a tyrosinase solution containing 400 units of enzyme was added immediately to the reaction solution after the 25-cc. sample had been withdrawn for determining the amount of quinone remaining at the end of thirty-four minutes. Suspecting the new substance formed as the *o*-benzoquinone disappears to be catechol, which is known to be oxidized rapidly by tyrosinase, 25-cc. portions of the reaction solution were withdrawn one and one-half and three and one-half minutes after the addition of the enzyme. On determining the quinone content it was found to have risen from 10 to 54% at the end of three and one-half minutes. Half of 90%, the loss in quinone at the end of thirty-four minutes, added to the 10% of quinone remaining, is equal to 55%. The experiment was repeated several times, at *p*H 4.5, and similar results were obtained. Thus, interrupting the disappearance of the *o*-benzoquinone, in one instance at 60% and in another at 38% quinone remaining, it was found that on the addition of enzyme the quinone content rose to 80 and 66%, respectively (calcd. 80 and 69%). Another point which should be mentioned is that the newly formed quinone is fugitive just like the original *o*-benzoquinone. The points indicated on the last part of the curve in Fig. 3 represent the quinone content of the reaction solution at the corresponding time intervals.

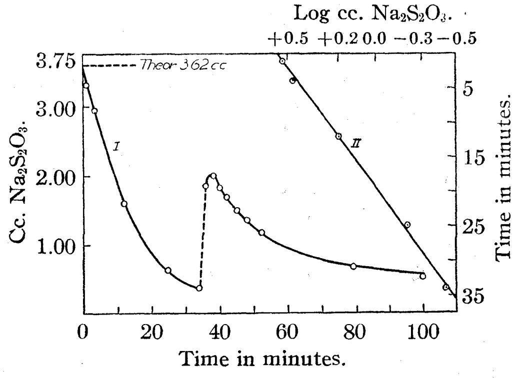

Fig. 3.—Showing the extent of disappearance of *o*-benzoquinone in aqueous solution, and the increase in quinone content, when the product resulting from the disappearing *o*-benzoquinone was oxidized by means of tyrosinase. *p*H = 4.8; temperature 25°; 1 cc. of thiosulfate soln. = 0.539 mg. of *o*-benzoquinone.

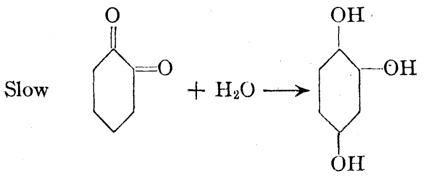
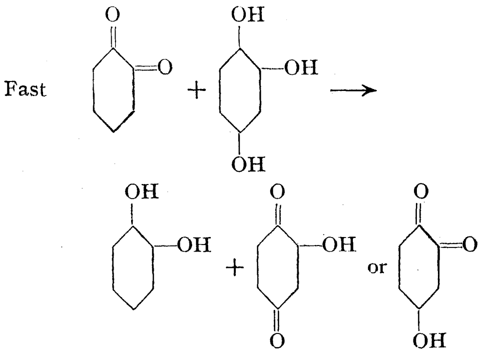
In attempting to interpret the data described above, the conclusion reached by Fieser and Peters[11] in their study of β-naphthoquinone is of interest. This quinone also tends to disappear in the presence of water. If the reactions involved in the disappearance of *o*-benzoquinone are similar to those occurring, according to these investigators, in the case of β-naphthoquinone, then they may be expressed in the form of equations (1) and (2)



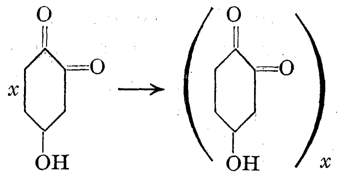
(1)



(2)

---

[11] L. F. Fieser and M. A. Peters, THIS JOURNAL, **53**, 793 (1931).



(3)

For every two molecules of *o*-benzoquinone disappearing, one molecule of catechol would be formed, and this in the presence of the enzyme would yield one new molecule of *o*-benzoquinone. Furthermore, if the reaction represented by equation (1) is slower than the reaction indicated in equation (2), then the rate of disappearance of the quinone should tend to be of the first order. The latter seems to be the case, since plotting the logarithms of the cc. of thiosulfate (measure of the quinone remaining) against time gives a straight line, *i. e.*, curve II in Fig. 3. By adding the assumption represented by equation (3) that the hydroxybenzoquinone disappears from the reaction solution, through polymerization, at a rate greater than that of the reaction represented by equation (1), then results such as those described above should be expected. That hydroxybenzoquinone is unstable, at least in alkaline solutions, has been shown by Eller,[12] who found that alkaline oxidation of hydroquinone or catechol results in the formation of humic acid, a dark brown, sparingly soluble polymer of hydroxybenzoquinone. Experiences in this Laboratory also show that aqueous solutions of *o*-benzoquinone, on standing, give rise to the formation of sparingly soluble material resembling humic acid in appearance. In some instances considerable difficulty was encountered in recognizing the disappearance of the starch–iodine blue color, when the quinone contents of solutions were determined by Dawson and Nelson's method.

Szent-Györgyi[13] noticed that the addition of catechol to an aqueous solution of *o*-benzoquinone accelerates the disappearance of the latter. Dawson and Nelson point out that the rate of disappearance of *o*-benzoquinone in dilute aqueous solutions conforms closely to a first order reaction, but deviates from the latter in the presence of higher concentrations of catechol. In the light of these observations, it is possible that the reactions indicated by equations (1) and (2) may only represent the course of the reaction when dilute solutions of catechol are oxidized rapidly by tyrosinase so as to avoid the presence of an appreciable quantity of unoxidized catechol and, under relatively acid conditions, *p*H 4.0–6.0.

Summary

1. Under conditions of low concentration of substrate, high concentration of enzyme, and *p*H 4.5–6.5, catechol is enzymatically oxidized to *o*-benzoquinone with the consumption of one atom of oxygen per mole of catechol.

2. The consumption of the second atom of oxygen per mole of catechol oxidized is also catalyzed by tyrosinase.

3. A substance is formed when *o*-benzoquinone disappears in aqueous solution at *p*H 4.5–6.5, which is aerobically oxidized to a quinone by means of tyrosinase.

4. The quantity of quinone compound formed in the oxidation of the substance mentioned in (3) corresponds to one-half of the *o*-benzoquinone which has disappeared.

5. The substance formed as the *o*-benzoquinone disappears in aqueous solution is oxidized faster by means of the enzyme than the *o*-benzoquinone itself.

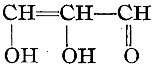
The Preparation and Properties of an Ene-diol. α-Phenyl-β-mesitoyl Acetylene Glycol

BY R. P. BARNES AND LEILA S. GREEN[1]

With the proof of the structure of ascorbic acid[2] there came a renewed interest in the chemistry of ene-diols.

Now heretofore, with the exception of reductone[3] (I), it has never been possible to isolate an ene-diol in an open chain compound except in a system with the chain —COCHOHCOCO—.[4]



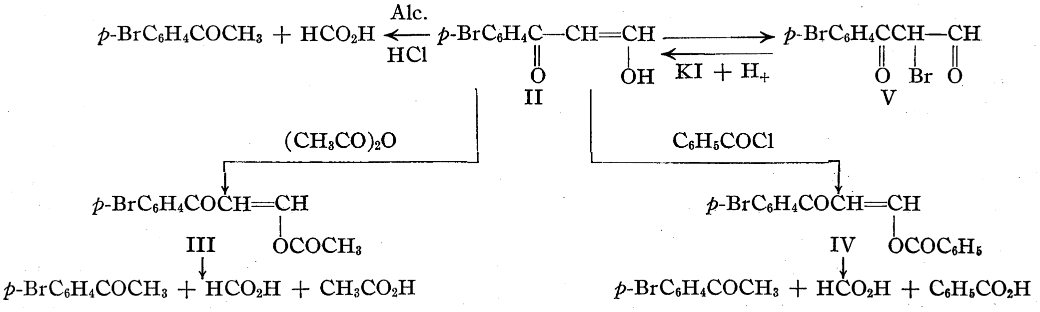
$$\underset{\text{OH}}{\text{CH}}=\underset{\text{OH}}{\text{CH}}-\underset{\text{O}}{\overset{}{\text{CH}}}$$

I

This investigation was undertaken in an attempt to make a new ene-diol with the same open chain carbon skeleton as is present in reductone. The likelihood of accomplishing this end seemed to lie in the possibility of obtaining a system with a chain —COCHOHCO— or —CHOHCOCO— with a hydrogen sufficiently active to shift. It had already been pointed out[5] that dibenzoylcarbinol, which contains the first of these chains, does not exist as an ene-diol. Kohler and Thompson[6] have shown that it is possible to follow, step by step, the isomerization of an hydroxy ketone in solution by way of an intermediate ene-diol, which, however, was too unstable to isolate.

More recently still, substances of an ene-diolic nature have been indicated in solution in connection with the reduction products of dimesitylbutanetrione enol and its methyl ethers.[7]

With a knowledge of the structure of reductone, and knowing that oxymethylene-*p*-bromoacetophenone (II) is enolic because of the presence of the very active aldehydic carbonyl group, we chose this substance as our starting material. The method of preparation of oxymethylene-*p*-bromoacetophenone[8] gives such poor yields that we had to modify the procedure in order to get sufficient material with which to work. This substance is 67% enolic; gives an O-acetate (III); an O-benzoate (IV); and a monobromo derivative (V). When the monobromo derivative, which is 100% enolic, was heated with potassium acetate in glacial acetic acid, decomposition with charring occurred, and no carbinol acetate could be isolated. We had hoped to hydrolyze the carbinol acetate to the carbinol which presumably would have shown some indications of an ene-diolic nature. The parent substance, as well as its acyl derivatives, is hydrolyzed in hydrochloric acid–alcoholic solution to *p*-bromoacetophenone



Kohler and Thompson[6] state that the group —CHCO-Mes promotes enolization and enhances the stability of the enol. Attention also has been called[9] not only to the activating influence of the mesityl nucleus upon an α-hydrogen in mesitylbenzylglyoxal and β-phenylbenzylmesitylglyoxal, but also to its stabilizing influence.

A similar activating effect on an α-halogen atom has also been observed in connection with the coupling reaction of α-bromo-β-phenylbenzyl-

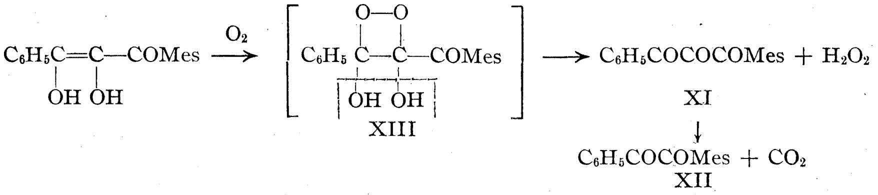
glyoxal[6] and the substitution reaction[9b] whereby it has been possible to obtain an α-oxy-α-diketone and its acetate, in spite of the fact that generally substitution on a methylene group α- to a carbonyl group has a tendency to decrease the activity of remaining substituents. Therefore we set out to test this effect on α-bromobenzylmesitylglyoxal (VI).

The enolic modification of benzylmesitylglyoxal was brominated in cold absolute ethereal solution, producing a golden-yellow oil (VI) which could not be crystallized from any solvent. In acetone solution with hydriodic acid this product is easily reduced to the parent enol. The golden-yellow monobromo compound is 24% enolic. It was dissolved in glacial acetic acid and refluxed with an excess of freshly fused potassium acetate, whereupon potassium bromide separated out. There was no noticeable change in color of the solution. Contrary to the opinion held by Kohler and Brown,[10] and contrary to the mechanism proposed by Blatt,[11] this α-bromo-α-diketone reacts by way of a direct substitution reaction to produce the acetate (VII) of the α-oxy-α-diketone. This substance could not be obtained solid. Its methyl alcoholic solution is of a deep red-wine color. On standing overnight in the cold, this solution deposits a beautiful pale peach-colored solid (VIII), which gives a cherry-red color with alcoholic ferric chloride, and is 100% enolic. This enolic modification of the acetate (VIII) is hydrolyzed simultaneously and cleaved by means of alkaline hydrogen peroxide with the production of benzoic and trimethylbenzoic acids and ethyl acetate.

When the monoacetate (VIII) is refluxed with acetyl chloride it is converted quantitatively into the diacetate (IX). This substance is a pale lemon-yellow solid which produces no color with alcoholic ferric chloride. These acetates are recovered unchanged after refluxing their alcoholic solutions with both hydrochloric and sulfuric acids.

Both the mono- and diacetates dissolve in concd. sulfuric acid with the production of deep orange-colored solutions. When poured over finely crushed ice, an odor of ethyl acetate and a light yellow solid are formed. The yellow solid is the ene-diol (X). It gives a deep greenish-blue color with alcoholic ferric chloride, and is 37% ene-diolic in methyl alcoholic solution as indicated by titration with standard iodine solution.

The ene-diol (X) is not a very stable substance. In the solid state or in solution in peroxide-free ether, it quite readily undergoes autoxidation with production of the tri- and diketones,[12] (XI) and (XII), respectively, and hydrogen peroxide. The course of the reaction is best followed in peroxide-free ether, for thus an acidulated potassium iodide solution rapidly colors up red due to the peroxide oxidation of hydriodic acid to free iodine. The oxidizing substance must be hydrogen peroxide, since oxidation by means of the organic peroxide (XIII) probably would result in a cleavage of the molecule to benzoic and mesitylglyoxylic acids.



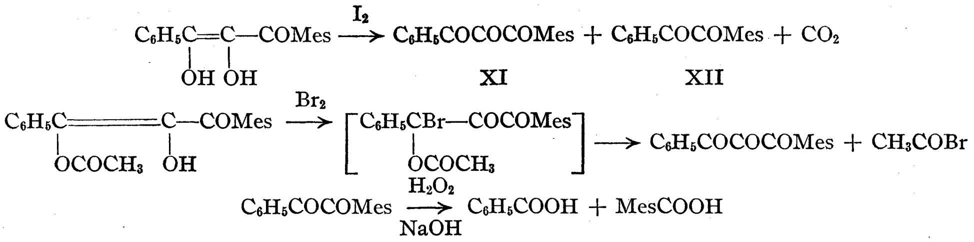
---

[10] E. P. Kohler and F. W. Brown, THIS JOURNAL, **55**, 4299 (1933).

[11] A. H. Blatt, *J. Wash. Acad. Sci.*, **28**, 1 (1938).

[12] Gray and Fuson, THIS JOURNAL, **56**, 739 (1934); Weinstock and Fuson, *ibid.*, **58**, 1233 (1936).

The ene-diol (X) also suffers oxidation in an acidulated iodine solution. The products of this reaction are the tri- and diketones (XI) and (XII), respectively. The triketone is a deep orange-colored solid, melting at 94°; the diketone is pale yellow and melts at 134°. When the monoacetate (VIII) is brominated in chloroform and heated, the resulting yellow compound is exclusively the diketone. The diketone (XII) is cleaved quantitatively by alkaline hydrogen peroxide to benzoic and trimethylbenzoic acids.



$$\mathrm{C_6H_5\underset{OH}{C}{=}\underset{OH}{C}{-}COMes \xrightarrow{I_2} \underset{XI}{C_6H_5COCOCOMes} + \underset{XII}{C_6H_5COCOMes} + CO_2}$$

$$\mathrm{C_6H_5\underset{OCOCH_3}{C}{=}\underset{OH}{C}{-}COMes \xrightarrow{Br_2} \left[C_6H_5\underset{OCOCH_3}{CBr}{-}COCOMes\right] \longrightarrow C_6H_5COCOCOMes + CH_3COBr}$$

$$\mathrm{C_6H_5COCOMes \xrightarrow[NaOH]{H_2O_2} C_6H_5COOH + MesCOOH}$$

This behavior of the triketone (XI) is consistent with what is known of the chemistry of polyketones, for Gray and Fuson[13] have found that dimesityl tetraketone (XIV) upon heating in alcoholic or glacial acetic acid solution is changed into the corresponding triketone (XV). It seems therefore that dimesityl triketone is far more stable than phenylmesityl triketone, a fact which still further substantiates the stabilizing effect of the mesityl group.

$$\mathrm{\underset{XIV}{MesCOCOCOCOMes} \longrightarrow \underset{XV}{MesCOCOCOMes}}$$

Further investigation of the properties of this ene-diol and its derivatives is in progress.

Experimental

Preparation of Oxymethylene-*p*-bromoacetophenone (II).—A solution of 7.0 g. of metallic sodium in a mixture of 30 cc. of absolute alcohol and 100 cc. of absolute benzene was obtained on long refluxing. It solidified on cooling. To this crystalline mass was added 52 g. of *p*-bromoacetophenone dissolved in 35 g. of pure ethyl formate. The reaction mixture warmed up; the alcoholate dissolved; the solution became brown and a crystal meal was formed. It was allowed to stand overnight at room temperature, and was then filtered and washed with alcohol and finally with ether. The yield was 52 g. of cream colored solid. This sodium compound was dissolved in a large volume of water, filtered and acidified with cold dilute sulfuric acid with rapid stirring. A yield of 45 g. of hard yellow needles, melting at 71°, was obtained. Kurt Myer titrations show that this compound is 67% enolic.

The Acetate of Oxymethylene-*p*-bromoacetophenone (III).—A solution of 5.0 g. of oxymethylene-*p*-bromoacetophenone was made by warming with the smallest possible amount of acetic anhydride. To the solution was added one drop of concd. sulfuric acid. The solution turned red and became hot. The mass solidified. It was dried overnight *in vacuo*, yielding 6.2 g. of crude solid. It was crystallized from methyl alcohol in glistening light yellow scales melting at 125°.

Anal. Calcd. for $C_{11}H_9O_3Br$: C, 48.8; H, 3.4. Found: C, 49.0; H, 3.4.

This substance decolorizes permanganate and bromine solutions. It produces no immediate color with alcoholic ferric chloride, but a cherry-red color slowly develops on standing. It is hydrolyzed completely by alcoholic hydrochloric acid to ethyl acetate and *p*-bromoacetophenone, identified by comparison with an authentic sample.

The Benzoate of Oxymethylene-*p*-bromoacetophenone (IV).—To a solution of 2.27 g. of the oxymethylene-*p*-bromoacetophenone in 50 cc. of ether was added 2 g. of benzoyl chloride. Slowly and with constant shaking, 10% sodium hydroxide was added dropwise to this ethereal solution. With the addition of each drop of alkali an orange-red color was produced. The color disappeared on shaking. The addition of sodium hydroxide was continued until the aqueous layer was permanently alkaline. A yellow solid separated out. The ether was blown off, the solid filtered and washed with sodium hydroxide solution and finally with water. The crude dry material weighed 3.5 g. It was recrystallized from methyl alcohol in bright yellow crystals, melting at 112°.

Anal. Calcd. for $C_{16}H_{11}O_3Br$: C, 58.0; H, 3.4. Found: C, 58.4; H, 3.7.

The benzoate also reduces potassium permanganate, adds bromine and very slowly develops a cherry-red color with alcoholic ferric chloride. It is completely hydrolyzed by alcoholic hydrochloric acid to ethyl benzoate and *p*-bromoacetophenone, identified by comparison with an authentic sample.

α-Bromo-oxymethylene-*p*-bromoacetophenone (V).—To a chilled solution of 16.5 g. of bromine in 150 cc. of chloroform was added slowly and with rapid stirring 20 g. of the sodium derivative of oxymethylene-*p*-bromoacetophenone. The solution finally became colorless. Sodium bromide was formed. The suspension was filtered and the sodium bromide washed thoroughly with chloroform. The chloroform was evaporated and the colorless glassy residue was taken up in hot glacial acetic acid from which it crystallized in shining colorless crystals, melting at 112°.

Anal. Calcd. for $C_9H_6O_2Br_2$: C, 35.3; H, 2.0. Found: C, 35.9; H, 2.5.

The bromo compound gives a beautiful light red color in alcoholic ferric chloride solution. In acetone solution it is reduced quantitatively to oxymethylene-*p*-bromoacetophenone by means of potassium iodide in acid solution.

A differential Kurt Meyer titration indicates that the

---

[13] Gray and Fuson, THIS JOURNAL, **56**, 2100 (1934).

bromo compound is 100% enolic, for two atoms of iodine are liberated per mole of bromo compound.

α-Bromobenzylmesitylglyoxal (VI).—An absolute ethereal solution of 15.5 g. of benzylmesitylglyoxal in 100 cc. of absolute ether was chilled and treated dropwise with the calculated quantity of bromine. With the addition of each drop of bromine the red color faded on shaking. Finally copious fumes of hydrogen bromide were given off. The hydrogen bromide and ether were pumped off, leaving 20.2 g. of a golden-yellow oil which could not be crystallized from any solvent.

Anal. Calcd. for $C_{18}H_{17}O_2Br$: C, 62.3; H, 4.9. Found: C, 62.3; H, 5.1.

The bromo compound gives a red color with alcoholic ferric chloride, and is easily reduced by hydriodic acid to the parent α-diketone. Differential titrations show it to be 24% enolic.

The Acetate of α-Oxybenzylmesityl-α-diketone (VII–VIII).—The bromo compound above (20.2 g.) was dissolved in 100 cc. of glacial acetic acid and refluxed for thirty minutes with 40 g. of freshly fused potassium acetate. Potassium bromide crystallized out. The solution was allowed to cool and was poured into a large volume of water. A deep yellow oil separated out. The yield was 15 g. It was dissolved in methyl alcohol, producing a deep red wine-colored solution, which could not be crystallized immediately. On standing overnight in the cold, however, a very pale peach-colored crystalline solid separated out. The yield was 11 g., melting at 71°.

Anal. Calcd. for $C_{20}H_{20}O_4$: C, 74.0; H, 6.2. Found: C, 74.3; H, 6.4.

It gives a red wine-colored solution with alcoholic ferric chloride and is 100% enolic. It is recovered unchanged after refluxing its alcoholic hydrochloric or alcoholic sulfuric acid solution for one hour.

Upon treatment with alkaline hydrogen peroxide an odor of ethyl acetate is observed and the compound is cleaved, yielding benzoic and trimethylbenzoic acids, each of which was identified by comparison with authentic samples.

The Diacetate of α-Phenyl-β-mesitoylacetylene Glycol (IX).—Excess acetyl chloride was added to 3 g. of the acetate of α-oxybenzyl-α-diketone in which it dissolved. It was refluxed for thirty minutes. The acetyl chloride was pumped off over solid sodium hydroxide. A glassy residue was left. It was dissolved in hot methyl alcohol from which it crystallized in pale lemon-yellow crystals, melting at 131°.

Anal. Calcd. for $C_{22}H_{22}O_3$: C, 72.1; H, 6.0. Found: C, 72.1; H, 6.4.

It produces no color with alcoholic ferric chloride, but reduces permanganate and adds bromine. When refluxed in alcoholic hydrochloric or alcoholic sulfuric acid solution, it is recovered unchanged.

α-Phenyl-β-mesitoylacetylene Glycol (X).—To 30 cc. of chilled concd. sulfuric acid was added 2.5 g. of the monoacetate. In three minutes, with stirring, a deep orange-red transparent solution resulted. This solution was poured over finely crushed ice, with the production of a light yellow solid. The suspension was allowed to stand overnight in the cold protected from air. A granular crystalline solid was obtained on filtering and washing with iced water. The yield was 2.2 g., melting at 79–80°.

Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.6; H, 6.4. Found: C, 76.4; H, 6.9.

This substance produces a deep green-blue color with alcoholic ferric chloride. The color fades slowly to yellow.

Iodine Titration of Ene-diol.—The following samples of the ene-diol were dissolved in 20 cc. of 95% alcohol each and acidified with 3 cc. of 10% sulfuric acid. Excess of standard iodine solution was then added, and the unused iodine titrated immediately with standard thiosulfate, 1.0 cc. of *N* iodine = 0.142 g. of ene-diol.

No.	Wt. of sample, g.	Vol. of *N* I used as 0.1056 *N* I, cc.	Vol. of *N* thio required as 0.1003 *N* thio, cc.	Vol. of I used up, cc.	% Ene-diol
I	0.0168	1.7334	1.6890	0.0444	37.48
II	.0714	1.8846	1.6990	.1856	36.49
					Mean 36.98

The Tri- and Diketones (XI and XII).—These polyketones are obtained under a variety of conditions.

When the solid ene-diol is exposed to atmospheric oxygen it becomes sticky and finally solidifies. It then produces no color with alcoholic ferric chloride. This solid upon solution in methyl alcohol and chilling gives a deep orange solid, melting at 94°.

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.14; H, 5.7. Found: C, 77.03; H, 5.8.

The mother liquor from this crystallization on concentrating gives a light yellow solid melting at 134°.

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 80.9; H, 6.4. Found: C, 81.1; H, 6.6.

It is sparingly soluble in methyl alcohol. It is cleaved quantitatively by alkaline hydrogen peroxide to benzoic and trimethylbenzoic acids, identified by comparison with authentic samples.

When an ethereal solution of the ene-diol is allowed to stand for a few minutes, it loses its ability to produce color with alcoholic ferric chloride. It liberates iodine very rapidly from an acidulated potassium iodide solution; and on evaporation leaves a residue which upon crystallization from methyl alcohol yields a deep orange solid, melting at 94° and a lighter yellow substance whose melting point is 134°. Mixed melting points with the above analyzed samples are unchanged.

A solution of 2 g. of the ene-diol in 30 cc. of alcohol was acidified with 5 cc. of 10% sulfuric acid. To this solution approximately 0.1 *N* iodine was added slowly. The alcoholic solution decolorized the iodine solution very rapidly. Finally it was allowed to stand overnight in the presence of excess iodine. Deep orange crystals melting at 94° were obtained. The mother liquor from a recrystallization gave the 134° product.

A solution of 1 g. of the ene-diol in 10 cc. of chloroform was treated in the cold with 0.6 g. of bromine in 5 cc. of chloroform. The chloroform solution avidly absorbed each drop of the bromine. Hydrogen bromide was evolved. The chloroform was pumped off and the residue taken up in methyl alcohol. The product of this crystallization was exclusively the light yellow substance, melting point and mixed melting point with the above analyzed sample unchanged.

A solution of the ene-diol in alcoholic ferric chloride produces a deep green-blue color which gradually fades to yellow on standing. Evaporation of this solution yields a light yellow solid, melting point and mixed melting point with the above 134° melting compound unchanged.

Summary

Herein are reported the preparation and properties of a new ene-diol having the open chain  $-\underset{\mathrm{OH}}{\underset{|}{\mathrm{C}}}=\underset{\mathrm{OH}}{\underset{|}{\mathrm{C}}}-\underset{\mathrm{O}}{\underset{\|}{\mathrm{C}}}-$, and some further evidences of the activating influence of the mesityl nucleus upon α-substituents together with its stabilizing effects on the resulting compound.

Derivatives of 4-Aminobenzenesulfonanilide. I

BY G. L. WEBSTER AND L. D. POWERS

Following the observation made by Trefouel, Trefouel, Nitti and Bovet[1] that 4-aminobenzenesulfonamide was a valuable therapeutic agent in the treatment of infections caused by the β-hemolytic streptococcus, a large number of derivatives and analogs of this compound were tested in the search for other compounds which would be effective against the same and other organisms. Biological tests have shown only a few substances which have comparable action against bacterial organisms of any type.

It has been shown by Buttle, Gray and Stephenson[2] and by Rosenthal, Bauer and Branham[3] that, when given in equal molecular doses, 4-aminobenzenesulfonanilide is just as effective against pneumococcic infections in mice as is 4-aminobenzenesulfonamide. It has also been shown[1,3] that the presence of an amino group para to the sulfonamide group is necessary for therapeutic action.

Only a few derivatives of 4-aminobenzenesulfonanilide, in which an amino or a nitro group has been substituted for a hydrogen atom of the anilide ring, have been reported in the literature. Whitby[4] has published results on the protective action of the tartrates of 4,4′-diaminobenzenesulfonanilide and 4,3′-diaminobenzenesulfonanilide against experimental infections in mice and Bauer and Rosenthal[5] have reported their results with the first of these two diamines and with 4-aminobenzenesulfon-4′-nitroanilide. The authors of these papers presented no syntheses or chemical characterization of these compounds.

We have prepared a series of derivatives of 4-aminobenzenesulfonanilide in which a hydrogen atom of the anilide ring has been substituted with a nitro, amino or hydroxyl group in the hope that biological tests might disclose active chemotherapeutic agents.

Preliminary reports to us have indicated that several of these compounds show some slight protective action against experimental streptococcal infections in mice and one, 4-acetaminobenzenesulfon-4′-aminoanilide, has been described as moderately effective.[6] A more detailed report will be published elsewhere by Dr. Long.

Nitro derivatives of 4-acetaminobenzenesulfonanilide were prepared by the action of 4-acetaminobenzenesulfonchloride on a hot solution of the nitroaniline in dimethylaniline.

The corresponding amino derivatives were prepared by the ferrous hydroxide reduction method of Jacobs and Heidelberger.[7]

The hydroxyl derivatives of 4-acetaminobenzenesulfonanilide were prepared by the action of 4-acetaminobenzenesulfonchloride on a hot aqueous solution of the corresponding aminophenol and also by the method used for preparing the nitro derivatives.

Preparation of derivatives of 4-aminobenzenesulfonanilide was accomplished by boiling the acetamino compounds with an alcoholic solution of hydrochloric acid.

Diazotization of 4-acetaminobenzenesulfon-3′-aminoanilide and heating the resulting solution yielded the corresponding 3′-hydroxy derivative. Diazotization of 4-acetaminobenzenesulfon-4′-aminoanilide and boiling the diazonium solution

yielded 4-aminobenzenesulfon-4′-hydroxyanilide. When 4-acetaminobenzenesulfon-2′-aminoanilide in dilute sulfuric acid solution was treated with nitrous acid the *o*-diazoimide of 4-acetaminobenzenesulfonanilide was formed.

Experimental Part

4-Acetaminobenzenesulfonnitroanilides.—A solution of 13.8 g. (0.1 mole) of 2-(3- or 4)-nitroaniline in 50 cc. of dry, hot dimethylaniline was treated with 23.3 g. (0.1 mole) of crude 4-acetaminobenzenesulfonchloride[8] added in several portions.[9] The mixture was heated for one hour, on a steam-bath, cooled and the dimethylaniline removed by treating the mixture with cold 1:1 hydrochloric acid. The 2′- and 4′-nitroanilides were obtained first as gums which crystallized after repeated washings with the dilute acid. The 3′-nitroanilide was obtained as a granular mass immediately. The yield of the 2′-nitroanilide was 10 g.; 3′-nitroanilide, 30 g.; 4′-nitroanilide, 15 g.

4-Acetaminobenzenesulfonaminoanilides.—A solution of 200 g. of technical ferrous sulfate in 500 cc. of water was made alkaline with a 10% solution of sodium hydroxide (about 700 cc.). A solution of 33.5 g. (0.1 mole) of the 4-acetaminobenzenenitroanilide in 250 cc. of 10% sodium hydroxide solution was added and the mixture well stirred for fifteen minutes. The mixture was filtered through a large suction filter and the ferric hydroxide residue extracted again with about 300 cc. of water. The combined filtrates were acidified to litmus paper with acetic acid and the precipitated aminoanilide recovered by filtration.

4 - Acetaminobenzenesulfonhydroxyanilides.—These compounds were made (a) by the method described above for the preparation of the nitro derivatives. The yields of hydroxyanilides were smaller than those obtained by the following method. (b) A solution of 21.8 g. (0.2 mole) of 4-aminophenol in 1800 cc. of water at 75° containing 17 g. of anhydrous sodium acetate was treated with 58 g. of partially dried crude 4-acetaminobenzenesulfonchloride, estimated to be 80% pure, with mechanical stirring. Stirring was continued for thirty minutes, the mixture cooled and filtered. The yield of crude, air-dried product was 42 g. The isomeric hydroxyanilides were prepared in like yield.

The derivatives of 4-acetaminobenzenesulfonanilide described above are insoluble in water, ether and benzene; soluble in alcohol, acetone, dioxane and acetic acid. They may be crystallized from alcohol or from diluted alcohol of suitable concentration (50–20%). They dissolve in dilute (10% or less) sodium hydroxide solutions from which the sodium salt is precipitated by the addition of more concentrated alkali. The amino derivatives dissolve in dilute solutions of mineral acids.

4,4′ - Diacetaminobenzenesulfonanilide.—This compound was prepared from 4-acetaminobenzenesulfon-4′-aminoanilide by warming with an excess of acetic anhydride. It is insoluble in water and most of the usual organic solvents. It can be crystallized from a large volume of acetic acid.

Hydrolysis of the Acetyl Group.—A mixture of 10 g. of the 4-acetaminobenzenesulfonanilide in 200 cc. of alcohol and 15 cc. of concd. hydrochloric acid was refluxed on a

---

(8) *Org. Syntheses*, **5**, 3 (1925).

(9) Ullmann and Gross, *Ber.*, **43**, 2694 (1910), prepared toluenesulfontoluide by this method using diethylaniline as a solvent.

steam-bath for two hours. The alcohol was distilled off and the residue dissolved or suspended in 75 cc. of water. The aqueous mixture was cooled and made alkaline with ammonium hydroxide and then slightly acid with acetic acid. The desired 4-aminobenzenesulfonanilide was obtained by filtration.

The derivatives of 4-aminobenzenesulfonanilide prepared as described above are insoluble in ether and benzene; slightly soluble in cold water but appreciably soluble in boiling water; soluble in alcohol, acetone, dioxane and acetic acid. They may be crystallized from diluted alcohol (50% for the nitro derivatives, 35–20% for the amino derivatives) or from water (hydroxy derivatives). Amino and hydroxy derivatives were crystallized in an atmosphere of carbon dioxide. All of these compounds are soluble in dilute sodium hydroxide solutions and in dilute mineral acids.

4,4'-Diaminobenzenesulfonanilide Dihydrochloride.—To a solution of 1.2 g. of the pure base in a mixture of 10 cc. of alcohol and 1 cc. of concd. hydrochloric acid an additional 5 cc. of concd. hydrochloric acid was added. The precipitated dihydrochloride was filtered and dried in a desiccator over calcium chloride and sodium hydroxide. The white crystals begin to decompose at 200°. A solution (1:1000) in water has *p*H 2.5. *Anal.*[10] Calcd. for $C_{12}H_{15}O_2N_3Cl_2S$: Cl: 21.10; Found: Cl, 21.27.

Diazotization of 4-Acetaminobenzenesulfon-2'-aminoanilide.—A solution of 3.05 g. (0.1 mole) of 4-acetaminobenzenesulfon-2'-aminoanilide in a mixture of 250 cc. of water and 5 cc. of concentrated sulfuric acid was diazotized with 0.7 g. (0.1 mole) of sodium nitrite, dissolved in 14 cc. of water, at room temperature. The *o*-diazoimide of 4-acetaminobenzenesulfonanilide is precipitated from the reaction mixture immediately.

The product was filtered from the reaction mixture and washed with hot water to remove inorganic compounds and recrystallized from 50% alcohol. The yield was 2.5 g. This compound was stable at the boiling temperature of the mixture but, when recrystallized and dried, it decomposed at 138–140°. The reaction is analogous to that reported by Morgan and Micklethwait[11] in the diazotization of benzenesulfon-2'-aminoanilide. *Anal.* Calcd. for $C_{14}H_{12}O_3N_4S$: N, 17.72; S, 10.14. Found: N (Dumas), 17.82; S, 10.07.

Diazotization of 4-Acetaminobenzenesulfon-3'-aminoanilide.—A solution of 1.5 g. of the 4-acetaminobenzenesulfon-3'-aminoanilide in a mixture of 5 cc. of concd. sulfuric acid and 25 cc. of water was diazotized with 0.35 g. of sodium nitrite in 7 cc. of water without cooling. The solution was heated on a steam-bath for one hour, cooled and filtered. After recrystallization from 20% alcohol, the compound melted at 217–218°. The mixed melting point with the product obtained from coupling 3-aminophenol with 4-acetaminobenzenesulfonchloride was unchanged.

Diazotization of 4-Acetaminobenzenesulfon-4'-aminoanilide.—Three grams of 4-acetaminobenzenesulfon-4'-aminoanilide dissolved in a mixture of 10 cc. of concd. sulfuric acid and 50 cc. of water was diazotized, without cooling, with 0.7 g. of sodium nitrite in 14 cc. of water. A precipitate formed which dissolved when the temperature of the solution was raised to 75°. The solution was heated at 90–95° for three hours and then briefly boiled. After cooling, the solution was made alkaline with ammonium hydroxide and then acid with acetic acid. Recrystallized from water the product melted at 195–196°. The mixed melting point with 4-aminobenzenesulfon-4'-hydroxyanilide was unchanged, indicating that hydrolysis of the acetyl group had taken place.

Summary

The preparation of a number of new nitro, amino and hydroxy derivatives of 4-aminobenzenesulfonanilide and 4-acetaminobenzenesulfonanilide has been described. Work is in progress on other derivatives of these compounds.

Sterols. XXXV. Carbinols from Stallions' Urine

BY RUSSELL E. MARKER, ELMER J. LAWSON, EWALD ROHRMANN AND EUGENE L. WITTLE

Although the presence of oestrone in stallions' urine has been reported by several investigators,[1] apparently no work has been done on the neutral fractions from this source.

As part of an extensive investigation of the steroid substances in various urines, we have made a preliminary study of stallions' urine. After hydrolysis of the urine, and removal of the phenolic and acidic substances with alkali, the neutral extract was treated with Girard's reagent. Only a very small amount of ketonic material, amounting to 100 mg. per 200 gallons (760 liters) was obtained. The non-ketonic fraction was treated with phthalic anhydride and pyridine to separate the carbinols. The carbinol fraction was treated with digitonin to separate the β-sterols. From the digitonide a sterol of m. p. 134° was obtained. This sterol does not decolorize bromine in acetic

---

[1] For the literature on this subject, see Fieser, "Chemistry of Natural Products Related to Phenanthrene," 2nd ed., Reinhold Publishing Corp., New York, N. Y., 1936, pp. 198–199.

acid, yields an acetate melting at 124°, and remains largely unepimerized after treatment with sodium in boiling xylene. In view of its source, this sterol has been named β-equistanol. Oxidation of β-equistanol yields the corresponding ketone, equistanone, m. p. 115°. This ketone does not correspond in its solubility behavior or melting point to cholestanone, stigmastanone, ergostanone, or γ-sitostanone. The following table summarizes the properties of these compounds:

	M. p., °C.		M. p., °C.		M. p., °C.
β-Equistanol	134	β-Equistyl acetate	124	Equistanone	115
β-Cholestanol	142	β-Cholestyl acetate	115	Cholestanone	130
Stigmastanol	138.5	Stigmastyl acetate	135	Stigmastanone	160
γ-Sitostanol	144	γ-Sitostyl acetate	143	γ-Sitostanone	...
Ergostanol	151	Ergostyl acetate	144	Ergostanone	164

Evidently this sterol is different from any of the known sterols. Analytical data on β-equistanol, β-equistyl acetate and equistanone are in best agreement with the formula $C_{30}H_{54}O$ or $C_{31}H_{56}O$. We are inclined at present to regard β-equistanol as a phytosterol which is utilized incompletely, or not at all, in the metabolism of the stallion. In view of the herbivorous diet of the animal and of the widespread occurrence of β-sitosterol in plants, it is surprising that no β-sitosterol is present in stallions' urine.

Butenandt[2] has reported the presence of cholesterol in human male urine (4 mg./gal.), while Marker[3] has observed its presence in human pregnancy urine. We have found no evidence of cholesterol either in stallion urine or in mares' pregnancy urine. The occurrence of equistanol in both stallion urine and mares' pregnancy urine[4] indicates that it probably originates from the food and is not a product resulting from the condition of pregnancy.

We cannot overlook the fact that equistanol may be identical with dihydro-α-tritisterol prepared by Karrer, Salomon and Fritzsche.[5] Their compound has 30 carbon atoms with a melting point about the same as ours, but because of a lack of derivatives we are unable to make further comparisons.

The mother liquors from the digitonide were concentrated and the resulting carbinol mixture was epimerized with sodium and boiling xylene to convert any sterols of the *allo* series, originally present in the alpha form at C_3, to the corresponding beta compounds. Digitonin treatment of the epimerized mixture yielded an insoluble digitonide, a somewhat soluble digitonide and a carbinol mixture freed of compounds of the 3(β)-type. The soluble digitonide yielded β-equistanol, showing that the original carbinol mixture from stallions' urine contained, besides β-equistanol, about an equal amount of its epimer, α-equistanol. The latter compound could not, however, be isolated as such from any carbinol fractions.

The insoluble digitonide yielded a mixture of carbinols from which a triol, m. p. 295°, and a tetrol, m. p. 295°, were obtained by crystallization of the less volatile fractions obtained after vacuum sublimation of the mixture. The triol, m. p. 295°, yielded a triacetate, m. p. 140–145°. Analytical data agree best with the formula $C_{21}H_{36}O_3$ for this triol. It is evidently a compound of the *allo* series, and contains a 3(β)-hydroxyl group. As it existed in the urine the 3-OH group was in the epimeric form. We may suppose, by analogy to other carbinols present in urines, that one of the two remaining hydroxyls is at C_{20}, but the position of the third hydroxyl group is completely unknown. It should be noted that this carbinol is not present as such in stallions' urine, but rather is a transformation product of a triol of the *allo* series, having a 3(α)-hydroxyl group, which was originally present in the stallions' urine. These remarks on our knowledge of the triol, m. p. 295°, also apply to the tetrol, $C_{21}H_{36}O_4$, m. p. 295°. This tetrol may be a derivative of the products isolated from cortical extracts by Reichstein,[6] Wintersteiner and Pfiffner,[7] and Kendall.[8] Thus, it is possible that this compound may be a 3(β),11,20,21-*allo*-pregnanetetrol derived from corticosterone.

The epimerized carbinol mixture not precipitable with digitonin was oxidized, and the ketonic fraction distilled. A considerable amount of a mixture of ketones with a fruity odor was collected at 80°. After obtaining smaller fractions at 110–120°, and 120–160°, a fraction distilling at 160–200° was obtained. Crystallization of this

fraction from methanol yielded the known uranetrione, m. p. 247°, as proved by direct comparison with an authentic sample. Since the carbinol fraction which yielded uranetrione contained sterols of the 3(α)-OH type belonging to the normal series in respect to C_5, it is likely that the uranetrione was formed from the same uranetriol which has been found in mares' pregnancy urine.[9] The probable existence of uranetriol in stallions' urine suggests that uranetriol may not be derived from compounds having the function of sex hormones. Rather, it is possible that uranetriol may be derived from the suprarenal cortex or from some hormone of unknown function. The latter view receives some support from the isolation of uranol-11-one-3[10] uranedione,[9] and uranediol-3(β)-11[11] from mares' pregnancy urine.

Experimental Part

Isolation of Carbinol Fraction from Stallions' Urine.—The concentrated extract from 200 gallons (760 liters) of stallions' urine weighed 40 lb. (18.2 kg.). It was steam distilled for twelve hours with 25 lb. (11.4 kg.) of sodium hydroxide in 30% aqueous solution, and then extracted with ether. The ether was evaporated, the residual tar steam distilled with 5 liters of concd. hydrochloric acid and 5 liters of water, and the non-volatile oil extracted with 10 liters of butanol. To the butanol extract was added 15 liters of heptane, causing the precipitation of much tar. The solution was decanted from the tar, treated with boneblack, and the solvents removed *in vacuo*. The sirupy residue was steam distilled with an excess of 30% aqueous sodium hydroxide for three hours, and extracted with ether. The ether was distilled and the residue treated with Girard's reagent to obtain about 100 mg. of ketonic material. The non-ketonic fraction was dried by distillation with benzene, and treated with 125 g. of phthalic anhydride and 150 cc. of pyridine to give 68 g. of carbinols. The carbinol mixture was dissolved in 1 liter of hot alcohol and a solution of digitonin added. The next day the mixture was filtered, and washed with alcohol and ether. There was obtained 8.3 g. of digitonide.

β-Equistanol.—The digitonide obtained as described above was decomposed by warming for fifteen minutes with 90 cc. of pyridine. The solution was poured into 500 cc. of ether and the precipitate collected and washed with ether. The ethereal filtrate was washed with dilute hydrochloric acid and water and evaporated to dryness. The residue was crystallized three times from methanol to give 250 mg. of β-equistanol as needles, m. p. 133°. This sterol is not very soluble in methanol, somewhat more soluble in acetone and readily soluble in ether. It does not decolorize bromine in acetic acid solution.

Anal. Calcd. for $C_{30}H_{54}O$: C, 83.7; H, 12.6. Found: C, 84.0; H, 12.3.

Twenty-five milligrams of β-equistanol was refluxed for twenty minutes with 2 cc. of acetic anhydride. On chilling the solution β-equistanyl acetate crystallized as shining plates, m. p. 124°.

Anal. Calcd. for $C_{32}H_{56}O_2$: C, 81.3; H, 12.0. Found: C, 81.4; H, 11.6. Mol. wt. calcd. for $C_{32}H_{56}O_2$, 472.5; calcd. for $C_{33}H_{58}O_2$, 486.5. Found: 485.

Nine milligrams of β-equistanol in 3 cc. of xylene was refluxed with 80 mg. of sodium for six hours. At the end of this time the sodium was decomposed with alcohol, the solution neutralized with dilute hydrochloric acid, and the organic matter extracted with ether. The ethereal solution was washed with water, and evaporated to dryness. The residue was dissolved in a little hot alcohol and to it was added a solution of 50 mg. of digitonin in 1.5 cc. of hot alcohol. The next day the precipitated digitonide was filtered and washed with alcohol and ether. The dried digitonide weighed 40 mg., corresponding to a recovery of 8 mg. of the sterol. This shows that β-equistanol is a sterol of the *allo* series.

β-Equistanone.—To a solution of 100 mg. of β-equistanol in 10 cc. of acetic acid was added a solution of 30 mg. of chromic acid in 5 cc. of 90% acetic acid. After standing for one hour, the solution was diluted with water, extracted with ether, and the ethereal extract washed with sodium carbonate solution and water. The ether was evaporated and the residue distilled in a high vacuum. The fraction distilling at a bath temperature of 120–150° was crystallized from diluted methanol to obtain β-equistanone, m. p. 115°. β-Equistanone is quite soluble in methanol, differing in this respect from cholestanone, β-sitostanone, and ergostanone.

Anal. Calcd. for $C_{30}H_{52}O$: C, 84.0; H, 12.2. Found: C, 84.2; H, 12.1.

β-Equistanol from α-Equistanol in Stallions' Urine.—The filtrate from the precipitation of β-equistanol digitonide was evaporated and extracted with ether to separate the α-sterols from some β-equistanol digitonide, which is somewhat soluble in alcohol. The ethereal solution was evaporated and the residue refluxed with 600 cc. of xylene and 25 g. of sodium for nine hours. The sodium was destroyed with alcohol, the solution neutralized with dilute hydrochloric acid, and the mixture extracted with ether. The ethereal extract was washed with water, evaporated, and the residue, in hot alcohol, treated with a solution of 25 g. of digitonin in 750 cc. of alcohol. After standing overnight in a refrigerator, the precipitated digitonide was filtered and washed thoroughly with alcohol and ether. The digitonide so obtained was set aside for further investigation. The filtrate was evaporated to dryness, leached with ether, and the soluble digitonide present decomposed by warming with 20 cc. of pyridine for thirty minutes. The resulting solution was poured into ether, the precipitated digitonin filtered, and the ethereal filtrate washed with dilute hydrochloric acid and water. After evaporating the ether, a crystalline residue remained. This residue was crystallized from acetone–methanol, and ethyl acetate, to give a product which proved to be β-equistanol, m. p. 134°.

Anal. Calcd. for $C_{30}H_{54}O$: C, 83.6; H, 12.6. Found: C, 83.8; H, 12.6.

The sterol did not decolorize bromine in acetic acid.

---

(9) Marker, Kamm, Oakwood, Wittle and Lawson, THIS JOURNAL, **60**, 1061 (1938).

(10) Marker, Lawson and Crooks, *ibid.*, **60**, 1559 (1938).

(11) Marker, Rohrmann and Wittle, *ibid.*, **60**, 1561 (1938).

When warmed with concentrated sulfuric acid, it gave an orange-red color with a green fluorescence.

Ten mg. of the sterol was refluxed for thirty minutes with 5 cc. of acetic anhydride. On cooling, the acetate separated as shining plates. After recrystallization from methanol, the pure acetate was obtained as needles melting at 124°. This acetate did not depress the melting point of β-equistanyl acetate, but showed a marked depression with β-sitostanyl acetate.

Anal. Calcd. for $C_{32}H_{56}O_2$: C, 81.3; H, 12.0. Found: C, 81.4; H, 11.7. Mol. wt. calcd. for $C_{32}H_{56}O_2$, 472.5; for $C_{33}H_{58}O_2$, 486.5. Found: 485.

allo-Triol and allo-Tetrol from Stallions' Urine.—The insoluble digitonide from the epimerization of the α-sterols in stallions' urine was warmed with 50 cc. of pyridine for thirty minutes and the resulting solution poured into ether. After filtering and washing the precipitated digitonin, the filtrate was washed with dilute hydrochloric acid and water. The ether was evaporated giving 3.1 g. of residue. Crystallization of the residue from 15 cc. of methanol gave 120 mg. of a product melting at 295°. The analysis is that of an *allo*-pregnanetriol.

Anal. Calcd. for $C_{21}H_{36}O_3$: C, 74.9; H, 10.8. Found: C, 74.6; H, 10.9.

This compound gave a triacetate melting at 140–145°.

Anal. Calcd. for $C_{27}H_{42}O_6$: C, 70.1; H, 9.2; mol. wt., 462. Found: C, 70.3; H, 9.3; mol. wt., 457.

This compound originally existed in the urine as the *epi* form at C_3 but due to isomerization with sodium was converted and isolated as the β-form. It is saturated to bromine. The *allo*-configuration at C_5 is established by the isomerization with sodium to a product precipitated by digitonin.

The filtrate from the above triol was sublimed *in vacuo* and the portion that would not sublime below 200° was crystallized from methanol. This yielded 12 mg. of a carbinol melting at 290–295° which gave a depression in melting point when mixed with the first triol. The composition is that of a tetrol.

Anal. Calcd. for $C_{21}H_{36}O_4$: C, 71.6; H, 10.0; mol. wt., 352. Found: C, 71.1; H, 9.85, mol. wt., 362.

Uranetrione from Oxidation of Stallions' Urine Residues.—The ethereal leachings from the soluble digitonide described in the previous experiment contained chiefly α-sterols of the regular series at C_5. This ethereal solution was evaporated to dryness and the residue dissolved in 1 liter of acetic acid, and distilled to remove alcohol and other solvents. The residue was dissolved in 500 cc. of acetic acid and a solution of 20 g. of chromic acid in 90% acetic acid added with cooling over a period of fifteen minutes. The solution was diluted with water and extracted with ether. The ethereal solution was freed of acids by washing with sodium carbonate solution, and then with water. The ether was evaporated and the residue, dissolved in 500 cc. of alcohol, was heated for thirty minutes with 20 g. of Girard's reagent. Ice was added, and the solution diluted with water and extracted with ether. The aqueous layer was heated for thirty minutes on a steam-bath with an excess of hydrochloric acid. The cooled solution was thoroughly extracted with ether, and the ethereal solution evaporated. The residue was distilled in a high vacuum. A fraction, weighing 1.6 g. and distilling at 80°, had a fruity odor. However, it apparently was a mixture. A fraction weighing 500 mg. was collected at 110–120°, and another at 120–160°. A fourth fraction, distilling at 160–200°, was crystallized from methanol and washed with cold ether. The product melted at 247° and gave no depression with uranetrione.

Anal. Calcd. for $C_{21}H_{30}O_3$: C, 76.4; H, 9.1. Found: C, 76.4; H, 9.3.

We wish to thank Dr. Oliver Kamm and Parke, Davis and Company for their generous help and assistance in various phases of this work.

Summary

Stallions' urine yields a carbinol fraction from which a saturated β-sterol of the *allo* series may be obtained. This sterol, β-equistanol, yields β-equistanone on oxidation. The presence of the epimer, α-equistanol, and of two triols is also demonstrated. One of these triols yields uranetrione on oxidation, but the other triol is probably of the *allo* series. It also gave a compound of the composition of an *allo*-pregnanetetrol.

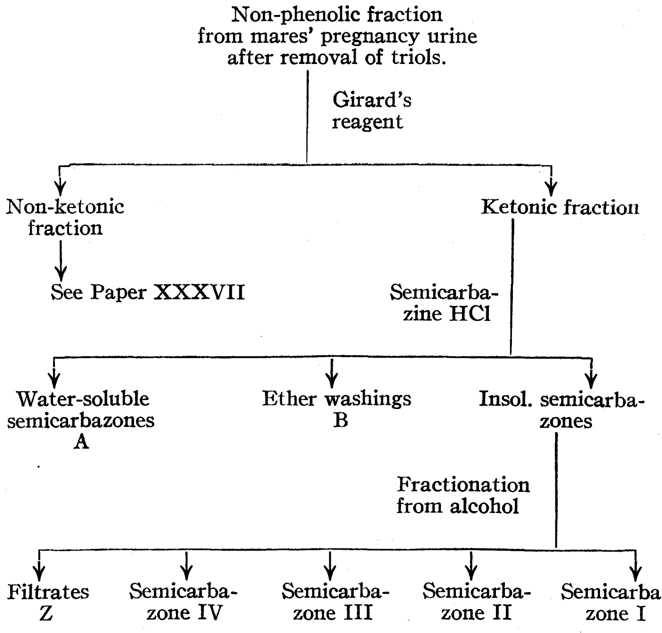
Sterols. XXXVI. Ketones from Mares' Pregnancy Urine

BY RUSSELL E. MARKER, ELMER J. LAWSON, EUGENE L. WITTLE AND HARRY M. CROOKS

As part of an extensive investigation of urines from various animal sources, we have been studying during the past two years the steroid content of mares' pregnancy urine. We already have reported the presence of pregnanediol,[1] *allo*-pregnanediol,[1] uranetriol,[2] pregnanetriol,[2] and uranediol[3] in the carbinol fraction from mares' pregnancy urine. The presence of a pregnanetriol which is probably identical with our pregnanetriol, was reported earlier by Haslewood, Marrian and Smith.[4] More recently these authors also have reported[5] the presence of pregnanetriol-3,17,20 in the pregnancy urine of women afflicted with cortical tumors. In the description of our investigation of the carbinol fraction of mares' pregnancy urine we reported the separation of a ketonic fraction from this source. Since Heard[6] has announced the isolation of a number of ketones from mares' pregnancy urine, we feel obliged to report the progress we have made in the course of a similar study. We are able to confirm the presence in mares' urine of the ketone, m. p. 252°, reported by Heard and in addition we have found a number of other steroids present. While a direct comparison of our compound with Heard's ketone has not been made, we believe that the two are identical in view of their apparently similar properties. However, molecular weight determinations of our substance (mol. wt. 672) gave a value twice that of a steroid, indicating that it may be a combination of two sterol molecules through their oxygen atoms. This would account for the inactivity of these atoms. We are not planning further work on this compound since we feel that Dr. Heard is entitled to priority in its discovery.

The accompanying diagram shows the scheme of isolation of our various ketones. The crude semicarbazone mixture from 30,000 gallons (114,000 liters) of mares' pregnancy urine yielded a water solution (A) containing Heard's water-soluble semicarbazone, an ethereal solution (B) containing chiefly non-steroidal semicarbazones, and a solid crude semicarbazone mixture. The latter on systematic fractional crystallization from alcohol yielded solid semicarbazones I, II, III and IV and a mother liquor Z. Each fraction was hydrolyzed with alcoholic sulfuric acid, and further purifications were effected by high-vacuum distillation, half-succinate separation, and fractional crystallization.

FLOW SHEET



We were surprised to find that all of the semicarbazones yielded both hydroxylated and hydroxyl-free ketones. This occurrence of hydroxyl-free ketones in mares' pregnancy urine is in contrast to the almost complete absence of such ketones in human pregnancy urine.[7] Possibly the course of reduction of progesterone and other hormones in the mare follows a somewhat different path, or else reduction may be more complete in man.

From the most insoluble semicarbazone frac-

tion (I) we have isolated two substances: a ketone which corresponds in properties to Heard's ketone, $C_{19}H_{26}O_3$, m. p. 252°, but has a molecular weight of 672, and *allo*-pregnanedione. We have also some indication of the presence of at least one other ketone in this hydrolyzed semicarbazone mixture (I). The presence of *allo*-pregnanedione and pregnanedione in mares' pregnancy urine lends further support to the hypothesis that progesterone is the source of most of the steroidal carbinols and ketones, such as pregnanediol, *allo*-pregnanediol, pregnanetriol-3(α),4(β),20(α),[8] *allo*-pregnanol-3(α)-one-20, pregnanol-3-(α)-one-20, pregnanediol-3(β),20(α),[9] pregnenediol-3(β),-20(α),[9] pregnanedione, and *allo*-pregnanol-3(β)-one-20.

Semicarbazones II and III proved to contain the same components. From the hydrolyzed semicarbazones there was obtained a new hydroxyketone, uranol-11-one-3, the known pregnanedione, and *allo*-pregnanol-3(β)-one-20. The structure of uranol-11-one-3 is proved by its composition and oxidation to uranedione. It did not form a half-succinate ester, in agreement with the usual postulated inertness of a hydroxyl group at C_{11}. It gave a Zimmermann test showing the presence of a carbonyl group at C_3. The isolation of this substance lends support to the hypothesis that uranedione and the uranediols (α,α and β,α) may be related to some hormone of as yet unknown function,[10] although it is possible that these substances may be derived from the cortical hormone. The isolation of *allo*-pregnanol-3(β)-one-20 from mares' pregnancy urine is interesting in view of the fact that it was first isolated from corpus luteum extracts.[11-14] The structure of our substance was proved by the composition, melting point, precipitation with digitonin, and oxidation to *allo*-pregnanedione. This is the first 3(β)-hydroxyketone to be isolated from urine, although its occurrence had been foreseen in the light of a proposed course of the reduction of progesterone.

We have not as yet completed our investigation of the ketones from semicarbazones A, B, and Z, since the mixtures have proved to be rather intractable. Semicarbazones B and Z yield a mixture of neutral and hydroxylated ketones. The hydroxyketone mixture from semicarbazone Z does not precipitate digitonin, and therefore no *allo*-pregnenol-3(β)-one-20 is present. Distillation of the neutral and hydroxylated ketones from B gives chiefly ketones subliming below 125°, and possessing characteristic odors. Apparently almost no steroidal ketones are present in fraction B.

Because of the small amounts of ketones present in mares' pregnancy urine, a more extensive investigation of 150,000 gallons (570,000 liters) of urine is now in progress, and the results of this study will be reported shortly.

Experimental Part

Isolation of Ketonic Fractions.—The non-phenolic fraction from 30,000 gallons (114,000 liters) of mares' pregnancy urine from which the uranetriol and pregnanetriol had been removed was dissolved in about 2.5 liters of alcohol and heated for one half hour with 400 g. of Girard's reagent. Ice and water were added and the non-ketonic material extracted thoroughly with ether. The aqueous layer was acidified with an excess of hydrochloric acid and warmed for one hour on a steam-bath. The ketonic matter was extracted with ether and the ether extract washed and concentrated. The residual oil was treated again with Girard's reagent to remove a small amount of inert material which was carried through mechanically. About 30 g. of ketonic material was obtained.

The ketone mixture was dissolved in 300 cc. of alcohol and boiled for one hour with 50 g. of semicarbazide hydrochloride and 60 g. of sodium acetate. The mixture was distilled to remove almost all the alcohol and the resulting paste was stirred with water, filtered, and washed with water and with ether. The water washings were set aside as semicarbazone fraction A, and the ether washings as semicarbazone fraction B. The solid semicarbazone mixture, amounting to about 15–20 g., was fractionated from alcohol. This gave semicarbazone solution Z, and semicarbazones I, II, III, and IV Semicarbazone solutions A and Z were evaporated to dryness to yield semicarbazones A and Z. These six semicarbazone fractions were hydrolyzed separately by boiling for one hour with fifty parts of alcohol and fifteen parts of 1:2 dilute sulfuric acid. Each hydrolysate was diluted with water, extracted with ether, the ether layer washed with water, and then evaporated to dryness. With the exception of the ketones from semicarbazone I, the residues were converted into the acid succinates in order to separate hydroxylated ketones from OH-free ketones.

allo-Pregnanedione and Ketone I from Semicarbazone I.—Hydrolysis of semicarbazone I gave 1.4 g. of solid ketones which could not be separated readily by crystallization. Accordingly, the total ketonic material was distilled in a high vacuum and fractions collected at bath temperature up to 110, 110–140 and 140–180°. The first and third fractions were too small to be investigated fur-

ther. Considerable residue remained in the distillation vessel. The fraction subliming at 110–140° was crystallized repeatedly from dilute acetone and yielded *allo*-pregnanedione, m. p. 196–200°, which gave no depression in melting point when mixed with authentic *allo*-pregnanedione.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.3; H, 10.3.

The non-distillable residue in the sublimation flask was crystallized from benzene–pentane, and yielded a crude ketone (ketone I) which melted at 220°. This ketone approximated the properties of Heard's ketone (m. p. 252°) upon further crystallization.

Anal. Found: C, 76.06; H, 9.85; mol. wt. (several determinations), 672.

The semicarbazone prepared from this ketone melted at 300°.

allo-Pregnanol-3(β)-one-20.—A preliminary investigation of the hydroxyketone from semicarbazones II and III showed that one substance was present in both fractions, which were therefore combined. This hydroxy ketone was sublimed in a high vacuum at a bath temperature of 185°, and the sublimate crystallized from carbon tetrachloride to give a ketone melting at 193°. This ketone depressed the melting point of *allo*-pregnanol-20(β)-one-3 (m. p. 195°), showed no unsaturation to bromine in acetic acid and gave a heavy precipitation with an alcoholic solution of digitonin.

A portion oxidized with chromic acid in the usual manner gave *allo*-pregnanedione, m. p. 197–199°, and showed no depression with an authentic sample of *allo*-pregnanedione, m. p. 200°.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.7; H, 10.1.

Uranol-11-one-3, Pregnanedione, and Ketone II from Semicarbazones II and III.—The ketones from semicarbazones II and III were distilled separately and fractions collected at bath temperatures of 135–160°, 160–200°, leaving considerable amounts of glassy residue. The fraction 135–160° was crystallized from diluted acetone to yield a solid melting over the range 100–135°. The material in the mother liquors was then crystallized repeatedly from dilute acetone, sublimed in a high vacuum, and then crystallized from ether–pentane to give pregnanedione, m. p. 118°, which did not depress the melting point of an authentic sample.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.5; H, 10.7.

The fraction subliming at 160–200° was a mixture which could be separated only with difficulty. Repeated crystallization from dilute alcohol and dilute acetone yielded a ketone which melted at 165°, and depressed the melting points of uranedione (m. p. 180°) and *allo*-pregnanedione (m. p. 200°).

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 79.2; H, 10.8.

It gave a gelatinous semicarbazone melting at 250° with decomposition.

Oxidation of a sample with chromic acid in the customary fashion yielded uranedione, m. p. 175–176°, which showed no depression with an authentic sample of uranedione.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.7; H, 10.5.

The glassy residues from sublimation of the neutral ketones up to 200° were combined and crystallized from benzene–pentane to yield about 100 mg. of a ketone melting at 115–120°. It did not precipitate with digitonin.

Anal. Found: C, 74.3; H, 9.65; mol. wt., 462.

We wish to thank Dr. Oliver Kamm and Parke, Davis and Company for their generous help and assistance in various phases of this work.

Summary

The ketonic fraction of mares' pregnancy urine yielded pregnanedione, *allo*-pregnanedione, *allo*-pregnanol-3(β)-one-20, and uranol-11-one-3 in addition to the ketone reported by Heard.

Sterols. XXXVII. Uranediol from Mares' Pregnancy Urine

BY RUSSELL E. MARKER, EWALD ROHRMANN AND EUGENE L. WITTLE

In paper XXIX[1] of this series the isolation of uranetriol from mares' pregnancy urine was reported. The urane compounds were shown to differ in structure from pregnane compounds in the configuration at C_9. In the pregnane series the hydrogen at C_9 is *trans* to the methyl group at C_{10}, while in the urane series the hydrogen atom is considered to be *cis* to the methyl group. Clemmensen reduction of uranetrione gave the parent hydrocarbon, urane, which is different from either pregnane or *allo*-pregnane. Evidence was presented to show that the hydroxyl groups in uranetriol are located at the 3-, 11- and 20-positions. The presence of uranediol in mares' pregnancy urine was indicated by the fact that oxidation of a mixture of crude diols gave a diketone which on Clemmensen reduction yielded the hydrocarbon urane.

We have now succeeded in isolating uranediol from the digitonin precipitated fraction of the ketone-free carbinol fraction of mares' pregnancy

---

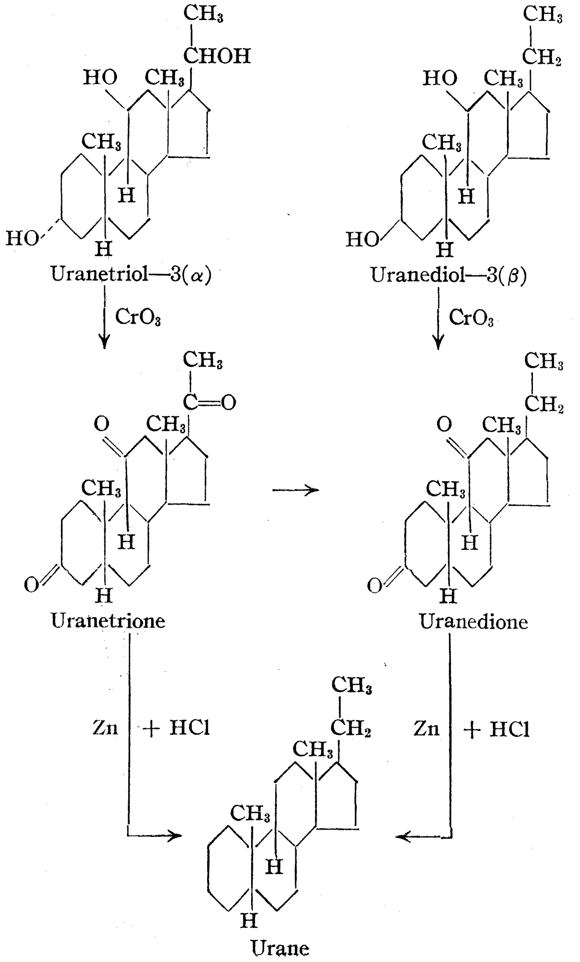
[1] Marker, *et al.*, THIS JOURNAL, **60**, 1061 (1938).

urine. Upon oxidation the diol yields a dione which is identical with that reported in paper XXIX.[1] The fact that the substance is precipitated by digitonin indicates the presence of a β-hydroxyl group in the C_3-position. The dione formed only a monosemicarbazone and a mono-2,4-dinitrophenylhydrazone which indicates that the second hydroxyl group is in the hindered C_{11}-position rather than in the C_{20}-position as in the pregnanediols.

Treatment of uranedione in acetic acid at room temperature with PtO_2 catalyst apparently reduces only the ketonic group at C_3, since epimerization of the resulting reduction products with sodium in xylene results in destruction of the material. Uranediol forms a diacetate.

Isomerization with sodium in xylene yielded material which gave very little precipitation with digitonin, indicating that the substance has the normal configuration at C_5.

The relationship of uranetriol to uranediol is given in the chart.



It is a striking fact that while uranetriol occurs in nature with the *epi* configuration with respect to the hydroxyl at C_3, uranediol possesses the normal or beta configuration at that position. The two compounds are closely related chemically as is shown by the fact that both can be reduced to the hydrocarbon, urane. It is probable, therefore, that they are closely related biologically. If not related to the active principles of the suprarenal cortex they may owe their origin to some as yet uncharacterized hormone.

The separation of uranediol from other digitonin-precipitated substances is greatly facilitated by the fact that it forms a digitonide which is relatively soluble in 95% ethanol. The soluble digitonide is separated by removing most of the alcohol and precipitating with ether. The digitonide so formed on decomposition with pyridine yields uranediol in relatively pure form. Mares' pregnancy urine contains approximately 5 mg. of the substance per gallon.

At present uranediol is the only compound which has been found in urine having the beta configuration at C_3 and the regular configuration at C_5. That other regular compounds with the beta configuration at C_3 are absent is indicated by the fact that when a mixture of digitonin-precipitated compounds was epimerized with sodium and xylene and the resulting $C_3(\alpha)$ compounds oxidized to ketones the only ketone obtained was uranedione.

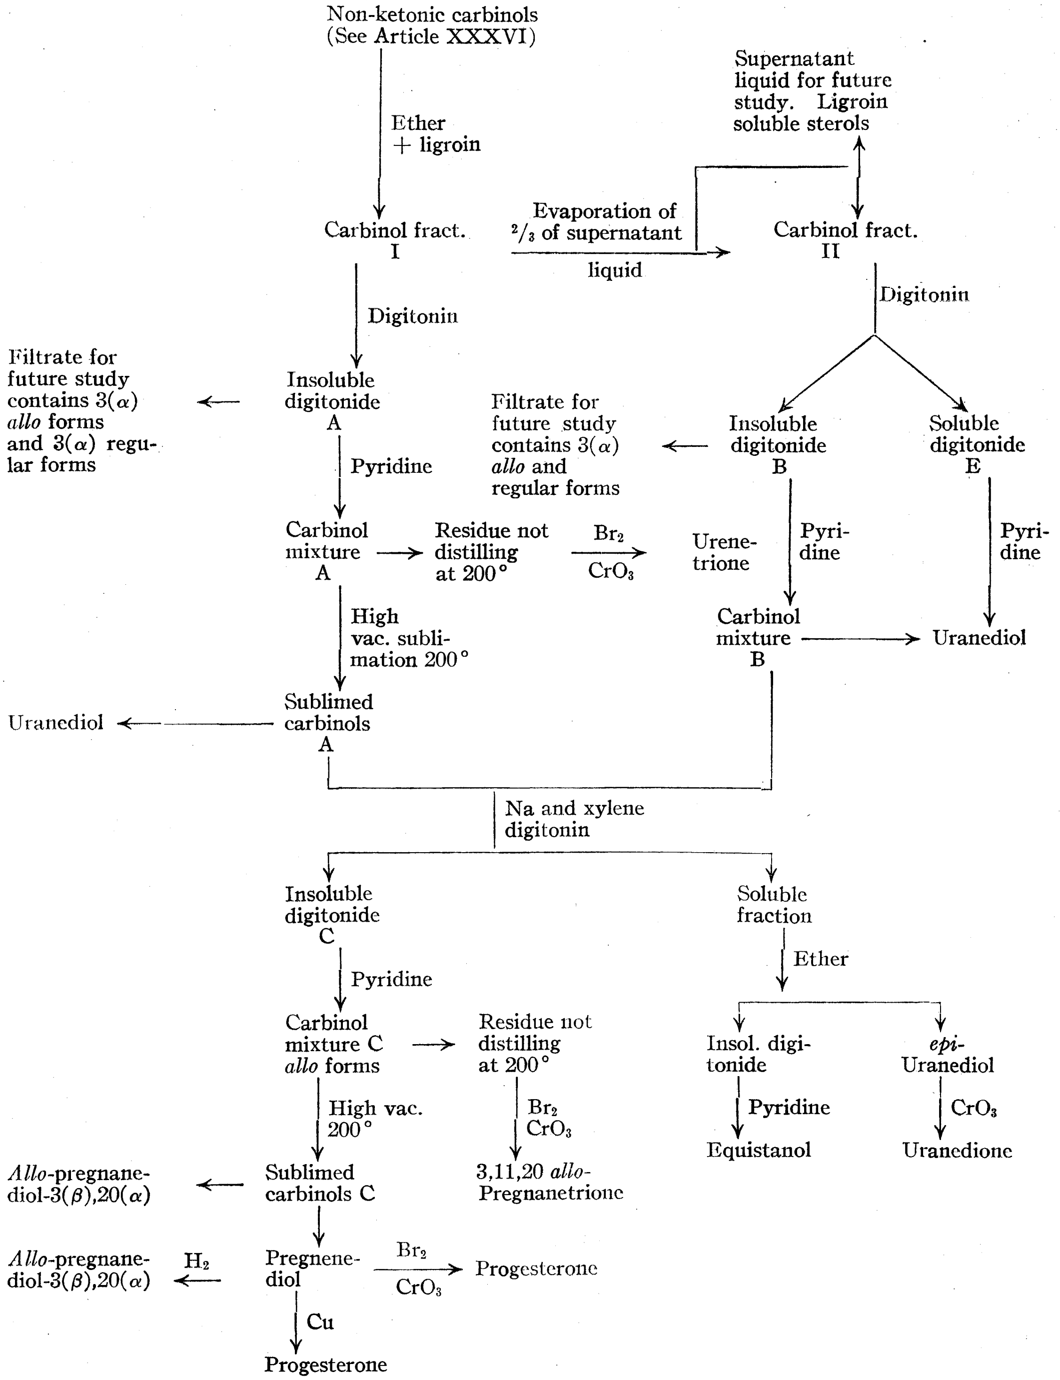
The steps involved in the experimental work reported in this paper and in the two following articles are outlined in the attached Flow Sheet.

Experimental Part

Precipitation of Mares' Pregnancy Urine Carbinols with Digitonin.—A concentrate of mares' urine carbinols corresponding to 1000 gallons (3700 liters) of urine from which all ketones had been removed previously with Girard's reagent was dissolved in 400 cc. of ether. To this solution was added 2 liters of ligroin and the mixture cooled in a salt–ice bath for one hour, and the upper liquid decanted from the precipitated tar. This gave carbinol fraction I. The supernatant liquid was distilled until approximately two-thirds of the solvent was removed. The resulting mixture was cooled in a salt–ice bath and the supernatant liquid poured from the precipitated tar. This gave carbinol fraction II.

Fraction I was made up to a volume of 2 liters with 95% ethanol. The solution was heated to boiling on the steam-bath and a boiling solution of 30 g. of digitonin in 1 liter of 95% ethanol was added. A precipitate formed at once. The mixture was cooled to 20°, and after three hours was filtered. The solid was washed with 500 cc. of 95% ethanol, resuspended in 500 cc. 95% ethanol and refiltered. This

FLOW SHEET



fraction, referred to as digitonide-A, was obtained in a yield of 38 g.

Carbinol fraction II was made up to a volume of 750 cc. with 95% ethanol. It was heated to boiling and a hot solution of 25 g. of digitonin in 1.5 liters of 95% ethanol was added. A precipitate formed after a few minutes. The mixture was cooled to 18°, filtered after two hours and washed with 95% ethanol. This fraction, referred to as digitonide-B, was obtained in a yield of 26 g. The filtrate was evaporated to a volume of about 50 cc. and 1 liter of ether was added. The precipitate was filtered and washed with ether. The residue of soluble digitonide-E weighed 8 g.

Digitonides A and B were reserved for other work. The filtrates likewise were reserved for investigation of the non-digitonin-precipitated substances.

Uranediol from Mares' Urine.—The soluble digitonide-E from carbinol fraction II was dissolved in 50 cc. of hot pyridine and the mixture heated thirty minutes on the steam-bath. The resulting solution was then poured into 1000 cc. of ether and the precipitate filtered and washed with ether. The filtrate was washed first with dilute hydrochloric acid and then with water. The ether was distilled, the crystals which separated were recrystallized from 15 cc. of acetone and washed with cold ether. After two additional recrystallizations from acetone the product was obtained in the form of white needles, m. p. 210°.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.8; H, 11.3.

The compound did not discolor bromine and gave a 20° depression in melting point when mixed with 3(β),20(α)-*allo*-pregnanediol.

Preparation of Uranediol Diacetate.—Approximately 75 mg. of uranediol was refluxed with 4 cc. of acetic anhydride for thirty-five minutes. The acetic anhydride was evaporated in vacuum and the crystalline residue recrystallized from methanol to a constant melting point. It crystallized in the form of small white plates, m. p. 160°.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.4; H, 10.0. Found: C, 74.6; H, 10.0.

Oxidation of Uranediol to Uranedione.—Uranediol (100 mg.) was dissolved in 30 cc. of glacial acetic acid. A solution of 150 mg. of chromic anhydride in 10 cc. of 90% acetic acid then was added at room temperature. A precipitate separated at first, but dissolved after the addition of chromic anhydride was completed. The mixture was allowed to stand at room temperature for forty-five minutes. Water was added and the mixture extracted twice with 75-cc. portions of ether. The combined ether extracts were washed with water and then with saturated sodium carbonate solution. The ether was evaporated and the crystalline residue dissolved in 5 cc. of methanol and cooled in a salt–ice bath. One-half cc. of water was added slowly, the precipitate collected and recrystallized from 90% methanol. Recrystallization from acetone gave a product which melted at 177.5° and which gave no depression in melting point when mixed with a sample of uranedione prepared from uranetriol.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.78; H, 10.3.

Uranedione Semicarbazone.—A solution of 20 mg. of uranedione, 30 mg. of semicarbazide hydrochloride and 30 mg. of sodium acetate in 10 cc. of alcohol was refluxed on the steam-bath for one hour, diluted with water and filtered. The product was washed with ether and crystallized from alcohol to yield uranedione monosemicarbazone, m. p. 245°, dec.

Anal. Calcd. for $C_{22}H_{35}O_2N_3$: C, 70.7; H, 9.4. Found: C, 70.4; H, 9.1.

Uranedione Mono-2,4-dinitrophenylhydrazone.—A solution of 30 mg. of uranedione and 40 mg. of 2,4-dinitrophenylhydrazine in 10 cc. of refluxing alcohol was acidified with two drops of concd. sulfuric acid and refluxed for five minutes. The solution was allowed to cool, the crystalline product separated by filtration and crystallized from ethyl acetate to give the mono-2,4-dinitrophenylhydrazone of uranedione, m. p. 200° dec.

Anal. Calcd. for $C_{27}H_{36}O_5N_4$: C, 65.4; H, 7.2. Found: C, 65.0; H, 7.3.

Epimerization of Steroids in the Mother Liquors.—The mother liquors from the crystallization of uranediol were evaporated and the residue dissolved in 200 cc. of xylene. Sodium (5 g.) was added and the mixture refluxed for eight hours. The excess sodium was destroyed with 95% ethanol and the resulting solution washed with dilute hydrochloric acid and water. The xylene was evaporated in vacuo at 40°. The sticky residue obtained was dissolved in 100 cc. of 95% ethanol and a boiling solution of 10 g. of digitonin in 250 cc. of 95% ethanol was added. A flocculent precipitate separated almost at once. The mixture was cooled at 20° for two hours, filtered and washed with 95% ethanol; 10.5 g. of white digitonide was obtained. The ethanol was distilled from the filtrate until a volume of about 50 cc. remained and 250 cc. of ether was added. The precipitate was collected and washed with ether. The ether was evaporated from the filtrate, leaving a sticky residue.

The residue was dissolved in 100 cc. of glacial acetic acid, 2.5 g. of chromic anhydride in 60 cc. of 60% acetic acid was added, and the mixture allowed to stand at room temperature for forty-five minutes. The mixture was then poured into 800 cc. of water and extracted with 800 cc. of ether. The ether extract was washed with water and aqueous sodium carbonate. The residue obtained by evaporation of the ether was sublimed in high vacuum at 130–150°. The sublimed material consisted almost entirely of uranedione, indicating the absence in pregnancy urine of other substances having a beta configuration at C_3 and the coprostane configuration at C_5.

We wish to thank Dr. Oliver Kamm and Parke, Davis and Company for their generous help and assistance in various phases of this work.

Summary

Uranediol, the presence of which in mares' pregnancy urine previously has been demonstrated, now has been isolated. It is shown to have the structure of uranediol-3(β),11. This is the first sterol derivative to be obtained from urine possessing the β-configuration on C_3 and the coprostane configuration on C_5. On oxidation it yields uranedione which, however, forms only a mono-semicarbazone and a mono-2,4-dinitrophenylhydrazone.

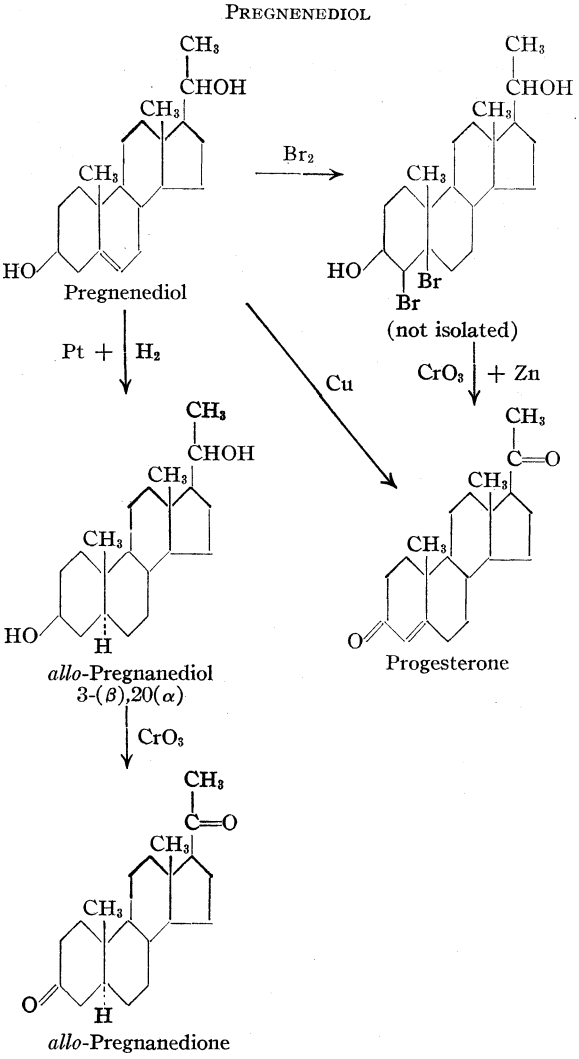
Sterols. XXXVIII. Pregnenediol in Mares' Pregnancy Urine and its Conversion into Progesterone

BY RUSSELL E. MARKER AND EWALD ROHRMANN

It is now fairly well established that pregnanediol and *allo*-pregnanediol are the final *in vivo* reduction products of progesterone. A number of intermediate reduction products, however, also have been isolated from both mares' and human pregnancy urines. *epi*-Pregnanolone[1] and *epi-allo*-pregnanolone[2] represent such partial reduction products which have been isolated from human urine. In addition to these, pregnanedione, *allo*-pregnanedione, and *allo*-pregnanol-3(β)-one-20 have been isolated from the ketonic fraction of mares' pregnancy urine.[3] The presence of these substances in pregnancy urine suggests that other possible reduction products might be present, specifically, compounds derived from $\Delta^{5,6}$-pregnene.

A preliminary study of the digitonin precipitated non-ketonic fraction of mares' pregnancy urine has shown the presence of two other reduction products of progesterone, namely, pregnenediol-3(β),20(α) and *allo*-pregnanediol-3(β),20(α). The fact that these products occur in the digitonin precipitated fraction indicates that the hydroxyl group at C_3 possesses the β-configuration. With the exception of *allo*-pregnanol-3(β)-one-20 all of the previously reported intermediate reduction products of progesterone have been of the *epi*- or (α)-configuration.

Pregnenediol was contaminated with another unsaturated compound, probably urenediol, which rendered complete purification difficult. Reduction of the pregnenediol with platinum catalyst yielded *allo*-pregnanediol-3(β),20(α) which upon oxidation with chromic anhydride gave *allo*-pregnanedione. Sublimation of the pregnenediol with copper yielded progesterone. Bromination followed by oxidation with chromic anhydride likewise yielded progesterone. The reactions involved are illustrated in the chart.



In addition to the reduction products of progesterone referred to above, there was isolated from the carbinol fraction of pregnant mares' urine the sterol β-equistanol, obtained previously from stallion urine.[4] We have found no evidence of the occurrence of cholesterol in mares' pregnancy urine.

Experimental Part

The insoluble digitonides A and B isolated in the work described in the preceding paper were used in this study. They were obtained from the neutral non-ketonic fraction from 1000 gallons (3700 liters) of mares' pregnancy urine. The Flow Sheet presented in Paper XXXVI should be consulted.

Decomposition of Digitonides from Carbinol Fraction I.—The 38 g. of digitonide A from carbinol fraction I was dissolved in 125 cc. of pyridine, the resulting solution was heated on the steam-bath for twenty-five minutes and poured into 1 liter of ether. The precipitate was filtered

(1) Marker and Kamm, THIS JOURNAL, **59**, 1373 (1937).

(2) Marker, Kamm and McGrew, *ibid.*, **59**, 616 (1937).

(3) Marker, Lawson, Wittle and Crooks, *ibid.*, **60**, 1559 (1938).

(4) Marker, Lawson, Rohrmann and Wittle, *ibid.*, **60**, 1555 (1938).

and washed with ether. The filtrate was then washed first with an excess of dilute hydrochloric acid and then with water. The ether was evaporated on the steam-bath and the residue sublimed in high vacuum at a temperature of 130 to 200°. The sublimed material appeared to be a complex mixture of substances which would not readily crystallize.

The residue from this distillation was reserved for another study.

Decomposition of Insoluble Digitonides from Carbinol Fraction II.—The 26 g. of insoluble digitonide obtained was dissolved in 150 cc. of hot pyridine and the solution heated on the steam-bath for thirty minutes and poured into 1.5 liters of ether. The precipitate was filtered and washed with ether. The filtrate was washed as usual, the ether was distilled off, and the orange colored residue dissolved in methanol and treated with Norite.

This material was combined with the sublimed fraction obtained from digitonide A.

Epimerization of Carbinols from Insoluble Digitonides A and B.—The residues obtained from the decomposition of digitonides A and B were combined and dissolved in 150 cc. of xylene, 7 g. of sodium was added and the mixture refluxed for seven hours. The excess sodium was destroyed with ethanol and the mixture washed with dilute hydrochloric acid and water. The xylene was evaporated *in vacuo* at 40°. The residue was dissolved in 250 cc. of boiling alcohol and to this was added a hot solution of 15 g. of digitonin in 250 cc. of alcohol. The mixture was cooled at 20° for one hour, filtered, and washed with alcohol to give insoluble digitonide C.

The alcohol was evaporated from the filtrate to a volume of about 50 cc., 500 cc. of ether was added and the small amount of precipitate was filtered and washed with ether to give a soluble digitonide D.

Equistanol from Digitonide D.—The 500 mg. of soluble digitonide D was dissolved in 5 cc. of pyridine, heated on the steam-bath for thirty minutes and the solution poured into 100 cc. of ether. The white precipitate was filtered and washed with ether. After washing the filtrate as before, the ether was evaporated from the steam-bath and the residue crystallized from methanol, giving white needles melting at 130°. This material gave no depression in melting point when mixed with a sample of equistanol from stallion urine.

Anal. Calcd. for $C_{30}H_{54}O$: C, 83.6; H, 12.6. Found: C, 84.0; H, 12.3.

Decomposition of Digitonide C.—Digitonide C (18 g.) was decomposed as before, the carbinols sublimed up to a temperature of 200°, and the sublimed material combined. The residue which did not distil at 200° was reserved for further study.

allo-Pregnanediol-3(β),20(α) from Mares' Pregnancy Urine.—The distilled solid from the decomposition of digitonide C containing only *allo* and unsaturated compounds was leached with a small amount of boiling acetone. The mixture was filtered and the insoluble residue was recrystallized from methanol to give small white plates, m. p. 216°, which gave no depression with an authentic sample of 3(β),20(α)-*allo*-pregnanediol.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.4; H, 11.3.

Pregnenediol-3(β),20(α) from Mares' Pregnancy Urine.—The filtrate obtained after separation of the *allo*-pregnanediol-3(β),20(α) was evaporated to dryness and the residue fractionally crystallized from acetone. Pure material was difficult to isolate due to contaminating substances of an unsaturated character, possibly urenetriol or urenediol. The material melted poorly at 160–170°. Recrystallized from benzene and then from acetone it melted at 172–176°. It readily took up bromine in acetic acid solution.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 78.9; H, 11.1.

Reduction of Pregnenediol-3(β),20(α).—Pregnenediol (200 mg.) was dissolved in 50 cc. of ether, 0.5 g. of Adams platinum catalyst was added and the material reduced for one hour at room temperature and 45 pounds (3 atm.) pressure. The catalyst was filtered and the ether evaporated from the filtrate. The resulting residue was crystallized from 90% ethanol to give material melting at 217°. This gave no depression in melting point when mixed with an authentic sample of *allo*-pregnanediol-3(β),20(α).

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.7; H, 11.2.

allo-Pregnanedione from allo-Pregnanediol-3(β),20 (α).—100 mg. of the *allo*-pregnanediol-3(β),20(α) obtained by reduction of pregnenediol-3(β),20(α) was dissolved in 10 cc. of glacial acetic acid; 200 mg. of chromic anhydride in 10 cc. of 90% acetic acid was added and the mixture allowed to stand at room temperature for thirty minutes. The mixture was then poured into water and extracted with ether. The ether extract was washed with aqueous sodium carbonate and water. The ether was evaporated and the residue crystallized from acetone to give white crystals melting at 199°. This gave no depression in melting point when mixed with an authentic sample of *allo*-pregnanedione.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.6; H, 10.2.

Progesterone from Pregnenediol by Copper Oxidation.—Pregnenediol (100 mg.) was mixed thoroughly with 0.5 g. of Baker precipitated copper. The resulting mixture was heated at 230° at 20 mm. for thirty minutes. The mixture was then sublimed in high vacuum at 125°. The sublimed material was dissolved in 4.5 cc. of alcohol and 1.8 cc. of water was added to the resulting solution. After clarification with Norite the filtrate was cooled in salt–ice and the walls of the container were scratched vigorously. White crystals formed, m. p. 118–119°. This gave no depression in melting point when mixed with a sample of natural progesterone.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.1; H, 9.6. Found: C, 80.0; H, 9.5.

Progesterone from Pregnenediol by Chromium Oxidation.—Pregnenediol (200 mg.) was dissolved in 25 cc. of glacial acetic acid and the theoretical amount of bromine in acetic acid was added. To this solution was added 150 mg. of chromic anhydride dissolved in 20 cc. of 90% acetic acid. The mixture was allowed to stand for thirty minutes at room temperature, 5 cc. of alcohol and 1 g. of zinc dust were added and the mixture heated on the steam-bath for thirty minutes. The mixture was filtered and the filtrate diluted with water and extracted with 250 cc. of ether. The ether extract was washed with sodium carbonate solution and water, the ether evaporated, and the residue sublimed in high vacuum at 125°. After crystallization from 70% ethanol it melted at 118°.

We wish to thank Dr. Oliver Kamm and Parke, Davis and Company for their generous help and assistance in various phases of this work.

Summary

Pregnenediol-3(β),20(α) and *allo*-pregnanediol-3(β),20(α) have been isolated from mares' pregnancy urine. Pregnenediol-3(β),20(α) upon oxidation gave progesterone and upon catalytic reduction gave *allo*-pregnanediol-3(β),20(α). β-Equistanol, previously obtained from stallion urine, has now been detected also in mares' pregnancy urine.

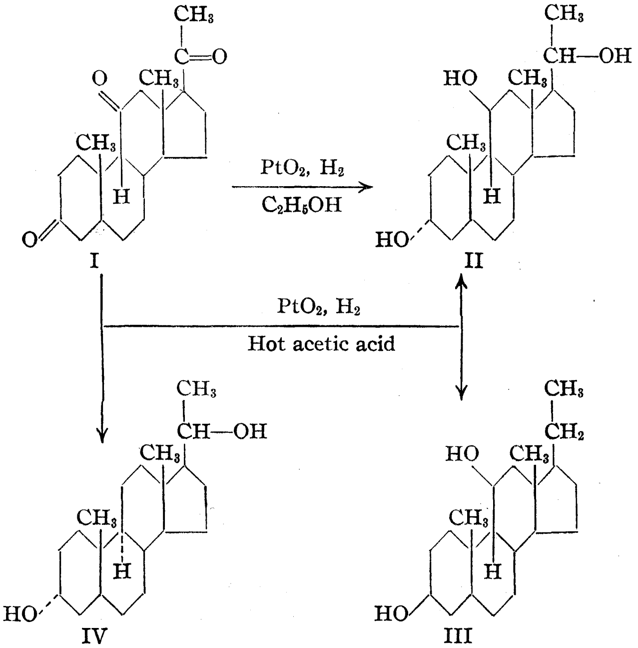
Sterols. XXXIX. The Reduction of Uranetrione

BY RUSSELL E. MARKER, EUGENE L. WITTLE AND THOMAS S. OAKWOOD

Uranetrione (I) is a 3,11,20-triketo-urane which has been found in previous work[1] to give uranedione (3,11-diketo-urane)[2] and pregnanedione when subjected to a series of reactions, the first step being catalytic reduction. In this paper a study of the reduction of uranetrione is presented.

Catalytic reduction of uranetrione (I) with platinum oxide in ethyl alcohol gave a product which on treatment with digitonin yielded a digitonide corresponding to approximately 10% of the product. The major unprecipitated fraction was found to contain a trihydroxy compound (II), as shown by the formation of a triacetate which is unaffected by further vigorous reduction or by chromic acid oxidation. This fraction, which did not precipitate with digitonin, was practically pure triol, showing that reduction of the carbonyl group at C-11 proceeded with the formation of only one of the two possible epimers. This behavior on reduction is therefore similar to that of the carbonyl group at C-20 which also gives only one epimer. The formation from uranetrione of a triol which forms a triacetate is in contrast to the reduction of a cortical steroid studied by Kendall.[3] His acid 1B (3-β-hydroxy-11-keto-aetio-*allo*-cholanic acid) was hydrogenated catalytically, and the resulting dihydroxy-aetio-*allo*-cholanic acid partially oxidized to give acid 1D (3-keto-11-hydroxy-aetio-*allo*-cholanic acid), which was stereoisomeric at C-11 with his dihydro acid 2. Acid 1D does not react with thionyl chloride or with acetylating reagents, and has a configuration at C-11 opposite to that of the natural cortical steroids.



According to our early prediction, uranetriol[1] now can be assigned definite stereochemical configurations. According to the arguments presented in an earlier paper,[1] a C-11α-hydroxyl group in a urane derivative is much more blocked than the epimeric C-11β-hydroxyl group, and, unlike the latter, will not form an acetate. Since triol (II), like uranetriol, forms a triacetate and does not precipitate with digitonin the configurations of the 3- and 11-hydroxyls in both these triols are established to be of the α- and β-configuration, respectively. The two triols, which

---

(2) Marker, Rohrmann and Wittle, *ibid.*, **60**, 1561 (1938).

(3) Mason, Hoehn, McKenzie and Kendall, *J. Biol. Chem.*, **120**, 719 (1937).

are not identical, can therefore differ only in regard to the configuration of the hydroxyl group at C-20. By analogy with the pregnanediols, in which only 20α-hydroxyl groups occur naturally and only 20β-hydroxyl groups are formed on catalytic reduction, the configurations of uranetriol-(3α,11β,20α) and triol (II) (3α,11β,20β) are therefore established.

Reduction of uranetrione in hot acetic acid gave a product which was again separated with digitonin. The digitonide, corresponding in this case to approximately 20% of the product, gave on decomposition practically pure uranediol (III) which was identical with uranediol isolated from mares' pregnancy urine.[2] The diacetate prepared from diol (III) was also identical with uranediol diacetate. Thus in this case also the reduction of the carbonyl group at C-11 gave only the β- or natural configuration of the hydroxyl group. The fraction which did not precipitate digitonin was quite impure and could not be crystallized. It was treated with acetic anhydride and the product on crystallization gave the triacetate of triol (II) identical with that obtained from reduction of uranetrione (I) in ethyl alcohol.

The formation of uranediol suggests an alternate mechanism by which in previous work uranedione and pregnanedione were obtained. It now appears that vigorous reduction in hot acetic acid partially removed the carbonyl group at C-20 to form uranediol, and must have partially removed the carbonyl group at C-11, with inversion of the configuration at C-9 from a urane to a pregnane structure, to give pregnanediol (IV). The resulting carbinol mixture on oxidation gave a mixture of uranedione and pregnanedione. The formation of uranediol and pregnanediol could only have taken place in the first step of the transformation of uranetrione to uranedione and pregnanedione[1] as triol II, the other product of reduction, forms a triacetate which in the course of the other reactions to which the mixture was subjected could not give these two products.

It is to be noted that both carbonyl groups which were removed in the above reduction are alpha to a tertiary hydrogen; so the reduction is similar to that of 7-keto-cholesteryl chloride.[4]

Partial reduction of uranetrione in ethyl alcohol gave, besides some unchanged uranetrione, a product which precipitated digitonin (β-hydroxyl group at C-3) and gave an analysis corresponding to a hydroxy diketone $C_{21}H_{32}O_3$. It formed a monoacetate when treated with acetic anhydride. The reduction of uranetrione thus resembles that of the pregnanediones[5] in which the carbonyl group at C-3 is the first to undergo reduction.

In an attempt to isomerize uranediol (III) with sodium in boiling xylene to effect inversion at C-3 the compound was recovered largely in the original form and only a small amount of material not precipitated by digitonin could be obtained. Uranetriol, possessing an α-configuration at C-3, is also changed only slightly by this treatment. It thus appears that the urane compounds are more difficult to isomerize in this manner than those of the pregnane series.

Experimental Part

The Reduction of Uranetrione in Ethyl Alcohol.—A suspension of 50 mg. of platinum oxide in a solution of 500 mg. of uranetrione in 50 cc. of ether and 50 cc. of ethyl alcohol was shaken with hydrogen at 3 atmospheres pressure and 25° for five hours and then filtered to remove the catalyst. The filtrate was distilled until all of the ether was removed and then added to a solution of 300 mg. of digitonin in 50 cc. of ethyl alcohol and allowed to stand for four hours. The digitonide was collected and dried (250 mg.). The filtrate was evaporated to 10 cc. and diluted with 100 cc. of ether. The precipitated digitonin was filtered off and the filtrate after several washings with water was evaporated to dryness leaving a white solid which was very soluble in methyl and ethyl alcohols. It was crystallized from ether–pentane to yield 300 mg. of triol (II), m. p. 255°.

Anal. Calcd. for $C_{21}H_{36}O_3$: C, 74.9; H, 10.8. Found: C, 74.6; H, 10.6.

The triacetate, prepared by refluxing 50 mg. of this compound with 2 cc. of acetic anhydride for one-half an hour, was crystallized from methyl alcohol, m. p. 192°.

Anal. Calcd. for $C_{27}H_{42}O_6$: C, 70.1; H, 9.2. Found: C, 70.2; H, 9.2.

This compound was treated with platinum oxide and hydrogen in acetic acid at 85° but was recovered unchanged. On treatment with an equal weight of chromic anhydride in acetic acid at 25° it was also recovered unchanged.

Reduction of Uranetrione in Hot Acetic Acid.—A suspension of 1 g. of platinum oxide in a solution of 100 cc. of glacial acetic acid containing 0.8 g. of uranetrione was shaken with hydrogen at 3 atmospheres and 85° for eight hours and then filtered from the catalyst while hot. The filtrate was evaporated to dryness in vacuum and the residue was dissolved in ether, washed with a sodium carbonate solution and water, and the solution was evaporated to dryness. The residue was dissolved in 50 cc. of alcohol and to it was added a solution of 1 g. of digitonin in 50 cc. of alcohol. After standing overnight the digitonide

---

(4) Marker, Kamm, Fleming, Popkin and Wittle, THIS JOURNAL, **59**, 619 (1937).

(5) Marker, Kamm and Wittle, *ibid.*, **59**, 1841 (1937).

was collected, washed and dried (800 mg.) and heated for one hour on a steam-bath with 10 cc. of pyridine. The solution was diluted with 100 cc. of ether, filtered from digitonin, and the filtrate was washed with dilute hydrochloric acid until acid, and then with water. The ether was evaporated to dryness and the residue was crystallized from methyl alcohol to yield 150 mg. of uranediol, m. p. 215°. It gave no depression in melting point when mixed with uranediol (213°) isolated from mares' pregnancy urine.

The acetate was prepared from this compound in the usual manner, m. p. 160°. It gave no depression in melting point when mixed with uranediol diacetate.

Anal. Calcd. for $C_{26}H_{40}O_4$: C, 74.4; H, 10.0. Found: C, 74.2; H, 10.1.

The filtrate from the digitonide was concentrated to 10 cc. and diluted with 100 cc. of ether to precipitate the excess digitonin. This was filtered off and the filtrate after several washings with water was evaporated to dryness and the remaining oil was found to resist crystallization. The solution was evaporated to dryness and the oily residue was converted to the acetate by refluxing it for one hour with 10 cc. of acetic anhydride and evaporating the solution in vacuum. The residue was crystallized from methyl alcohol to yield the triacetate of triol (II) m. p. 188°. It gave no depression in melting point with the triacetate of triol (II) obtained previously m. p. 192°.

Partial Reduction of Uranetrione in Alcohol.—A suspension of 200 mg. of platinum oxide in a solution of 300 mg. of uranetrione in 200 cc. of ethyl alcohol and 100 cc. of ether was shaken with hydrogen at 3 atmospheres and 25° for one hour and then filtered from the catalyst. The filtrate was distilled to remove the ether and then added to a solution of 2 g. of digitonin and allowed to stand for eight hours. The digitonide (200 mg.) was decomposed as usual, giving 50 mg. of white solid which was purified by crystallization from methyl alcohol, m. p. 225° (fibrous clusters).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.8; H, 9.7. Found: C, 76.0; H, 9.7.

A portion of this compound was converted to the acetate which melted at 250° (from alcohol).

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.7; H, 9.2. Found: C, 73.6; H, 9.2.

Attempted Isomerization of Uranediol.—Uranediol (150 mg.) was dissolved in 50 cc. of xylene, 2 g. of sodium was added and the mixture was refluxed for nine hours. The recovered product was dissolved in 50 cc. of ethyl alcohol and treated with 2 g. of digitonin. The digitonide was filtered off, dried and heated in pyridine for one hour. The solution was diluted with ether and filtered, and the filtrate yielded on evaporation a product which on crystallization from acetone gave 100 mg. of the original uranediol, m. p. 214°. The portion not precipitated by digitonin could not be crystallized to a pure product.

The authors wish to express their thanks to Parke, Davis & Co. of Detroit, Michigan, for a grant of funds supporting this work.

Summary

The reduction products of uranetrione were studied and found to be uranediol, a new triol and uranol-3β-dione-11,20.

A New Fluorination Method

BY ALBERT L. HENNE

Principle of the Method.—This paper reports the use of nascent mercuric fluoride as a method for replacing one or several halogen atoms by fluorine in various types of compounds. In practice, the method consists in passing a stream of hydrogen fluoride through a well-stirred mixture of mercuric oxide and the substance to be fluorinated. The reaction between the acid and the oxide occurs instantly, and so also does the one between the mercuric fluoride so generated and the organic material. Since a great deal of heat is evolved, means must be provided to prevent the reaction from escaping control, and also to avoid the loss of volatile or easily destroyed reaction products. These means vary with the substances undergoing fluorination and therefore merely call for some ingenuity.

Dry and Nascent Mercuric Fluoride.—The use of anhydrous mercuric fluoride as a fluorinating agent has been described before.[1] It was pointed out at the time that only the anhydrous salt could be used, and this statement was verified repeatedly. Attempts to manufacture the dry salt by methods more conventional than the action of fluorine upon mercuric chloride forced the conclusion that aqueous reagents invariably would yield a dihydrated salt which could not be converted to the anhydrous salt because it always would lose hydrofluoric acid in preference to water. In an effort to circumvent this, mercuric oxide and hydrogen fluoride were allowed to react in an inert organic liquid. This reaction generates one molecule of mercuric fluoride and only one

(1) Henne and Midgley, THIS JOURNAL, **58**, 884 (1936).

molecule of water, or possibly the monohydrated salt, and it was hoped that this monohydrate in contrast to the dihydrate might be dried to the anhydrous salt. Methylene chloride and chloroform were chosen as reaction media because organic chlorides are not appreciably affected by mercuric fluoride at room temperature, because their low boiling points would automatically maintain the reaction at 40 or 60°, respectively, and because it was hoped that their high densities might cause the water to separate in a top layer. The result of the experiments, however, was quite unexpected, because the white crystalline salt thus obtained was pure mercuric chloride, instead of fluoride, an indication that the nascent mercuric fluoride had reacted instantly with the organic chloride despite the low temperature and the presence of water. An examination of the volatilized reaction products disclosed the presence of methylene fluoride and difluorochloromethane, respectively, two substances described in a preceding paper.[2] This confirmed the interpretation of the reaction course.

Practical Adaptation.—The fluorination of acetylene tetrabromide was studied quantitatively to supply a gage of the practical work of this new fluorination method, and the following simple procedure was found convenient for laboratory operation.

Three gram molecules of acetylene tetrabromide was placed in a tall metal container, preferably made of nickel, and cooled externally with water. One gram molecule of red mercuric oxide was added to the liquid, and immediately stirred to prevent the formation of a heavy paste or cake. Dry hydrogen fluoride from a commercial cylinder was led into the liquid through a metal tube (flexible copper tubing is convenient). The flow of gas was regulated so that the temperature of the reaction mixture never exceeded 40 to 50°. The red color of the mercuric oxide fades progressively to pink, yellow, grayish white and finally to gleaming white; this is the end of the reaction. At this point it was found that about 2.3 gram molecules of hydrogen fluoride had been used, which is an excess of 15% over the theoretical quantity required. The white salt is pure mercuric bromide, with a correct mercury content of 55.6%. It may be noted that an aqueous layer of concentrated hydrofluoric acid floats on the surface. At the end of the reaction the mixture was poured onto cracked ice and washed roughly by decantation to remove the excess of acid. It was then placed in a distilling flask, with twice its volume of water, and heated with a free flame, kept in constant motion to prevent foaming. Steam distillation of the fluorinated material takes place promptly and carries along some acetylene tetrabromide. The distillate was decanted from the water, dried and rectified; it yielded 0.6 gram molecule of CHF_2CHBr_2 and 0.4 gram molecule of $CHFBrCH_2Br$, which is an 80% fluorination yield, based on the mercuric oxide. The material left unsteamed in the distilling flask was cooled overnight, preferably on ice; this causes the mercuric bromide to crystallize out completely and facilitates filtration. The aqueous layer was separated as completely as practical, and the remainder filtered with suction and air dried on the filter. The filtrate separates into a layer of acetylene tetrabromide and a layer of water. The solid material was removed from the filter, placed in a bottle, covered with chloroform, vigorously shaken for twenty minutes, and then filtered by suction. Pure mercuric bromide is left on the filter, while the filtrate is a chloroform solution containing from 75 to 100 cc. of acetylene tetrabromide. Distillation of the chloroform makes it possible to recover the latter material.

Mercury Recovery.—As described so far, this method would be quite costly if the mercury could not be recovered and reoperated. This, however, was performed as follows. The mercury bromide was dropped in small quantities into an aqueous solution of sodium hydroxide. A great deal of heat was evolved, and a black precipitate of mercury oxides was generated, which settled very slowly. The mixture was brought to boiling, then allowed to settle overnight. After decantation of the aqueous layer, water was added and brought to boiling. After again settling overnight the liquid was decanted from the black substance which was then allowed to dry in air, after which it was placed in a steel container (made of pipe fittings), equipped with a screw cap and a delivery tube leading into a pan of water. The steel container was heated with a large gas burner to decompose the mercury oxides and distil the mercury into the water. More mercury was recovered by pouring the distillation residue into water. The recovery of the mercury is quite complete when large enough quantities are used in each batch to avoid mechanical losses.

Temperature and Yields.—The new reaction was then applied to the fluorination of $CH_2BrCHBr_2$, and it was found that $CHFBrCH_2Br$ and CHF_2CH_2Br were generated, as expected, but the fluorination yield of about 30% was at first disconcerting. The mercury bromide was recovered quantitatively, but the tribromoethane was not, and its loss corresponded to the missing fluorinated material. The reaction was tried at different temperatures and it was promptly found that the yield improved as the temperature was lowered. At 0° the yields increased to 50%, and at −20° the yields became about 65 to 70%. This showed that the yield is mostly a matter of adequate temperature control.

Generality of the Reaction.—In order to test the generality of the reaction, the new method was applied to different compounds, at room temperature, with and without saturated hydrocarbons as diluents. Fluorination always occurred instantly and yields were obtained even on small batches and without many precautions, which were always considerably higher than 50%, usually about 70%. More careful handling, tried in only a few cases, always improved the yields markedly. The results were as follows: $AcOCH_2CH_2F$ was obtained from $AcOCH_2CH_2Br$; $AcOCH_2CHF_2$ from $AcOCH_2CHBr_2$; CH_2F_2 from CH_2Cl_2; $CHClF_2$ from $CHCl_3$; CH_3CHF_2 from CH_3CHCl_2; $CH_3(CH_2)_5CHF_2$ from $CH_3(CH_2)_5CHCl_2$; $(C_6H_5)_2CF_2$ from $C_6H_5CCl_3$; $(C_6H_5)_3CF$ from $(C_6H_5)_3CCl$; CF_2ClCF_2Cl from $CFCl_2CFCl_2$, CHF_2CClF_2 from $CHCl_2CClF_2$ and

---

[2] Henne, This Journal, **59**, 1400 (1937).

from CHF_2CCl_3. In no case was the fluorination reaction accompanied by loss of hydrogen chloride or hydrogen fluoride and consequently no ethylenic by-product was found. There was usually no tar formation, but a very small quantity was formed in the worst cases, when reagents of "technical" grade were employed.

Summary

A method of fluorination is described which consists in passing a stream of hydrogen fluoride through a mixture of the substance to be fluorinated and mercuric oxide. Practical directions are given for obtaining good yields and for a simple method of recovering the mercury.

Variations in the Relative Abundances of the Isotopes of Common Lead from Various Sources

BY ALFRED O. NIER[1]

Because of the apparently constant atomic weight of common or ore lead, the assumption usually has been made that its isotopic composition also is constant. Whereas several isolated isotopic analyses of common lead have been made, there is no record of any systematic study having been undertaken for the purpose of checking the constancy of the relative abundances. In the present work twelve samples were studied with a mass spectrometer and considerable variations were found. The investigation is of particular interest, as the specimens examined vary greatly in both geologic age and geographic origin. Moreover, of the twelve samples, nine have had chemical atomic weight determinations made on them—all in the same laboratory.

Apparatus and Procedure.—The mass spectrometer used for obtaining the results to be presented here already has been described.[2] Positive ions of lead are formed by the collision of electrons with lead iodide vapor. The ions are drawn out of the region where they are formed, are accelerated and sent around a 180° magnetic analyzer where the ion currents are measured with an electrometer tube amplifier.

During an analysis, the portion of the tube containing the semicircular analyzer is kept at room temperature. The part where the ions are formed is held around 400°, and the side-tube from which the lead iodide vapor diffuses into the ionizing region is maintained at approximately 300°, the exact temperature depending on the pressure desired in the ionizing region. In actual practice, this pressure was between 10^{-4} and 10^{-5} mm. The amount of material needed for an analysis is very small. During a typical run, where no attempt was made to economize on material, less than 13 mg. of lead iodide, *i. e.*, less than 6 mg. of lead, was consumed. With reasonable care it should be possible to obtain reliable results on 1 mg. of lead.

The procedure in making an analysis was as follows: the sample to be studied was attached in the evening and the mass spectrometer tube evacuated and baked overnight in order thoroughly to out-gas it. Measurements were taken the next morning and afternoon. The side-tube containing the sample was removed and the mass spectrometer was again baked overnight, this time to remove the lead iodide. The following morning the apparatus was baked for several hours with iodine vapor flowing through it to combine with any metallic lead deposited in the tube from the thermal decomposition of lead iodide. Baking of the tube continued until late in the evening in order to remove the remaining traces of lead iodide. A new sample could then be attached and the procedure repeated. It is seen that an analysis may be performed every two days. Actually, in one case, fifteen samples were examined in thirty-four consecutive days.

Because of the careful treatment of the apparatus between samples, described above, the relative abundances of the isotopes obtained for a given specimen did not depend upon the previous history of the apparatus. That is to say, there was no contamination due to previous samples. In fact, one even could change from a sample of ordinary lead to one of radiogenic lead and then back again to the ordinary lead and reproduce the original results exactly.

The lead iodide was prepared by precipitation

---

[1] National Research Fellow.

[2] Nier, *Phys. Rev.*, **52**, 933 (1937).

from a solution of the nitrate (in a few cases from the chloride) with a solution of sodium iodide, washing and drying. Since the groups $I^{127}Br^{79}$ and $I^{127}Br^{81}$ have the same masses as two of the isotopes of lead, the iodine from which the iodide was prepared was carefully freed from bromine, as well as chlorine.

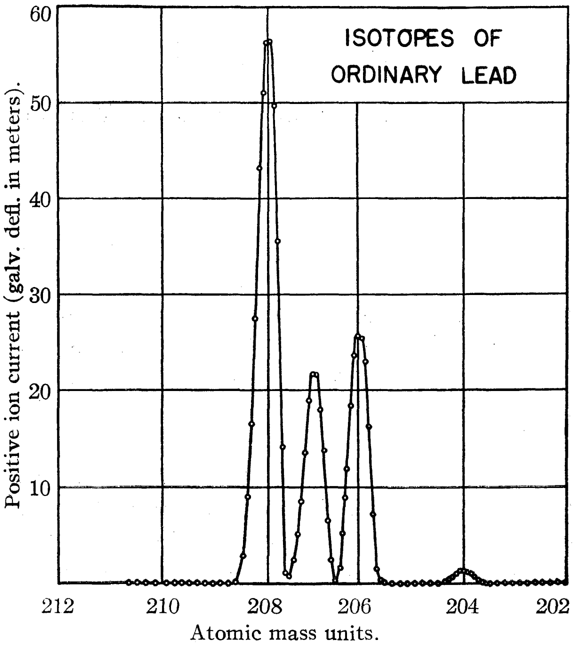

Fig. 1.—Mass spectrum showing the isotopes of common lead. Positive ion current expressed in terms of cm. deflection of galvanometer at its highest sensitivity. One cm. represents about 2.5×10^{-15} ampere.

Results

Preliminary reports on the results to be presented here have already been given.[3] A typical mass spectrum obtained is shown in Fig. 1. The relative abundances of the isotopes are assumed to be proportional to the relative heights of the positive ion current peaks. This assumption is justified in view of the fact that the relative heights as measured were found to be independent of variable conditions in the tube, such as electron current, pressure, etc. As a further check upon any possible discrimination in the apparatus, mercury vapor was admitted occasionally, and the Hg^{198}/Hg^{204} abundance ratio measured under conditions similar to those employed while the lead measurements were being taken. At no time was this ratio found to differ appreciably from that previously given.[2]

Figure 2 gives the lower part of Fig. 1 in greater detail. It can be seen from this that Pb^{204} produces a very definite peak that can be measured with nearly the same accuracy as the other peaks. Inasmuch as the apparatus was thoroughly baked and liquid air used on the traps, the height of the Hg^{204} peak is negligible, since even Hg^{202}, which exists with over four times the abundance of Hg^{204}, cannot be discerned in Fig. 2. In addition, no traces appear of the isotopes Pb^{210}, Pb^{209}, Pb^{205}, and Pb^{203}, at one time reported by Aston[4] with abundances indicated by the horizontal lines above the corresponding mass number position. Later, Aston[5] withdrew these isotopes in view of the fact that in a number of elements his rarer isotopes were found to be of a spurious origin. In particular, Bainbridge and Jordan[6] showed that Pb^{209} could not exist with even one-tenth the abundance originally claimed for it by Aston. That the withdrawal of the other rare lead isotopes was justified is shown by the present work. It is now possible to say that if Pb^{210}, Pb^{209}, Pb^{205}, and Pb^{203} exist, it must be with abundances less than $^1/_{100}$, $^1/_{1000}$, $^1/_3$, and $^1/_{20}$ of those originally given by Aston.

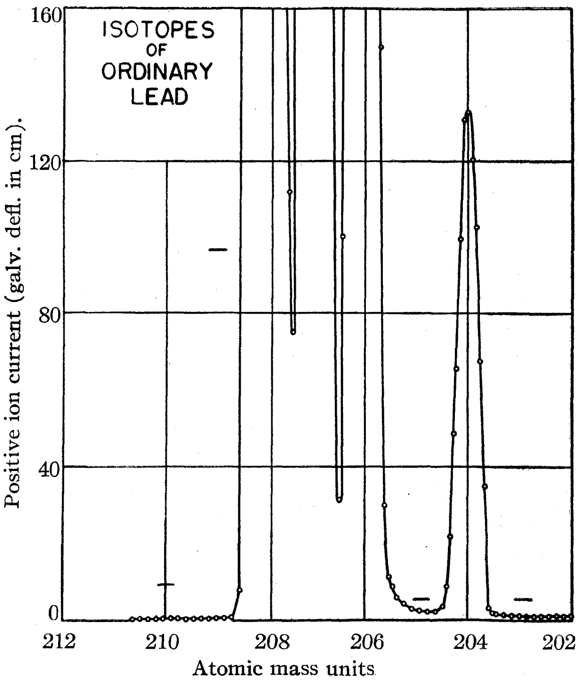

Fig. 2.—Lower portion of Fig. 1, drawn with enlarged ordinate scale.

Columns 4, 5, 6, and 7 of Table I give the relative abundances of the isotopes found for twelve samples of lead varying vastly in both geologic

[a] Sample calculation: 207.218 = 207.243 × (1 + 1.55 × 10^{-4})/1.000275. [b] Marble, THIS JOURNAL, **59**, 653 (1937). [c] Baxter and Grover, *ibid.*, **37**, 1027 (1915). [d] Baxter and Alter, *ibid.*, **57**, 467 (1935). [e] Baxter, Faull and Tuemmler, *ibid.*, **59**, 702 (1937). [f] Sample 12 was obtained from Dr. A. V. Grosse, of the University of Chicago, who believed it to be a sample of galena from Saxony, Germany.

age and geographic origin. The abundance of 204 has been chosen arbitrarily as a reference, as it is not produced, as far as is known, by radioactive decay. An examination of the results reveals that variations occur in the relative abundances with different samples. These variations lie outside the possible experimental errors, as is evidenced by the fact that with the four samples where analyses were repeated the agreement was within at least one per cent. The probable error in the measurements is of the order of 0.5%.

In the last two columns of Table I are given the atomic weights as determined by the physical and chemical methods. In computing the atomic weight from the physical data, the mean mass number is first calculated from the relative abundances. The result so obtained is converted to the chemical scale as follows. The conversion factor in going from the physical to the chemical scale is taken as 1.000275.[7] The packing fraction of lead was found by Aston[4] to be between 0 and +1.0, whereas a value of +2.0, or greater, is deduced from Dempster's[8] data. In computing the atomic weight from the physical data, a packing fraction of +1.55 is chosen arbitrarily, as it brings the physical and

(8) Dempster, *Phys. Rev.*, **53**, 64 (1938).

chemical values into the best possible agreement.

Table II gives the results of previous investigators as well as the results obtained by the writer for his two extreme samples, numbers 1 and 7. All abundances are given in percentages for the sake of comparison. In view of the relatively large variations reported in the present work, no serious discrepancies exist between the work of the various experimenters. It should be mentioned, however, that the measurements on Pb^{204} here reported are the only accurate ones obtained to date.

TABLE II

	208	207	206	204	Mean mass number
Aston[4]	50.1	20.1	28.3	1.5	207.173

Mattauch[10]	52.95	21.35	24.55	1.15	207.25
Nier, Sample 1	52.29	22.64	23.59	1.48	207.243
Nier, Sample 7	51.43	20.00	27.31	1.26	207.203

Discussion

An examination of the variations shows that they are definitely not of a random nature; those samples which contain relatively more Pb^{206} also contain relatively more Pb^{207} and Pb^{208}. Within the experimental errors samples 1, 2, 3, and 10 have the same isotopic constitution and also contain the least amounts of Pb^{206}, Pb^{207}, and Pb^{208}. The fact suggests that one consider the other samples as made up of this kind of lead plus contaminations of uranium lead (Pb^{206} and Pb^{207}) and thorium lead (Pb^{208}). For want of a better name for the lead low in Pb^{206}, Pb^{207}, and Pb^{208}, one may call it "uncontaminated" lead. As the three oldest samples have the isotopic constitution of "uncontaminated" lead there is a strong temptation to identify it tentatively with primeval lead—that is, lead as it existed when the earth's crust formed. The discovery of a sample of common lead containing less Pb^{206}, Pb^{207}, and Pb^{208} might force one to make a quantitative change in the argument to be presented here, but it seems doubtful that one will be found which differs enough to compel one to make a qualitative change.

Samples 1, 2, and 3 will thus be considered tentatively as "uncontaminated" lead. In columns 8, 9, and 10 are then recorded the excess amounts of 206, 207, and 208, *i. e.*, radiogenic contamination, for the other "contaminated" samples. The isotopic constitution of sample 1 is arbitrarily chosen as that for "uncontaminated" lead in making the subtraction. Thus, the amount of excess 206 for sample 4 is obtained by subtracting 15.93 from 18.43, etc. The choice of sample 1 as typical "uncontaminated" lead is a rather unfortunate one in spite of the great age of this sample, as it came from the Great Bear Lake region (a source of uranium ores), and hence might possibly have become contaminated. However, this sample does contain as little 206, 207, and 208 as any of the others, so that the choice is as good a one as can be made at this time.

An examination of the amounts of excess isotopes reveals that the excess 208 is practically equal to the excess 206, whereas the excess 207 is approximately 10% of the excess 206 in each case, the averages for all the contaminated samples being, excess 208/206 = 1.13, excess 207/206 = 0.10. It should be mentioned that the minerals from which the lead was extracted were essentially free of thorium and uranium, and hence, in all probability, the contamination of the "uncontaminated" lead by radiogenic lead took place before the mineral was formed. In the case of the Joplin material, a rough calculation shows that if the excess isotopes were generated by thorium and uranium present as impurities in the galena, the amounts would have to be, respectively, *two and six times as great* as the total amount of lead present!

It is a common belief among many students of ore deposits that ore lead has its ultimate origin in the igneous rocks or the magmas of these rocks. If such is the case, one should expect it to consist of primeval lead contaminated by radiogenic lead, inasmuch as the igneous rocks are known to contain uranium and thorium, and, consequently, radiogenic lead as well as common lead.

The values found for the two ratios for excess isotopes are not at all unreasonable, as far as supporting the contamination hypothesis is concerned, in view of other information at our disposal. If one assumes the age of the earth to be around 2 × 10^9 years, and if one further assumes that the radiogenic lead appearing in the above samples was being formed during the time between the formation of the earth and the formation of the minerals, one may assume the average age of the radiogenic contaminations to be of the order of 1.5 × 10^9 years, the exact value assumed being quite immaterial. As the rate of decay of ura-

---

(10) Mattauch, *Naturwissenschaften*, **25**, 763 (1937).

nium is approximately three times that of thorium, the Th/U ratio in the substance in which the radiogenic lead was formed then must have been $3 \times 1.13 = 3.4$. Due to the difference in the rates of decay of thorium and uranium, the Th/U ratio of such a source would be today $3.4/0.85 = 4.0$.

Holmes[11] assumes this ratio to lie between 1.6 and 2.4 for igneous rocks. Evans and Raitt[12] believe the value to be considerably higher, possibly between 5 and 10. Finney and Evans[13] give values between 3.2 and 10.6, with an average of about 7. The Pb^{208}/Pb^{206} ratios found by the writer for the excess lead are thus not inconsistent with the view that ore lead is a concentration from igneous rocks or the magmas of such rocks.

The ratio of excess $Pb^{207}/Pb^{206} = 0.10$ lends further support to this hypothesis, as it is roughly of the right order of magnitude for old uranium lead. An actual calculation using new data available for the relative abundances of the uranium isotopes[14] indicates that for the uranium lead formed during the period between 2×10^9 and 5×10^8 years ago the Pb^{207}/Pb^{206} ratio would be approximately 0.14. In view of the fact that the numbers given in the column of excess Pb^{207} are obtained by subtracting two numbers very nearly equal, one can hardly expect better agreement. Moreover, this ratio depends in a somewhat critical way on what one assumes the isotopic constitution of primeval lead to be. The disagreement might well indicate that "uncontaminated" lead differs slightly from primeval lead.

In a recent paper, Holmes[11] makes use of the constancy of the atomic weight of common lead (and the alleged isotopic constancy) in an attempt to prove that it cannot be a concentration from granitic or basaltic rocks, or their respective magmas, but must have its origin in some deeper source in the earth. The present work shows definitely that the relative abundances of the isotopes of common lead do vary, but that the manner of variation is such as to have little effect upon the atomic weight. Moreover, the data are not inconsistent with the view that ore lead is related to ordinary igneous rocks, provided that one assumes the Th/U ratio in such rocks to be around 4.0, rather than 1.6 to 2.4 as is assumed by Holmes. Nine of the twelve samples studied by the writer were the *identical* samples which appear among those listed in Holmes' Table IV.

On a simple igneous rock derivation picture one should expect the oldest samples to contain a minimum of radiogenic lead contamination and the youngest a maximum. In this respect the data have some deficiencies which may or may not be of a serious nature. Except for the fact that the three oldest samples contain a minimum of apparent contamination there is no direct correlation between the age of the deposit and the amount of contamination. In fact, sample 10, a young mineral, has essentially the same isotopic constitution as the assumed "uncontaminated" lead. Such apparent difficulties may be only a manifestation of the fact that the total amounts of uranium and thorium in rocks vary greatly from specimen to specimen, and hence the proportion of radiogenic lead to ordinary lead in such specimens also varies quite independently of any variation with time.

In conclusion, the writer wishes to emphasize the fact that the explanation for the variations advanced in this paper is to be taken as tentative only. The accumulation of more data may lead the way to a better theory. However, with the information now available, the interpretation does seem to be reasonable and not in serious disagreement with any well established fact. An objection may be raised that the variations might be present in primeval lead itself. In answer to this, one can only say that the variations are much larger than any that have been reported for other elements (with the possible exception of hydrogen and a few other isolated cases, where the variations can be explained very easily by isotopic separation taking place in nature). It does not seem likely that the variations reported here can be due to isotopic separation, as one would expect them to be a monotonic function of the mass. The view entertained by some that common lead may be only a mixture of thorium and uranium leads generated since the earth's beginning certainly is not correct for at least two reasons, namely, (1) common lead contains Pb^{204} which apparently is not produced by the disintegration of uranium or thorium, and (2) the Pb^{207}/Pb^{206} ratio in common lead is far too high to be consistent with our knowledge of the relative rates of decay of the actinium and uranium series,

provided one assumes the age of the earth to be of the order of 2×10^9 years.

The writer wishes to express his appreciation to Professor G. P. Baxter of the Department of Chemistry, Harvard University, who very kindly prepared and furnished eleven of the twelve samples used. It was only through his interest and coöperation that this work was possible.

Summary

1. A mass spectrographic study of the isotopes of twelve samples of common lead shows that the relative abundances vary considerably in spite of a nearly constant atomic weight.

2. A tentative explanation for the variations is found if one arbitrarily considers some of the samples to be "uncontaminated" lead and the others "uncontaminated" lead to which has been added approximately equal quantities of uranium and thorium leads. As the minerals from which the lead was obtained are essentially free of thorium and uranium, such contamination probably took place before the mineral was formed.

3. A search for the isotopes Pb^{210}, Pb^{209}, Pb^{205}, and Pb^{203} indicated that if such isotopes exist at all they must exist with much lower abundances than was at one time supposed.

Studies on Aging and Properties of Precipitates. XXII. The Induced Precipitation of Mercuric Sulfide from Sodium Mercuric Sulfide Solutions by Zinc Sulfide. A New Case of Postprecipitation

BY I. M. KOLTHOFF, FRANK S. GRIFFITH AND D. ROMUND MOLTZAU

It was found by Feigl[1] that when a solution of a zinc salt is added to a solution of sodium mercuric sulfide under such conditions that the resulting liquid phase is not supersaturated with regard to mercuric sulfide, the precipitate which separates contains mercury and its color varies from white to yellow, orange or brown, depending upon the amount of mercury in the precipitate. The mercury is not removed readily from the precipitate by extracting with sodium sulfide solutions. Moreover, Feigl found that the sulfides of cadmium, lead and manganese acted in a manner similar to zinc sulfide whereas the sulfides of silver, cupric and cuprous copper, ferrous and ferric iron, thallium, bismuth and cobalt did not induce the precipitation of mercuric sulfide from a sodium mercuric sulfide solution. In the present paper it is shown that the induced precipitation of mercuric sulfide by zinc sulfide is a phenomenon of postprecipitation. This case of postprecipitation is different from others[2] previously investigated in this Laboratory, in that the mercuric sulfide is taken up by the zinc sulfide from a solution which is *not supersaturated* with regard to the former. Such a postprecipitation will occur only when the following two conditions are fulfilled: (1) the postprecipitated substance is soluble in the primary precipitate or forms a compound with it; (2) the speed of separation of the primary precipitate is greater than that of the postprecipitated substance. If the former condition is not fulfilled no postprecipitation can occur from solutions which are not supersaturated with regard to the second precipitate. If the first condition is fulfilled but not the second a coprecipitation and not a postprecipitation will take place.

Materials Used

Zinc sulfate solutions were made from recrystallized C. P. chemicals. They were standardized against potassium ferrocyanide.[3]

Mercuric perchlorate solutions were made from reagent quality mercuric oxide and perchloric acid. A 0.05 *M* perchloric acid solution in equilibrium with mercuric oxide was found to be 0.004 *N* in free acid.

Sodium Sulfide.—The commercial products available were not suitable for the present work because of large amounts of impurities (thiosulfate). Therefore, the sodium sulfide solutions were made by passing washed hydrogen sulfide through a measured quantity of 5.30 *N* sodium hydroxide. A slight excess of hydrogen sulfide as measured by the increase in weight of the solution, was absorbed and the concentrated solution diluted with oxygen-free water. The solution was then analyzed for sulfide and total basicity and the appropriate amounts of

sodium hydroxide solution and water needed to give the desired composition were calculated and added. In order to guard against air oxidation the air above the liquid was swept out with nitrogen.

Air Oxidation of Sodium Sulfide Solutions.—Most of the work was first carried out without taking precautions against air oxidation of the sulfide. The results were not well reproducible and were sometimes confusing due to air oxidation of sulfide. This oxidation can be considerable after a relatively short time of exposure to air as is evident from the following experiments. Two hundred milliliters of a freshly prepared sodium sulfide solution which was 0.1 N in excess of sodium hydroxide was distributed between four 250-ml. flasks, the latter were partially stoppered with one-hole rubber stoppers and shaken gently with a rotary motion for twenty-four hours. The contents of the flasks were mixed and analyzed for sulfide, polysulfide, thiosulfate and total basicity (see below). The freshly prepared solution was 0.189 M in sulfide, the total alkalinity being 0.472 N. After exposure for twenty-four hours the sulfide concentration was 0.110 M, that of polysulfide less than 0.001 M, the thiosulfate concentration 0.035 M and the total alkalinity 0.402 N. Hence about 37% of the sulfide was oxidized after twenty-four hours of exposure to air. This air oxidation is prevented by taking precautions to exclude air. A large number of experiments were run in which the flasks containing the sulfide solutions were swept out with nitrogen both before the solutions (kept under nitrogen) were added and before the flasks were stoppered. Under such conditions only 0.53% of the sulfide was found to be oxidized after twenty-four hours.

Methods of Analysis.—The sum of sulfide, polysulfide and thiosulfate was determined by oxidation with bromine (bromate–bromide and acid) to sulfate.[4] The thiosulfate was determined by the method recommended by the Committee on Analytical Reagents of the American Chemical Society[5] for testing the purity of sodium sulfide. The sulfide and polysulfide are precipitated by adding an excess (enough to remove excess of alkali) of oxygen-free zinc sulfate solution. After standing for half an hour the solution is filtered and an aliquot portion of the filtrate titrated with standard iodine. The polysulfide was usually determined by Schulek's[6] method in which it is transformed into thiocyanate. The latter is oxidized to bromocyanide and determined iodometrically.

The total alkalinity was determined by titrating with standard acid. Just before the end-point most of the hydrogen sulfide was removed by aspiration of air and the titration finished with methyl orange as indicator.

Mercury.—In the study of the postprecipitation of mercuric sulfide with zinc sulfide from sodium mercuric sulfide solutions the remaining mercury in solution was determined volumetrically.

After investigating various procedures the following method was found to be suitable for routine analyses. An excess of hydrochloric acid was added to the sodium mercuric sulfide solutions to precipitate the mercuric sulfide, the solution boiled for a few minutes to remove hydrogen sulfide and then 2 ml. of concentrated nitric acid added. Oxidation was complete within a few seconds but boiling was continued for a few minutes to remove oxides of nitrogen and to gather the finely divided sulfur into larger particles. After removing the flask from the hotplate 5 ml. of 6 N sodium hydroxide was added, the solution cooled, indicator added and the solution exactly neutralized. If the indicator is added to the strongly acid solution it is sometimes oxidized. A mixture of equal volumes of brom cresol green (0.1%) and methyl red (0.1%) was found to be a very suitable indicator, the color change being from red (acid) to blue (alkaline). After neutralization, the mercury is determined by the cyanide method[3] (p. 198) by adding an excess of standard potassium cyanide solution and titrating back with standard hydrochloric acid.

$$\mathrm{HgCl_2 + 2KCN \longrightarrow Hg(CN)_2 + 2KCl}$$
$$\mathrm{KCN + HCl \longrightarrow HCN + KCl}$$

Degree of Saturation of Sodium Mercuric Sulfide with Mercuric Sulfide.—Although the air oxidation of sulfide was prevented by carrying out the experiments in an atmosphere of nitrogen, it was desirable, especially in long period experiments, to have a quick method available to test for an accidental change of the sulfide concentration solution. This can be done roughly by titrating with a standard mercuric chloride solution until the turbidity does not disappear on further shaking.

$$\mathrm{2S^{=} + HgCl_2 \longrightarrow HgS_2{}^{=} + 2Cl^-}$$
$$\mathrm{HgS_2{}^{=} + HgCl_2 \longrightarrow 2HgS + 2Cl^-}$$

As the solubility of mercuric sulfide in sodium sulfide is dependent upon the concentration of sodium hydroxide,[7] the method cannot be used to determine accurately the sulfide content of solutions. It is suitable, however—with an accuracy to 1 to 2%—to determine the amount of mercuric salt needed to saturate a sodium sulfide (or sodium mercuric sulfide) solution with mercuric sulfide.

Experimental Results

Rate of Postprecipitation of Mercuric Sulfide from Sodium Mercuric Sulfide Solutions in the Presence of Freshly Precipitated Zinc Sulfide.—In the following experiments zinc sulfate solution was added to the sodium mercuric sulfide solution which contained an excess of sulfide. Ten ml. of 0.05 M zinc sulfate was added to a mixture of 25 ml. of 0.189 M sodium sulfide which was 0.094 N in sodium hydroxide and 10 ml. of 0.044 M mercuric perchlorate which was 0.004 N in free acid. If no co- or postprecipitation occurred the supernatant liquid after precipitation of 0.5 mmol. of zinc sulfide would be 0.051 N in sodium hydroxide, 0.075 M in sodium sulfide and 0.0098 M in sodium mercuric sulfide. About 8 ml. of the 0.044 M mercuric perchlorate solution could be added before the solution became saturated with mercuric sulfide. Before mixing the solutions in screw-cap bottles the air was swept out with nitrogen, and this gas was passed over again before screwing the caps on. The bottles were shaken for a given length of time, centrifuged and 25 ml. was taken for analysis for mercury. The color of the freshly formed zinc sulfide was white, indicating that *no coprecipitation of mercuric* sulfide had occurred, after two

minutes of shaking a yellow tinge of the precipitate was noticeable and after one hour the precipitate was of a cadmium sulfide yellow. The results on the rate of postprecipitation of mercury are given in Table I. A similar set of experiments was run in the presence of a larger excess of sodium sulfide. After precipitation of 0.5 mmol. of zinc sulfide the supernatant liquid was 0.062 N in sodium hydroxide, 0.19 M in sodium sulfide and 0.011 M in sodium mercuric sulfide. The results are given in Table II.

TABLE I

RATE OF POSTPRECIPITATION OF MERCURIC SULFIDE WITH ZINC SULFIDE

Time of shaking	6 min.	52 min.	7.5 hrs.	24 hrs.	7 days
Mercury pptd., %	14.0	27.9	32.1	34.0	34.2, 35.5

TABLE II

RATE OF POSTPRECIPITATION OF MERCURIC SULFIDE IN THE PRESENCE OF LARGER EXCESS OF SULFIDE

Time of shaking	5 min.	35 min.	2.5 hrs.	45 hrs.	7 days
Mercury pptd., %	8.4	12.8	14.0	16.4	15.5

A comparison of Tables I and II (see also Fig. 1) reveals that the amount of postprecipitation mercury decreases to about one-half when the excess of sulfide in solution is doubled. Moreover, it is evident that after about one to two days of shaking with freshly precipitated zinc sulfide a state of equilibrium in the distribution of mercury between solution and the solid state is attained.

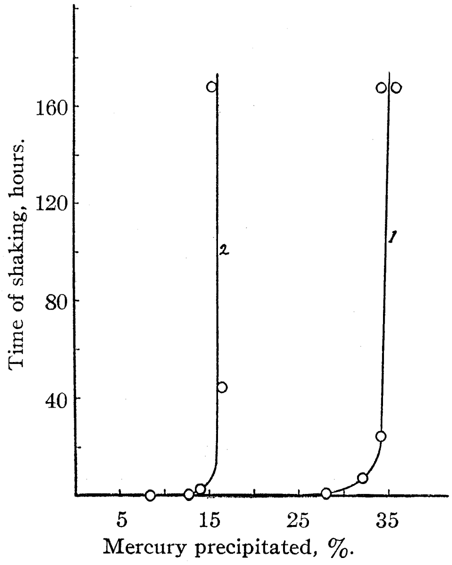

Fig. 1.—1, Small excess of sulfide; 2, larger excess of sulfide.

Rate of Postprecipitation of Mercuric Sulfide with Zinc Sulfide of Varying Degree of Perfection and Age.—The results of the following experiments in which sodium mercuric sulfide solution was added to a zinc sulfide suspension show conclusively that the induced precipitation of mercuric sulfide by zinc sulfide is a phenomenon of postprecipitation. The rate of this postprecipitation decreases with increasing degree of perfection and decreasing surface development of the zinc sulfide. Zinc sulfide samples of various degree of perfection and age were prepared.

1. Precipitation from and Aging in Alkaline Solution.—Ten ml. of 0.05 M zinc sulfate was added to 2.8 ml. of a solution which was 0.19 M in sodium sulfide and 0.116 N in sodium hydroxide. The bottles were swept out with nitrogen and the zinc sulfide aged for the indicated periods of time.

2. Precipitation from and Aging in Slightly Acid Medium (*p*H about 5).—Ten ml. of 0.05 M zinc sulfate containing 0.25 g. of sodium acetate trihydrate was saturated with hydrogen sulfide. After aging for the given period of time most of the excess of hydrogen sulfide was removed by evacuating the bottle while swirling well (blanks showed that only about 0.004 mmol. of hydrogen sulfide stayed in solution after this treatment). After evacuation 0.17 ml. of 0.19 M sodium sulfide, 0.25 ml. of 5.3 N sodium hydroxide and 2.4 ml. of water were added, thus making the volume, amount of sulfide and hydroxide the same as in the suspensions of product 1.

3. Precipitation from and Aging in More Acid Solution (final *p*H about 1.15).—Ten ml. of 0.05 M zinc sulfate was saturated with hydrogen sulfide. After aging the samples were subjected to the same treatment as products 2. If the samples were aged for less than one hour a small amount of the zinc might have remained unprecipitated. For complete precipitation of zinc sulfide Jeffries and Swift[8] recommend a *p*H of 1.6.

Procedure of Postprecipitation Experiments

The 100-ml. bottles containing the zinc sulfide suspensions which had been aged for the indicated periods of time were swept out again with nitrogen whereupon 35 ml. of sodium mercuric sulfide solution of about the same composition as that used in Table I was added. Immediately after mixing, the liquid phase was 0.058 N in sodium hydroxide, 0.0845 M in sodium sulfide and 0.0105 M in sodium mercuric sulfide. The bottles were stoppered and shaken vigorously, some for two hours and some for two days, centrifuged and 25 ml. of the supernatant liquid was analyzed for mercury by the procedure outlined previously. The mercuric sulfide separating from mixtures containing acetate (products 2) was filtered off, washed, and treated with aqua regia. The fibers of filter paper were filtered off before titrating the mercury. The filtration of mercuric sulfide was necessary as the acetate interferes with the mercury titration. The results are given in Table III and reproduced graphically in Fig. 2.

When a range of time is given in the table the shorter time refers to zinc sulfide products 1, and the longer time to products 2 and 3. The experiments referring to an age of zinc sulfide of zero (in parentheses in Table III) were carried out in a way similar to those in Tables I and II; the zinc sulfate solution was added to a solution containing sodium mercury sulfide, sodium sulfide and sodium hydroxide of appropriate concentrations so that after precipitation of the zinc sulfide the solution had the same composition as prevailed in the other experiments. It is seen that zinc sulfide precipitated in the absence of mercury and which was only seven minutes old (product 1) is

---

7 days hot[a]	0.9	0	−1	8.0	0.7	−1

[a] Aged on gravel at a temperature of about 80–90°.

about as effective as fresh zinc sulfide precipitated in the presence of mercury.

Products 3 are much coarser and more perfect than samples 2 and the latter more so than products 1. The rate of postprecipitation of mercuric sulfide (see 3–7 minutes old zinc sulfide) decreases in the order of products 1, 2, 3. It is also evident that product 3 ages much more rapidly at a *p*H of 1.15 than product 2 at a *p*H of 5 and the latter more than product 3 in alkaline medium. After aging for seven days at room temperature product 3 hardly takes up any mercury even after shaking for two days with the sodium mercuric sulfide solution. Product 1 ages very slowly at room temperature but the perfection becomes pronounced when aged at 80–90°. Apparently the speed of postprecipitation of mercuric sulfide with zinc sulfide is a good indicator of the degree of perfection of the latter.

Effect of Varying Amounts of Zinc Sulfide and of Mercury and Sulfide Concentrations.—During the postprecipitation of mercuric sulfide the sodium sulfide concentration in the solution increases: $Na_2HgS_2 \longrightarrow [HgS] + Na_2S$. When the initial sulfide composition of the solutions is identical, but the amount of postprecipitation after attainment or approximate attainment of equilibrium different, a quantitative comparison of the results is not simple. A series of experiments was run adding different amounts of zinc sulfate and mercuric perchlorate to sodium sulfide solutions of such concentrations that the sulfide concentrations after the formation of the zinc sulfide and mercuric sulfide complex were identical. The amount of postprecipitation was determined after four days of shaking at room temperature. For the sake of brevity the experimental details are omitted and the results given in a condensed form in Table IV.

Postprecipitation at 80°.—In the following experiments the state of equilibrium of the distribution of mercuric sulfide between solution and the solid was approached at 80°. After running some preliminary series the sulfide concentration in each set was adjusted in such a way as to give identical sulfide concentrations in the solutions after attainment of distribution equilibrium. The bottles containing the sodium mercuric sulfide solution were placed in a beaker of hot water until the temperature of the contents was 90° and then zinc sulfate solution (25°) was added from a pipet. After thorough mixing the bottles were capped and kept for two days at a temperature of 80° in the beaker of hot water, the contents of the bottle being shaken by hand several times during the course of an experiment. After the heating period the bottles were allowed to cool to room temperature, centrifuged and an aliquot part of the supernatant liquid analyzed for mercury. In several cases a thin film of black mercuric sulfide separated at the gas–liquid interface during the heating process which after cooling did not dissolve easily in the solution although the latter was far from saturated with mercuric sulfide. The amount of mercuric sulfide formed at the interface was less than 1% of the total amount of mercury present and was not considered in the calculation of the results which are reported in an abbreviated form in Table V.

TABLE V

POSTPRECIPITATION OF MERCURIC SULFIDE AT 80° AFTER SHAKING FOR 2 DAYS

Extractability of Mercuric Sulfide from the Mixed Zinc-Mercuric Sulfide.—A mixed precipitate containing 0.125 mmol. of mercuric sulfide and 0.5 mmol. of zinc sulfide which had been aged for two weeks was extracted several times with 0.2 *M* sodium sulfide solutions. In the first extraction the precipitate was shaken for ten hours with the sulfide solution; only 0.043 mmol. of mercury was found in the solution. After removing the supernatant liquid the precipitate was shaken with a fresh 50-ml. portion of sodium sulfide solution for two days after which time only 0.018 mmol. of mercury had been further removed from the precipitate. A further extraction for a day with a new portion removed only 0.007 mmol. of mercury.

The resulting precipitate was washed once with water and then extracted once with 0.5 *N* hydrochloric acid saturated with hydrogen sulfide; this treatment removed 95% of the zinc. After adding the acid the orange precipitate darkened slowly, within three minutes it was orange-brown and within ten minutes it was black. The acid was removed after seventy minutes of shaking, the precipitate washed with water and extracted for three hours with 50 ml. of sodium sulfide solution. The remainder of the mercury (0.059 mmol.) was thereby extracted. Feigl[1] also found that mercury was difficultly extractable from the mixed precipitate by sodium sulfide, but our interpretation is quite different from his.

Discussion

All the results reported so far tend to show that the postprecipitation of mercuric sulfide from solutions which are far from saturated with this compound is to be attributed to a solid solution formation with zinc sulfide. If such a solution of mercuric sulfide in zinc sulfide is considered ideal, it is possible to calculate the distribution coefficient of mercury between liquid and solid phases.

If the solution is in thermodynamic equilibrium with the solid, the thermodynamic potential of the mercuric sulfide in both phases is identical. Taking the activity of the mercuric sulfide in the pure solid as the standard state, we find that in case the solid solution behaves as an ideal solution

$$(a\text{HgS})_1 = S_{\text{HgS}} \cdot N_{\text{HgS}} \qquad (1)$$

in which $(a\text{HgS})_1$ denotes the activity of the mercuric sulfide in the liquid phase, S_{HgS} the solubility product of mercuric sulfide and N_{HgS} the mole fraction of mercuric sulfide in the solid.

In the presence of an excess of sulfide practically all of the mercury in the liquid phase is present in the form of $\text{HgS}_2^=$ ions; from practical viewpoint we are interested in the distribution of total mercury between solution and solid.

$$\text{HgS}_2^= \rightleftarrows (\text{HgS})_1 + \text{S}^=$$

or

$$(a\text{HgS})_1 = K_{\text{HgS}_2^=} \frac{a\text{HgS}_2^=}{a\text{S}^=} \qquad (2)$$

Since both HgS_2 and S ions are divalent their activity coefficients at various ionic strengths may be expected to be of the same order of magnitude and equation (2) may be approximated to

$$(a\text{HgS})_1 = K_{\text{HgS}_2^=} \frac{[\text{HgS}_2^=]}{[\text{S}^=]} \qquad (3)$$

in which the symbols between brackets denote the molar concentrations in solution. Combining (1) and (3) gives

$$\frac{[\text{HgS}_2^=]}{[\text{S}^=]} = \frac{S_{\text{HgS}}}{K_{\text{HgS}_2^=}} N_{\text{HgS}} = KN_{\text{HgS}} \qquad (4)$$

According to Knox[7] S_{HgS} at 25° is equal to 2.8×10^{-54}, and K_{HgS^-} to 1.96×10^{-55}. Hence, when equilibrium distribution is established and if the solution is ideal

$$[\text{HgS}_2^=] = KN_{\text{HgS}}[\text{S}^=] = 14.3\ N_{\text{HgS}}[\text{S}^=]\ (25°) \qquad (5)$$

From the results given in Table IV it is possible to calculate the value of *K* at 25°. In these experiments the volume of the solutions was 45 ml., the excess of sulfide in the first four experiments being 3.45 mmols. (average), and in the last four 7.04, corresponding to sodium sulfide concentrations of 0.0766 *M* and of 0.156 *M*, respectively. The concentrations of excess of sodium hydroxide corresponded to 0.064 *N* in the first four experiments and to 0.062 *N* in the last four experiments. Taking the second ionization constant of hydrogen sulfide equal to 10^{-15} and the ionic product of water equal to 10^{-14}, we find from the hydrolysis equation of the sulfide ion

$$\frac{[\text{OH}^-][\text{SH}^-]}{[\text{S}^=]} = \frac{K_{\text{w}}}{K_{2(\text{H}_2\text{S})}} = 10 \quad (25°) \qquad (6)$$

If the HS^- ion concentration is designated by *X*, then $[\text{OH}^-] = C_{\text{NaOH}} + X$ and $[\text{S}^=] = C_{\text{Na}_2\text{S}} - X$. Introducing these expressions into equation (6) yields a quadratic equation which can be solved for *X*.

The values of *K* calculated in this way from the results of experiments in Table IV are given in Table VI and plotted in Fig. 3.

An attempt was made to calculate the values of *K* at 80° from the results reported in Table V. According to Jellinek and Czerivinski[9] the degree of hydrolysis of sodium sulfide solutions does not change between 0 and 25°. On the basis of this result we have assumed in our calculations that the hydrolysis constant of the sulfide at 80° is equal to that at 25°. This is probably incorrect as is also evidenced by the fact that the values of *K* calculated from experiments in

TABLE VI

DISTRIBUTION COEFFICIENT *K* OF MERCURIC SULFIDE BETWEEN SODIUM MERCURIC SULFIDE AND ZINC SULFIDE AT 25 AND AT 80°

Temp., °C.	N_{HgS}	$[HgS_2^{=}]$ molar	$[S^{=}] \times 10^3$	*K*
25	0.242	0.341	1.06	29.6
25	.218	.222	1.06	21.4
25	.378	.696	1.06	38.6
25	.332	.502	1.06	31.6
25	.214	.727	3.28	23.0
25	.226	.854	3.28	25.6
25	.146	.329	3.28	15.3
25	.144	.416	3.28	19.6
80	.300	.286	1.06	20.0
80	.242	.180	1.06	15.6
80	.527	.444	1.06	17.7
80	.387	.368	1.06	19.9
80	.246	.673	3.28	18.6
80	.268	.817	3.28	20.7
80	.156	.315	3.28	13.7
80	.169	.398	3.28	16.0

which the sodium sulfide concentration was 0.0766 *M* fall on a different line than those in which the sodium sulfide concentration was 0.156 *M* (see Fig. 3). On the other hand, the values of *K* calculated from the results of experiments at room temperature at different sulfide concentrations fall approximately on one straight line. It is seen from the results and particularly from Fig. 3 that the value of *K* is not constant, but increases as a linear function of the mole fraction of mercury in the solid solution. A similar result was found by Yutzy and Kolthoff[10] for the change of the distribution coefficient of bromide between aqueous solutions and mixed crystals of silver chloride and bromide at different mole fractions of bromide in the solid.

The change of *K* with the mole fraction of mercury in the solid shows that the solid solutions do not behave as ideal solutions, and that activities cannot be taken equal to mole fractions. It is gratifying that the values of *K* are of the order of magnitude of the calculated value of 14.3 based on the assumption of ideal solutions and equilibrium constants of Knox.

From the graph it is seen that at 80° the values of *K* increase less with increasing mole fraction of mercury than at 25°. Hence, at higher temperatures the system approaches that of an ideal system. Qualitatively, a similar result was found again by Yutzy and Kolthoff,[10] who at 100° found in the system silver chloride–bromide a value of the distribution coefficient which was independent of the composition of the solid.

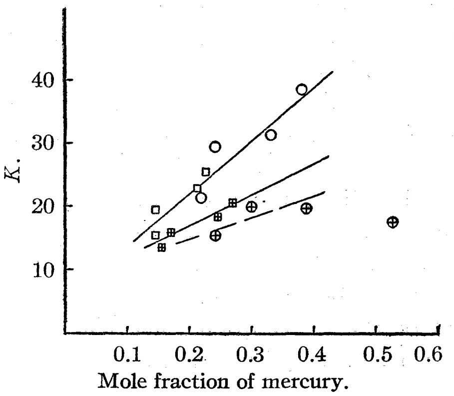

Fig. 3.—○, in 0.0766 *M* Na_2S at 25°; □, in 0.156 *M* Na_2S at 25°; ⊕, in 0.0766 *M* Na_2S at 80°; ⊠, in 0.156 *M* Na_2S at 80°.

Figure 3 shows that at high mole fractions of mercuric sulfide with solid (at $N_{HgS} > 0.5$) the value of *K* does not increase further with increasing N_{HgS} at 80°. This might indicate that the solid consists of two phases, the second phase being mercuric sulfide or, more likely, a solution of zinc sulfide in mercuric sulfide.

It is of interest to note that according to equation (5) the distribution coefficient of the mercuric sulfide between solution and precipitate is independent of the chemical nature of the solid as long as the latter can form ideal solid solutions with mercuric sulfide. Hence, it may be expected that under comparable conditions the distribution of mercuric sulfide between sodium mercuric sulfide solution and zinc, lead or manganese sulfides will be of the same order of magnitude.

Direct evidence from X-ray measurements of mixed crystal formation between mercuric and zinc sulfide was given by Moltzau and Kolthoff.[11] They found that zinc sulfide dissolved in mercuric sulfide to a limited extent. The present study shows that mercuric sulfide is soluble—at least to a certain extent—in zinc sulfide.

An X-ray examination of an orange colored precipitate, kindly made for us by Mr. M. L. Fuller of the New Jersey Zinc Co., showed that it had a zinc sulfide cubic lattice expanded about 1%. The broadness of the lines on the film prevented an exact measurement.

Summary

1. Mercuric sulfide is postprecipitated with

---

[10] H. C. Yutzy and I. M. Kolthoff, THIS JOURNAL, **59**, 916 (1937).

[11] D. R. Moltzau and I. M. Kolthoff, *J. Phys. Chem.*, **40**, 637 (1936).

zinc sulfide from sodium mercuric sulfide solutions which are undersaturated with mercuric sulfide. Such a postprecipitation occurs only when the mercuric sulfide is soluble in the primary precipitate, and the speed of separation of the latter from solution is greater than the speed of dissociation of the $HgS_2^=$ ion into HgS and $S^=$.

2. The distribution coefficient of mercuric sulfide between aqueous solution and solid has been determined at 25 and 80°. The solid solution does not behave as an ideal solution, but the values of the distribution coefficient are of the same order of magnitude as the value calculated upon the basis of formation of ideal solutions. This calculated value is independent of the nature of the solid, as long as the latter acts as a solvent for mercuric sulfide.

3. The speed of attainment of distribution equilibrium between sodium mercuric sulfide solution and zinc sulfide is a good indicator of the degree of perfection and the progress of aging of the latter. It is shown that zinc sulfide precipitated at a *p*H of 1.15 is more perfect and ages more rapidly at this *p*H than the sulfide formed and aged at a *p*H of 5 and the latter more so than the sulfide formed and aged in alkaline medium.

Hydroxyalkyl Ethers of Basic Phenols. The Antipneumococcic Activity of Some 8-Quinolyl Ethers

By C. L. Butler and Alice G. Renfrew

It appeared to be of considerable general interest to extend the application of the hydroxyalkylation method used in the cinchona alkaloid field[1] to other types of basic phenolic substances. More specifically, it was hoped that studies carried out on simpler basic phenols would give a partial explanation, at least, of the low yields obtained in attempts to hydroxyethylate phenolic cinchona alkaloids with ethylene chlorohydrin.[2] Further, the preparation of simpler substances, related structurally to these alkaloids, was of interest in the chemotherapeutic study of pneumonia. Experiments undertaken with these considerations in view are described in the present report.

Phenol, aniline, *p*-aminophenol, *p*-acetaminophenol, *m*-diethylaminophenol and 8-hydroxyquinoline were chosen as suitable starting materials for the investigations. The compounds were alkylated in the usual way with benzyloxyalkyl *p*-toluenesulfonates[3] and the resulting aminoaryl benzyloxyalkyl ethers were hydrolyzed in dilute hydrochloric acid to hydroxyalkyl derivatives.[1] Yields were high in nearly all cases. The reaction with *p*-aminophenol was complicated by nitrogen alkylation. *p*-Acetaminophenol, however, gave with benzyloxyethyl *p*-toluenesulfonate, a high yield of the benzyloxyalkyl ether, which was readily converted to β-hydroxyphenetidine. Hydroxyalkylation of *m*-diethylaminophenol and 8-hydroxyquinoline was accomplished without difficulty.

It seemed possible that the failure of ethylene chlorohydrin to hydroxyethylate phenolic cinchona alkaloids[2] might be due to the presence in the cinchona structure of basic groups, with which this substance reacted with greater ease than with the phenolic group; or by which it was destroyed before it could react. Several alkylations with ethylene chlorohydrin were carried out in attempts to get further information on this point. According to Rindfusz[4] a 50% yield of hydroxyethyl phenyl ether is obtained on alkylation of sodium phenolate with this reagent. In the present work the reaction was carried out in the presence of one molecular equivalent of triethylamine. Only 13% of the theoretical quantity of hydroxyethyl phenyl ether was obtained in this experiment. The presence of triethylamine, however, did not decrease the yield of alkylation product when benzyloxyethyl *p*-toluenesulfonate was used as alkylating reagent. 8-Hydroxyquinoline, on alkylation with ethylene chlorohydrin, gave only 19% of the theoretical amount of

[a] Detailed results will be published by the medical staff associated with the Mellon Institute in the chemotherapeutic study of pneumonia.

hydroxyethyl 8-quinolyl ether, as compared with the 50% yield obtained by Rindfusz[4] in the hydroxyethylation of phenol, where there could be no question of complication with basic nitrogen groups. Hydroxyethyl 8-quinolyl ether was obtained in 67% yield, using benzyloxyethyl *p*-toluenesulfonate. *m*-Diethylaminophenol gave practically identical quantities of hydroxyethyl ether with the two reagents. It is believed that these results confirm the opinion that the unfavorable yields reported in the earlier work on hydroxyalkylation of cinchona alkaloids with ethylene chlorohydrin[2] were due to complications involving the two nitrogen atoms of the alkaloids. The difficulty can be avoided to a very large extent by the use of the benzyloxyalkyl aromatic sulfonates for alkylations of this type.

The preparation of the quinoline derivatives had an added interest because of the structural relationship of these compounds to the cinchona alkaloids, and because of the marked germicidal activity of many substances of this type.[5] Hirschfelder and co-workers[6] found that 8-hydroxyquinoline sulfate was highly active *in vitro* against the pneumococcus. In spite of this observation the possibility of the usefulness of simpler quinoline derivatives as antipneumococcic agents has received very little attention. More recently, a series of eighteen quinoline derivatives was investigated by Bührmann[7] and several substances derived from 2-phenyl-4-amino- and 4-amino-6-hydroxyquinolines, were found which inhibited the growth of pneumococci. In view of Hirschfelder's results,[6] it seemed advisable to have further tests run on 8-hydroxyquinoline and the 8-quinolyl ethers prepared in the course of this work. Interest in these compounds was enhanced by the suggestion that 8-hydroxyquinoline may stimulate the defense mechanism of the body[5] (p. 33). In Table I, both the mouse toxicity and the pneumococcicidal activity are seen to be reduced sharply by alkylation of the phenolic hydroxyl group. Some pneumococcicidal activity is maintained in the ethyl and hydroxyethyl derivatives. Further biological examination of these substances would appear to be desirable, especially in view of their very low toxicities.

Experimental

Half molecular quantities of the compounds to be alkylated were converted to potassium salts with the calculated amount of potassium hydroxide in about 300 cc. of absolute alcoholic solution. The alkylating reagent was then added and the mixture was refluxed for two to two and one-half hours on a water-bath. When ethylene chlorohydrin was used as alkylating reagent, the reaction mixtures were worked up directly in the usual way for hydroxyethyl ether. The crude reaction products from the benzyloxyalkyl *p*-toluenesulfonate alkylations were isolated by evaporating the solvent from the filtered alcoholic solution and separating from alkali-soluble material. The benzyl derivatives were hydrolyzed in dilute hydrochloric acid to hydroxyalkyl ethers as previously described[1] and the products were worked up and purified by the usual methods.

Phenoxyethyl Benzyl Ether.—The ether was obtained as an oil on alkylation of phenol with benzyloxyethyl *p*-toluenesulfonate. The product was purified by fractional distillation; yield 67%; b. p. 175° at 3 mm.

In a second experiment, conditions were altered by adding to the alkylation mixture one equivalent of triethylamine. The presence of this base did not interfere with the desired reaction, as was evidenced by the high yield (78% of the theoretical) of ether obtained.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.9; H, 7.1. Found: C, 79.05; H, 6.9.

β-Hydroxyethyl Phenyl Ether.[4]—The alkylation of phenol with ethylene chlorohydrin was carried out in the usual way except that one equivalent of triethylamine was added to the reaction mixture. The yield of β-hydroxyethyl phenyl ether was only 12.5%, as compared with the 50% yield obtained by Rindfusz.[4]

β-Hydroxyethylaniline.—Aniline was alkylated with benzyloxyethyl *p*-toluenesulfonate and the crude benzyl-

oxyethylaniline was hydrolyzed in 11% hydrochloric acid[1] to β-hydroxyethylaniline; yield 50%; b. p. 157–158° at 13 mm.

A portion of the hydroxyethylaniline was converted to N-benzoxyethyl benzanilide with benzoyl chloride, in 80% yield. The melting point was 91–92°, which agrees with the figure found by Schorigin and Below.[8]

Alkylation of *p*-Aminophenol with Benzyloxyethyl *p*-Toluenesulfonate.—The only product which could be isolated in this experiment was a crude trialkylated substance of probable structure $C_6H_5CH_2OCH_2CH_2OC_6H_4N(CH_2CH_2OCH_2C_6H_5)_2$. A small amount of this material was converted to a crystalline sulfate and analyzed.

Anal. Calcd. for $C_{33}H_{37}O_4N \cdot 0.5\,H_2SO_4$: SO_4, 8.5. Found: SO_4, 7.7.

The main portion of the reaction product was hydrolyzed in dilute hydrochloric acid to remove benzyl groups. The yield of hydrolysis product was very low. Since the crude substance formed only mono-acyl derivatives with *p*-toluenesulfonyl chloride and acetyl chloride, it consisted probably of phenylmorpholine *p*-hydroxyethyl ether.

Anal. Amorphous *p*-toluenesulfonyl derivative. Calcd. for $C_7H_7SO_3CH_2CH_2OC_6H_4N(CH_2CH_2)_2O$: $C_7H_7SO_3K$, 55.7. Found: $C_7H_7SO_3K$, 55.4.

Crystalline acetyl derivative from alcohol; m. p. 118–119°. Calcd. for $CH_3CO_2CH_2CH_2OC_6H_4N(CH_2CH_2)_2O$: CH_3CO, 16.2. Found: CH_3CO, 16.4, 16.7.

Benzyloxyethyl *p*-Acetaminophenyl Ether.—*p*-Acetaminophenol was readily alkylated with benzyloxyethyl *p*-toluenesulfonate. The solid ether was purified by crystallization from absolute alcohol; yield 88%; m. p. 88°.

Anal. Calcd. for $C_{17}H_{19}O_3N$: C, 71.6; H, 6.7. Found: C, 71.3; H, 7.0.

β-Hydroxyphenetidine.—Benzyloxyethyl *p*-acetaminophenyl ether was hydrolyzed in 11% hydrochloric acid in the usual way[1] to β-hydroxyphenetidine; yield 80%. A sample recrystallized from alcohol melted at 73°.

Anal. Calcd. for $C_8H_{11}O_2N$: N, 9.15. Found: N, 9.2.

A small sample was converted to a crystalline diacetyl derivative with acetyl chloride. The melting point was 128°, which was in fair agreement with the figure found by Katrak.[9]

β-Hydroxyethyl *m*-Diethylaminophenyl Ether.—*m*-Diethylaminophenol, on alkylation with ethylene chlorohydrin, gave a 62% yield of β-hydroxyethyl *m*-diethylaminophenyl ether. An identical over-all yield was obtained when the hydroxyalkylation was carried out through the intermediate benzyloxyethyl derivative. There is, therefore, no advantage in the use of benzyloxyethyl *p*-toluenesulfonate in this case; b. p. 148° at 3 mm., m. p. 41°.

Anal. Calcd. for $C_{12}H_{19}O_2N$: N, 6.7; C, 68.9; H, 9.1. Found: N, 7.9; C, 69.3; H, 9.6.

An acetyl derivative was obtained as a viscous liquid with acetic anhydride and sodium acetate.

Anal. Calcd. for $C_{14}H_{21}O_3N$: CH_3CO, 17.1. Found: CH_3CO, 16.9, 17.4.

β-Hydroxyethyl 8-Quinolyl Ether.—8-Hydroxyquinoline was alkylated with benzyloxyethyl *p*-toluenesulfonate, and the crude benzyloxyethyl 8-quinolyl ether was hydrolyzed to β-hydroxyethyl 8-quinolyl ether in dilute hydrochloric acid. The substance was purified by crystallization of its hydrochloride from absolute alcohol; yield 70%; m. p. 199–200°.

Anal. Calcd. for $C_{11}H_{11}O_2N \cdot HCl$: Cl, 15.7. Found: Cl, 15.8.

The base was recovered from the hydrochloride and crystallized from alcohol; m. p. 83–84°.

Anal. Calcd. for $C_{11}H_{11}O_2N$: C, 69.8; H, 5.9; N, 7.4. Found: C, 69.5; H, 6.1; N, 7.3.

β-Acetoxyethyl 8-quinolyl ether was obtained by acetylation of the hydroxyethyl ether with acetyl chloride. It was purified by crystallization of its hydrochloride from alcohol; m. p. 153°.

Anal. Calcd. for $C_{13}H_{13}O_3N \cdot HCl$: CH_3CO, 16.1; Cl, 13.25. Found: CH_3CO, 16.8; Cl, 13.1.

A more direct preparation of β-hydroxyethyl 8-quinolyl ether was accomplished by alkylation of 8-hydroxyquinoline with ethylene chlorohydrin. The yield, however, was only 19% using this method.

α-Methyl-β-hydroxyethyl and γ-Hydroxy-*n*-propyl 8-Quinolyl Ethers.—The compounds were prepared by alkylation of 8-hydroxyquinoline with the appropriate benzyloxyalkyl *p*-toluenesulfonates and hydrolyzing the intermediate benzyloxyalkyl ethers to the desired hydroxyalkyl derivatives.

α-Methyl-β-hydroxyethyl 8-quinolyl ether was purified by crystallization of its hydrochloride from alcohol; yield 40%.

Anal. Calcd. for $C_{12}H_{13}O_2N \cdot HCl$: Cl, 14.8; N, 5.8. Found: Cl, 14.6; N, 6.3.

The base was liberated from the hydrochloride and crystallized from ether; m. p. 65°. With acetyl chloride it gave a solid acetyl derivative, which was crystallized from acetone; m. p. 99°.

Anal. Calcd. for $C_{14}H_{15}O_3N$: CH_3CO, 17.5. Found: CH_3CO, 17.0, 18.1.

γ-Hydroxy-*n*-propyl 8-quinolyl ether was similarly purified; yield 59%; m. p. 129°.

Anal. Hydrochloride. Calcd. for $C_{12}H_{13}O_2N \cdot HCl$: Cl, 14.8. Found: Cl, 14.5. Base. Calcd. for $C_{12}H_{13}O_2N$: N, 6.9. Found: N, 7.1.

γ-Acetoxy-*n*-propyl 8-quinolyl ether was obtained as a reddish oil on acetylation with acetic anhydride and sodium acetate.

Anal. Calcd. for $C_{14}H_{15}O_3N$: CH_3CO, 17.5. Found: CH_3CO, 17.5, 17.6.

8-Ethoxyquinoline.—8-Hydroxyquinoline was alkylated in the usual way with ethyl *p*-toluenesulfonate; b. p. 178° at 28 mm.[10] The base was converted to hydrochloride, which was crystallized from alcohol.

Anal. Calcd. for $C_{11}H_{11}ON \cdot HCl$: Cl, 16.9. Found: Cl, 16.9.

Summary

The preparation of several hydroxyalkyl ethers of basic phenols has been described. Some

The Wagner–Meerwein Rearrangement. A Kinetic Reinvestigation of the Isomerization of Camphene Hydrochloride[1]

BY PAUL D. BARTLETT AND IRVING PÖCKEL

About a year ago we reviewed the evidence[2] that the rearrangement of camphene hydrochloride (I) into isobornyl chloride (II), and of pinene hydrochloride (III) into bornyl chloride (IV) involves complete Walden inversion at carbon atom no. 2 of the camphane ring system (the point of attachment of the chlorine in bornyl and isobornyl chlorides). Analogy with well-known cases of Walden inversion led us to propose that this rearrangement was a collision process, involving donors or acceptors of chloride ions, or both. Such a potential donor and acceptor is always present in solutions of camphene hydrochloride, since this compound dissociates rapidly and reversibly into camphene and hydrogen chloride, and this equilibrium is attained more rapidly than the rearrangement occurs.

III IV

If hydrogen chloride played an essential part in the rearrangement, the reaction could not be a spontaneous, monomolecular one as reported by Meerwein and van Emster.[3] Since these authors had not considered higher orders of reaction, we recalculated their data in terms of first, second and three-halves order equations and found that in six of the nine solvents studied the data were best fitted by the formulation of the second order with respect to camphene hydrochloride, while in the remaining three solvents the three-halves order formulation was best. This left it quite uncertain in what manner hydrogen chloride entered into the rearrangement process.

We have now carried out a number of kinetic experiments designed to provide clear evidence of the order of the reaction. Nitrobenzene was chosen as a solvent because it allows the rearrangement to proceed at the most convenient rate for measurement. The results show clearly that the rearrangement involves one molecule of camphene hydrochloride and one of hydrogen chloride, and they provide a complete explanation for the apparent variation of the order of the reaction with change of solvent under the conditions of measurement used by Meerwein and van Emster and, initially, by ourselves. The dissociation equilibrium

$$\text{Camphene hydrochloride} \rightleftarrows \text{Camphene} + \text{HCl} \quad (1)$$

lies, in the case of most of our solutions, more than 94% to the left. With pure camphene hydrochloride, the hydrogen chloride concentration in the solution will be proportional to the square root of the camphene hydrochloride concentration, and hence the rate of reaction is proportional to the $^3/_2$ power of the camphene hydrochloride concentration. However, when a large excess of camphene is present, the amount of hydrogen chloride at equilibrium is diminished and its concentration becomes proportional to that of the camphene hydrochloride. The reaction under these conditions is slowed down and becomes apparently bimolecular with respect to camphene hydrochloride. The explanation of the fact that the rearrangement seems to be sometimes second and sometimes $^3/_2$ order is that it is almost im-

---

(1) Most of this material was included in a paper presented at the Organic Symposium at Richmond, Va., on December 30, 1937.

(3) Meerwein and van Emster, *Ber.*, **55B**, 2500 (1922).

possible to prepare camphene hydrochloride free from camphene. If the amount of camphene present in a particular sample is small enough, the reaction will approximate the $^3/_2$ order, but it easily may be great enough to make the second order a better approximation.

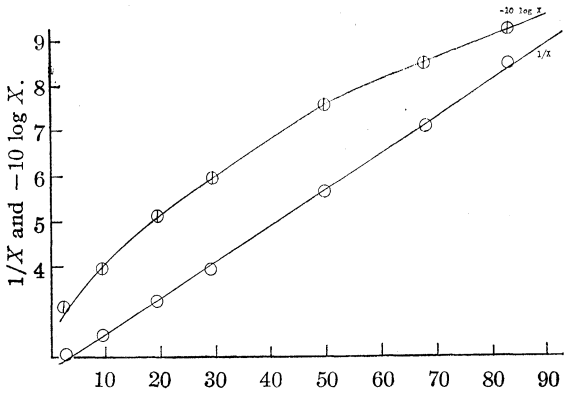

Fig. 1.—Rate of rearrangement of camphene hydrochloride to isobornyl chloride in nitrobenzene solution at 20° in the presence of excess free camphene: ○, $1/X$; ⦶, $-10 \log X$.

There are several quantitative tests, described in full below, which show that this description of the kinetics of the rearrangement is correct. First, with our purest samples of camphene hydrochloride, we were able to duplicate Meerwein's kinetic data which fit the equation of the $^3/_2$ order. Second, by the addition of excess camphene the reaction is made strictly bimolecular (Fig. 1). Third, such additions of camphene diminish the rate of the reaction to the extent predicted from the assumption that there is no spontaneous rearrangement not involving hydrogen chloride (Fig. 2). Fourth, the velocity constant for the reaction between camphene hydrochloride and hydrogen chloride is the same for the rapid reaction in which excess hydrogen chloride is present as for the slow reaction with excess camphene. Fifth, a general equation, derived on the assumption here set forth, fits the kinetic data under these conditions and in those intermediate cases where neither of the limiting formulations holds.

The supposed spontaneous rearrangement of camphene hydrochloride is therefore a process catalyzed by hydrogen chloride. Nevertheless, the balance of the evidence does not seem to be in favor of the donor hypothesis which led us to undertake this investigation. The free chloride ion, which should be the best possible donor, is without effect on the rate of the rearrangement in acetone solution, as shown by kinetic runs with and without lithium chloride. Although all the catalysts for the rearrangement reported as such by Meerwein and van Emster contain chlorine and hence are potential donors of chloride ions, we find that *o*-cresol is not only a good solvent for the rearrangement, as reported by these authors, but a specific catalyst when dissolved in nitrobenzene. Its catalytic efficiency is about one-third that of hydrogen chloride, and it takes the place of hydrogen chloride kinetically. No cresol is consumed in this reaction. Since lithium chloride, which can be a donor, is not a catalyst, and cresol, a good catalyst, cannot be a donor, this way of explaining the Walden inversion attending the rearrangement is untenable.

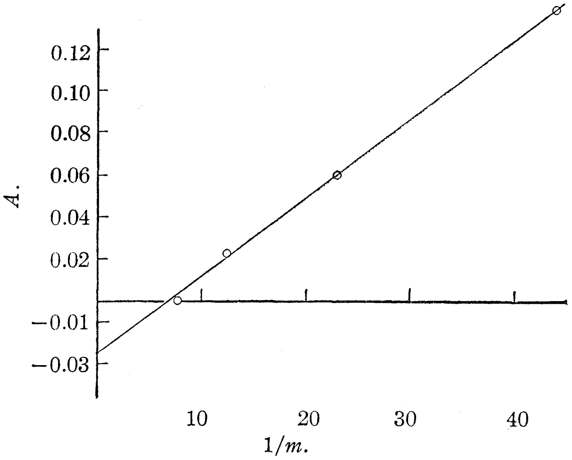

Fig. 2.—Plot of A against $1/m$: A is free camphene added; m is bimolecular rate constant.

Nevertheless, from the occurrence of the Walden inversion in the rearrangement, it seems clear to us that either the carbonium ion has spatial properties quite different from those that have been currently attributed to it, or else the mechanism of Meerwein requires important modification. We are continuing our work and hope to be able to choose between these alternatives. Further discussion of the mechanism is therefore postponed to a later paper.

The fact that hydrogen chloride is necessary to the otherwise uncatalyzed rearrangement explains the anomalous position of ether among the solvents of Meerwein and van Emster. Ether, though not possessing the lowest dielectric constant of the series of solvents which these authors studied, was unique for the slowness with which the rearrangement proceeded in it. A glance at their list of solvents shows that ether is the only one with definitely basic properties. Hydrogen chloride in this solvent must exist largely as diethyloxonium chloride, in which form it is incapable of assisting the removal of chloride ion from the camphene hydrochloride molecule. In harmony with this conclusion, we have found that acetone, which also possesses a basic oxygen atom, also allows the rearrangement to proceed much more slowly than corresponds to its position in the dielectric constant series. Meerwein and van Emster[3] (p. 2511) correlated the effect of ether with its basicity, although the connection could not be clear when the rearrangement was regarded as largely uncatalyzed.

Derivation of the Kinetic Equations

Wynne-Jones has shown[4] that hydrogen chloride behaves as a normal, undissociated and unassociated solute in nitrobenzene. Let x, y, and z denote the concentrations of camphene hydrochloride, hydrogen chloride, and isobornyl chloride, respectively. During any run there is a constant difference between the concentrations of hydrogen chloride and camphene, and the latter accordingly can be designated by $y + c$. By the conditions of equilibrium 1

$$K = \frac{y(y + c)}{x} \tag{2}$$

so that

$$y = \sqrt{Kx + \frac{c^2}{4}} - \frac{c}{2}$$

The general rate equation is

$$\frac{dz}{dt} = -\frac{dx}{dt} - \frac{dy}{dt} = kx\left(\sqrt{Kx + \frac{c^2}{4}} - \frac{c}{2}\right)$$

For the purpose of integration we make the substitution

$$v = \sqrt{Kx + \frac{c^2}{4}}$$

Then

$$-dv - \frac{2v dv}{K} = \frac{k}{K}\left(v^2 - \frac{c^2}{4}\right)\left(v - \frac{c}{2}\right) dt$$

The integrated form is

$$\frac{c - K}{c^2} \ln \frac{v + c/2}{v - c/2} + \left(1 + \frac{K}{c}\right)\frac{1}{v - c/2} = kt + \text{Constant} \tag{3}$$

This integral is a linear function of time for all our runs, whether c be large or small, positive or negative. The use of this equation requires a knowledge of the values of c and K. When c is small its value is uncertain by reason of the great difficulty of obtaining samples of camphene hydrochloride which contain an excess of neither camphene nor hydrogen chloride. We have not found any titration method for camphene suitable in the presence of camphene hydrochloride, and hence to obtain the best estimate of K we have made use of the following considerations.

When c is large compared to y, we may replace $(y + c)$ in Equation (2) with c. This leads to the expression

$$y = Kx/c$$

whence, if K is small enough so that x is much greater than y

$$\frac{dz}{dt} = -\frac{dx}{dt} = k\frac{K}{c}x^2$$

and

$$\frac{1}{x} = \frac{kK}{c}t + \text{Constant} \tag{4}$$

The reaction under these conditions is therefore of the second order with respect to camphene hydrochloride, and the second order rate constant is equal to kK/c.

We now make up a series of runs by adding different known amounts A of camphene to portions of a stock solution of a single sample of camphene hydrochloride containing an unknown excess c_0 of camphene. In these runs

$$c = c_0 + A$$

Denoting the observed bimolecular rate constants for these runs by m, we get the relationship

$$m = kK/(c_0 + A)$$

which can be transformed to

$$A = (kK/m) - c_0 \tag{5}$$

According to this, if the known values of A be plotted as ordinates against the observed $1/m$ values as abscissas, the plot should be a straight line of slope kK and of intercept $-c_0$ on the axis of ordinates. Figure 2 shows this plot for a series of runs made on the stock solution without added camphene and with three known concentrations of camphene added. The bimolecular formulation is not valid for the run without added camphene, since the value of c in this case is not high enough to make the assumptions valid. This point has nevertheless been put on the graph for comparison. It can be seen that the three points for which Equation (4) is valid fall on a good straight line and allow an extrapolation to be made which gives a value of 0.0253 for c_0 and of 3.72×10^{-3} for kK. Knowing the true values of c for all the runs, we can now calculate a value of K for each point of the kinetic run where we

---

[4] Wynne-Jones, *J. Chem. Soc.*, 1064 (1930).

have values of both x and y. Among all the determined quantities, y is the least certain, since hydrogen chloride has a great tendency to escape during the sealing and opening of the ampoules. However, the average values of K for the several runs are in good agreement, and we take the general average of 1.8×10^{-3} as the most probable value. This K is used wherever Equation (3) has been applied. The use of Equation (3) on the run of the present series to which no camphene was added yields a k of 2.45 in as good agreement with the value 2.07 determined from the slope of the line in Fig. 2 as the uncertainty of K would lead us to expect.

When c becomes zero, Equation (2) becomes

$$K = y^2/x$$

and the kinetic equations are

$$\frac{dz}{dt} = -\frac{dx}{dt} - \frac{\sqrt{K}}{2\sqrt{x}}\frac{dx}{dt} = k\sqrt{K}\,x^{3/2}$$

and

$$\frac{2}{\sqrt{Kx}} + \frac{1}{2x} = kt + \text{Constant} \qquad (6)$$

In the concentration range actually used, only the first term of the integral is of importance, and the reaction should therefore be of the $^3/_2$ order. In only a few of our runs, and of Meerwein's, was the camphene hydrochloride pure enough to approach this behavior; for even the small amount of camphene present in the run of Fig. 1 causes the run to be more nearly second than $^3/_2$ order.

In the presence of a large excess of hydrogen chloride, y is practically equal to $-c$, and only then will the reaction be kinetically of the first order with respect to camphene hydrochloride.

Equation (3) can be shown, by the usual methods of evaluating limits, to approach these special cases under appropriate conditions.

Materials and Experimental Procedure

The nitrobenzene used as solvent was purified by distillation through a nine-foot (2.75-meter) column. It boiled at 98° at 19 mm. and melted at 5.3°.

The camphene was prepared by the methods of Ullmann and Schmid[5] and Bertram and Walbaum.[6] All samples of camphene melted above 49°.

Camphene hydrochloride was prepared at first by the method of Meerwein and van Emster. This method of preparation involves keeping for some time in a vacuum desiccator over alkali, which in our experience always results in a preparation containing excess camphene. Our samples of the hydrochloride most free from camphene were obtained by keeping the product, after drying, in an atmosphere of hydrogen chloride for one hour. This resulted in preparations containing as much as 20% of isobornyl chloride. Run 3.5, which shows $^3/_2$ order kinetics, was carried out with a sample prepared in this manner. In the run with acetone as a solvent, it was found necessary to allow the samples to stand with sodium methoxide for two hours instead of one, to ensure complete decomposition of the camphene hydrochloride.

The technique of Meerwein and van Emster was used in the kinetic runs, except for the substitution of methyl red for iodoeosin as indicator. For comparison with the results of Meerwein, the temperature of 20° was chosen and used throughout. The temperature was controlled by a thermostat within less than 0.1°.

Most of the runs were carried beyond 70% completion, to make possible a clear differentiation between orders of reaction.

Kinetic Results

Our conditions were so chosen that the order of reaction in most cases can be seen clearly from a plot of the function of concentration of camphene hydrochloride which should vary linearly with time. Figure 1 shows such a plot for one of the runs with excess camphene. In this case the reaction should be second order if hydrogen chloride is essentially involved in it, and first order if it is a spontaneous reaction of the camphene hydrochloride. The figure shows that it is second order.

The problem of calculating the rate constant from a given run is essentially that of finding the slope of the best straight line through the experimental points. One can determine this quantity by the method of least squares, but for runs with relatively few points there is no better way than plotting the points and drawing the line by inspection, determining its slope graphically. This is the method which we have employed. It has the further advantage of providing a visible check for each run that the kinetic formulation employed is that which actually gives a straight line without trend.

The most stringent test of the correctness of our formulation of the reaction is provided by the comparison, in Table I, of the values of the rate constant, referred to camphene hydrochloride and hydrogen chloride concentrations, obtained from runs with excess camphene, excess hydrogen chloride, and the purest available camphene hydrochloride, using in each case the suitable equation for the interpretation of the data.

In spite of the benefit which we have gained from the publication in full of the original data of Meerwein and van Emster, we are reporting here only sample data for each type of run, in ac-

				Average	1.4

In all experiments the samples analyzed were 4.954 cc. each.

For a test of the effect of chloride ion on the rate of the rearrangement we were obliged to go to acetone as a solvent, since this solvent dissolves lithium chloride in amount sufficient for the test. Figure 3 shows the rates of reaction with and without 0.02 M lithium chloride. Although these runs are plotted according to Equation (4), the reaction appears to be of higher order than this. This may be due to the fact that over the long period of duration of the run, acetone is condensing with itself under the influence of the hydrogen chloride, and the nature of the solvent is thus undergoing change. There is also the possibility, which we have not investigated, that the equilibrium between isobornyl chloride and camphene hydrochloride may be more in favor of the latter in this solvent, so that the reaction cannot so well be treated as irreversible. The coincidence of the two curves in this case is good evidence that lithium chloride has no appreciable catalytic influence upon the reaction.

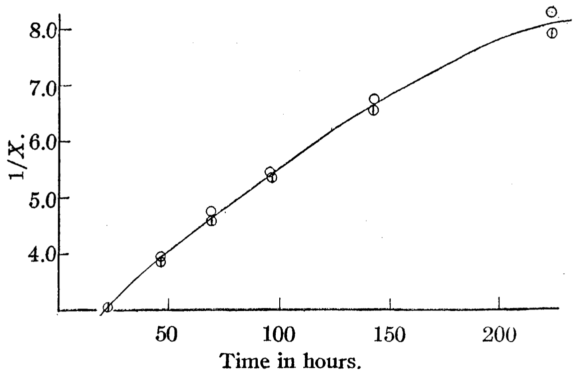

Fig. 3.—Rate of rearrangement of camphene hydrochloride into isobornyl chloride in acetone solution at 20° both in the presence of 0.02 mole/liter of LiCl and without the presence of LiCl: X = concn. camphene hydrochloride in moles/liter: ⦶, lithium chloride present; ○, lithium chloride not present.

For investigating the catalytic effect of *o*-cresol on the rearrangement, we chose to use an excess of camphene, in order that the hydrogen chloride-catalyzed reaction might be repressed to a minimum. Under these conditions the reaction in the absence of cresol would be strictly second order with respect to camphene hydrochloride, in accordance with Equation (4). The reaction actually observed in the presence of *o*-cresol is faster than this, and is first order over 70% of the total reaction, as shown in Fig. 4. From the known values of the rate constants we calculate that the reaction due to hydrogen chloride is less than 5% of the total reaction observed under these conditions. The order of the reaction shows (1) that hydrogen chloride is not involved in the cresol-catalyzed rearrangement, and (2) that cresol is not consumed and is thus a true catalyst. The velocity constant for reaction between camphene hydrochloride and cresol is 0.88. Cresol is thus about one-third as effective a catalyst for the reaction as hydrogen chloride.

A similar experiment using acetic acid instead of cresol showed that this compound too has a feeble catalytic activity in the Wagner–Meerwein rearrangement. The velocity constant here is 0.063. This constant, however, is not directly comparable to that for cresol, since acetic acid in nitrobenzene solution exists in the form of double molecules[7] in which the acid hydrogen is probably bound up in the formation of a chelate ring. The small catalytic activity observed may be that of the small fraction present as monomeric acetic acid. This uncertainty does not apply to the case of cresol.

Summary

1. The rearrangement of pure camphene hydrochloride into isobornyl chloride in solution requires the participation of hydrogen chloride. Since this hydrogen chloride is in equilibrium with camphene and camphene hydrochloride, the reaction rate varies with the camphene hydrochloride concentration in a manner which depends upon whether hydrogen chloride, or camphene, or neither, is present in excess.

2. A number of kinetic experiments under these various conditions support the quantitative implications of the essentially catalytic nature of the reaction.

3. The chloride ion is not a catalyst for the reaction. *o*-Cresol is a strong catalyst and acetic acid is a weak one.

4. The importance of hydrogen chloride in the reaction explains the slowness of the reaction in the basic solvents, ether and acetone.

5. Further work is being done on the mechanism of the rearrangement.

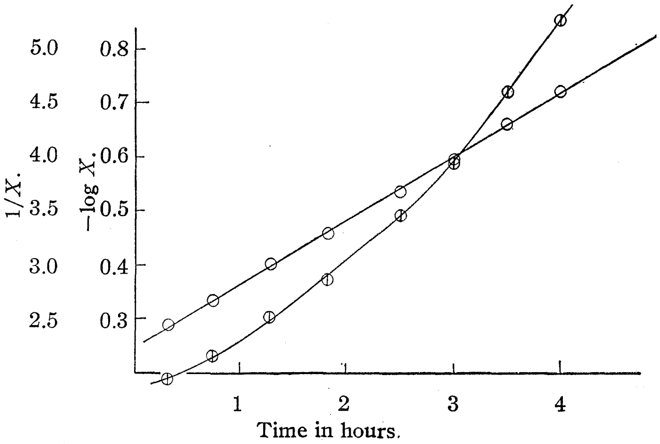

Fig. 4.—The rate of rearrangement of camphene hydrochloride to isobornyl chloride in nitrobenzene solution at 20° in the presence of 0.300 mole/liter of excess camphene and 0.311 mole/liter of *o*-cresol: ○, $-\log X$; ⦶, $1/X$.

Amino Alcohols Derived from Carbazole[1]

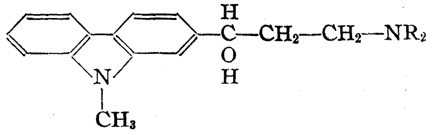
BY LEONE RUBERG AND LYNDON SMALL

In previous reports from this Laboratory the synthesis of numerous derivatives of the phenanthrene and dibenzofuran series has been described.[2] Many of these compounds bear a superficial resemblance to morphine in containing a portion of the morphine nucleus, to which is attached one or more of the peripheral groups that appear to be important for the analgesic action and other physiological effects of morphine. Those derivatives carrying an amino group and an alcoholic hydroxyl group, attached directly to the nucleus or in a side chain, have proved to be particularly active.[3] Diethylaminomethyl-3-phenanthrylcarbinol, for example, produces in the cat marked analgesia and a physiological picture very like that of morphine.[4]

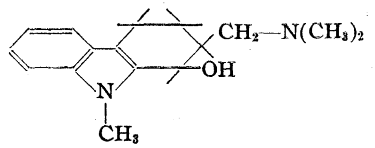
Certain substitution products derived from dibenzofuran show analgesic action even stronger than the analogous derivatives of phenanthrene,[3b] and, as a working hypothesis, the assumption seems justified that various carbocyclic or heterocyclic nuclei, in themselves indifferent, may be activated by, or serve to carry, groups conferring the desired type of physiological effect.

We were therefore led to extend our investigations to the simple amino and amino-9-methylcarbazoles, which were found to possess definite and prolonged analgesic action, combined with relatively low toxicity.[5] Systematic studies on a series of alkylamino and alkyldiamino carbazoles will be presented in a later paper. The present communication deals with the preparation of carbazole amino alcohols resembling the phenanthrene amino alcohols that have been found to possess the most desirable physiological action.

The two types of amino alcohols that have been synthesized are represented by formulas I and II.



I



II

In formula I, —NR_2 represents the dimethylamino, diethylamino, or tetrahydroisoquinolino group. These compounds were prepared by application of the Mannich reaction to 2-acetyl-9-methylcarbazole, using the modification of van de Kamp and Mosettig,[6] *i. e.*, by treatment of the ketone with paraformaldehyde and the hydrochlorides of the respective secondary amines. The amino ketones were then reduced catalytically to the corresponding amino alcohols. The compound of formula II was prepared by analogous reactions, starting with 1-keto-9-methyl-1,2,3,4-tetrahydrocarbazole.

Whereas 2-(3-dimethylamino-1-hydroxy-*n*-propyl)-9-methylcarbazole (I, R = CH_3) yielded a well crystallized hydrochloride, for reasons which are not obvious the diethylamino and tetrahydroisoquinolino analogs were decomposed by alcoholic hydrogen chloride. The cyclic alcohol II apparently suffered loss of water in the presence of alcoholic hydrogen chloride to yield a compound that we believe to be 2-dimethylaminomethyl-9-methyl-3,4-dihydrocarbazole hydrochloride. The tendency of similar amino alcohols in the tetrahydrophenanthrene series to split out water has been pointed out by Burger and Mosettig.[7]

The experimental work in this series will be extended to the resolution of the diethylamino alcohol of type I, and to the preparation of similar compounds in the benzocarbazole series.

The most active of the substances here described is 2-(3-diethylamino-1-hydroxy-*n*-propyl)-9-methylcarbazole (I, R = C_2H_5). This approaches codeine in analgesic action, but has a

disadvantageous convulsant effect. In experiments on mice, it may be remarked that some of the animals showed the Straub reaction (erection of the tail in S form) that is so typical of morphine derivatives.

Experimental

Amino Ketones.—The method of Plant and Williams[8] for the preparation of 2-acetyl-9-methylcarbazole proved to be so laborious for making the ketone on a large scale that the following procedure was used. A suspension of 2,9-diacetylcarbazole (once recrystallized) in acetone, mechanically stirred, was treated dropwise with dimethyl sulfate and excess concentrated potassium hydroxide solution. Hydrolysis and methylation took place in a single step, and the product was easily purified by recrystallization from dilute acetic acid (70% by volume). The yield averaged 77% of the calculated amount. The amino ketones were all prepared in the same general way, by treating under reflux for fifteen or twenty minutes a mixture of 2-acetyl-9-methylcarbazole or 1-keto-9-methyl-1,2,3,4-tetrahydrocarbazole (1 mole), the amine hydrochloride (1.2 moles), and paraformaldehyde (2.5 moles) in isoamyl alcohol. The quantity of ketone was usually 10 to 15 g., in 100 to 150 cc. of isoamyl alcohol. In some experiments the amino ketone hydrochloride precipitated from the reaction mixture when it was cooled, or diluted with ether. In these instances the precipitate was filtered out and washed with ether or acetone. In other reactions, dilution with ether caused the hydrochloride to separate as an oil, which was then extracted into water. The free bases were obtained by treating the aqueous solution of the hydrochloride with dilute ammonia, and filtering or extracting with ether, according to the consistency of the precipitate.

2-(3-Dimethylamino-1-oxopropyl)-9-methylcarbazole.—The yield of pure ketone obtained was 18% of the calculated amount. A large amount of starting material was recovered, but was very difficult to purify. The amino ketone crystallized from ethyl acetate in transparent, colorless plates of m. p. 111.5–113.5°.

The hydrochloride precipitated as fine silky needles, m. p. 191.5–193°, when alcoholic hydrogen chloride was added to a solution of the base in absolute alcohol.

Anal. Calcd. for $C_{18}H_{21}ON_2Cl$: C, 68.22; H, 6.68. Found: C, 68.17; H, 6.61.

2-(3-Diethylamino-1-oxopropyl) - 9 - methylcarbazole.—The yield of purified amino ketone was from 20 to 25% of the calculated amount; it is rather unstable. It crystallized from ligroin (b. p. 70–90°) in creamy-white irregular crystals that sintered at 69° and melted at 70.5–72.5°.

Anal. Calcd. for $C_{20}H_{24}ON_2$: C, 77.87; H, 7.85. Found: C, 77.72, 77.49; H, 7.41, 7.93.

The hydrochloride crystallized from absolute alcohol in glistening leaflets that softened at about 160° and melted at 163.5–166°.

Anal. Calcd. for $C_{20}H_{25}ON_2Cl$: Cl, 10.29. Found: Cl, 10.11.

2-(3-Tetrahydroisoquinolino-1-oxopropyl)-9-methylcarbazole.—The hydrochloride of this amino ketone precipitated after the reaction mixture had been boiled for two to three minutes, and heating was then discontinued. The salt was only slightly soluble in water, and was converted to the base by trituration with dilute ammonia. The base crystallized from ethyl acetate in glistening leaflets of m. p. 123–125°; yield 37% of the theoretical amount.

Anal. Calcd. for $C_{25}H_{24}ON_2$: C, 81.48; H, 6.56. Found: C, 81.62; H, 6.77.

The hydrochloride crystallized from absolute alcohol–acetone mixture in short colorless rods that sintered at 209° and melted at 211–213°.

Anal. Calcd. for $C_{25}H_{25}ON_2Cl$: Cl, 8.76. Found: Cl, 8.89.

2-Dimethylaminomethyl-1-keto-9-methyl-1,2,3,4-tetrahydrocarbazole.—The starting material for this synthesis was obtained by methylation of 1-keto-1,2,3,4-tetrahydrocarbazole according to the method of Smith and Tucker;[9] yield nearly quantitative. 1-Keto-9-methyl-1,2,3,4-tetrahydrocarbazole crystallized from methanol in long colorless prisms, m. p. 101.5–103.5°.

Anal. Calcd. for $C_{13}H_{13}ON$: C, 78.35; H, 6.58. Found: C. 78.16; H, 6.21.

By the Mannich reaction with dimethylamine hydrochloride the above ketone was transformed in 10–15% yields to (crude) 2-dimethylaminomethyl-1-keto-9-methyl-1,2,3,4-tetrahydrocarbazole. This compound crystallized from petroleum ether in almost colorless transparent plates that sintered at 72.5° and melted at 74–75°.

Anal. Calcd. for $C_{16}H_{20}ON_2$: C, 74.95; H, 7.87. Found: C, 74.90; H, 8.12.

The hydrochloride of the amino ketone crystallized from a mixture of absolute alcohol and acetone in short, colorless rods, which sintered at about 180°, and melted with decomposition at about 190°. Both the base and the hydrochloride were unstable and became colored after a few weeks.

Anal. Calcd. for $C_{16}H_{21}ON_2Cl$: C, 65.61; H, 7.23; N, 9.58. Found: C, 65.74; H, 7.44; N, 9.47.

Amino Alcohols.—The hydrochlorides of the amino ketones were hydrogenated in solution in 60% alcohol, using platinum oxide catalyst. It was found to be essential for the success of the hydrogenation that the salts be of a high degree of purity. In most instances reduction stopped after slightly more than one mole of hydrogen had been absorbed.

2-(3-Dimethylamino-1-hydroxy-*n*-propyl)-9-methylcarbazole.—The reduction of 5.3 g. of the amino ketone in the presence of 0.25 g. of platinum oxide required about three hours. The catalyst was removed, and the solvent was distilled off under diminished pressure, leaving a residue which was taken up in water, treated with ammonia, and extracted with ether. The residue from distillation of the ether crystallized from ligroin (b. p. 90–120°) in colorless rosets, of m. p. 96.5–99°; yield of purified amino alcohol, 80% of the calculated amount.

---

[8] Plant and Williams, *J. Chem. Soc.*, 1142 (1934).

[9] Smith and Tucker, *ibid.*, **123**, 2140 (1923).

Anal. Calcd. for $C_{18}H_{22}ON_2$: C, 76.55; H, 7.86. Found: C, 76.37; H, 7.71.

The hydrochloride was prepared in absolute alcohol with alcoholic hydrogen chloride; it crystallized as fine colorless needles of m. p. 195–196.2°. It is very soluble in water.

Anal. Calcd. for $C_{18}H_{23}ON_2Cl$: Cl, 11.13. Found: Cl, 11.24.

The *p*-nitrobenzoate hydrochloride was prepared by combining equivalent amounts of the amino alcohol and *p*-nitrobenzoyl chloride in dry benzene. The yellow amorphous compound was washed with absolute ether and was recrystallized from a mixture of absolute alcohol and ether. It formed short yellow rods that softened at 164° and melted at 165–166.5°.

Anal. Calcd. for $C_{25}H_{26}O_4N_3Cl$: N, 8.99; Cl, 7.58. Found: N, 8.93; Cl, 7.24.

2-(3-Diethylamino-1-hydroxy-*n*-propyl)-9-methylcarbazole.—Reduction of the diethylamino ketone (11 g.) with platinum oxide (0.55 g.) proceeded like that of the dimethylamino derivative, and the product was isolated in the same way. The amino alcohol was purified by fractional crystallization from petroleum ether, from which it separated as soft, glistening irregular crystals that sintered at 73° and melted at 75.2–76°; yield 80% of the calculated amount.

Anal. Calcd. for $C_{20}H_{26}ON_2$: C, 77.36; H, 8.45. Found: C, 77.14; H, 8.47.

It is particularly important in this reduction that the amino ketone salt be pure. In one reduction, apparently with less pure material, absorption of hydrogen proceeded slowly and a precipitate formed. This was warmed into solution, the catalyst removed, and the solution was permitted to crystallize. Long yellow needles were deposited, which were purified from alcohol and melted at 133–135°. The new compound was not basic, and formed an oxime, colorless prisms from alcohol, m. p. 172–173°; its nature has not been determined. From the mother liquors, the amino alcohol could be obtained, but was very difficult to purify.

The amino alcohol did not form a crystalline hydrochloride, but was extensively decomposed by alcoholic hydrogen chloride.

The picrate crystallized from alcohol in golden-yellow needles of m. p. 136–138.5°.

Anal. Calcd. for $C_{26}H_{29}O_8N_5$: C, 57.86; H, 5.42. Found: C, 57.98; H, 5.63.

The *p*-nitrobenzoate hydrochloride crystallized from a mixture of absolute alcohol and ether in short yellow rods, which sintered at 177° and melted at 179–180.5°.

Anal. Calcd. for $C_{27}H_{30}O_4N_3Cl$: C, 65.36; H, 6.10; N, 8.48. Found: C, 65.57; H, 6.03; N, 8.25.

2-(3-Tetrahydroisoquinolino-1-hydroxy-*n*-propyl)-9-methylcarbazole.—After reduction of the amino ketone hydrochloride, the reaction mixture was warmed with additional solvent until the separated material redissolved, and the catalyst was removed. A small amount of amino alcohol base crystallized from the cooled solution. The solution was concentrated under diminished pressure and made alkaline with ammonia. The yield of crude product (m. p. 148–152°) was 90% of the calculated amount. It crystallized from alcohol in long colorless prisms of m. p. 151.5–153°. Repeated recrystallization and sublimation did not effect further purification. The following analyses were made on different samples.

Anal. Calcd. for $C_{25}H_{26}ON_2$: C, 81.03; H, 7.08. Found: C, 81.23, 81.52, 81.64, 81.43, 81.37, 81.73; H, 6.64, 7.29, 7.22, 7.03, 6.96, 7.07.

The amino alcohol was insoluble in dilute hydrochloric acid, and was decomposed by alcoholic hydrogen chloride.

The styphnate crystallized from alcohol in small orange clusters that sintered above 135° and melted with decomposition at 171–175°.

Anal. Calcd. for $C_{31}H_{29}O_9N_5$: C, 60.46; H, 4.75. Found: C, 60.21; H, 4.75.

The *p*-nitrobenzoate hydrochloride crystallized from absolute alcohol in small yellow prisms that sintered at 153° and melted at 159.5–161°.

Anal. Calcd. for $C_{32}H_{30}O_4N_3Cl$: C, 69.10; H, 5.44. Found: C, 69.13; H, 5.73.

2-Dimethylaminomethyl-1-hydroxy-9-methyl-1,2,3,4-tetrahydrocarbazole.—After reduction of the amino ketone hydrochloride and removal of the catalyst and solvent as described above, the residue was dissolved in water, and the solution was extracted with ether. The base was liberated from the aqueous layer with ammonia, and extracted into ether. The product was recrystallized successively from dilute alcohol and from ethyl acetate–petroleum ether mixture (1:15), and consisted of colorless six-sided plates of m. p. 123.5–125°. The yield of pure amino alcohol was 46% of the calculated amount.

Anal. Calcd. for $C_{16}H_{22}ON_2$: C, 74.36; H, 8.59; N, 10.85. Found: C, 74.36, 74.50; H, 8.38, 8.63; N, 10.89.

Attempts to prepare the hydrochloride of this amino alcohol resulted in the formation of a hydrochloride which analysis showed to lack the elements of water from the expected formula. The compound, tentatively designated as 2-dimethylaminomethyl-9-methyl-3,4-dihydrocarbazole hydrochloride, crystallized from absolute alcohol on addition of ether as colorless irregular crystals that sintered at about 180° and melted with decomposition at 192–194°. It was somewhat unstable, and showed a lower melting point after a few weeks.

Anal. Calcd. for $C_{16}H_{23}ON_2Cl$: C, 65.16; H, 7.87; N, 9.51. Calcd. for $C_{16}H_{21}N_2Cl$: C, 69.41; H, 7.65; N, 10.13. Found: C, 69.71; H, 7.67; N, 10.21.

Summary

The preparation of amino alcohols derived from 9-methylcarbazole and from 1-keto-9-methyltetrahydrocarbazole is described. Several of these amino alcohols show marked analgesic action, the most effective being 2-(3-diethylamino-1-hydroxy-*n*-propyl)-9-methylcarbazole.

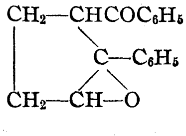
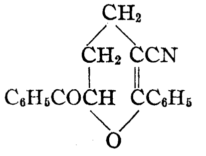
A Synthesis of 3-Benzoyl-2-phenylcyclopentanone

BY REYNOLD C. FUSON, ROBERT JOHNSON AND WAYNE COLE

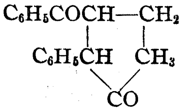
3-Benzoyl-2-phenylcyclopentanone (III) has been obtained by rearrangement of 1-phenyl-5-benzoylcyclopentene oxide (I),[1] and by the action of hot phosphoric acid on 2-phenyl-3-cyano-6-benzoyl-5,6-dihydro-1,4-pyran (II).[2]



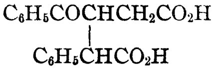
I



II



III

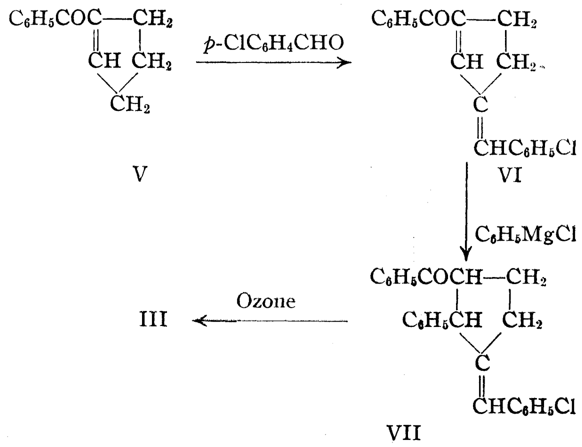


IV

The structure of the cyclopentanone (III) could hardly be deduced from the manner in which it originates, for the transformations which lead to its formation might be expected to yield a variety of products. It was necessary, therefore, to establish the structure of III in some other way. The first attempt consisted in oxidizing the cyclopentanone to the open-chain dibasic acid, β-benzoyl-α-phenylglutaric acid (IV). This compound was isolated in the two forms required by theory,[3] but since these had not been synthesized hitherto the proof of structure was inconclusive.

We have now established the structure of the cyclopentanone (III) by a synthesis based on the principle of vinylogy.[4] From this principle it was to be expected that 1-benzoylcyclopentene (V) like 1-benzoylcyclohexene and similar α,β-unsaturated ketones would have active hydrogen atoms in the γ-position,[5] and may condense with aldehydes.

This expectation was realized. 1-Benzoylcyclopentene reacted with p-chlorobenzaldehyde to give the normal p-chlorobenzal derivative (VI). The next step in the synthesis was the addition of phenylmagnesium bromide to the benzal derivative. It was foreseen that 1,2-, 1,4- and 1,6-addition are possible, but because of the phenyl groups in positions 1 and 6 the addition was expected to be primarily of the 1,4-type. This proved to be the case. 1-Benzoyl-2-phenyl-3-(p-chlorobenzal)-cyclopentane (VII) was obtained in two forms which were evidently stereoisomers since they yielded the same ozonization products. These were p-chlorobenzaldehyde and the desired cyclopentanone (III). The latter proved to be identical with the compound derived from the oxide (I) and the cyanopyran (II).



Experimental

1-Benzoylcyclopentene (V).—This material was prepared by the Friedel–Crafts reaction. Forty-four grams of aluminum chloride was added slowly to a mixture of 20 g. of cyclopentene, 43 g. of benzoyl chloride and 180 g. of carbon disulfide, which was kept at −5° during the addition. Decomposition with ice gave a crude addition product which, after three hours of heating with 28 g. of diethylaniline at 180°, yielded 16 g. (32% of the theoretical) of 1-benzoylcyclopentene, boiling at 119–122° (3 mm.); $n^{20}\text{D}$ 1.5668.

Anal. Calcd. for $C_{12}H_{12}O$: C, 83.72; H, 7.00. Found: C, 83.41; H, 7.15.

1-Benzoyl-3-(p-chlorobenzal)-cyclopentene (VI).—A sodium methylate solution prepared from 2.5 g. of sodium and 25 cc. of methanol was added to a methanol solution of 10 g. of benzoylcyclopentene and 14 g. of p-chlorobenzaldehyde. After standing at room temperature for twelve hours, the solution was acidified with glacial acetic acid and cooled; the product separated as crystals. These were recrystallized from methanol; the yield of the condensation product, melting at 118°, was 8.2 g. (48% of the theoretical).

Anal. Calcd. for $C_{19}H_{15}OCl$: C, 77.43; H, 5.09; Cl, 12.05. Found: C, 77.26; H, 4.92; Cl, 12.30.

1-Benzoyl-2-phenyl-3-(*p*-chlorobenzal)-cyclopentane (VII).—A Grignard reagent containing 0.0046 mole of phenylmagnesium bromide was added to a solution of 1 g. of 1-benzoyl-3-(*p*-chlorobenzal)-cyclopentene in anhydrous ether. The mixture was refluxed for one hour, then hydrolyzed by shaking with 5% hydrochloric acid. The product was recrystallized from ethanol, yielding 1 g. (79% of the theoretical) of the addition compound, melting at 171° (corr.). Larger runs were made with equivalent yields.

Anal. Calcd. for $C_{25}H_{21}OCl$: C, 80.56; H, 5.64; Cl, 9.52. Found: C, 80.76; H, 5.74; Cl, 9.53.

A solution of 0.7 g. of the addition product in 400 cc. of ethanol was refluxed with excess hydroxylamine. Concentration of the solution gave a small quantity of an oxime, melting at 115–120°.

Anal. Calcd. for $C_{25}H_{22}ONCl$: N, 3.62. Found: N, 3.69.

A solution of 1 g. of the addition compound (m. p. 171°) in 20 cc. of methanol was refluxed with 0.25 cc. of 10% sodium hydroxide solution for twenty minutes. An isomer melting at 178° (corr.) crystallized when the solution was cooled.

Anal. Calcd. for $C_{25}H_{21}OCl$: C, 80.56, H, 5.64. Found: C, 80.55; H, 5.91.

This isomerization seemed to be hastened by the presence of a small quantity of *p*-chlorobenzaldehyde, for in the presence of this aldehyde the compound underwent rearrangement in ten minutes. A mixture of these two isomers melted at 158–161°.

Ozonization of 1-Benzoyl-2-phenyl-3-(*p*-chlorobenzal)-cyclopentane.—One-half gram of the addition product (either form) was suspended and partly dissolved in 200 cc. of glacial acetic acid. This suspension was treated with ozone for four hours at 10°; during this time the material dissolved completely. The ozonide was decomposed with a mixture of 100 cc. of water, 3 g. of zinc dust and 1 cc. of 5% silver nitrate solution. This mixture was then filtered to remove zinc, steam distilled to remove the aldehyde and most of the acetic acid, and neutralized with sodium bicarbonate. Concentration of the ether extract of neutral material yielded crystals of 3-benzoyl-2-phenylcyclopentanone (III) which, after recrystallization from methanol and from ethyl acetate–petroleum ether, melted at 158°. A mixture of this material with a sample (m. p. 159°) prepared by Babcock and Fuson[3] also melted at 158°.

When the lower-melting isomer of 1-benzoyl-2-phenyl-3-(*p*-chlorobenzal)-cyclopentane was used in the ozonization, the yield of 3-benzoyl-2-phenylcyclopentanone was 0.08 g. (22% of the theoretical amount); when the higher-melting isomer was used, the yield was 0.2 g. (56% of the theoretical amount).

Oxidation of the crude aldehyde with hydrogen peroxide gave 0.1 g. of *p*-chlorobenzoic acid, melting at 239–240°. This acid was also precipitated by acidification of the sodium bicarbonate washings.

3-Benzoyl-2-phenylcyclopentanone formed an *oxime* which after recrystallization from ethyl alcohol melted at 222–224°.

Anal. Calcd. for $C_{18}H_{17}O_2N$: C, 77.4; H, 6.1; N, 5.02. Found: C, 77.1; H, 6.2; N, 5.08.

3-Benzoyl-2-phenyl-5-(*p*-chlorobenzal)-cyclopentanone.—A solution of 0.2 g. of 3-benzoyl-2-phenylcyclopentanone and 0.2 g. of *p*-chlorobenzaldehyde in 7 cc. of methanol containing one drop of 10% sodium hydroxide solution was refluxed for eight minutes. When the solution was cooled, crystals of 3-benzoyl-2-phenyl-5-(*p*-chlorobenzal)-cyclopentanone separated. These melted at 207° and gave no depression in melting point when mixed with the compound prepared by the method of Babcock and Fuson.[3]

Summary

1-Benzoylcyclopentene has an active methylene group, in accordance with the prediction based on the principle of vinylogy, and condenses with *p*-chlorobenzaldehyde.

This condensation product gives 1,4-addition of phenylmagnesium bromide as shown by ozonization of the addition compound to give *p*-chlorobenzaldehyde and 3-benzoyl-2-phenylcyclopentanone.

This synthesis of the cyclopentanone constitutes a proof of structure.

Fermentation of Cellulose and Cellulose Humic Acid and Lignin and Lignin Humic Acid

BY E. BERL AND W. KOERBER

Those scientists who believe that lignin is the parent material of bituminous coal, as well as of lignites, base their belief on the assumption that cellulose, and other carbohydrates which form the bulk of plants, are decomposed by bacteria much more quickly and more completely than lignin. This assumption has found friends and opponents. Olson and Peterson[1] found that very small amounts of lignin (1%) inhibit the fermentation of pulp by cellulose fermenting bacteria. One of us has expressed the opinion that lignin and its derivatives are not the exclusive parent material for bituminous coals. It has been shown that under conditions which may have existed geochemically (high temperature and pressure) and with *p*H values above 7, bituminous coals could be obtained by artificial incoalification of carbohydrates. Those artificial carbohydrate coals show exactly the same properties as natural bituminous coals. This result never could be obtained with lignin and its derivatives, like lignin humic acid.

During the first stage of their conversion, with the *p*H above 7, cellulose and other carbohydrates form partly saccharinic acids which, upon further incoalification (with the formation of carbon dioxide, water, and lower hydrocarbons), give carbohydrate (cellulose) humic acids.

Until now all those alkali-soluble materials present in peat and lignites resulting from the decomposition of plants have been considered as lignin humic acids, and not as mixtures of cellulose humic acids and lignin humic acids. As yet no method of determining the amount of cellulose humic acids in these mixed acids has been found. We know that cellulose humic acids, in their chemical composition and in their behavior toward further incoalification, are fundamentally different from lignin humic acids. Furthermore, as may be shown in another publication, their heat stability is completely different from the heat stability of carbohydrates and of lignin, and lignin humic acids.

It was of great interest to find out how certain anaerobic and aerobic bacteria which decompose cellulose[2,3] would behave toward cellulose (carbohydrate) humic acid, lignin humic acid, and lignin. These experiments, which are described below, have been carried out and show a remarkable result. Anaerobic and aerobic bacteria which decompose cellulose do not attack cellulose humic acids, lignin, and lignin humic acids at all. They do not attack natural humic acids isolated from peat.

It has been shown that rather little cellulose, as such, may be present in peat and lignites and that under certain conditions the carbohydrate content of peat and lignites decreases with age. This does not lead to the conclusion that cellulose and lower carbohydrates are completely converted into gases and water-soluble compounds. They are very likely transformed into carbohydrate humic acids which resist the action of bacteria because of their phenolic structure. That cellulose humic acids may be present in those alkali-soluble materials obtained from peat can be seen by the fact that the peat humic acid used in our experiments contains only a few per cent. of methoxyl compared with 10.6% of methoxyl found in the lignin humic acid produced under very drastic conditions at 250° in a rotating closed vessel. A certain amount of methoxyl may be split off by the action of bacteria (see Waksman[4]).

Experimental Part

Cellulose, cellulose humic acid, lignin humic acid, and humic acid from peat were used for the fermentation experiments. The preparation of these materials was carried out in the following way.

(a) **Cellulose** was used in the form of wadding.

(b) **Cellulose Humic Acids.**—Linters were heated at 250° for ten hours with *N*/sodium hydroxide in a revolving bomb. The product was filtered and the dark brown filtrate obtained was acidified with hydrochloric acid, the precipitated humic acids filtered and dried. The finely pulverized material was washed with water until the chloride reaction disappeared and then dried over calcium chloride. The dark brown humic acids were dissolved in acetone, the solvents evaporated, and the residue dried *in*

vacuo over phosphorus pentoxide: C, 68.2; H, 6.1; O, 25.7; CH_3O, 0.

(c) **Lignin.**—Lignin was prepared from sawdust according to the hydrochloric acid method of Willstätter. The product obtained was refluxed with 5% sulfuric acid for five hours, filtered, and washed. A treatment with copper ammonium hydroxide at room temperature for twenty-four hours was added. The residue was thoroughly washed with hot acidified water and dried over phosphorus pentoxide: C, 62.4; H, 5.8; O, 27.8; CH_3O, 14.6.

(d) **Lignin Humic Acids.**—The lignin as described under **c** was treated with *N* sodium hydroxide at 250° for three hours in a revolving bomb. The further preparation was carried out as described under b: C, 63.8; H, 6.7; O, 29.5; CH_3O, 10.5.

(e) **Humic Acids from Peat.**—Peat from Wisconsin was finely pulverized and extracted with *N* sodium hydroxide on a shaking machine for twenty-four hours. The alkali-soluble part was separated by filtration, acidified, and the humic acids isolated as described under **b**: C, 63.4; H, 4.8; O, 31.8; CH_3O, 1.9.

Isolation of Aerobic Cellulose Fermenting Bacteria.—A cellulose fermenting bacillus was isolated from horsedung according to the method described by Snieszko.[5] Control experiments were carried out with cellulose in salt media of *p*H 7.4 and 6.

Conical flasks of 300 cc. were each charged with 200 cc. of a salt medium containing 0.1% KNO_3, 0.1% $MgSO_4$, 0.1% K_2HPO_4, 0.5% peptone, exactly 2 g. of calcium carbonate and 3 g. of cellulose (latter dried over phosphorus pentoxide), *p*H 7.4. After sterilization the flasks were inoculated with the above-mentioned cellulose fermenting culture and incubated for five days at 55°. After this time the flasks were removed from the incubator and each of them titrated with *N* hydrochloric acid. From the titrated calcium carbonate the total acid formed was calculated. More acid was added and the contents of the flasks filtered and washed. The residue was unattacked cellulose; 25 cc. of 80% H_3PO_4 was added to the filtrate, which was then steam distilled. The distillate was titrated with *N* sodium hydroxide (volatile acids expressed as acetic acid). In order to determine the alcohol, the neutral distillate was ether-extracted three times, the ether evaporated, and the extract refluxed with acetyl chloride for two hours. After neutralization the solution was ether-extracted again, hydrolyzed with 10 ml. of 0.5 *N* sodium hydroxide, and back-titrated with 0.5 *N* hydrochloric acid (Tables I, II).

Aerobic Fermentation Experiments on Cellulose Humic Acids, Lignin, Lignin Humic Acids, and Humic Acids from Peat.—The above materials were exposed to the action of the cellulose-fermenting bacteria under the same conditions as were used in the control experiments on cellulose. None of these products could be fermented by those cultures which were active on cellulose. Even after four weeks no fermentation could be obtained with *p*H 7.4 and 6.

Isolation of Anaerobic Cellulose Fermenting Bacteria.—*Amylobacter navicula* was isolated from human feces under anaerobic conditions as described by Clausen.[6] Control experiments were performed with cellulose in a salt medium with *p*H 7.4 and 6.

Tubes were each charged with 150 ml. of a salt medium containing 0.1% $(NH_4)_2SO_4$, 0.1% $MgHPO_4$, 0.05% NaCl, and 1 g. of calcium carbonate; 1.5 g. of cellulose (dried over phosphorus pentoxide) accurately weighed, was added, *p*H 7.4. After sterilization the tubes were inoculated with an active cellulose fermenting culture of *amylobacter navicula* and incubated at 37° for five days under anaerobic conditions. After this time the tubes were removed from the incubator, their contents filtered, the residue washed and dried over calcium chloride *in vacuo*. The only fermentation products being gases, no other determinations were carried out than the weighing of the undecomposed cellulose.

Anaerobic Fermentation Experiments on Cellulose Humic Acids, Lignin, Lignin Humic Acids, and Humic Acids from Peat.—The above materials were exposed to the action of the anaerobic cellulose-fermenting bacteria under the same conditions as were used in the control experiments on cellulose. None of these products could be fermented by those cultures which were active on cellulose. Even after four weeks no fermentation could be obtained with *p*H 7.4 and 6.

We thank Professor Harold L. Lang for his kind support of this investigation.

Summary

1. (a) A cellulose fermenting bacillus isolated from horse-dung showed in agreement with Sineszko a decomposition of approximately 70% of the cellulose used. Fermentation products are volatile acids, non-volatile acids, and alcohol in medium of *p*H 7.4. (b) The fermentation in medium of *p*H 6 by the same bacteria showed a decomposition of about 20% of the original cellulose.

2. Fermentation experiments carried out with the same culture on cellulose humic acids, lignin, lignin humic acids, and humic acids from peat showed that none of those products can be fermented, neither in medium of *p*H 7.4 or *p*H 6, even after four weeks of incubation.

3. (a) The anaerobic cellulose fermenting *amylobacter navicula* isolated from human feces as described by Clausen showed a fermentation of 63% of cellulose in salt medium of *p*H 7.4 under anaerobic conditions. (b) The same culture in medium of *p*H 6 fermented cellulose in an amount of approximately 15%.

4. Fermentation experiments carried out with the same culture on cellulose humic acids, lignin, lignin humic acids, and humic acids from peat showed that none of those products can be fermented, neither in medium of *p*H 7.4, nor *p*H 6, even after four weeks of incubation.

These experiments prove that derivatives of carbohydrates, like cellulose humic acids, which are formed from carbohydrates of plants are resistant toward the action of bacteria used in these experiments. These cellulose humic acids probably form bituminous coals and crude oil without further activity of bacteria.

The Crystal Structure of Diketopiperazine

BY ROBERT B. COREY

Introduction

For many years 2,5-diketopiperazine, "glycine anhydride,"  $\mathrm{OC}\left\langle\begin{matrix}\mathrm{CH_2{-}NH}\\ \mathrm{NH{-}CH_2}\end{matrix}\right\rangle\mathrm{CO}$, has been of considerable interest to those concerned with the constitution of proteins. Substituted diketopiperazines have been shown to be present among the products of protein hydrolysis[1] and much experimental evidence has suggested that these compounds might play a major role in the elucidation of the structure of protein molecules.[2] Although this importance of diketopiperazine as a basic unit in protein chemistry is not now generally conceded, its relation to the amino acids and dipeptides renders a determination of its structure of fundamental value to further knowledge of these compounds. The present investigation was therefore

undertaken as a part of a program of research on the structure of proteins now being carried on in this Laboratory.

Bernal, in an extensive survey,[3] tabulated the results of a preliminary study of fifteen amino acids and related compounds, including diketopiperazine, by means of X-rays. Diketopiperazine is there described as having a monoclinic unit with $a_0 = 5.19$ Å., $b_0 = 11.5$ Å., $c_0 = 3.96$ Å., $\beta = 83°$, containing two molecules. The space group is $C_{2h}^5 - P2_1/a$. Cleavage is along (010) and (101). The crystals possess negative birefringence with α nearly perpendicular to (101), indicating approximately flat molecules lying in or near this plane. From these data he inferred that "diketopiperazine is built from centro-symmetrical, almost flat, hexagonal molecules linked together in ribbons by their residual electrical forces." No attempt was made, however, to determine from X-ray intensity data the positions of the atoms in this compound or in any other of the compounds studied.

Experimental

The crystals used in this study were prepared by G. A. Albrecht. They consisted of monoclinic prisms, varying in shape from thin needles, elongated in the direction of the *c*-axis, to tiny tabular specimens, less than a half-millimeter in greatest dimension.

Goniometric measurements of the crystals, oscillation and rotation photographs and Weissenberg photographs taken about the *b*- and *c*-axes, using Cu–K radiation, showed diketopiperazine to be built upon a monoclinic unit cell having the dimensions $a_0 = 5.19_2$ Å., $b_0 = 11.50_5$ Å., and $c_0 = 3.96_4$ Å. The angle β is $83 \pm 1°$. The general absence of all ($h0l$) reflections having h odd and of odd orders of ($0k0$) established the space group as $C_{2h}^5 - P2_1/a$. These observations thus confirmed the unit cell and space group previously assigned by Bernal.

Data from ($hk0$) Reflections.—The relative intensities of ($hk0$) reflections were obtained from a series of equatorial Weissenberg photographs made with exposure times varying from one hour to thirty-six hours. The specimen used was a needle-shaped crystal about 1 mm. long and less than 0.1 mm. in diameter. It gave sharp, well-defined spots, the intensities of which readily could be estimated by superposition of the films. The data thus obtained are listed in Table I.

The presence of two molecules in the unit cell requires the placing of four atoms each of O, C, methylene C, and N in the four general positions xyz, $\bar{x}\bar{y}\bar{z}$; $^1/_2 - x, y + {}^1/_2, \bar{z}$; and $x + {}^1/_2, {}^1/_2 - y, z$. This results in a grouping of the atoms in pairs about two centers of symmetry which are connected by the operation of the glide-plane at $y = {}^1/_4$ with glide parallel to the a-axis. For convenience, the atoms were arranged about the center of symmetry at ($^1/_2\ ^1/_2\ ^1/_2$) and its equivalent ($00^1/_2$), each of which thus became the center of symmetry of a molecule.

As a first tentative model, the bonds between C, CH_2, and NH were assumed to form tetrahedral angles with each other to give a "puckered" ring similar to that found for such saturated, six-membered ring structures as benzene hexabromide and hexachloride,[4] dioxane,[5] cyclohexane,[6] and paraldehyde.[7] The C–O bond was oriented so as to be coplanar with the adjacent C–C and C–N bonds and to form equal angles with them. The interatomic distances within the molecule were assumed to be C–O, 1.25 Å., C–N, 1.47 Å., and C–C, 1.54 Å. Packing radii for determining contacts between atoms, or groups, in different molecules were taken as O, 1.35 Å., C, 0.77 Å., CH_2, 1.86–2.00 Å., and NH, 1.5–1.8 Å. Space-filling considerations alone soon made it apparent that CH_2 and NH groups could not lie far from the (101) plane, and investigations were thus limited to rotations near this plane about the center of symmetry.

In all calculations the scattering power of oxygen was assumed to be that determined in single crystals of urea.[8] For carbon and nitrogen the values used were those found in urea and hexamethylenetetramine.[9]

Although some regions were found in which approximate packing was attained, no agreement could be reached between observed and calculated intensities for even the simplest planes. Planes (200), (110), (020), (040), (210), and (120) were most useful since, if the contribution of oxygen were disregarded, the values for their scattering powers were practically unaffected by the angular position of the C–N–C ring. By their use it could be shown that no parameters whatsoever

could be assigned to the oxygen atom which would bring agreement between observed and calculated intensities. This model therefore had to be abandoned.

A completely coplanar molecule was next assumed, with interatomic distances the same as in the preceding one except that the distance between the keto carbon and the nitrogen atom was shortened to 1.32 Å. The bond angles were taken to be C–N–C, 110°; N–C–CH_2, 125°; C–CH_2–N, 125° and N–C–O, 117°. This molecule was rotated about the center of symmetry with all atoms in the (101) plane. Excellent agreement for all sixty (*hk*0) reflections was obtained when a line joining the oxygen atoms made an angle of 35° with the XZ-plane, corresponding to the parameters.

O : $x = 0.15$, $y = 0.37$
C : $x = 0.32$, $y = 0.43$
CH_2 : $x = 0.545$, $y = 0.37$
NH : $x = 0.29$, $y = 0.545$

Inspection of the structure factors showed that no change was to be expected in the signs (except in the case of "absent" reflections) without major alterations in atomic positions. A two-dimensional Fourier analysis of the distribution of scattering power in the crystal unit projected on the (001) plane was made according to the equation

$$\rho(x,y) = \text{constant}\ \Sigma_h\Sigma_k\ F_{(hk0)} \cos 2\pi(hx + ky)$$

using the observed *F*'s for all planes with signs obtained from the structure factors as listed in Table I. The plot of $\rho(x,y)$ over half of the unit cell is shown in Fig. 1. The positions of the peaks as shown by contour lines indicate small but definite changes in the positions of all atoms except carbon. The corresponding parameters then become

O : $x = 0.160$, $y = 0.368$
C : $x = 0.320$, $y = 0.430$
CH_2 : $x = 0.545$, $y = 0.380$
NH : $x = 0.280$, $y = 0.544$.

In Table I structure factors calculated from these parameters are compared with those obtained from the estimated intensities.

Data from (*h*0*l*) Reflections.—Considerable difficulty was experienced in obtaining a crystal which would yield good photographs when rotated about the *b*-axis. Although most of the thin, needle-like crystals were comparatively perfect and gave excellent reflections, their elongation in the c-direction made them of little value for the collection of data about [010]. Attempts were made to mount such specimens rigidly on the b-axis and then reduce them to cylindrical form by dissolving away the end portions, but the excessive softness and fragility of the crystals rendered such efforts fruitless. It was therefore necessary to select tiny tabular specimens having dimensions as nearly equal in all directions as possible. Such crystals were generally very imperfect as the result of twinning and internal strains and distortion. Two specimens were finally selected which gave good equatorial reflections with the Weissenberg camera, the first about 0.7 mm. and the second less than 0.3 mm. in greatest dimension. Even with these samples, the slight differences in shape of reflections from planes of widely different position made the estimation of relative intensities less exact than in the case of ($hk0$) reflections. Added to this was the fact that the scattering powers of most planes were structurally weak, so that long exposures, in one case seventy-two hours, were necessary. The estimated intensities and scattering powers calculated from them for all ($h0l$) planes capable of reflection are listed in Table II.

As a start in determining the z-parameters, the molecule was still assumed to be completely coplanar with all atoms lying in the (101) plane and having the x-parameters already accurately determined from ($hk0$) reflection data. Structure factors calculated from these parameters

O : $x = 0.160, y = 0.84$
C : $x = 0.320, y = 0.68$
CH_2 : $x = 0.545, y = 0.455$
NH : $x = 0.280, y = 0.72$

showed general agreement with observed values although some planes, notably (002), ($40\bar{1}$), ($20\bar{3}$), and (204), indicated the necessity for further refinement. Since simultaneous displacement of all atoms was probable, recourse was had to a second Fourier analysis, using only those planes whose signs were considered certain. Values of the function

$$\rho(x,z) = \text{constant}\ \Sigma_h\Sigma_l\, F_{(h0l)} \cos 2\pi(hx + lz)$$

were plotted along lines of constant x corresponding to this parameter for each atom. Definite changes in all z-parameters were indicated from which structure factors were calculated, to determine the signs of planes previously in doubt. All planes were then introduced into the Fourier summation and the positions of the resulting peaks used to complete the determination

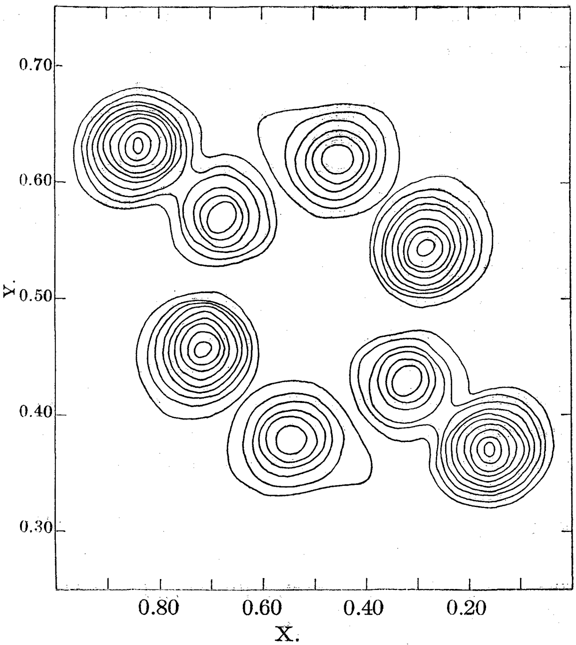

Fig. 1.—Distribution of scattering power, $\rho(x, y)$, for diketopiperazine projected upon the (001) face. Contour lines represent values of $\rho(x, y)$ from 2 to 11.

of the atomic arrangement. The final parameters were found to be

O	: $x = 0.160$,	$y = 0.368$,	$z = 0.885$
C	: $x = 0.320$,	$y = 0.430$,	$z = 0.705$
CH_2	: $x = 0.545$,	$y = 0.380$,	$z = 0.495$
NH	: $x = 0.280$,	$y = 0.544$,	$z = 0.695$

A comparison of the observed scattering powers of all ($h0l$) planes with those calculated for these positions is shown in Table II. Although careful study of both the Fourier plot and structure factor calculations failed to give justification for any departures from these parameters, certain discrepancies in the agreement between observed and calculated values are to be noted. Most conspicuous is (404), for which the calculated scattering is about equal to that of ($60\bar{1}$) but which gave faint reflections on all films. The reason for this is doubtless to be found in the fact that this plane is practically parallel with the plane of the molecule, a position for which thermal agitation would have greatest effect in reducing the atomic scattering factors with increased sin θ. Thus it is seen that for planes (201), (002), (401), and (402) the intensity observed is less than that calculated, whereas the reverse is true for planes ($20\bar{1}$), ($40\bar{1}$), and ($20\bar{3}$). The positions of these planes relative to the plane of the molecule are shown in Fig. 2. It is seen that those having positive index l are more nearly parallel to the molecular plane than are those of negative index. Discrepancies in these cases are thus doubtless to be attributed in part to the predictable effect of orientation upon atomic scattering factors in crystals of this and similar structure.

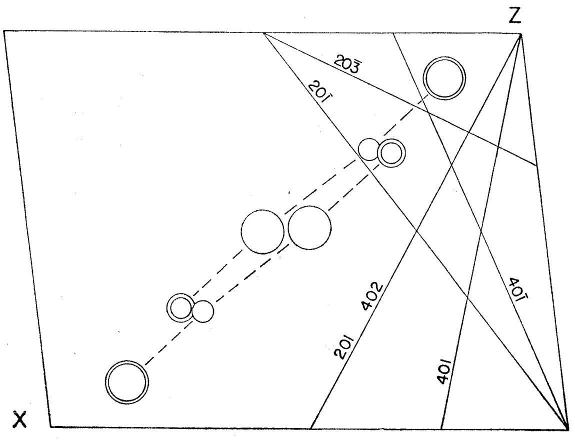

Fig. 2.—The relative positions of some planes (having positive and negative values of l) with respect to the plane of the molecule.

Discussion of the Structure

The positions of the atoms in an elementary unit cell and in three adjacent cells are shown in Fig. 3a. The molecule of diketopiperazine is found to be a nearly plane hexagon inclined at about 5.5° to (101). Interatomic distances within the molecule are C–O, 1.25 Å.; C–N, 1.33 Å.; C–C, 1.47 Å.; and N–CH_2, 1.41 Å., all accurate to about ± 0.03 Å.

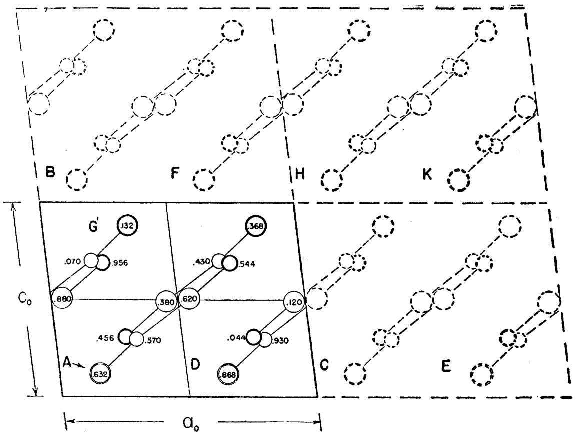

Fig. 3a.—Arrangement of diketopiperazine molecules in the unit cell. Numerals show the y-parameters of the atoms. Letters refer to subsequent packing drawing.

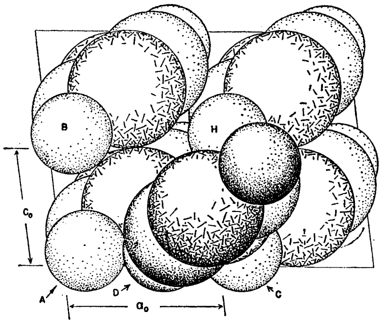

Fig. 3b.—A packing drawing of diketopiperazine viewed along the b-axis showing four molecules in the same layer at the centers of adjacent unit cells and one in the layer immediately above.

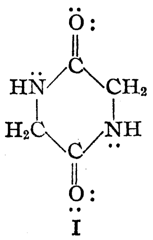
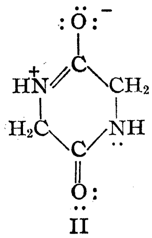
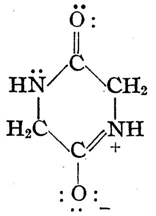
The molecule may be expected to resonate among the structures



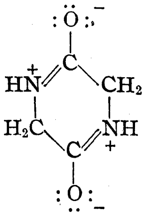
I



II



III



IV

The bond distances for C–O and C–N should then have the values characteristic of resonance of this type, which are about 1.25 and 1.33 Å., respectively, as observed. Similar values are also found for other resonating molecules of like type.[6] In urea[9b] the interatomic distances within the molecules were found to be C–O, 1.24 Å. and C–NH_2, 1.37 Å., and in thiourea[10] C–NH_2 is 1.35 Å. The shortening of the CH_2–N and CH_2–C distances below the single bond values 1.47 and 1.54 Å., respectively, is surprising. It is possible that it is to be attributed, in part at least, to the effect of electric charge,[11] and perhaps to a resonance of a new type, involving double bonds with the methylene group. It is of interest that in hexamethylenetetramine[9b] the separation CH_2–N is 1.42 Å., almost exactly that found in the present structure (1.41 Å.).

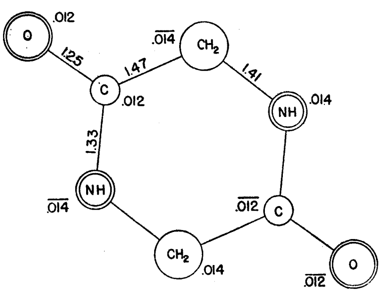


Fig. 4.—The diketopiperazine molecule as viewed perpendicular to a median plane. Dimensions are in Ångström units.

The angles between all bonds are 120 ± 3°. The extent to which the molecule, indicated by the parameter values, departs from true planarity is most readily shown by passing a median plane between the atoms and observing the distance of each atom from this plane. Figure 4 is a view perpendicular to such a plane in which numerals, positive and negative, show the distances in Ångström units of each atomic position above and below it. It is seen that none deviates from the plane by as much as 0.015 Å., which is within the limit of error of the determination of the atomic positions themselves. The completely coplanar configuration is, of course, expected for resonance among the structures I to IV, in consequence of the stereochemical properties of the C–N double bonds in the ring. Thus the observed coplanarity provides strong evidence for resonance, inasmuch as all known six-membered rings, involving only single bonds, are puckered.[4–7]

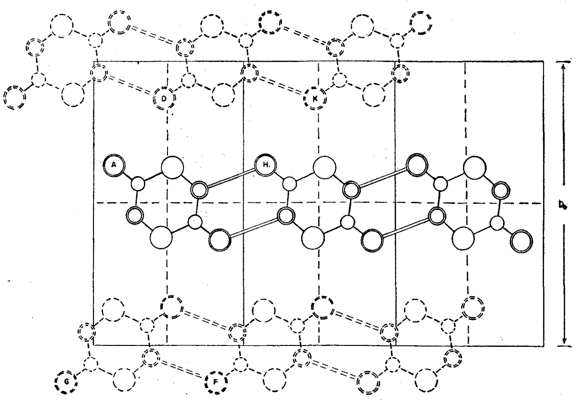

Fig. 5a.—A view perpendicular to (101) showing chains of molecules held together by hydrogen bonds.

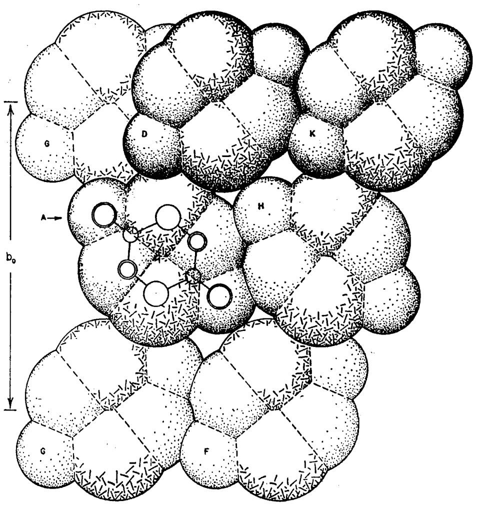

Fig. 5b.—A packing drawing of some of the molecules of Fig. 5a. The radius of the carbon atom is too small to permit its appearance in this and other packing figures.

The packing of the molecule is shown in Figs. 3b, 5b, and 6. In these drawings CH_2 is given a radius of 1.98 Å.; NH, 1.8 Å. and O, 1.35 Å. The radius of carbon (0.77 Å.) is too small to permit its appearance. Each CH_2 group is at a distance of 3.96 Å. from four other CH_2 groups, two in the same layer with it and two others above or below.

(11) N. Elliott, THIS JOURNAL, **59**, 1380 (1937).

Figure 3b shows the packing of adjacent CH_2 groups in the same layer, contacts between those in different layers being indicated in Figs. 5b and 6. Each oxygen is in contact with two CH_2 groups, one at 3.32 Å. in the same layer (B in Fig. 3b) and one at 3.33 Å. in the layer above or below (C in Figs. 3b and 6). Each nitrogen is distant 3.55 Å. from a CH_2 group (molecules A and B, Fig. 6) and 3.69 Å. from another nitrogen (Fig. 5b). The very pronounced cleavage along (010) and that along (101) are clearly brought out in Fig. 6.

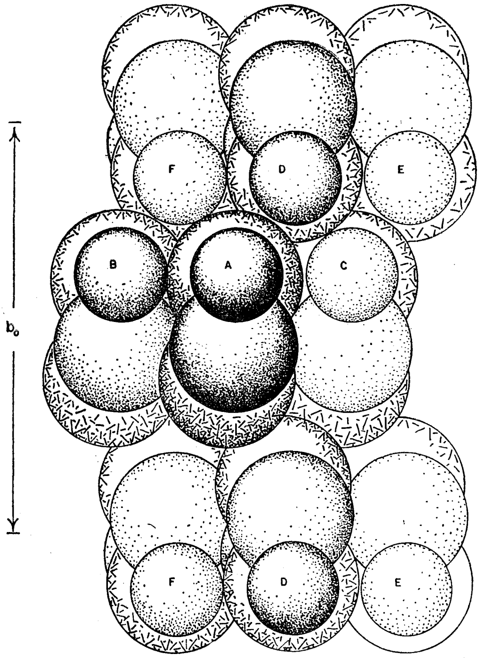

Fig. 6.—A packing drawing of the molecules of diketopiperazine viewed in the direction of the molecular chains.

Assuming tetrahedral bond angles and a C–H distance 1.08 Å., parameters could be assigned to the two methylene hydrogen atoms as follows

H_1: $x = 0.658, y = 0.334, z = 0.664$
H_2: $x = 0.472, y = 0.319, z = 0.322$

The distances between hydrogen atoms in adjacent methylene groups then become 2.68 Å. in the same layer, and 2.66 Å. in the next layer. These separations correspond to an atomic domain for hydrogen of radius 1.33–1.34 Å., which is slightly greater than the value 1.29 Å. suggested by Mack[12] from consideration of the packing of organic molecules in which there is no free rotation. Distances between oxygen and hydrogen are 2.57 Å. in the same layer and 2.48 Å. in the next layer, which are slightly less than analogous distances (2.68–2.70 Å.) observed in metaldehyde.[13]

Acknowledgments.—This investigation has been made possible by the financial support of the Rockefeller Institute for Medical Research and the courtesy of the California Institute of Technology in providing the facilities of its laboratories. The author is indebted to Professor Linus Pauling for proposing the subject of this research and for his many suggestions and criticisms throughout the progress of the work, to Dr. J. H. Sturdivant for assistance with experimental details, and to W. R. Newton for the construction of special equipment.

Summary

X-Ray examination of crystals of 2,5-diketopiperazine shows them to be built upon a simple monoclinic unit having $a_0 = 5.19$ Å., $b_0 = 11.50$ Å., $c_0 = 3.96$ Å., and $\beta = 83°$, containing two molecules. All atoms are in the general positions of the space group $C_{2h}^5 - P2_1/a$ with the following parameters: oxygen, $x = 0.160$, $y = 0.368$, $z = 0.885$; carbon, $x = 0.320$, $y = 0.430$, $z = 0.705$; methylene carbon, $x = 0.545$, $y = 0.380$, $z = 0.495$; nitrogen, $x = 0.280$, $y = 0.544$, $z = 0.695$. The molecule is a nearly flat hexagonal ring possessing a center of symmetry, the angles between all bonds being 120 ± 3°. The interatomic distances within the molecule are: carbon–oxygen 1.25 Å., carbon–carbon 1.47 Å.; carbon–nitrogen 1.33 Å. and nitrogen–methylene carbon 1.41 Å., each ± 0.03 Å. All molecules are held together by hydrogen bonds to form long, parallel chains throughout the crystal. Packing of the molecules is discussed.

The Electron Diffraction Study of Digermane and Trigermane

BY LINUS PAULING, A. W. LAUBENGAYER AND J. L. HOARD

In order to obtain information about the covalent radius and bond angle of germanium we have prepared and analyzed electron diffraction photographs of digermane and trigermane, with the results described below.

Preparation and Purification of Substances.—A mixture of the hydrides of germanium was prepared by the action of dilute hydrochloric acid on magnesium germanide which had been made from very pure germanium and magnesium.[1] This mixture of hydrides was then subjected to fractionation in a vacuum apparatus.[2] The sample was cooled with liquid air and all of the free hydrogen contaminating the hydrides was pumped off. The monogermane, GeH_4, was removed by holding the hydrides at $-130°$ and distilling off all of the material which was volatile at that temperature. The residue was warmed to $-70°$ and the digermane, Ge_2H_6, was distilled off. This fraction was found to possess the characteristic constants reported for digermane. The remaining material was freed of the last traces of digermane by distillation at $-60°$ for several hours. The temperature was then raised to $-20°$ and a fraction was collected. This fraction possessed the properties of pure trigermane, Ge_3H_8.

Preparation of the Photographs.—The electron diffraction photographs were prepared in the usual manner.[3] The sample of trigermane was allowed to vaporize into the evacuated apparatus for a minute or two at 0° to remove any residuum of digermane, and was then heated to about 20° for exposure of the photographs. The stopcock was held open for a few seconds before each exposure at this temperature. The entire sample of the substance was evaporated in the preparation of the series of photographs. About ten photographs were prepared and measured for each substance.

Analysis of the Photographs.—The photographs obtained for the two substances are closely similar in appearance. They show eight well-defined rings, with the measured s_0 values and estimated intensity values given in Table I. The appearance of the rings does not differ greatly from that corresponding to a single sin ls/ls curve; the intensity drop between the third ring and the fourth ring seems larger than for the other steps.

The radial distribution curve[4] calculated for digermane with use of the c values given in the table, obtained from the estimated intensity values by multiplication by the factor $s^3e^{-As^2}$ as recommended by Schomaker and Degard,[5] is given in Fig. 1. The curve shows a peak at 2.41 Å., representing the Ge–Ge distance. The other interatomic distances in the molecule are of less importance in the intensity function and are not apparent in the radial distribution curve.

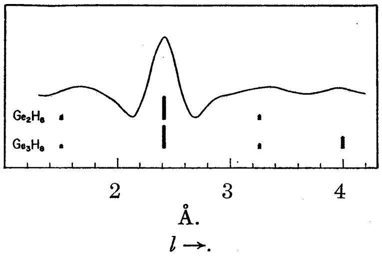

Fig. 1.

The simplified intensity curve corresponding to the model with Ge–Ge = 2.44 Å. and Ge–H = 1.52 Å. (the sum of single-bond covalent radii) and with all angles 109°28′, shown in Fig. 2, agrees well with the photographs in appearance. The quantitative comparison given in Table I leads to the average value 2.40 Å. for the Ge–Ge distance, the first three s_0 values being ignored as unreliable.

The radial distribution curve for trigermane, for which the same I values were estimated as for digermane, is not appreciably different from that for the latter substance shown in Fig. 1, except that the Ge–Ge peak occurs at 2.42 Å. It is surprising that there is no definite indication of a Ge–Ge peak at 4.0 Å., corresponding to the distance between the two end germanium atoms. It

2		9	5	5.97	5.80	(2.37)	5.91	5.68	(2.35)
	3			7.19	7.08	2.40	7.28	7.16	2.40
3		8	10	8.52	8.38	2.40	8.43	8.30	2.40
	4			9.83	9.60	2.38	9.80	9.41	2.34
4		6	10	11.13	10.84	2.38	11.11	11.03	2.42
	5			12.47	12.21	2.39	12.40	12.13	2.39
5		5	9	13.73	13.56	2.41	13.64	13.47	2.41
	6			15.00	14.88	2.42	14.93	14.94	2.44
6		4	6	16.29	16.10	2.41	16.20	16.03	2.42
	7			17.62	17.29	2.40	17.53	17.10	2.38
7		3	3	18.92	18.56	2.39	18.78	18.80	2.44
	8			20.24	20.00	2.41	20.11	19.97	2.42
8		2	1	21.56	21.34	2.42	21.25	21.24	2.44
Average						2.40 Å.			2.41 Å.
Radial distribution value						2.41 Å.			2.42 Å.

[a] Calculated for the model with Ge–Ge = 2.44 Å., Ge–H = 1.52 Å., and all angles 109°28′. [b] Calculated for the model with Ge–Ge = 2.44 Å., Ge–H = 1.52 Å., angle Ge–Ge–Ge = 112°, angles H–Ge–Ge = 109°28′.

is possible that the bending frequency of the Ge–Ge–Ge chain is very low, and that in consequence the longer Ge–Ge separation varies widely at room temperature, causing the peak to be flattened out.[6] The possibility that the photographs obtained from the trigermane sample are really due to digermane has occurred to us. We believe, however, that the procedure followed was such as to make this unlikely.

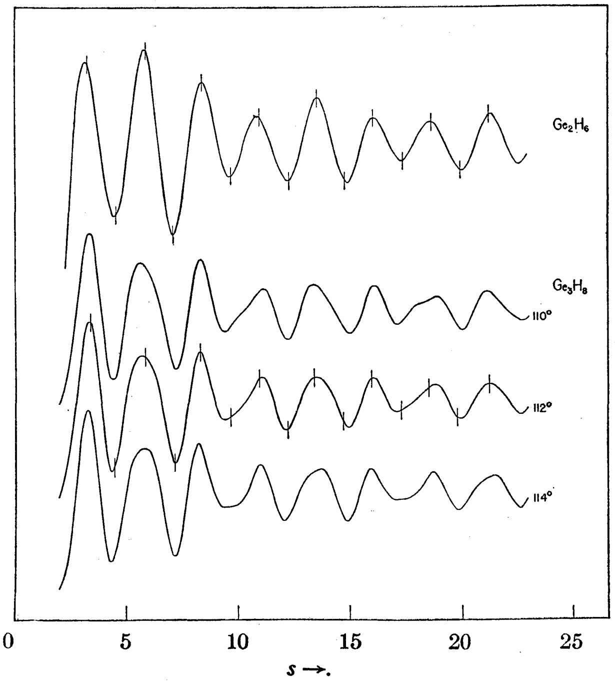

Fig. 2.

The radial distribution curve shows that the photographs cannot be used to evaluate the Ge–Ge–Ge bond angle reliably. Of the three simplified intensity curves shown in Fig. 2, calculated for the distances Ge–Ge = 2.44 Å. and Ge–H = 1.52 Å. and the angles H–Ge–Ge = 109°28′ and Ge–Ge–Ge = 110, 112 and 114°, respectively, the 112° curve seems to resemble the photographs somewhat more closely than the others. The quantitative comparison with this curve leads to the value 2.41 Å. for the Ge–Ge distance.

Discussion of Results.—The investigation shows that the Ge–Ge bond distance in both digermane and trigermane is about 2.41 (± 0.02 Å.). There is some small evidence that the value for trigermane is 0.01 Å. larger than that for digermane; this difference is, however, less than the estimated probable errors of the values.

The Ge–Ge distance in elementary germanium, which crystallizes with the diamond structure, is 2.44 Å. This is the basis for the value 1.22 Å. assigned as the single-bond covalent radius of germanium.[7] The decrease of about 0.03 Å. in interatomic distance observed for digermane and trigermane is probably real, and suggests that the covalent radius of germanium for use in compounds may be as low as 1.21 or 1.20 Å. The decrease may be due either to some

---

(6) Temperature effects of this kind will be discussed by Dr. V. Schomaker in a paper to be published soon.

(7) L. Pauling and M. L. Huggins, *Z. Krist.*, **87**, 205 (1934).

interaction with the Ge–H bonds in the germanes or to partial metallic character (incomplete covalent character) of the element; in the former case the value 1.22 Å. for the radius would be the more generally applicable and in the latter case a smaller value. The uncertainty of 0.01 or 0.02 Å. in the radius is not of great significance.

The Ge–H bond distance in the substances is probably about 1.50 Å., and the bond angles are probably close to the tetrahedral value 109°28′; these values are, however, not derived from the experimental data.

Acknowledgment.—We wish to thank Dr. K. S. Palmer and Dr. V. Schomaker for assistance in the preparation and measurement of the photographs.

Summary

The Ge–Ge bond distance in both digermane and trigermane is found by the electron diffraction method to be about 2.41 ± 0.02 Å.

The Activity Coefficients of Lead Chloride in Aqueous Solutions of Mannitol at 25°[1]

BY H. D. CROCKFORD AND J. C. LOFTIN

An extensive study of the activity of lead chloride in aqueous solutions at 25° has been made by Carmody.[2] For this study he employed the following chemical cell

$$\text{Pb–Hg (2 phase)} \mid PbCl_2(m_1) \mid \text{AgCl–Ag}$$

By the use of their extended Debye–Hückel equation La Mer, Gronwall and Greiff[3] employed the data of Carmody to calculate the mean distance of closest approach of the ions of lead chloride. Crockford and Thomas[4] and Crockford and Farr[5] employed the same cell to determine the activity coefficients of lead chloride in aqueous solutions of cadmium nitrate and barium nitrate at 25°. The purpose of the work was to test the relationship proposed by Crockford and Thomas[4] for the calculation of the $\bar{a}$ parameter in solutions containing two electrolytes. In this paper are given the results of a series of studies designed to determine the effect of mannitol on the activity of lead chloride in aqueous solutions at 25°. From the data obtained has been calculated the mean distance of closest approach of the ions.

The chemical cell given above was used in the work. Four series of data were obtained: (I) constant molality of mannitol and varying concentrations of lead chloride; (II) constant ratio of lead chloride and barium nitrate and varying concentrations of mannitol; (III, IV) constant molalities of lead chloride and varying concentrations of mannitol.

The mannitol used was the Pfanstiehl C. P. grade; it was dried and kept in a vacuum desiccator until used. For the purification of other materials, preparation of solutions, preparation of electrodes, and general experimental technique the same procedures as employed by Crockford and Farr[5] were followed. Except for the very dilute solutions the e. m. f. values given are reproducible to 0.05 mv.

Results and Calculations

Tables I–IV give a summary of the experimental data and the calculated values for the activity coefficients and the a values.

The activity coefficients were calculated from the equation

$$E(\text{mv.}) + 88.7308\,(0.200687 + \log m) = E_0(\text{mv.}) - 88.7308 \log f$$

this being the equation for a chemical cell without transference after the proper constants for a 1–2 salt at 25° have been introduced. The value $E_0 = 0.34320$ v. calculated by La Mer, Gronwall and Greiff[3] from the data of Carmody[2] was used in the calculations.

5	.7313	.52702	.506	1.25

TABLE IV

Series IV. Constant Molality of $PbCl_2$ 0.023455

	m_3 Mannitol	E, v.	f	a, Å.
1	0.0000	0.49724	0.493	1.80
2	.0990	.49827	.480	1.71
3	.2899	.50000	.459	1.50
4	.5604	.50224	.433	1.30
5	.7304	.50470	.406	1.29

The ion size parameter values were calculated graphically according to the procedure outlined by La Mer, Gronwall and Greiff.[3] It is to be noted that the value for the dielectric constant varied with the concentration of mannitol. The values for the various solutions used can be calculated from the data of Åkerlöf,[6] who has made a thorough study of the dielectric constant of aqueous mannitol solutions. However, in the construction of the family of curves necessary for the determination of the a parameter the dielectric constant of pure water was used. The error so introduced is very small. But in the evaluation of the $10^{-8}K$ function for the various solutions the value for the dielectric constant obtained from the data of Åkerlöf was employed.

Discussion of Results

An inspection of the data in Series III and IV shows that the activity coefficient of the lead chloride decreases with increasing concentration of mannitol. Series I illustrates the same point when compared with the results of Carmody.[2] Series III and IV show that the a value decreases with increasing concentration of mannitol. In the solutions with zero concentration of mannitol the a values are close to the value of 1.75 Å. as calculated by La Mer, Gronwall and Greiff.[3] According to the equation of Crockford and Thomas[4] the $\bar{a}$ values in Series II should remain constant. Based on data given by Crockford and Farr[5] the value should be 2.53 Å., a value very close to that obtained in solution 6 which contains no mannitol. However, as in Series III and IV this value decreases with increasing concentration of mannitol.

We wish to acknowledge our indebtedness to the Rockefeller Foundation for financial aid in the original purchase of part of the equipment used.

Summary

The activity coefficients of lead chloride in aqueous solutions of mannitol at 25° have been determined. In Series I the molality of mannitol was kept constant. In Series II the ratio of lead chloride to barium nitrate was kept constant but the molality of the mannitol was varied. In Series III and IV the molality of lead was kept constant but the molality of mannitol was varied.

From the activity coefficients in Series I, III and IV the a parameter values for lead chloride were calculated. From Series II the mean $\bar{a}$ values for mixtures of lead chloride and mannitol were calculated.

The data obtained show that the activity coefficients and the a parameter values decrease with increasing concentrations of mannitol.

Unilateral Triple Ion Formation in Aqueous Hydrofluoric Acid

BY CHARLES BUSHNELL WOOSTER

The phrase "unilateral triple ion formation" has been coined[1] to describe the situation in which a single ionic equilibrium of the type, $B^- + AB \rightleftarrows AB_2^-$, is superposed on the customary binary ionization of the electrolyte, AB, and to distinguish this situation from that in which the corresponding equilibrium $A^+ + AB \rightleftarrows A_2B^+$, is also involved.[2] In a previous paper[1] it has been shown that with suitable approximations the conductance function for unilateral triple ion formation may be obtained in the linear form[3]

$$\left(\frac{f\Lambda}{m}\right)^2 \frac{C}{(1 - \Lambda/\Lambda_0)} = \Lambda_0^2K + \frac{(2\Lambda_0\lambda_0 - \Lambda_0^2)K}{k}\left(1 - \frac{\Lambda}{\Lambda_0}\right) C \quad (1)$$

and this equation was applied successfully to the conductivity of dilute solutions of the metal ketyl, sodium benzophenone, in liquid ammonia. Because of the unusual character of this electrolyte and also due to the fact that additional equilibria must be considered in the analysis of this conductance curve in the more concentrated regions, it is very desirable to test equation 1 independently by applying it to another electrolyte. However, instances of unilateral triple ion formation are relatively rare since they may generally be expected to occur only when some specific interaction (formation of a chemical bond) between a simple ion and an ion pair is possible.[4] The only well established instance seems to be in aqueous hydrofluoric acid solutions where the equilibrium, $F^- + HF \rightleftarrows HF_2^-$, was first suggested by Pick,[5] who carried out an analysis of the conductance data by assuming arbitrary values for the limiting conductivity of the triple ion. His conclusions were substantially verified by Davies and Huddleston[6] through a study of the anionic transference numbers.[7]

It is the purpose of this paper to present the results of applying equation 1 to the analysis of the conductance curves for aqueous hydrofluoric acid solutions and to compare them with the results which may be obtained by a substantially independent method from the transference data of Davies and Huddleston. The use of equation 1 involves the assumption that only the solute species H^+, F^-, HF and HF_2^- and the equilibria $HF \rightleftarrows H^+ + F^-$ and $HF_2^- \rightleftarrows HF + F^-$ need be considered and that the species F_2^{--} and H_2F_2 are present only in negligible proportions, if at all. Since it is probable that the hydrofluoride ion owes its existence to hydrogen bridge formation,[8] it is evident that there is no corresponding justification for assuming the existence of F_2^{--}. The existence in the gaseous state[9] of H_6F_6 suggests the possible presence of H_2F_2 (or higher polymers) in solution, but the results of the present analysis decisively exclude this possibility in aqueous solutions of hydrofluoric acid at concentrations 1 *N* and less. This result may be interpreted as indicating that H_2F_2 is a very strong acid or that the addition of a second proton to the hydrofluoride ion greatly weakens the hydrogen bridge, or both. In Section III the results obtained from the data on hydrofluoric acid are applied to the interpretation of the conductivity of potassium hydrofluoride.

I. Analysis of the Conductance Curve

The conductance data of Deussen[10] were chosen as the most reliable of those available and two series one at 25° and one of probably lesser accuracy at 0° were employed in the calculations. In order to apply equation 1 it is also necessary to have independent values of the limiting equivalent conductance, the dielectric constant and the

---

[1] Wooster, THIS JOURNAL, **59**, 377 (1937).

[2] Fuoss and Kraus, *ibid.*, **55**, 2387 (1933).

[3] C is the total concentration in equivalents (as AB) per liter, Λ is the equivalent conductance, $K = [A^+][B^-]/[AB]$, the constant for binary dissociation, $k = [B^-][AB]/[AB^-_2]$, the dissociation constant for the triple ion equilibrium, Λ_0 the limiting value of Λ, λ_0 the sum of the limiting values of the mobility of the triple ion and of the single ion with opposite charge, f the activity coefficient defined by $-\log f = \beta\Lambda_0^{-1/2}\sqrt{C\Lambda}$ and m a mobility coefficient defined as $1 - \alpha\Lambda_0^{-3/2}\sqrt{C\Lambda}$. The constants α and β have the same significance as in the paper of Fuoss and Kraus [THIS JOURNAL, **55**, 476 (1933)]. In water at 25° $\alpha = 0.228\Lambda_0 + 59.7$ and $\beta = 0.504$; at 0°, $\alpha = 0.220\Lambda_0 + 29.0$ and $\beta = 0.486$.

[4] It is also conceivable, of course, that coulomb forces alone occasionally may give rise to a situation which closely simulates unilateral triple ion formation in media of appropriate dielectric constant, if one of the simple ions is much larger than the other and particularly if the larger ion is unsymmetrical.

[5] Pick, *Nernst's Festschrift*, 360 (1912).

[6] Davies and Huddleston, *J. Chem. Soc.*, **125**, 260 (1924).

[7] The only other attempt at analysis of these conductance data is that of Kendall [THIS JOURNAL, **39**, 7 (1917)] on the basis of a more or less empirical equation for "transition electrolytes."

viscosity. The values which were used, $\Lambda_0 = 404$, $D = 78.57$, $\eta = 0.00895$ at 25° and $\Lambda_0 = 255$, $D = 88$, $\eta = 0.01794$ at 0°, were obtained from a variety of sources but do not differ in any important respect from the values given in the "International Critical Tables."

Plots of $f^2C\Lambda^2/m^2(1-\Lambda/\Lambda_0)$ against $C(1-\Lambda/\Lambda_0)$ appear in Fig. 1 where curve I represents values based on the measurements at 25° and curve II at 0°. It is evident that, in accordance with the requirements of equation 1, the points fall very nearly on a straight line. By applying the method of least squares to the ten points covering the dilution range 1–512 liters at 25° the values 351.5 for the slope and 112.4 for the intercept were obtained and in a similar way a slope of 201.1 and intercept of 71.2 were obtained from nine points at 0° over the dilution range 1–256 liters. The lines in Fig. 1 are drawn in accordance with these values from which the equilibrium constants are found to be $K = 6.89 \times 10^{-4}$ at 25° and 10.95×10^{-4} at 0°, $k = 0.320(2\,\lambda_0/\Lambda_0 - 1)$ at 25° and $0.354\ (2\lambda_0/\Lambda_0 - 1)$ at 0°. The ionization constant obtained at 25° differs very little from that (6.9×10^{-4}) obtained by other investigators[11] but the value at 0° is somewhat higher than that in the literature[11] (9×10^{-4}).

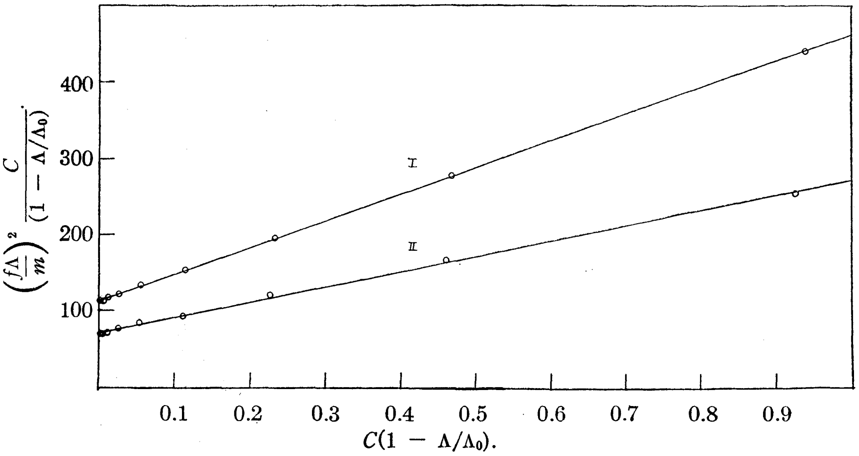

Fig. 1.—Unilateral triple ion formation in aqueous hydrofluoric acid.

The excellent agreement with equation 1 at such high total concentrations requires some explanation which is afforded by the facts that due to the low value of the ionization constants and the high values of the triple ion dissociation constants[12] the dielectric constant of the medium reduces the interionic (coulomb) forces so much that the approximate forms of the Debye–Hückel–Onsager equations employed serve adequately to calculate the effective values of the activity and mobility coefficients.

The applicability of equation 1 to unilateral triple ion equilibria is also determined by the degree to which the ratio λ_0/Λ_0 approximates unity, since this approximation was used to dispose of a second order term in the derivation of the equation. In general, this ratio may not be obtained directly from the conductance data and the sole available test of the validity of this approximation may often be the extent to which the linear form of equation 1 is satisfied by the data. In the present instance, however, additional information is available from two sources. First, the difference between λ_0 and Λ_0 is determined entirely by the difference in the limiting mobilities of the simple anion (F^-) and the triple anion (HF_2^-) which is doubtless so small in comparison with the high mobility of the hydrogen ion (351 at 25° and 229 at 0°) that the ratio λ_0/Λ_0 cannot differ widely from unity. Second, the value for the limiting mobility of the triple anion which may be obtained from the transference data (see Section II) yields the value $\lambda_0 = 437$ at 25° so that at this temperature $\lambda_0/\Lambda_0 = 1.08$. The maximum alteration in the slope of the plot due to neglect of the second order term in deriving equation 1 is given in percentage by $100(1 - \lambda_0/\Lambda_0)^2/[(2\lambda_0/\Lambda_0 - 1) + (1 - \lambda_0/\Lambda_0)^2]$ which on substituting 1.08 for λ_0/Λ_0 becomes 0.55% and is well within the limits of the experimental errors involved in Deussen's measurements.

It may also be noted at this point that evaluation of the ratio λ_0/Λ_0 permits the calculation of $k = 0.371$ at 25° and (assuming λ_0/Λ_0 independent of temperature as it would be if Walden's rule applies) 0.411 at 0°.

Using the slopes and intercepts given above the conductance curve (Λ against log V) has been calculated as previously described[1] and the re-

---

[11] "International Critical Tables," McGraw-Hill Book Co., Inc., New York, N. Y., 1929, Vol. VI, p. 260.

[12] The order of magnitude of k is given by 0.320 at 25° and 0.354 at 0° since the coefficient $(2\lambda_0/\Lambda_0 - 1)$ does not differ widely from unity.

sults appear in Fig. 2 where the smooth curves represent the calculated values and the circles represent the experimental points. The arrows indicate the limits beyond which the smooth curve represents an extrapolation, the experimental points in these regions not having been used in determining the slopes and intercepts given. The experimental points lie very close to the calculated curve except in the most dilute region. Due to experimental difficulties in maintaining a constant temperature at 0° under the conditions of Deussen's measurements, the data at this temperature, particularly in the more dilute region, are less reliable than that at 25°.

II. Analysis of Transference Data

By combining values for the anionic transference numbers with those for the equivalent conductances at various concentrations, Davies and Huddleston[6] have calculated the values for the triple ion dissociation constant and the mobility, U, of the triple ion which appear in the second and third rows of Table I.

TABLE I

CONSTANTS FROM TRANSFERENCE DATA AT 25°

V	1	2	4	8	16	32
k	0.212	0.215	0.210	0.199	0.165	0.137
U	73.0	68.3	64.9	61.0	53.4	47.3
k corr.	0.338	0.338	0.324	0.356	0.340	0.288
U_0	85.6	83.6	83.5	89.0	89.3	84.3

It may be observed that Davies and Huddleston's values of k show an average deviation of 13.7% from the mean 0.190 which, itself, is much lower than the figure 0.371 obtained in the previous section. The two values are not strictly comparable, however, since these authors introduced no corrections for the effect of interionic forces on the activities and mobilities of the ions. The effect of this omission is particularly evident in their values for the mobility of the triple ion, which show a 12.1% average deviation from the mean and a pronounced trend toward decreasing values of U with decreasing concentration, whereas the true mobilities of ions should increase with decreasing concentration.

In the fourth and fifth rows of the table are given values of k and of the *limiting* mobility of the triple ion, U_0, which have been obtained from the same data by introducing activity and mobility coefficients.

This method of calculation uses Davies and Huddleston's equations[13] with the following substitutions: K/f^2 for K_1[14]; 351 m_a for a, and 53 m_b for b. The figures 351 and 53 represent the limiting mobilities of the hydrogen and the fluoride ions and the m's are mobility coefficients calculated by the use of the following form of Onsager's equation for the mobility of an ion of the type j.

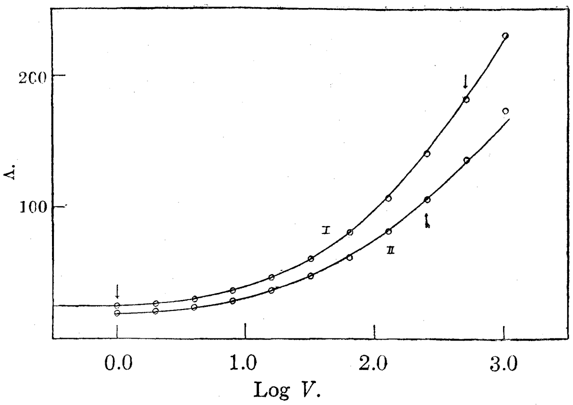

Fig. 2.—Conductance curves for aqueous hydrofluoric acid.

$$\Lambda_j = \Lambda_j{}^0 \left\{ 1 - \left[\frac{8.15 \times 10^5}{(DT)^{3/2}\,\Lambda_0{}^{1/2}} + \frac{41}{\Lambda_j{}^0 (DT)^{1/2} \eta \Lambda_0{}^{1/2}} \right] \sqrt{C\Lambda} \right\} \quad (2)$$

In the present instance this reduced to the following values for the mobility coefficients, $m_a = 1 - 0.0156\sqrt{C\Lambda}$ and $m_b = 1 - 0.0395\sqrt{C\Lambda}$. The values for the limiting mobility of the triple ion were obtained from the values, U, of the mobility at various concentrations also by the use of equation 2 in the reduced form

$$U_0 = \frac{U + 1.49\sqrt{C\Lambda}}{1 - 0.0113\sqrt{C\Lambda}} \quad (3)$$

It is evident on inspection of Table I that the "corrected" calculations give more consistent values of k (0.331 ± 4.9%) and of U_0 (85.9 ± 2.6%) which, unlike U, should be independent of concentration. It is further noteworthy that the value of k from transference data now agrees reasonably well with that obtained substantially independently[15] from conductance data. Al-

---

(13) Equation 9 of Davies and Huddleston[6] (p. 267) is in error due to a misprint and should read

$$[\mathrm{F}'] = \frac{p - r}{2b} - \frac{\sqrt{(p - r)^2 - 8bK_1(aC - p)}}{2b}$$

(14) For the sake of consistency the value 6.89×10^{-4} was used for K instead of the figure 7.4×10^{-4} employed by Davies and Huddleston. It may also be noted that their $K_2 = 1/k$.

(15) It is true that U_0 from transference data was used to obtain $k = 0.371$ from conductance data, but this apparent dependence could be avoided easily by comparing $k = 0.320\ (2\lambda_0/\Lambda_0 - 1)$ from conductance data alone with $k = 0.286\ (2\lambda_0/\Lambda_0 - 1)$ from transference data by the "corrected" method of Davies and Huddleston; the direct comparison of the k values is more convenient, however.

though the difference of 11.4% between these values is greater than the average deviation of the transference k values from the mean, it must be noted that the error in U_0 is also involved in making the comparison. Furthermore, it is doubtful that the precision of the transference data is sufficient to render the mean value 0.331 reliable to within less than 12% as an *absolute* value of k.[16]

III. The Conductivity of Potassium Hydrofluoride

Data for the conductivity of potassium hydrofluoride over the dilution range 50–1000 liters based on the measurements of Walden[17] are given in the "International Critical Tables"[11] (p. 251).

Since the conductivity of this electrolyte exceeds that of potassium fluoride at corresponding concentrations, Walden concluded that the salt decomposed into potassium fluoride and hydrofluoric acid. Although his conclusion appears to be substantially correct at low concentrations, it was based partly on the erroneous assumption that the mobility of the hydrofluoride ion could not exceed that of the fluoride ion.

In view of the results obtained with hydrofluoric acid in Sections I and II and the fact that potassium fluoride is a strong electrolyte, it is likely that only the following solute species: K^+, H^+, F^-, HF_2^-, HF and equilibria: $HF \rightleftarrows H^+ + F^-$, $HF_2^- \rightleftarrows HF + F^-$ need be considered in interpreting the conductivity of potassium hydrofluoride, but this restriction is insufficient to permit direct analysis of the data. It is possible, however, to use the equilibrium constants and mobilities which have been obtained for independent calculations of the equivalent conductance at various concentrations.

The equivalent conductance is related to the total concentration and the concentrations of the several ionic species (indicated by the terms in parentheses) by equation 4

$$C\Lambda = 74m_{K^+}(K^+) + 83m_{HF_2^-}(HF_2^-) + 53m_b(F^-) + 351m_a(H^+) \quad (4)$$

where the numerals are the values of the limiting mobilities and the m's represent the Onsager mobility coefficients. The mobility and activity coefficients may be approximated with sufficient accuracy for the present calculations by setting the total ion concentration equal to $2C$ so that

$$-\log f = 0.504\sqrt{C} \text{ and } Mj = 1-(0.228 + 29.9/\Lambda j^0)\sqrt{C}$$

The concentration (K^+) is given directly by $(K^+) = C$, and the concentrations of the other four species are related by the following four independent equations.

$$(H^+)(F^-)/HF = K/f^2 \quad (5)$$

$$(HF)(F^-)/(HF_2) = k \quad (6)$$

$$C = (HF_2^-) + (HF) + (H^+) \quad (7)$$

$$2C = 2(HF_2^-) + (HF) + (F^-) \quad (8)$$

On solving these simultaneously it is possible to obtain the concentration of the fluoride ion from the cubic equation

$$(F^-)^3 + k(F^-)^2 + k[K/f^2 - C](F^-) - 2CkK/f^2 = 0 \quad (9)$$

by the usual methods, and the other two ionic concentrations by successive substitution in equations 10 and 11

$$(HF_2^-) = (F^-)[2C - (F^-)]/[k + 2(F^-)] \quad (10)$$

$$(H^+) = (F^-) + (HF_2^-) - C \quad (11)$$

Using the values $K = 6.89 \times 10^{-4}$, $k = 0.368$, the following results were obtained at $C = 0.0200$: $(F^-) = 0.02007$, $(HF_2^-) = 0.00098$, $(H^+) = 0.00105$, $(HF) = 0.01797$ and $\Lambda = 136.0$; the observed value of Λ is 138.

At lower concentrations decomposition of the hydrofluoride ion is so great that the solution of the cubic equation becomes too sensitive to the value of k to be useful. A better approximate calculation of Λ is then obtained by setting $(HF_2^-) = 0$, so that the other ion concentrations are given by equations 12 and 13.

$$2(H^+) = -[C + K/f^2] + \sqrt{[C + K/f^2]^2 + 4KC/f^2} \quad (12)$$

$$(F^-) = C + (H^+) \quad (13)$$

The complete results are given in Table II.

It is unfortunate that data are not available at higher concentrations where the triple ion equilibrium plays a more important part, although it is true that at much higher ion concentrations the interionic coulomb forces will

---

(16) In fact, it is probable that a part of the self-consistency of the results from transference data is due to the fact that Davies and Huddleston used values interpolated from a smoothed curve and not the direct experimental measurements. The same values were used in the above calculations in order to obtain results comparable with those of Davies and Huddleston. Since the conductance data are much more precise than the transference data, and since a satisfactory equation for the conductance curve is now available, it would seem a more advisable procedure to use the experimentally determined transference data in combination with interpolated (and, where necessary in the concentrated region, extrapolated) conductance data. This method applied to the ten transference measurements in the concentration range 2.33 to 0.327 moles per liter yielded $k = 0.327 \pm 5.8\%$, $U_0 = 83.0 \pm 6.1\%$, from which it is evident that the results are less self consistent, although the agreement of the mean with the results from the conductance equation is substantially unchanged: k from conductance equation using $U_0 = 83.0$ to calculate λ_0 is 0.368. The difference from 0.327 is 11.8% of the mean.

(17) Walden, *Z. physik. Chem.*, **2**, 49 (1888).

complicate the analysis. The relatively large deviation at $C = 0.006$ is, of course, due to the error introduced by neglecting the concentration of the hydrofluoride ion; at lower concentrations this error becomes of less importance.

TABLE II

Summary

It has been shown that the conductance function for unilateral triple ion formation applies satisfactorily to the conductance data for aqueous hydrofluoric acid at 25 and at 0°. The constants determined in this way are consistent with the substantially independent values which may be obtained from transference measurements and they may be employed successfully to calculate the conductivity of potassium hydrofluoride solutions.

The Critical Increment of Ionic Reactions. III. The Influence of Dielectric Constant and Ionic Strength

BY JAMES LANDER[1] AND W. J. SVIRBELY

Recently,[2] equations were derived which predicted the influence of dielectric constant and ionic strength upon the critical increments of ionic reactions. The critical increments obtained by means of the theoretical equations were then compared with the experimental critical increments obtained for the reaction between ammonium and cyanate ions in methanol–water mixtures of constant dielectric constants. In the present investigation, the same reaction was studied over a temperature range of 30 to 60° in mixtures of water with ethylene glycol at the fixed dielectric constants of 63.5, 60, 55, 50, 45 and 40 in order to observe if there would be any specific medium effects due to the use of a different solvent. The experimental critical increments were then compared with the values obtained by means of the theoretical equations.[2]

Experimental

The ethylene glycol used was Eastman Best Grade (Highest Purity). The glycol was distilled and the fraction boiling sharply at 197° (uncorr.) was used. All other materials were prepared or purified as described in previous papers[3] which also describe the procedure used in this investigation. All temperatures were checked against a thermometer calibrated by the Bureau of Standards. Thermostat temperatures were maintained constant within ±0.01°. Dielectric constants for glycol–water mixtures were taken from the work of Åkerlöf.[4]

Average values of the limiting velocity constants were determined by means of the equation[3b,2]

$$k_0t = \left\{\frac{1 + 4A\sqrt{C}}{C}\right\} - \left\{\frac{1 + 4A\sqrt{C^0}}{C^0}\right\} \qquad (1)$$

and are listed in Table I. Deviations (δ) of the experimental value of $C/(1 + 4A\sqrt{C})$ from the value calculated from the average k_0 are plotted[3b] against the experimental values of this function in Figs. 1 and 2. The filled circles represent values of $C^0/(1 + 4A\sqrt{C^0})$. In Table II, we give velocity constants (k_1) at $\sqrt{\mu} = 0.194$ obtained from k_0 by the relation[3b]

$$k_1 = k_0/(1 + 2A\sqrt{\mu}) \qquad (2)$$

In Fig. 3, log k_0 is plotted against $1/T$ for the various media. These lines, as well as those obtained by plotting log k_1 against $1/T$, can be expressed by the general equation

$$\log k = \log K - (E/4.58T) \qquad (3)$$

Values of $\log K_0$ and E_0 and of $\log K_1$ and E_1 obtained by means of equation (3) are listed in Tables I and II, respectively. The tables also contain values of k_0 and k_1 calculated by equation (3) using the tabulated values of log K and E.

E(eq. 3)	20,580		20,500		20,480		20,330		20,320		20,250	
E(eq. 6 at 50°)	20,400		20,330		20,360		20,330		20,360		20,310	

From the equation[2a]

$$(E^0)_{\text{fixed comp.}} = (E_D^{0*}) + 2.3RT^2\left(\frac{\partial \log k_0}{\partial D}\right)_T \frac{dD}{dT} \qquad (4)$$

one obtains in this case using water as the solvent of fixed composition

$$(E^0)_{H_2O} - (E_D^{0*}) = 605\,\frac{T}{D} \qquad (5)$$

Using equation (5) one calculates the difference between the critical increments in water and in glycol–water media of fixed dielectric constant to be 2800 cal. at 50°. Using the experimental values of the E_0s given in Table I and taking E_0 in water[2] to be 23,580 cal. one observes that the difference between the critical increments in water and in glycol–water media of fixed dielectric constant has an average value of 3620 cal. Thus E_D^{0*} is here apparently independent of dielectric constant.

By taking logarithms and differentiating equation (2) one obtains a relationship between E_0 and E at a fixed ionic strength, namely

$$E = E^0 + \frac{(12.5 \times 10^6\ \sqrt{\mu}\ RT)}{(TD)^{3/2} + 8.36 \times 10^6\ \sqrt{\mu}}\left(1 + \frac{d \ln D}{d \ln T}\right) \qquad (6)$$

Using equation (6) we have calculated E at $\sqrt{\mu} = 0.194$ from E_0 of the various media. The results are listed in Table II and are in fair agreement with the Es obtained by equation (3).

An equation for ionic reactions has been developed by Scatchard[5] from consideration of the dielectric effect of the medium, namely

$$\log k - \log k_0{}^* = \frac{e^2 Z_A Z_B}{2.3KTr}\left(\frac{1}{D^0} - \frac{1}{D}\right) \qquad (7)$$

where $k_0{}^*$ is the rate constant at zero ionic strength in a standard solvent of dielectric constant D^0 and k_0 is the corresponding rate constant at zero ionic strength in a solvent of dielectric constant D. Using water as the standard solvent we have plotted in Fig. 4 the values of ($\log k_0 - \log k_0{}^*$) against the corresponding differences in the reciprocals of D^0 and D at the different temperatures. The plots, according to equation (7), should be linear and have slopes varying from -108 at 60° to -119 at 30° (assuming $r = 2 \times 10^{-8}$ cm.). The curves depart from the predicted linearity. The limiting slopes of the curves are in fair agreement with the predicted values, increasing from ~ -88 at 60° to ~ -96 at 30°.

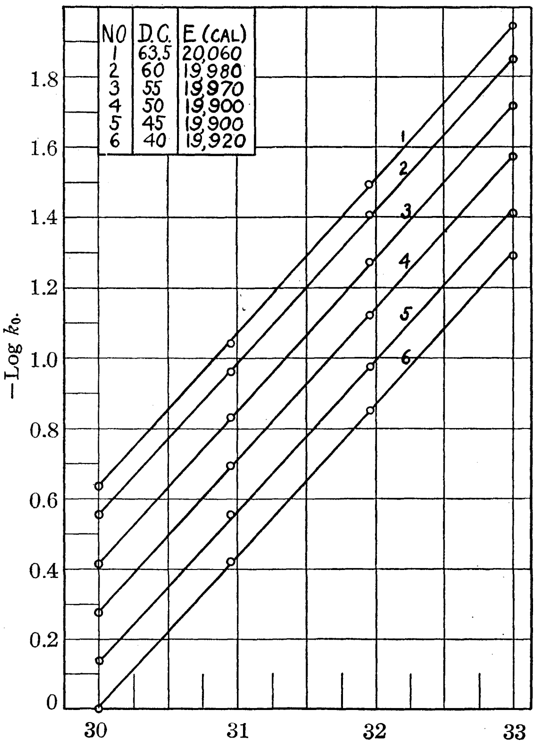

Fig. 3.—Influence of temperature on the rate of conversion of ammonium cyanate to urea in ethylene glycol–water media at zero ionic strength.

By reference to Table I, one observes that an empirical relation can be obtained between the dielectric effect and the temperature effect on the value of the limiting velocity constant for this reaction in glycol–water mixtures of constant dielectric constant, namely

$$\left(\frac{\Delta k_0}{\Delta D}\right)_T = -0.70\left(\frac{\Delta k_0}{\Delta T}\right)_D \qquad (8)$$

---

(5) Scatchard, *Chem. Rev.*, **10**, 229 (1932).

In the case of the methanol–water media, the constant on the right side of the equation was equal to unity.[2b]

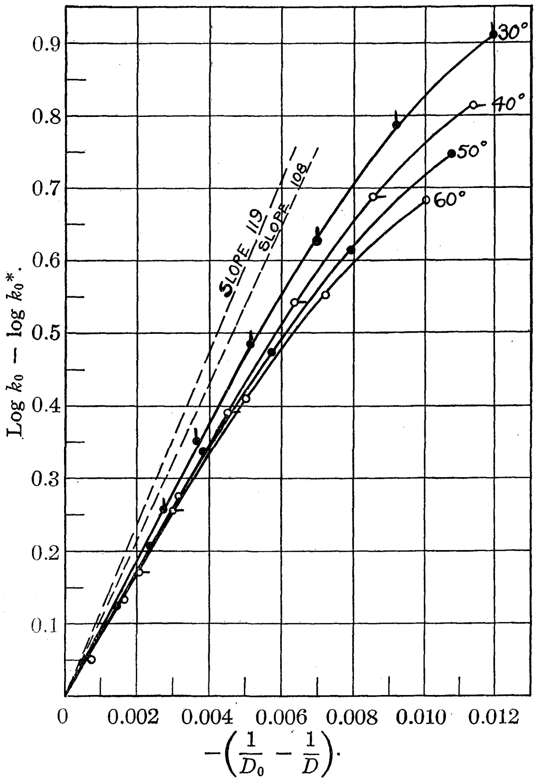

Fig. 4.

Discussion

It will be recalled that the equations previously derived[2] and used in this investigation were based on the assumption that the rate of reaction between ions depends only upon the temperature, the dielectric constant of the medium and the ionic strength. From previous investigations,[3b] and from the comparison of rates of the ammonium cyanate reaction in methanol–water media[2b] and in glycol–water media, we know that this assumption is only approximately true. However, considering these limitations the experimental data presented for this reaction in methanol–water media and in glycol–water media are in satisfactory agreement with those calculated by means of the equations and thus they very definitely show the influence of the dielectric constant and of the ionic strength upon critical increments.

We have summed up all of our observations in the two different solvent–water mixtures including some specific solvent influences:

(a) In methanol–water mixtures the log Ks for the constant dielectric constant media were constant, the average value being 11.77. In glycol–water media, however, the log Ks for the constant dielectric constant mixtures increase with decreasing dielectric constant.

(b) In methanol–water mixtures E_{D}^{0*} decreased with decreasing dielectric constant. In glycol–water media, however, E_{D}^{0*} is apparently independent of dielectric constant.

(c) In agreement with equation (6) the critical increments increased with ionic strength in both solvent–water mixtures of constant dielectric constant. In both cases calculated and experimental critical increments are in good agreement.

(d) The limiting slopes of the plots of (log k_0 − log k_0*) against ($1/D^0 - 1/D$) are in fair agreement with the predicted values in both cases.

(e) At 50° the rate constants in glycol–water mixtures are very nearly the same as those in isopropyl alcohol–water media and in dioxane–water media[3b] for the same constant dielectric constant mixtures.

As a result of the constancy of E_{D}^{0*} in glycol–water media, the suggestion previously made[2b] that possibly some of the decrease in E_{D}^{0*} with decreasing dielectric constant in methanol–water media was due to the method of calculating the k_0s, must either be dismissed or we must assume compensating medium effects operating in the glycol–water media. Unfortunately we cannot satisfactorily decide this question at present.

Summary

1. The rate of conversion of ammonium cyanate to urea has been studied over the temperature range 30 to 60° in glycol–water mixtures at the constant dielectric constants of 63.5, 60, 55, 50, 45 and 40.

2. The influence of ionic strength upon the observed critical increments at zero ionic strength is in good agreement with equations previously derived. It is observed that the critical increment is apparently independent of the dielectric constant in glycol–water media of constant dielectric constant.

3. Empirically it is shown that for this reaction in glycol–water mixtures of constant dielectric constant the following relation holds

$$\left(\frac{\Delta k_0}{\Delta D}\right)_T = -0.70\left(\frac{\Delta k_0}{\Delta T}\right)_D$$

4. The influence of the dielectric constant

of the solvent upon the rate constants is in fair agreement with the Scatchard–Christiansen theory.

5. The experimental results for this reaction are compared in methanol–water and in glycol–water mixtures.

On the Mechanism of the Catechol–Tyrosinase Reaction. II. The Hydrogen Peroxide Question

BY CHARLES R. DAWSON AND BERNARD J. LUDWIG

The dihydric phenol catechol has been used widely as an experimental substrate in the study of phenolic–oxidase action. These studies, and the widespread occurrence of catechol derivatives in nature, have motivated the suggestion that the utilization of molecular oxygen during the respiration of certain types of plants probably is largely dependent on this type of enzymatic action.[1] Robinson and McCance[2] in 1925 were among the first to show that the enzymatic oxidation of catechol results in the absorption of two atoms of oxygen per molecule of the dihydric phenol. Although it has been established definitely that *o*-benzoquinone is one of the initial products formed during the action of a phenolic oxidase such as tyrosinase on catechol,[3–5] the nature of the enzymatic action and the chemical mechanisms involved have not yet been explained satisfactorily.

The conversion of catechol to *o*-benzoquinone is an oxidation requiring theoretically only one atom of oxygen, and thus much of the controversy during the past decade has been in reference to the fate of the second oxygen atom. Since aerobic oxidations are attended frequently by the initial formation of hydrogen peroxide, it is not surprising that one of the first mechanisms, as suggested by Onslow and Robinson,[6] accounted for the second atom of oxygen by the formation of hydrogen peroxide, *i. e.*

$$C_6H_4(OH)_2 + O_2 \longrightarrow C_6H_4O_2 + H_2O_2$$

These investigators, and others,[7] have claimed to have detected traces of hydrogen peroxide in the reaction mixture resulting from the enzymatic oxidation of catechol, and they attributed the difficulty in detecting this substance to the presence of peroxidase and catalase in their tyrosinase or oxidase preparations. Others have attributed the difficulty of detecting hydrogen peroxide in many catalytic oxidations to the presence of small amounts of certain metals.[8,9]

The reliability of the methods used by Onslow and Robinson, and others,[7] for the detection of hydrogen peroxide has been questioned, and several workers have expressed doubt concerning the formation of hydrogen peroxide during the enzymatic oxidation of catechol. Pugh and Raper[4] studied the oxidation of catechol using tyrosinase preparations that possessed appreciable catalase activity, and observed that the total oxygen uptake did not deviate from two atoms per molecule of substrate. They pointed out that the presence of catalase would tend to decompose any hydrogen peroxide formed during the enzymatic oxidation and would thereby return the second atom of oxygen to the reaction mixture. These workers suggested that the second oxygen atom is consumed during further oxidation of *o*-benzoquinone. Furthermore, Nobutani[10] found that catalase has no effect on the oxygen consumption during the enzymatic oxidation of *p*-cresol, and therefore concluded that hydrogen peroxide is not formed during this reaction.

A study of the reports of Pugh and Raper and of Nobutani, however, reveals that their conclusions have been based on evidence that is not entirely convincing. These investigators did not indicate the strengths of the catalase preparations used nor did they demonstrate that the catalase remains active throughout the oxidation process.

Furthermore, it appears from some recent studies of Keilin and Hartree[11] that under certain conditions catalase may promote a secondary oxidation involving the hydrogen peroxide produced during an enzymatic oxidation. These authors have shown that when catalase functions in this capacity, the decomposition of the hydrogen peroxide does not result in the liberation of oxygen, *i. e.*, it does not return molecular oxygen to the reaction system. If, during the enzymatic oxidation of catechol, the introduction of catalase should promote such a secondary oxidation between hydrogen peroxide and some suitable intermediate, it is possible that the total oxygen uptake might not deviate from two atoms per molecule of substrate. Under such conditions, therefore, the formation of hydrogen peroxide would not be detected by oxygen uptake measurements.

In 1930 Pugh[12] reported that the activating action of traces of catechol and other dihydric phenols on the tyrosinase-monohydric phenol reaction could be attributed to the formation of either hydrogen peroxide or both hydrogen peroxide and *o*-quinone. More recently, Evans and Raper[13] have reported that the addition of purified peroxidase to the mealworm tyrosinase–tyrosine reaction causes a considerable decrease in the accumulation of dopa (3,4-dihydroxyphenylalanine). Since peroxidase itself has no action on mono- or dihydric phenols, they presented this as evidence that either hydrogen peroxide or an organic peroxide, which is capable of being activated by peroxidase, is produced in the tyrosinase–tyrosine reaction.

It has been found recently in these Laboratories[14] that the quinone produced during the enzymatic aerobic oxidation of catechol can be followed by iodimetric titration. When produced under certain conditions, *i. e.*, with an optimum amount of enzyme in very dilute solutions of catechol buffered in the *p*H range 4.2 to 6.6, the stability of the quinone is such that the stoichiometric relationship between it and catechol can be demonstrated. Since both quinone and hydrogen peroxide liberate iodine from hydriodic acid, it was apparent at an early stage in these studies that the indefinite status of the hydrogen peroxide controversy tended to cloud all interpretations. For this reason it became essential that more conclusive experimental evidence be obtained concerning the questionable role of hydrogen peroxide in this enzymatic oxidation.

In order to avoid the questionable reliability of the oxygen absorption methods which have been applied previously to this problem, the reaction course was followed by means of the iodimetric titration method previously described.[14] The study reported in this communication deals with the effect of hydrogen peroxide and the effect of catalase on the production and stability of the oxidation products formed during the catechol–tyrosinase reaction.

The Tyrosinase Preparations.—The tyrosinase preparations used in the present study were obtained from common mushrooms (common or field mushroom "*Psalliota campestris*"). The detailed procedure used for obtaining tyrosinase preparations from mushrooms will be published later. In brief, the mushrooms were frozen, ground, treated with cold acetone, and extracted with water. After an acetone precipitation and one or two ammonium sulfate precipitations, the enzyme was adsorbed on kaolin, eluted, and then adsorbed on alumina. The last step was followed by elution and dialysis, and the activity of the resulting preparation was measured according to the method proposed by Graubard and Nelson.[15]

The preparations were found to be free of peroxidase activity and to have negligible catalase activity. Typical data in support of this statement are compiled in Table I. These data were obtained using the procedure of Balls and Hale[16,17] for the determination of peroxidase activity.

The negligible magnitude of the catalase activity in the tyrosinase preparations can be judged by an inspection of the values of $(a - x)/t$ in column 1 of this table. The very small values of $(a - x)/t$ indicate a very low rate of decomposition of hydrogen peroxide by 5 cc. of the tyrosinase solution in the absence of pyrogallol. The absence of peroxidase activity in the tyrosinase solutions is shown by a comparison of the values of $(a - x)/t$ in columns 2 and 3 with those in column 1. The introduction of pyrogallol at

*p*H 6.6 did not increase the rate of decomposition of hydrogen peroxide, and at *p*H 7.8 caused a slightly lower rate of decomposition. Furthermore, as shown in columns 4 and 5, a mixture of 5 cc. of the tyrosinase solution with 5 cc. of a diluted horse radish peroxidase preparation had the same peroxidase activity as the peroxidase preparation alone.

The Effect of Hydrogen Peroxide on the Stability of the Oxidation Product Formed During the Enzymatic Oxidation of Catechol.—In dilute solutions buffered within the *p*H range 4.2 to 6.6 and in the presence of sufficient tyrosinase, catechol is rapidly and completely converted by air to an oxidized state that is equivalent to two atoms of iodine per molecule of catechol.[14] This iodine equivalency naturally suggests the oxidation product to be a benzoquinone, but does not preclude the possibility that the titration values may correspond to a mixture of a benzoquinone and hydrogen peroxide. Within this *p*H range the decrease in stability of the oxidation product with increase in *p*H is small, as can be seen in curves 1, 2 and 3 of Fig. 1, but at higher *p*H values the product is too unstable to be determined effectively. Since the tyrosinase preparations used in these experiments possess negligible catalase and peroxidase activity, hydrogen peroxide, if formed during the oxidation of catechol under these conditions, should be detectable, provided that the hydrogen peroxide does not undergo a secondary reaction with the benzoquinone.

To determine the conditions favoring such a secondary reaction between the benzoquinone and hydrogen peroxide, the enzymatic oxidation of catechol in the presence of given amounts of hydrogen peroxide at different hydrogen ion concentrations were studied. The results obtained are shown graphically in curves 5, 6 and 7 of Fig. 1. The experimental conditions and other points of information are given in the legend of this figure. As explained in this legend, 1.91 cc. of the thiosulfate solution is the titration value that represents complete conversion of 10 mg. of catechol to the quinone state, *i. e.*, to an oxidized state that is equivalent to two atoms of iodine per molecule of catechol. Thus, in the presence of an amount of hydrogen peroxide equivalent to 3.30 cc. of the thiosulfate solution per titration sample (see curve 4, Fig. 1), the complete enzymatic conversion of 10 mg. of catechol to this quinone state should be represented by a titration value of 5.21 cc. of thiosulfate solution, provided the hydrogen peroxide and quinone are perfectly compatible. Curves 6 and 7 of this figure show the quinone and hydrogen peroxide to be incompatible in solutions buffered to *p*H values of 5.5 and 6.7, respectively. However, at *p*H 4.1 hydrogen peroxide appears to have very little effect on the stability of the quinone produced in this enzymatic oxidation, as can be judged from a comparison of curve 5 with curve 1 in this figure. Since hydrogen peroxide and the quinone appear to be compatible at *p*H 4.1, it is evident that experiments designed for the detection of hydrogen peroxide as a reaction product in this enzymatic oxidation should be conducted in solutions buffered to approximately this *p*H value.

The Effect of Catalase on the Reaction Course as Determined by the Iodimetric Titration Method.—By the use of a sufficient amount of the enzyme catalase, the decomposition of hydrogen peroxide can be effected at a rate so rapid as to be practically immeasurable. For this reason, the presence of a relatively large amount of catalase in the reaction system, during the enzymatic oxidation of catechol at *p*H 4.1, should alter materially the reaction course, as determined by the iodimetric titration method, if hydrogen peroxide is responsible for any part of the titration values.

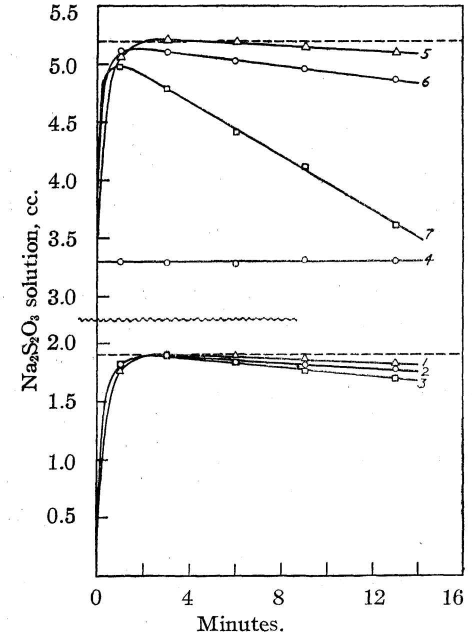

Fig. 1.—Curves showing the effect of *p*H and of hydrogen peroxide on the production and stability of the oxidation product formed in the catechol–tyrosinase reaction. 3.5 units of tyrosinase per mg. of catechol was used in solutions buffered to the following *p*H values: Curve 1, *p*H 4.1; 2, *p*H 5.3; 3, *p*H 6.7; 5, *p*H 4.1; 6, *p*H 5.5; 7, *p*H 6.7. The enzymatic oxidations represented by curves 1, 2 and 3 were run at 25° in a total reaction volume of 250 cc., of which 25 cc. was 0.2 *M* phosphate buffer; 5 cc. was 0.2% freshly prepared catechol solution (10 mg.), and 5 cc. was enzyme solution. The enzyme was added at zero time. With air bubbling through the reaction solution, 25-cc. samples were removed at the time intervals noted and added to 25 cc. of 2 *N* sulfuric acid. After adding 10 cc. of 10% potassium iodide they were allowed to remain in the dark for fifteen minutes before titrating the liberated iodine with standard thiosulfate solution. Thus the plotted volumes of thiosulfate solution required to take care of the iodine liberated in each sample are a measure of the amounts of oxidation product causing this iodine liberation. 1 Mg. of catechol per 25 cc. (0.1 reaction volume) when completely oxidized is equivalent to 9.10×10^{-6} mole of iodine which in turn is equivalent to 1.91 cc. of 0.00950 *N* sodium thiosulfate solution. The runs represented graphically by curves 5, 6 and 7 differ from those of curves 1, 2 and 3 in that the reaction system corresponding to the upper curves contained in addition to 10 mg. of catechol and 35 units of enzyme 2.0 cc. of approximately 0.15 *N* hydrogen peroxide. The titration values plotted in curve 4 (3.30 ± 0.01 cc.) are those obtained when the system contained only this amount of hydrogen peroxide. The upper dotted line (at 5.21 on the ordinate axis) is the sum of the hydrogen peroxide equivalent (3.30) and the catechol equivalent (1.91) in cc. of 0.00950 *N* sodium thiosulfate solution.

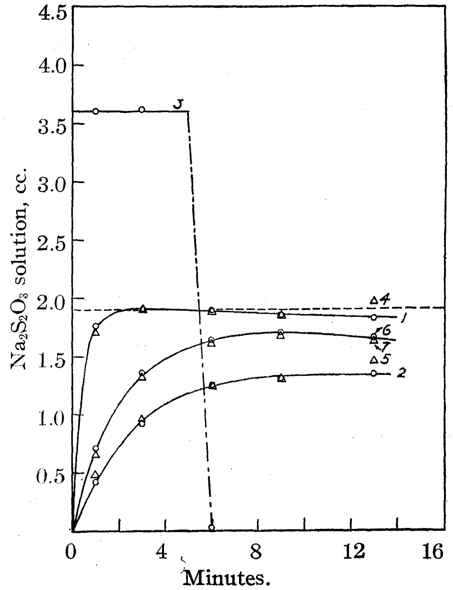

Fig. 2.—Curves showing the absence of hydrogen peroxide in the products resulting from the enzymatic oxidation of catechol. The data represented in curves 1, 2, 4 and 5 were obtained using 10 mg. of catechol per 250 cc. reaction volume (buffered to *p*H 4.1) according to the procedure described in the legend of Fig. 1. The data represented in curves 6 and 7 were obtained with similar solutions buffered to *p*H 5.6. Tyrosinase used per mg. of catechol: curves 1 and 4, 3.5 units; curves 6 and 7, 1.0 unit; curves 2 and 5, 0.5 unit. The systems represented by curves 4 and 5 differ from those of curves 1 and 2 only in that the initial reaction volume (250 cc.) of the former systems contained, in addition to catechol and tyrosinase, 2.0 cc. of a diluted catalase preparation. The data represented in curve 3, which has been included to give an indication of the catalase activity possessed by this amount of the catalase preparation, were obtained by use of the same titration procedure. The system contained initially only 2.0 cc. of approximately 0.17 *N* hydrogen peroxide in 250 cc. This amount of hydrogen peroxide is nearly twice that theoretically producible in the enzymatic oxidation of catechol under these conditions. As can be seen in this curve, one minute after the addition of 2.0 cc. of the diluted catalase preparation, only a negligible quantity of hydrogen peroxide remained. To demonstrate that the catalase remained active throughout the oxidation process, a similar amount of hydrogen peroxide (2.0 cc. of 0.17 *N* hydrogen peroxide) was added after the expiration of twelve minutes to the systems represented by curves 4 and 5. Had the catalase been inactivated completely the last titration value in each of these curves would have been greater by about 5.8 cc. of the thiosulfate solution. The system represented by curve 7 differs from that of curve 6 only in that the former contained initially 5 cc. of a diluted (1:20) peroxidase preparation in addition to the catechol and tyrosinase. The activity of this amount of peroxidase can be judged from an inspection of the data in column 4 of Table I. The titrations in the experiments represented by curves 6 and 7 were made with 0.00964 *N* sodium thiosulfate.

Curves 1 and 2 in Fig. 2 show the reaction course, as determined by this method, when 10 mg. of catechol in 250 cc. of solution buffered to *p*H 4.1 was oxidized rapidly with 35 units of tyrosinase and more slowly oxidized with 5 units of the enzyme. Curves 4 and 5 show the results obtained when the experiments were repeated in the presence of a relatively large amount of catalase. This negative effect of catalase on the reaction course was observed also at other *p*H values within the *p*H range 4.1 to 6.7. Experiments of this type were also conducted at several *p*H values using peroxidase rather than catalase for the purpose of detecting hydrogen peroxide. In no case did the presence of peroxidase alter the reaction course. A typical example is presented in the form of curves 6 and 7 of Fig. 2 (see legend). As explained in the legend and shown in curve 3 of this figure, the amount of catalase used in these studies was sufficient to decompose in about one minute nearly twice the amount of hydrogen peroxide that theoretically could be produced during this enzymatic oxidation. Since the catalase remained active throughout the enzymatic oxidation (see legend of Fig. 2) and caused no change in the course of the reaction as followed by this method, it can be concluded definitely that the titration values are in no part due to hydrogen peroxide.

Discussion

It is quite apparent that the uptake of the extra atom of oxygen over and above that which is required for the formation of *o*-benzoquinone from catechol cannot be accounted for in this enzymatic oxidation simply by the formation of hydrogen peroxide as suggested by Onslow and Robinson,[6] *i. e.*

$$C_6H_4(OH)_2 + O_2 \longrightarrow C_6H_4O_2 + H_2O_2$$

This statement, based largely on the evidence that has been presented above, has recently received further substantiation during the course of other investigations in these Laboratories. By simultaneously following the enzymatic oxidation of catechol with both oxygen uptake measurements and iodimetric titration measurements, Wagreich and Nelson[18] have found that the complete conversion of catechol to the quinone state, as indicated by iodimetric titration, requires the absorption of only one atom of oxygen. It appears quite probable that the second oxygen atom is used in oxidation of a product resulting from the action of water on *o*-benzoquinone.

The question of whether or not hydrogen peroxide has an intermediary function during the formation of the initial quinone may be considered to be still open to debate. For such to be the case, the hydrogen peroxide must perform this function at a rate greater than the rate of its own decomposition by relatively large amounts of catalase, and its concentration therefore at any given time must be extremely low. If the tyrosinase preparations had possessed appreciable peroxidase activity, such an intermediary function of hydrogen peroxide would be more readily conceivable. Considering the facts that have been presented above, there appears to be little reason at present for supporting such a view of the enzymatic oxidation of catechol.

Summary

1. The enzymatic oxidation of catechol has been studied using tyrosinase preparations having no peroxidase activity and negligible catalase activity.

2. In dilute solutions buffered within the *p*H range 4.1 to 6.7 the oxidation product formed in the initial stages of the catechol–tyrosinase reaction is equivalent to two atoms of iodine per molecule of catechol. This iodine equivalency corresponds to a benzoquinone.

3. This quinone and hydrogen peroxide are incompatible in solutions buffered to *p*H values above 4.1.

4. In the *p*H range 4.1 to 6.7, the course of the catechol–tyrosinase reaction, as followed by iodimetric titration, is unaltered by large amounts of catalase or peroxidase.

5. It is concluded that hydrogen peroxide is not responsible for any part of the titration values, and that the consumption of two atoms of oxygen per molecule of catechol during the enzymatic oxidation cannot be directly attributed to the formation of hydrogen peroxide.

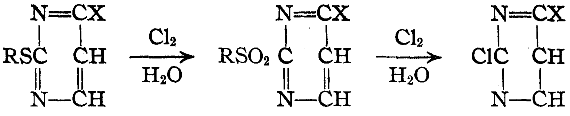
Researches on Pyrimidines. CLVIII. The Oxidation of Mercaptopyrimidines with Chlorine Water

BY TREAT B. JOHNSON AND JAMES M. SPRAGUE[1]

In a recent publication from this Laboratory by the authors[2] it was shown that chlorine gas and certain 2-mercaptopyrimidines interact smoothly in aqueous solution at low temperature with production of the corresponding 2-alkylsulfonyl derivatives. This reaction is applicable to 2-mercaptopyrimidines conforming in constitution to Formula I. By raising the reaction temperature, however, the chlorination process proceeds further with replacement of the sulfonyl grouping of the pyrimidine II by chlorine. These changes are expressed by Formulas I, II and III.

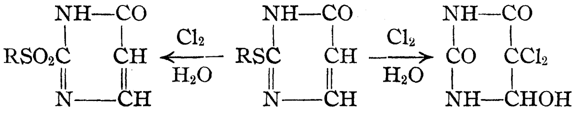


$$\begin{array}{c}N{=}CX\\ RSC\quad CH\\ N{-}CH\end{array} \xrightarrow[H_2O]{Cl_2} \begin{array}{c}N{=}CX\\ RSO_2C\quad CH\\ N{-}CH\end{array} \xrightarrow[H_2O]{Cl_2} \begin{array}{c}N{=}CX\\ ClC\quad CH\\ N{-}CH\end{array}$$

I II III

(X = halogen, OCH_3 or OC_2H_5, SC_2H_5 and NH_2).

During study of this chlorination reaction in 1935 we experimented also with several 2-mercapto-4-oxypyrimidine compounds but were unable to prepare the 2-alkylsulfonyl pyrimidines corresponding to Formula IV. The products of reaction were always sulfur free and they were identified as 2,4-diketohexahydropyrimidines as is represented by Formula VI.



$$\begin{array}{c}NH{-}CO\\ RSO_2C\quad CH\\ N{-}CH\end{array} \xleftarrow[H_2O]{Cl_2} \begin{array}{c}NH{-}CO\\ RSC\quad CH\\ N{-}CH\end{array} \xrightarrow[H_2O]{Cl_2} \begin{array}{c}NH{-}CO\\ CO\quad CCl_2\\ NH{-}CHOH\end{array}$$

IV V VI

In other words, the chlorination reaction in aqueous solution proved to be specific, and serves to differentiate between 2-mercaptopyrimidines represented by structures expressed in Formulas I and V, respectively. In pyrimidines of type I the unsaturation of the pyrimidine cycle is not changed by chlorination, and the mercapto grouping is oxidized, giving a stable sulfonyl pyrimidine II. In the case of pyrimidines of type V the chlorination process is more complicated. Here we are dealing with three different reaction changes: (1) oxidation of the 2-mercapto grouping, (2) saturation of the double bond in positions 5 and 6 of the pyrimidine cycle and (3) hydrolysis in position-2 with formation of an alkyl sulfonic acid and a 2,4-diketohexahydropyrimidine derivative.

This specificity of reaction is also exhibited by chlorination of mercaptopyrimidines in alcohol solutions. The mercaptopyrimidines of type V behave as the corresponding 2,4-diketotetrahydropyrimidines, giving the same products, the 2,4-diketohexahydropyrimidines.[3] This characteristic difference in chemical behavior is illustrated in the equations expressed under sections A and B below.

Several mercaptopyrimidines of type V have been utilized in different research programs in progress in this Laboratory, and in every case thus far examined the respective mercaptopyrimidine has undergone the characteristic transformations expressed under section B. These 2,4-diketohexahydropyrimidines are converted quantitatively into 2,4-diketotetrahydropyrimidine derivatives by digestion with reducing agents.

After diluting to 20 cc. with ice water chlorine gas was then bubbled slowly into the cold solution until the precipitation of a crystalline solid was complete. This reaction product (2 g.) was dried over phosphorus pentoxide and purified by crystallization from ethyl acetate. It melted at 125–126° and responded to qualitative tests for sulfur and chlorine.

Anal. Calcd. for $C_7H_{10}O_2N_3SCl$: N, 17.83; S, 13.61; Cl, 15.15. Found: N, 17.88; S, 13.77; Cl, 15.25; (active Cl, 15.05).

$C_2H_5SO_2\overline{C{=}NCH{=}C(CH_3)C(NH_2){=}N}$, **Formation of 2-Ethylsulfonyl-4-amino-5-methylpyrimidine.**—The above chloroaminopyrimidine was suspended in dilute sodium bisulfite solution and the mixture agitated vigorously for several minutes. The insoluble material was then filtered off, dried in vacuum and purified by crystallization from ethyl acetate. It melted at 136–137° and proved to be identical with the pyrimidine obtained by the action of ammonia on 2-ethylsulfonyl-5-chloro-5-methylpyrimidine.[5]

Anal. Calcd. for $C_7H_{11}O_2N_3S$: N, 20.88; S, 15.94. Found: N, 21.03; S, 16.06.

On exposure of this pyrimidine to the action of chlorine in dilute hydrochloric acid the chloroamino compound (above) was formed and melted at 125–126°.

$C_2H_5SO_2\overline{C{=}NC(CH_3){=}CHC(Cl){=}N}$, **2-Ethylsulfonyl-4-chloro-6-methylpyrimidine.**—This was prepared by suspending 10 g. of 2-ethylmercapto-4-chloro-6-methylpyrimidine[6] in 75 cc. of ice water and then saturating the cold solution with chlorine gas. This pyrimidine chloride separated as an oil. After extraction with ether and drying over calcium chloride the oil was purified by distillation. It boiled at 189–191° at 3.5 mm.; n^{25}_{D} 1.5422.

Anal. Calcd. for $C_7H_9O_2N_2Cl$: N, 12.70. Found: N, 12.60.

$NH_2C{=}N{-}\overline{C(CH_3){=}CHC(Cl){=}N}$, **Formation of 2-Amino-4-chloro-6-methylpyrimidine.**[7]—This is formed smoothly by interaction of 2-ethylsulfonyl-4-chloro-6-methylpyrimidine with cold saturated alcoholic ammonia solution. It is also formed by heating the chloropyrimidine with strong aqueous ammonia at 100° for one hour. The yield is 80% of the theoretical. After purification by crystallization from hot alcohol it melted at 182–183°.

Anal. Calcd. for $C_5H_6N_3Cl$: N, 29.27; Cl, 24.74. Found: N, 29.40; Cl, 24.65.

$C_2H_5SO_2\overline{C{=}NC(CH_3){=}CHC(NHCl){=}N}$, **2-Ethylsulfonyl-4-chloroamino-6-methylpyrimidine.**—Four grams of 2-ethylmercapto-4-amino-6-methylpyrimidine was dissolved in 5 cc. of dilute hydrochloric acid and the solution diluted with 35 cc. of ice water. The above pyrimidine was formed on saturating the cold aqueous solution with chlorine gas. The pyrimidine crystallizes from benzene and melts at 133–134°. Analysis of the compound after drying *in vacuo* at 100°: Calcd. for $C_7H_{10}O_2N_3SCl$: N, 17.83. Found: N, 17.86.

II. The Conversion of 2-Mercapto-4-oxypyrimidines into 2,4-Diketohexahydropyrimidines

$\overline{CONHCH(OCH_3)C(CH_3)ClCONH}$, **2,4-Diketohexahydro-5-methyl-5-chloro-6-methoxypyrimidine.**—Four grams of 2-ethylmercapto-4-oxy-5-methylpyrimidine[8] was dissolved in 50 cc. of methyl alcohol and the ice-cooled solution saturated with chlorine gas. The excess of alcohol was then removed below a temperature of 30° under diminished pressure. During this operation there was a distinct odor and lachrymator effect of ethyl sulfonyl chloride. The crystalline reaction product which separated (3 g.) was washed with cold water and petroleum ether, and then purified by crystallization from boiling water. The compound obtained was free from sulfur and crystallized from water in the form of needles melting at 220–221°.

Anal. Calcd. for $C_6H_9O_3N_2Cl$: N, 14.54; Cl, 18.42; methoxyl (OCH_3), 16.12. Found: N, 14.43; Cl, 18.60; methoxyl (OCH_3), 16.14.

This pyrimidine is very soluble in acetone, ethyl acetate, ethyl alcohol, ether and hot water. It is also soluble in dilute alkali solution from which it is precipitated by neutralization of the alkali with acids. On digesting the hexahydropyrimidine with hydriodic acid,[9] it is converted quantitatively into "thymine."

$\overline{CONHC(CH_3)(OCH_3)CClCONH}$, **2,4 - Diketotetrahydro-5,5-dichloro-6-methyl-6-methoxypyrimidine.**—Four grams of 2-ethylmercapto-4-oxy-6-methylpyrimidine[10] was chlorinated according to the experimental technique described in the preceding experiment. Five grams of the hexahydropyrimidine was obtained. This was purified by crystallization from methyl alcohol and melted at 274–275°, with effervescence. The compound failed to give a test for sulfur.

Anal. Calcd. for $C_6H_8O_3N_2Cl_2$: N, 12.33, methoxyl (OCH_3), 13.67. Found: N, 12.33; methoxyl (OCH_3), 13.60.

On digesting this pyrimidine with tin and hydrochloric acid,[11] it is converted quantitatively into 5-chloro-6-methyluracil, $CONHC(CH_3){=}CClCONH$. This crystallized from hot water in the form of needles.

Anal. Calcd. for $C_5H_5O_2N_2Cl$: N, 17.45. Found: N, 17.40.

$\overline{CONHCH(OCH_3)CCl_2CONH}$, **2,4-Diketotetrahydro-5,5-dichloro-6-methoxypyrimidine.**—This is formed quantitatively by chlorination in methyl alcohol solution of 2-ethyl or 2-methylmercapto-6-oxypyrimidine.[12] The pyrimidine melts at 225–226°[3] and is converted into 5-chlorouracil by digestion with tin and hydrochloric acid.

Summary

1. 2-Mercaptopyrimidines of types I and II, respectively, can be differentiated by their char-

The Volatile Constituents of Roasted Coffee

BY WILLIAM R. JOHNSTON AND CHARLES N. FREY

Our interest in the staling of roasted coffee led us to attempt to isolate and identify some of the aroma and flavor constituents. It is evident that any effort to prevent or retard the staling of roasted coffee can be undertaken with better prospects of success if the identity and nature of the substances responsible for its flavor and aroma can be more completely ascertained.

When we started our investigation the best information on the subject was contained in the patents issued to Staudinger and Reichstein.[1] They outlined a method of isolating coffee volatiles by vacuum distillation and listed a number of compounds supposedly present in roasted coffee. Some of the compounds reported were: hydrogen sulfide, methyl mercaptan, furfuryl mercaptan, dimethyl sulfide, acetaldehyde, furfuraldehyde, diacetyl, acetyl-propionyl, furfuryl alcohol, acetic acid, guaiacol, vinyl guaiacol, pyridine, pyrazine and N-methylpyrrole. However, in British Patent 260,960, the statement is made that the compounds reported were not actually found in coffee but were split products obtained by analysis—the real products being unstable and difficult to isolate. This statement is somewhat confusing since some of the substances mentioned have been reported previously by earlier investigators as being present in coffee. For example, pyridine, furfuraldehyde, furfuryl alcohol and acetic acid actually have been isolated from roasted coffee. The older literature on this subject has been surveyed critically by Prescott and his co-workers.[2] With this contradiction in mind, we decided to use the work of Staudinger and Reichstein as a guide and attempt to isolate the volatile coffee components as nearly unchanged as possible. Their procedure includes distillation at 2–5 mm. pressure at 100–110° and the use of steam or liquid water to assist in removal of volatile substances from roasted coffee. We believed that this treatment was not ideal because previous work on staling had convinced us that very small amounts of oxygen were sufficient to cause appreciable deterioration of the coffee and in addition that moisture had a distinct accelerating effect on this deterioration. Consequently, we decided to utilize a high vacuum apparatus and to avoid the use of water during the distillation. By distilling at low pressures and working in the practical absence of oxygen we have been able to isolate as actual constituents of coffee several of the substances reported by Staudinger and Reichstein. We also have detected methylacetylcarbinol as a new constituent of roasted coffee.

Shortly after we had completed our investigation, two excellent papers by Prescott and his associates[2,3] supplied valuable new information on the constituents of roasted coffee. Prescott and his collaborators relied on solvent extraction of coffee brew and dry roasted coffee to isolate several new substances which were identified in the usual manner. The following substances were reported: furfuryl alcohol, furfuraldehyde, acetic acid, formic acid, diacetyl, diethyl ketone, kahweol, vanillone, *p*-vinylguaiacol, guaiacol, *n*-heptacosane, *p*-vinylcatechol, sylvestrene, eugenol, and a hydrocarbon melting at 116–117°. Of these substances, formic acid, diethyl ketone, vanillone, *n*-heptacosane, *p*-vinylcatechol, sylves-

trene, eugenol, and the hydrocarbon (m. p. 116–117°) have not been mentioned specifically by previous workers.

Judging from this work and from our own it is likely that the substances reported by Staudinger and Reichstein were not split products but actual coffee constituents.

Although not directly concerned with coffee, the paper by Reichstein and Beitter[4] on the aroma constituents of roasted chicory is well worth the study of anyone interested in the chemistry of coffee. The methods of isolation and identification described by Reichstein and Beitter are very probably quite similar to those used previously by Staudinger and Reichstein.

Apparatus and Procedure

Dry Distillation of Roasted Coffee (Santos).—The high vacuum distillation equipment included a heavy copper flask of about 15-liters capacity which was suitable for holding a charge of 15 kg. of finely ground coffee; a Pyrex glass manifold carrying 3 receivers of 200-cc. and 3 of 100-cc. capacity, a trap for mercury vapor, a mercury vapor pump, and a Cenco Hy-vac pump as a backing pump.

After charging the copper distillation flask with coffee it was fitted with a rubber stopper carrying a glass tube which was sealed to the receiver manifold. The joints between the rubber stopper, copper and glass were sealed vacuum tight with hard deKhotinsky cement.

The larger receivers were cooled with solid carbon dioxide and the smaller ones with liquid air. Each was fitted with a ground joint which permitted the removal of the lower portion holding the condensate.

In carrying out the distillation, after all leaks had been eliminated, the pumps were operated for several hours to remove all of the oxygen in the system. During this time the distillation flask was at room temperature but even at this temperature appreciable amounts of carbon dioxide, water vapor, and volatile aroma and flavor constituents condensed in the receivers. Only traces of substances condensed in the final liquid air trap and only small amounts of gas, presumably carbon monoxide, passed this receiver, since the pressure at that point was usually about 0.005 mm. The pressure in the copper flask could not be measured at any time but since the bore of the manifold and receiver tubes was of the order of 1 cm. at all points, it is probable that no considerable drop in pressure existed between the distillation flask and the last receiver.

When oxygen had been eliminated completely from the system, the distillation flask was heated gradually to 100° on the water-bath and maintained at that temperature throughout the distillation. Condensate accumulated rapidly after the coffee was heated, most of the water condensing in the receivers cooled with solid carbon dioxide, while carbon dioxide, traces of water, and a small amount of a pale yellow liquid having a strong coffee aroma condensed in the liquid air receivers.

When it became necessary to remove a receiver, oxidation of the condensate was avoided by filling the manifold with pure nitrogen. After removal from the apparatus the receiver was sealed and stored in a packing of solid carbon dioxide until analysis of the condensate was undertaken. The distillation was continued until practically no more liquid condensed in the solid carbon dioxide receivers. This usually required about forty hours. After one charge of coffee had been distilled, the copper flask was removed, a fresh charge introduced, and the distillation continued, following the procedure just outlined. In a typical experiment in which 100 lb. (45 kg.) of coffee was distilled, about 850 cc. of condensate in the solid carbon dioxide receivers and approximately 50 cc. of condensate in the liquid air receivers were obtained. The amount of liquid air condensate (50 cc.) is exclusive of the condensed carbon dioxide which was not retained.

Examination of Condensates.—The condensate from the receivers cooled with liquid air was allowed to volatilize at atmospheric pressure, the effluent gas, chiefly carbon dioxide, being passed through receivers cooled with solid carbon dioxide. The gas finally escaping smelled strongly of hydrogen sulfide and of mercaptans or organic sulfides. Testing with lead acetate identified the hydrogen sulfide beyond question. The residual condensate (50 cc.) was a dilute aqueous solution supporting a thin layer of a pale yellow liquid. This mixture was distilled at atmospheric pressure on the water-bath at 75° in a slow stream of nitrogen until about 2 cc. of a pale yellow liquid condensed in a receiver cooled with solid carbon dioxide. The residual aqueous solution was combined with the primary condensate obtained in the three receivers cooled with solid carbon dioxide.

The pale yellow liquid was redistilled on a water-bath in an atmosphere of pure nitrogen, using receivers cooled with solid carbon dioxide. Three fractions were taken distilling at 25–35, 35–50 and 50–85°, only a trace of brownish residue remaining in the distilling flask. The first fraction (0.4 cc.) was mostly soluble in water and had an odor of acetaldehyde. This substance was identified by formation of its 2,4-dinitrophenylhydrazone, m. p. 162–164°. A mixed melting point with an authentic sample confirmed the identification. Judging by the amounts of hydrazone formed, acetaldehyde was the chief ingredient of this fraction. A trace of furan seemed to be present since a pine splinter gave a green reaction and a brown precipitate was obtained on treatment with concentrated hydrochloric acid.

The second fraction (0.8 cc.) also contained acetaldehyde and, in addition, a mixture of perhaps several aldehydes and ketones, for a mixture of 2,4-dinitrophenylhydrazones was obtained. An attempted separation was not successful because of the small amount of material available.

The third fraction (0.4 cc.) was found to contain a small amount of diacetyl which was isolated as a *bis*-semicarbazone, m. p. 281–282°. A mixed melting point of 281–282° confirmed the identification. The third fraction had a good coffee-like aroma and also a mercaptan-like odor. Sulfur was detected but mercaptans or sulfides could not be isolated or identified. A ketone was isolated in the form of a red 2,4-dinitrophenylhydrazone, m. p. 258–259°, but its identification was not completed, again because of the minute amounts of material available.

---

[4] Reichstein and Beitter, *Ber.*, **63B**, 816–826 (1930).

The primary condensate from the receivers cooled with solid carbon dioxide contained droplets of oil. Immediately on exposure to air the oil droplets turned reddish-brown and the solution gradually darkened and deposited a brownish resin or tar. This also took place when the condensate was heated to 100–110° in pure nitrogen. The oxidized oil droplets had an odor very similar to that of very stale coffee.

From a portion of the condensate diacetyl was precipitated as its characteristic osazone, *m. p.* 243–245°, the identification being confirmed by a mixed melting point with the osazone obtained from an authentic sample of diacetyl.

The bulk of the condensate was separated from the oil droplets and acids and then roughly fractionated. It was first distilled at about 50–60 mm. pressure in a slow stream of pure nitrogen to remove the water. After practically all the water had distilled over, the distillation was stopped and the oily residue sealed in nitrogen to be saved for further work. The aqueous distillate was saturated with potassium carbonate and extracted with pure ethyl ether. The ether extract was concentrated to yield a viscous brown oil (3–4 cc.) which was distilled at 20–30 mm. in a stream of nitrogen. Two fractions were taken: A (1 cc.) distilling at 20–35°; and B (1 cc.) 35–65°; and a residue of about 2 cc. was set aside. Fraction A was found to be mainly a mixture of aldehydes and ketones and was not investigated further. Fraction B had an odor of pyridine and yielded a picrate melting at 167–168°. A mixed melting point with an authentic sample of pyridine picrate confirmed the identification.

Fraction B was fractionated at atmospheric pressure in pure nitrogen to yield a main fraction of 0.5 cc. boiling at 145–165°. This distillate gave a phenylhydrazone melting at 97° which proved to be the phenylhydrazone of furfuraldehyde. A mixed melting point clinched the identification. The aniline acetate test was also positive.

A few drops of a higher boiling liquid were also obtained from fraction B which seemed to be furfuryl alcohol but the identification was not confirmed by preparation of a derivative.

The distillate from fraction B coming over at 145–165° also yielded a phenylhydrazone melting at 237–240° which on purification melted at 244–245°. A mixed melting point with diacetyl osazone was 244–245°, so it was evident that either diacetyl or methylacetylcarbinol must have been present in fraction B. But diacetyl is excluded by its boiling point so the compound was identified as methylacetylcarbinol which boils at 148° and yields diacetyl on oxidation. Its isolation may be ascribed to the care with which oxygen was excluded during manipulations. Its oxidation to diacetyl occurred during the preparation of the osazone in the presence of air.

Tests on the higher boiling fractions obtained from the aqueous condensate and on the small amount of water insoluble oils, indicated that phenols, nitrogenous compounds other than pyridine and high boiling aldehydes and ketones were present. The phenolic fractions had a coffee-like odor and were very sensitive to heat and oxygen.

Discussion

In the main, our work has been an extension, a general confirmation, and an elucidation of the patent disclosures of Staudinger and Reichstein. We have found high vacuum distillation to be very suitable for isolating the volatile coffee constituents and have isolated several coffee constituents which have been reported by Staudinger and Reichstein to be split products and not actual constituents. As mentioned previously, the indications are that most if not all of the substances listed by Staudinger and Reichstein are actually present in coffee.

The identification of diacetyl, furfuraldehyde, pyridine, and furfuryl alcohol further confirms previously published reports. The detection of acetaldehyde, furan and hydrogen sulfide confirms the work of Staudinger and Reichstein, but the isolation of methylacetylcarbinol is new. Separation of fractions containing phenols, nitrogenous compounds other than pyridine, and mixtures of aldehydes and ketones again confirms several previous investigations, but the detection of sulfur in a volatile fraction is the first confirmation in this respect of Staudinger and Reichstein's work. We are inclined to agree with their belief that the compounds containing sulfur are of major importance with respect to the distinctive character of coffee aroma. The fraction containing sulfur had a very intense odor which seemed to embody the unusual aroma and taste sensations imparted by roasted coffee.

The work of Prescott and his associates, mainly on the less volatile constituents of coffee, also confirms certain aspects of the researches of Staudinger and Reichstein and is of great importance in understanding the changes which take place on staling. We are in complete agreement with Prescott with respect to the probable changes occurring during the staling process Staling probably involves volatilization, oxidation, hydrolysis, and polymerization of the various flavor and aroma constituents, and has little if anything to do with the fat of coffee.

At the present time we have an imposing list of coffee aroma and flavor constituents which should be of great assistance in studying the staling of coffee and various other problems of the coffee industry.

Summary

The utilization of high vacuum distillation to isolate the volatile aroma and flavor components of roasted coffee is described. The identification

of diacetyl, methylacetylcarbinol, furan, furfuraldehyde, furfuryl alcohol, acetaldehyde, pyridine, and hydrogen sulfide is reported. The contributions of Staudinger and Reichstein and of Prescott and his associates are discussed and the relation of the volatile constituents to the staling of coffee is considered briefly. Coffee staling is probably concerned with changes in the volatile aroma and flavor substances and does not involve fat rancidity.

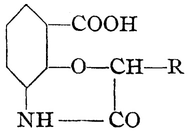
The Preparation of 2-Methyl-8-carboxy-3-keto-3,4-dihydro-1,4-benzoxazine

BY HAROLD W. COLES[1] AND WALTER G. CHRISTIANSEN[2]

In the search for new analgesics without the chemical structures said to cause agranulocytosis[3] we have been interested in the possibilities of the benzoxazine ring system, and particularly in the 8-carboxy-3-keto-3,4-dihydro-1,4-benzoxazines (I) since it is seen that these compounds



I

may be considered as derivatives of salicylic acid, and they also contain the skeleton of acetanilide. The carboxyl group not only acts in a detoxifying capacity, but also permits the preparation of a soluble sodium salt.

A number of carboxylated benzoxazines have been reported in the literature[4] but, so far as we know, were not tested pharmacologically. Therefore, 2-methyl-8-carboxy-3-keto-3,4-dihydro-1,4-benzoxazine (I, R = CH_3) was synthesized and, being physiologically inactive, no further members of this series were prepared.

The authors wish to record their appreciation for the interest and advice of Dr. George D. Beal, Assistant Director of Mellon Institute, during the progress of this work.

Experimental Part

3-(α-Bromopropionylamino)-salicylic Acid.—The procedure, here described, is adapted from directions given by Sanna[5] for the non-carboxylated aminophenols. One mole equivalent (4.25 g.) of 3-aminosalicylic acid and slightly more than one mole equivalent (6.25 g.) of α-bromopropionyl bromide was added to 50 g. of dry benzene. The aminosalicylic acid remained suspended in the benzene since it is quite insoluble. The Erlenmeyer flask contents were refluxed on a water-bath for twelve to fourteen hours with the evolution of acid fumes. The flask contents were chilled and the grayish crystalline material was removed to a Büchner funnel and washed repeatedly with cold benzene. The crystals, after drying in the air, weighed 8 g. representing a practically theoretical yield. It was recrystallized from a minimum of boiling 50% alcohol, washing repeatedly on the filter with distilled water. It was dried in an 80° oven. The white solid has an irritating odor, and in a melting point tube it softened quite sharply at 178°, but the column did not break until 188° (U. S. P. corr.).

Anal. (Kjeldahl). Calcd. for $C_{10}H_{10}O_4BrN$: N, 4.86. Found: N, 4.64.

The crystals are easily soluble in acetone, alcohol and alkalies, but sparingly soluble in water and benzene.

2-Methyl-8-carboxy-3-keto-3,4-dihydro-1,4-benzoxazine (I, R = CH_3).—3-(α-Bromopropionylamino)-salicylic acid (3.3 g.) was dissolved in 25 cc. of 10% sodium hydroxide solution and warmed on the water-bath at 60° for one hour. The color darkened considerably. The solution was cooled, filtered and dilute (1:1) hydrochloric acid added until the dark solution was acid to congo red. A dark precipitate came out on standing, and was washed repeatedly with distilled water. Recrystallized from a minimum of boiling absolute alcohol, the product was secured as colorless crystals (yield 60%). The substance is sparingly soluble in the usual solvents. It is readily soluble in alkalies; m. p. 285° (U. S. P. corr.).

Anal. Calcd. for $C_{10}H_9O_4N$: N, 6.61. Found: N, 6.76.

Pharmacological Tests.[6]—6-Carboxy-3-keto-3,4-dihydro-1,4-benzoxazine[4a] and 2-methyl-8-carboxy-3-keto-3,4-dihydro-1,4-benzoxazine, administered intravenously to mice, rats and rabbits, exhibited no antipyretic or hypnotic action in doses up to 2000 mg. per kg. The first compound shows some toxic effects above 500 mg. per kg., while the second is non-toxic at least up to a dosage of 1500 mg. per kg. The compounds were not tested as to possible local anesthetic properties. The effect of the introduction of the carboxyl group into the benzene ring is very marked

in this series, as benzoxazines without the carboxyl group, or with other groups such as the methyl group, have been reported as being of considerable medicinal value.[7]

Summary

3-(α-Bromopropionylamino)-salicylic acid was synthesized and, from this by treatment with alkali, 2-methyl-8-carboxy-3-keto-3,4-dihydro-1,4-benzoxazine. Both of these substances are new compounds.

Neither 2-methyl-8-carboxy-3-keto-3,4-dihydro-1,4-benzoxazine nor 6-carboxy-3-keto-3,4-dihydro-1,4-benzoxazine exerts either antipyretic or analgesic action in various test animals.

A New Method for the Purification of the Alcoholate of the Trimer of Hydroxypyruvic Aldehyde

BY WILLIAM E. EVANS, JR., C. JELLEFF CARR AND JOHN C. KRANTZ, JR.

Hydroxypyruvic aldehyde is of interest owing to its relationship to the intermediate metabolites of glucose. This compound has been prepared by the oxidation of dihydroxyacetone[1-4] and by the photochemical decomposition of glyoxal.[5] Evans and Waring[1] treated dihydroxyacetone with an excess of cupric acetate and removed the excess of copper by precipitation as sulfide. Friedemann[2] employed the same method but did not separate the compound from solution. This process was objectionable on account of the formation of sulfur derivatives of hydroxymethyl glyoxal which are toxic. Küchlin and Böeseken[3] decomposed the sulfur compounds with an excess of silver acetate at 30° and subsequently removed the excess of silver as chloride. Hynd[4] found that the use of silver acetate caused the formation of a highly polymerized product. He avoided the use of hydrogen sulfide by precipitating the excess copper with barium hydroxide. The barium was then removed as sulfate. Norrish and Griffiths[5] prepared small amounts of glycerosone by the photochemical decomposition of glyoxal and isolated it as the trimer combined with one molecule of alcohol.

Experimental

Preparation of Hydroxypyruvic Aldehyde.—One mol of dihydroxyacetone was dissolved in 10 mols of water and treated at room temperature with 2.25 mols of finely divided crystallized cupric acetate. The mixture was shaken frequently in order to keep the solution saturated with copper acetate. The reaction was allowed to proceed until the calculated amount of cuprous oxide was precipitated. The usual period of time necessary was five to seven days. At this time a grayish-colored precipitate of cupric oxalate began to appear. The excess of Cu^{++} was then precipitated carefully by the addition of a calculated amount of a 10% solution of oxalic acid. After filtering the solution was reduced to a small volume by distilling at 17 mm. at 35°. Successive portions of alcohol were added and the product was reduced to dryness at 17 mm. The residue was then dissolved repeatedly in small amounts of absolute alcohol and precipitated by the addition of ether. The ether–alcohol solutions were worked up later, using the same procedure, to recover some of the product. Substances which were insoluble in water and in absolute alcohol were removed and the product was dried *in vacuo* at 70°. The yield of the product was 87%. After purification for biological use the yield was 64%. The product gave a negative test for Cu^{++} or oxalate. It was obtained as a pale yellow amorphous solid which melted between 155 and 160°. A 1% aqueous solution exhibited a *p*H of 3.12 at 25°. It reduced Fehling's solution and mercuric chloride solution rapidly in the cold. No immediate reaction was obtained when Schiff's reagent was added to the freshly prepared solution but the characteristic color appeared within several minutes.

Anal. Calcd. for $(C_3H_4O_3)_3 \cdot C_2H_5OH$: C, 42.47; H, 5.85; mol. wt., 310. Found: C, 42.57; H, 5.42; mol. wt., 306.

This is in agreement with the results obtained by Norrish and Griffiths.[5]

On account of the ease of depolymerization, molecular weight determinations had to be made with the greatest possible rapidity.

The aqueous solution was depolymerized by long standing or by heating for ten minutes in a water-bath at 60–70°.

Mol. wt. Calcd. for $3C_3H_4O_3 + 1C_2H_5OH$: 77.6. Calcd. for $2C_3H_4O_3 + C_3H_4O_3 \cdot C_2H_5OH$: 103. Found 99.3. These mol. wts. confirm those of Norrish and Griffiths.[5]

Quinoxaline derivative: m. p. 250–251°; reported[5] m. p. 165°.

Phenylglycerosazone: m. p. 132°; reported[1,5] m. p. 132°. Hydroxymethylglyoxime: m. p. 134–135°. Reported[5] m. p. 168°.

Anal. Calcd. for $C_3H_6O_3N_2$: N, 23.7. Found: N, 23.4.

An aqueous solution of the dioxime gave a red color with cobalt acetate in the presence of sodium acetate. On careful addition of dilute sodium hydroxide to this solution a green base was precipitated.

Summary

1. The alcoholate of the trimer of hydroxypyruvic aldehyde was prepared free from sulfur derivatives.

2. The quinoxaline derivative, phenylosazone, and dioxime were prepared.

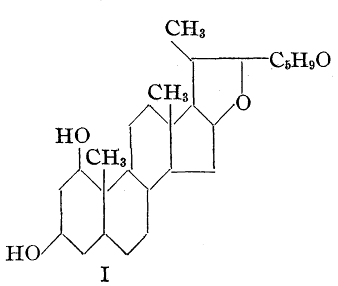
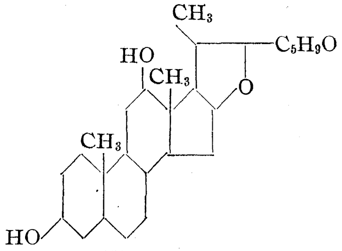
Saponins and Sapogenins. VI. Surface Films of Chlorogenin and Derivatives

BY C. R. NOLLER



I



II

In the last paper of this series[1] the tentative formulas, I and II, based on chemical evidence, were proposed for chlorogenin. Formula II was favored because the ketodibasic acid obtained on oxidation did not appear to be either an α- or a β-keto acid as would be required by formula I. The second hydroxyl group was assigned to position 12, since the diketone forms a dioxime which would not be expected if the hydroxyl group is at position 11.

Recent work on the surface films of structurally related compounds[2] indicates that those molecules having one or two hydroxyl groups in the end-ring give incompressible films in which the molecules stand on end and occupy an area that is predicted by models of the compounds. Cholestanol-6 and $\Delta^{4,5}$-cholestenol-7 (ψ-cholesterol) having hydroxyl groups in the second ring give highly compressible films indicating that the molecules are tilted or lying flat at low pressures.[3] Hence it was expected that if formula II is a possibility for chlorogenin, the molecules in surface films would lie flat at low pressures and give a highly compressible film. The data plotted in curve I show that this is actually the case. The molecules occupy at low pressures an even larger area than ψ-cholesterol, the film being gaseous at very low pressures. At higher pressures the curve appears as if it will coincide with that for gitogenin

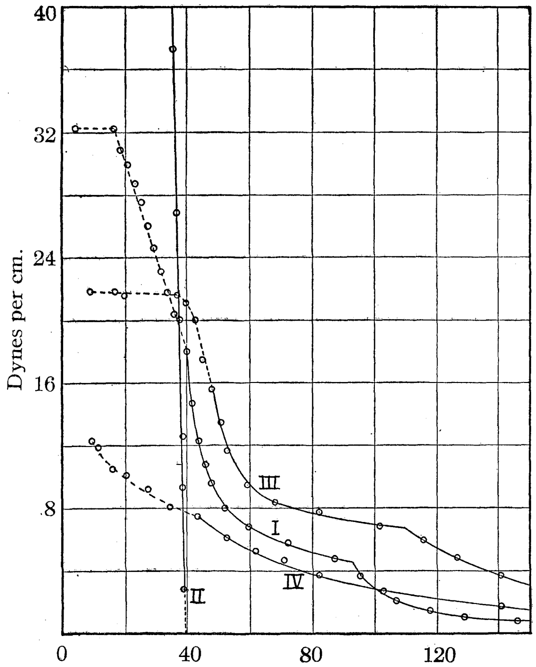


Fig. 1.—Pressure-area curves for surface films of: I, chlorogenin; II, gitogenin; III, chlorogenin diacetate; IV, diketone from chlorogenin.

but contraction begins at a pressure of about 15 dynes per centimeter and at higher pressures the film collapses. However, it remains mobile as shown by dusting with talc, even at 32 dynes per centimeter.

The data for gitogenin (curve II) were obtained using a sample kindly supplied to us several years ago by Dr. W. A. Jacobs of the Rockefeller Institute for Medical Research. The value of 39.5 Å. for the area per molecule at zero pressure is identical with that obtained previously[2] and served to check our technique and procedure. Evidently under pressure the molecules of chlorogenin can be made to stand on end and occupy an area very close to that occupied by gitogenin, thus furnishing additional evidence for the close relationship in the structure of these two compounds.

Chlorogenin diacetate gives a curve, III, which is very similar to that for chlorogenin except that the lower attraction of the acetate groups for water is manifest in the greater tendency to remain in the gaseous state and the greater instability of the close packed film. The diketone obtained by the oxidation of chlorogenin (curve IV) shows no tendency to form a close packed film but collapses at pressures of about 6 dynes per centimeter.

Experimental

The surface pressures were measured on a Cenco Hydrophil Balance by the general procedure developed by Adam and his co-workers.[3] The solvent used was a mixture of eight parts by volume of purified cyclohexane and two parts of purified dioxane. From 0.01 to 0.02 g. of compound was weighed accurately into a tared glass-stoppered 25-cc. Erlenmeyer flask and dissolved in 10–20 cc. of solvent with warming if necessary. After cooling to room temperature the flask was stoppered and the weight of solvent determined.

For placing the solution on the surface a 1-cc. ground-glass syringe was used, whose tip was drawn out and ground so that small drops would form and leave the pipet without wetting the outer surface of the tip. The tip was fitted with a small cap by means of a ground joint to prevent evaporation during the weighing of the syringe. The space between plunger and barrel of the syringe was sealed by a narrow band of glycerol.

All films were spread on 0.02 *N* hydrochloric acid. The films were not examined for collapse with a dark ground illuminator[3] but the phenomenon of contraction was observed shortly before collapse was obvious.

Summary

Measurements on surface films of chlorogenin, chlorogenin diacetate and the diketo derivative are in agreement with the view that the two hydroxyl groups are in different rings in the molecule. They also confirm the close relationship in structure previously assumed to exist between chlorogenin and gitogenin.

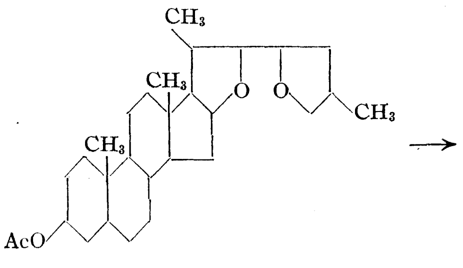
Saponins and Sapogenins. VII. The Structure of the Side Chain of Chlorogenin

By F. M. McMillan and C. R. Noller

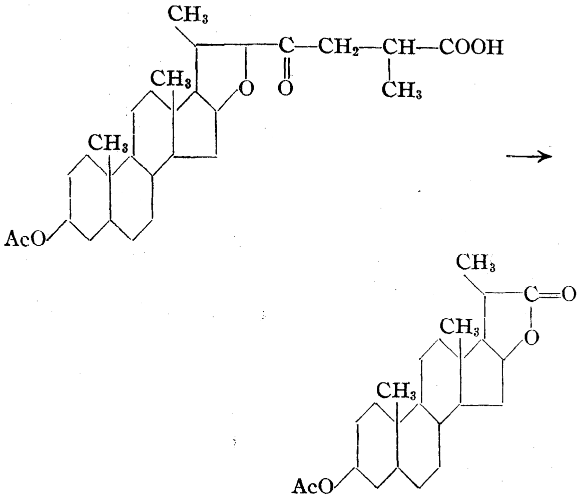
In previous chemical investigations on the structure of chlorogenin,[1] it has been assumed that the two unreactive oxygen atoms of chlorogenin are in a side chain whose structure is similar to that of the isomeric compound gitogenin and of other steroid sapogenins. This side chain is generally believed to consist of two tetrahydrofuran rings, the chief chemical evidence being the oxidation of tigogenin acetate[2] to an acid and a lactone as formulated in the equation



---

[1] Noller, This Journal, **59**, 1092 (1937); **60**, 1629 (1938).

[2] Tschesche and Hagedorn, *Ber.*, **68**, 1412, 2247 (1935).



Since the present work was completed, Fieser and Jacobsen[3] have reported the isolation of an acid from sarsasapogenin which they have named sarsasapogenoic acid and which is analogous to the acid obtained by Tschesche and Hagedorn from tigogenin. The acetate of the C_{22}-lactone from sarsasapogenin was first reported by Farmer and Kon.[4]

Oxidation of chlorogenin diacetate gives the diacetate of a C_{27}-acid which, in conformity with the nomenclature of Fieser and Jacobsen, we shall call chlorogenoic acid. Conditions have been worked out for obtaining directly the diacetate of the acid in good yields and little difficulty was encountered in its purification. In the case of sarsasapogenin Fieser and Jacobsen found it necessary to saponify the crude acetate and purify the dihydroxy acid. The tigogenoic acid of Tschesche and Hagedorn was likewise isolated after saponification. In both cases removal of the acetyl groups apparently takes place on extracting the acid with aqueous alkali. It is of interest to note the narrow range of temperature in which it is possible to get good yields of chlorogenoic acid diacetate. At 25° chlorogenin diacetate is not attacked whereas at 40° only difficultly crystallizable gums are formed.

Chlorogenoic acid diacetate crystallizes with a molecule of water of crystallization which at first led us to believe that a hydroxy acid was formed in the oxidation. This has been shown definitely to be not the case. Like tigogenoic acid and sarsasapogenoic acid, chlorogenoic acid diacetate does not form a semicarbazone under the usual conditions. We have not tried as yet the more drastic treatment with hydroxylamine by which Fieser and Jacobsen converted sarsasapogenoic acid into the compound $C_{27}H_{44}O_5N_2$.

Under the optimum conditions for preparing chlorogenoic acid diacetate, no neutral oxidation products could be detected. Under more drastic conditions very poor yields were obtained of a compound which has the characteristic properties of a lactone. If this is analogous to the lactones from tigogenin and sarsasapogenin, it should have the empirical formula $C_{26}H_{38}O_6$. Our analyses indicate the formula $C_{27}H_{44}O_7$. Similarly the saponified lactone should have the formula $C_{22}H_{34}O_4$, whereas our analyses indicate $C_{23}H_{40}O_5$. The best explanation seems to be that both of these compounds contain methyl alcohol of crystallization which would lead to the formulas $C_{27}H_{42}O_7$ and $C_{23}H_{38}O_5$, respectively.

Numerous attempts were made to obtain oxidation products intermediate between chlorogenoic acid diacetate and the lactone diacetate, most of which were unsuccessful. In several of the oxidations starting with chlorogenoic acid diacetate, minute amounts of an acid were obtained having the empirical formula $C_{27}H_{42}O_6$. This is the same as that for chlorogenoic acid but the compound is definitely different and we have no evidence concerning its structure.

By heating sarsasapogenin or gitogenin with a mixture of glacial acetic acid and concentrated hydrochloric acid, Jacobs and Simpson[5] obtained a liquid ketone which gave a semicarbazone melting at 119.5–120°. Chlorogenin behaves similarly except that the semicarbazone was extremely difficult to purify and the melting point could not be raised above 114–118°. The amount of this material was vanishingly small in spite of the fact that as much as 10 g. of chlorogenin was used in the decomposition.

It is planned to continue these investigations as soon as we can replenish our stock of raw materials.

Experimental

Chlorogenin Diacetate.—To 7 g. of chlorogenin, m. p. 272–276°, were added 38 cc. of 99% acetic anhydride, 4 cc. of glacial acetic acid and 6.5 g. of fused sodium acetate. The mixture was refluxed over a free flame until all of the sodium acetate dissolved and then heated on a steam-bath for two hours. The solution was poured into 400 cc. of water with rapid stirring. The product separated as an oil which soon crystallized. It was filtered, washed with water, dried and crystallized from 40 cc. of methyl alcohol

giving 6.1 g., m. p. 152.5–155°. On recrystallization it melted at 154–155° and a third crystallization did not change the melting point.

Anal.[6] Calcd. for $C_{31}H_{48}O_6$: C, 72.05; H, 9.37; sap. equiv., 258.3. Found: C, 72.14; H, 9.53; sap. equiv., 257.9, 259.3.

Chlorogenoic Acid Diacetate.—A solution of 4 g. of chlorogenin diacetate in 175 cc. of glacial acetic acid was kept at 32–33° in a water-bath while a solution of 5 g. of chromium trioxide in 75 cc. of 90% aqueous acetic acid was added slowly through a motor-driven hollow stirrer in order to ensure rapid mixing. The addition of the reagent required twenty-five minutes and stirring was continued for ten minutes after all the reagent had been added. The solution was poured into water, giving a light-colored gummy precipitate. After standing for several hours the precipitate hardened and was filtered, washed with water and dried. The product, weighing 3.5 g., was dissolved in ether and extracted with three portions of 5% aqueous sodium carbonate and washed with water. The aqueous extracts were counter extracted with ether which was added to the previous ether solution.

Evaporation of the ether solution gave about 0.3 g. of a light-colored glass which after three crystallizations from methyl alcohol gave crystals which were shown by melting point and mixed melting point to be unchanged chlorogenin diacetate.

Acidification of the combined sodium carbonate extracts gave a cream-colored precipitate which was filtered, washed and dried *in vacuo* over potassium hydroxide. It weighed 2.4 g. and melted at 102–106°. It was extremely soluble in all the common organic solvents with the exception of the paraffin hydrocarbons, in which it was only slightly soluble. It crystallized from 70% aqueous acetic acid, 70% aqueous acetone, and from ligroin (100–120°) containing a small amount of absolute ethyl alcohol. After the acid had been purified fairly well from 70% acetone, it could be crystallized readily from 80% aqueous methyl alcohol. It then melted at 114–116° to a viscous glass which gradually gave off bubbles and crystallized on the walls of the melting point tube, after which it melted again at 211–213.5°. This behavior was observed from all aqueous solvents. If, however, the compound was boiled in ligroin (100–120°) and then just sufficient absolute alcohol added to take it into solution, the crystals obtained on cooling melted at 210–211° without first melting at the lower temperature. The same result was obtained by heating at 140° at 20 mm. for five hours. As the analyses show, the acid melting at 114–116° is a monohydrate which goes over above its melting point to the anhydrous acid.

Anal. of hydrate. Calcd. for $C_{31}H_{46}O_8 \cdot H_2O$: C, 65.93; H, 8.57; acetyl, 15.25; OH, 6.00, neut. equiv., 564.7. Found: C, 65.43; H, 8.32; acetyl, 15.30, 14.72; OH (Zerewitinow), 7.03; neut. equiv., 566.3, 563.5, 563.5, 566.9.

Anal. (Anhydrous acid). Calcd. for $C_{31}H_{46}O_8$: C, 68.10; H, 8.49; OH, 3.10; neut. equiv., 546.7. Found: C, 67.87; H, 8.55; OH (Zerewitinow), 3.35; neut. equiv., 548.2.

In order to obtain satisfactory yields of chlorogenoic acid diacetate, the above conditions for the oxidation must be followed closely. If the reaction was carried out at 25° only a trace of acidic material was formed and a large amount of the diacetate was recovered unchanged. When carried out at 40° over a period of one and one-half hours, the acid fraction was a gum which could be recrystallized only with difficulty.

Chlorogenoic acid diacetate does not form a semicarbazone on refluxing for two hours with semicarbazine in 90% ethyl alcohol, nor does it form a triacetate or an unsaturated compound on heating with acetic anhydride.

On heating the hydrate at 140° and 20 mm. for two hours it lost weight equivalent to 3.37% of the original sample as compared with the calculated amount of 3.18% for loss of one molecule of water. The gas evolved on heating at its melting point contained no carbon dioxide and the decrease in volume on washing with ammoniacal cuprous chloride solution corresponded to only 3.5% of the amount calculated for the evolution of one mole of carbon monoxide. No other combustible gases could be detected. The residue after heating was recrystallized and proved to be unchanged chlorogenoic acid diacetate.

On heating the acid with concentrated sulfuric acid, the amount of gas evolved which could be absorbed by ammoniacal cuprous chloride solution corresponded to about 11% of that calculated for the evolution of one mole of carbon monoxide per mole of compound.

Chlorogenoic Acid.—The brown gummy residue remaining after the acetyl determinations on chlorogenoic acid diacetate, partially crystallized on standing. Crystallization from methyl alcohol gave white crystals which shrank from the tube at 161° and melted at 169–170°.

Anal. Calcd. for $C_{27}H_{42}O_6$: C, 70.09; H, 9.16. Found: C, 70.01; H, 9.00.

Methyl Ester of Chlorogenoic Acid Diacetate.—To a solution of 0.50 g. of chlorogenoic acid diacetate in methyl alcohol was added an ether solution of diazomethane until a slight excess was present. The solution was evaporated to a volume of about 4 cc. and filtered hot. On cooling 0.34 g. of methyl ester, m. p. 162.5–163°, crystallized and evaporation of the filtrate from this crop gave 0.15 g., m. p. 159–162°. Recrystallization from methyl alcohol did not raise the melting point above 163°. The same ester was obtained from the acid showing a double melting point as from the dehydrated material.

Anal. Calcd. for $C_{32}H_{48}O_8$: C, 68.54; H, 8.63; OH, none; sap. equiv., 186.9. Found: C, 68.39; H, 8.76; OH (Zerewitinow), 0.71, 0.79; sap. equiv., 187.7, 187.8.

Lactone Diacetate.—When the oxidation of chlorogenin diacetate was carried out under more vigorous conditions than described above, for example, at 40° for one and one-half hours, or 45° for six hours, crystalline chlorogenoic acid diacetate could not be isolated readily but a small amount of a neutral product was obtained from the ether solution after extraction with sodium carbonate. The crude product, m. p. 190–208°, after two crystallizations from methyl alcohol melted at 249–252°, after which there was no further change. The compound did not form an oxime on refluxing with hydroxylamine in methyl alcohol for three and one-half hours.

The compound was insoluble in cold aqueous alkali and

---

(6) All carbon and hydrogen analyses are by Dr. A. Schoeller, Berlin.

a solution in 50% aqueous alcohol absorbed no alkali on titration. A few milligrams of the compound was refluxed for forty-five minutes with 1 *N* ethyl alcoholic potassium hydroxide solution after which the solution was poured into water. No precipitation occurred but acidification with hydrochloric acid precipitated a compound which after solution in 50% alcohol absorbed no alkali on titration. These properties indicate that the neutral product is a lactone diacetate which is saponified by alcoholic alkali to a dihydroxy lactone.

Anal. Calcd. for $C_{26}H_{38}O_6$: C, 69.93; H, 6.58. Calcd. for $C_{26}H_{38}O_6 \cdot CH_3OH$: C, 67.76; H, 8.84. Calcd. for $C_{27}H_{44}O_7$: C, 67.46; H, 9.26. Found: C, 67.85; H, 9.36.

Attempts to determine the equivalent weight of the lactone diacetate by saponifying with an excess of standard alkali and back titrating did not give consistent results due to the hydrolysis of the sodium salt and reformation of the lactone. The **dihydroxy lactone** recovered from these saponifications consisted of needles, m. p. 255–256°.

Anal. Calcd. for $C_{22}H_{34}O_4$: C, 72.88; H, 9.46. Calcd. for $C_{22}H_{34}O_4 \cdot CH_3OH$: C, 70.01; H, 9.71. Calcd. for $C_{23}H_{40}O_5$: C, 69.66; H, 10.17. Found: C, 69.62; H, 10.01.

Oxidation of Chlorogenoic Acid Diacetate.—Of the many attempts made to obtain intermediate oxidation products between the acid and the lactone, the most successful was the oxidation with potassium permanganate. A neutral solution of the sodium salt from 0.1 g. of chlorogenoic acid diacetate was refluxed for thirty minutes with an aqueous solution of 0.038 g. of potassium permanganate. Precipitation of manganese dioxide began almost immediately and the purple color disappeared in a few minutes. After thirty minutes, the solution was filtered and the precipitate washed well with water. Acidification of the filtrate gave a flocculent white precipitate, m. p. 175–190°. After two crystallizations from 70% aqueous acetone and one from acetone it melted at 221–222°. The compound is much more soluble in 70% aqueous acetone than in acetone alone but is precipitated from the 70% acetone on further dilution with water.

Anal. Calcd. for $C_{27}H_{42}O_6$: C, 70.09; H, 9.16; neut. equiv., 462.6. Found: C, 69.81, 70.05; H, 9.23, 8.85; neut. equiv., 484.

The same acid was isolated in small amounts after oxidation of the sodium salt with hydrated manganese dioxide at 65–70° and in one of the chromic oxide oxidations at 40°. In none of the oxidations yielding this acid could the results be duplicated consistently since the acid appears to undergo further oxidation with the formation of oils and gums that could not be crystallized. Chlorogenoic acid diacetate was recovered unchanged after treatment in acetic acid solution with lead tetraacetate.

Cleavage of the Side Chain of Chlorogenin.—A fragrant oil was obtained on treating 10 g. of chlorogenin with acetic acid–hydrochloric acid according to the procedure of Jacobs and Simpson.[5] This was converted into a semicarbazone but extreme difficulty was encountered in attempting to isolate a pure product. Recrystallization from ether–petroleum ether mixtures failed to give a product melting above 100°. A large number of other solvents and solvent mixtures were tried without success. By passing an ether solution of the semicarbazone through a column packed with a mixture of magnesium oxide and Celite, evaporating successive portions of the filtrate separately and rubbing up the solid residues with small amounts of ether, a product was obtained from the middle fractions that melted at 114–118°. This material consisted of tiny microcrystals but was still somewhat gummy and could not be purified further by crystallization. The melting point given by Jacobs and Simpson for the semicarbazone of the ketone from sarsasapogenin and gitogenin is 119.5–120°.

Summary

Oxidative and acid degradation of chlorogenin indicates that the structure of the side chain is very similar to, if not identical with, that of the other steroid sapogenins.

Dielectric Constants of Some Fluorine Compounds

BY RAYMOND M. FUOSS

I. Introduction.—In contrast to the other halogens, the properties of fluorine compounds have been studied comparatively little. Recent technical interest in new refrigerants has, however, made a large number of fluorinated methanes and ethanes available. Below are presented the results of an investigation of the dielectric constants of fifteen fluorine compounds.

II. Materials, Apparatus and Method.—The fluorine compounds were presented to us by the Jackson Laboratory of E. I. du Pont de Nemours and Company, to whom grateful acknowledgment is made.

The bench apparatus consisted of a manifold to which were connected an oil pump, three distilling bulbs with an ascarite tube between the first two, a manometer and a guarded condenser. The ascarite served to remove traces of water or of hydrogen halides which might have been present. The stopcocks were lubricated with a sirup of phosphoric acid and anhydride for the higher boiling compounds; ordinary heavy grease was used for the others. The samples were distilled from the supply cartridges into the first bulb, and then distilled back and forth through the ascarite. After each of the first few condensations, the samples were pumped to remove small amounts of dissolved air. Then the sample was distilled from the first bulb in small portions, and a dielectric constant determination at several pressures was made on each portion. The third bulb was used as a receiver for the initial and final portions, so that the middle fraction could be redistilled to give a check determination. The vapor density of the middle fraction was determined by weighing against a matched counterpoise a bulb (volume 421.3 cc.) filled with the gas at known pressures and temperature.

The measuring condenser was a 100 $\mu\mu$f radio condenser mounted in a vacuum-tight brass case, and insulated from the latter by mica washers. The case was connected to the guard line in the Schering bridge circuit.[1] The leads (high potential and test) to the condenser plates were brought out as tungsten wires through glass insulation fused to fernico tubes which were soldered to the brass case. The condenser case was connected to the manifold by a graded seal between a fernico bushing and the Nonex glass of the manifold. The insulation between the two sets of brass condenser plates was isolantite; the insulation held up very well, but in the course of about six weeks use developed a slightly conducting film. (The original value of tan δ at 60 cycles for the cell was 0.0004; during use, it gradually rose to 0.0014.) The cell was mounted in a wooden box in order to surround it by a dead air space; the cell temperature was determined by means of a thermocouple inserted in a well soldered inside the case.

All measurements were made at 60 cycles and 100 v. across the cell. The temperature varied from about 22 to 30°, depending on room temperature, but the drift in any run was so slow that no appreciable error was introduced due to uncertainty in temperature for a given reading.

The polarization was obtained in several ways from the data, which consisted in a series of pressure and resistance measurements. Since the unknown arm of the bridge was substantially loss free, we have

$$C_x = SR_4/R_3 \tag{1}$$

where C_x is the unknown capacity, S is a 100 $\mu\mu$f standard capacity and R_4 and R_3 are the other two components of the bridge network. But the dielectric constant ϵ' is given by

$$\epsilon' = C_x/C_0 \tag{2}$$

where C_0 is the capacity of the evacuated condenser. In turn

$$C_0 = SR_4^0/R_3^0 \tag{3}$$

In the measurements, R_3 was kept fixed for all readings on a given compound, so that R_3 and S dropped out of the final result

$$\epsilon' = R_4/R_4^0 \tag{4}$$

R_3 was selected to make R_4^0 just above 10,000 ohms, so the bridge was made direct reading in dielectric constant

$$\epsilon' = 1 + 10^{-4}\Delta R_4 \tag{5}$$

where ΔR_4 was the difference between R_4^0 for the evacuated cell and R_4 for the cell filled with gas at pressure p. R_4 could be determined to $\pm 0.2\ \Omega$ which gives an accuracy of about ±0.002% in ϵ'. The polarization P was calculated by the Clausius-Mosotti formula

$$P = \frac{\epsilon' - 1}{\epsilon' + 2}\frac{M}{\rho} \tag{6}$$

where M is the molecular weight and ρ is the density, for the temperature and pressure at which ϵ' was determined. As a check on the consistency of the results $(\epsilon' - 1)/p$ was plotted against p, and P was calculated, using the ideal gas density[2] as follows

$$P = 2.097 \times 10^4\, T \lim_{p \to 0} \left(\frac{\epsilon' - 1}{p_{\text{mm.}}}\right) \tag{7}$$

Finally, a value of P was calculated from the low pressure data (where the deviations from ideal behavior were small) by the formula

$$P = 2.079\, T\,(\Delta R_4/\Delta p) \tag{8}$$

All pressures were corrected to 0° by the formula

$$p_0 = p\,(1 - 0.000175t) \tag{9}$$

Values of P calculated by (6), (7) and (8) for a given compound usually agreed within several per cent. or better. Lack of agreement was an indication of impurities in the sample, because (6) contains the actual density of the sample while (7) and (8) contain only the ideal gas density.

III. Results.—An abstract of the experimental results is given in Table I. The pressures have been corrected to millimeters at 0° and rounded off to three places. In order to make the tables more compact, the dielectric deviation δ is given in place of the dielectric constant ϵ'; the two are related by the equation

$$\epsilon' = 1 + 10^{-3}\,\delta \tag{10}$$

In Fig. 1 are given some examples of $\epsilon' - p$ curves, which illustrate the method of determining polarization by means of (8). It should be pointed out that the scattering of the points from the straight lines of Fig. 1 is a direct measure of the reproducibility of the Schering bridge readings; one unit in the δ-scale corresponds to 10 Ω in R_4. The absolute values of ϵ' are consistent to about ±0.002%, *i. e.*, several units in the fifth place.

Figure 2 illustrates the evaluation of polarization by means of the extrapolation of $(\epsilon' - 1)/p$ to zero pressure. As is well known, the limiting value of $(\epsilon' - 1)/p$ permits P to be calculated using ideal gas densities. It was, however, considered desirable in this work to make direct de-

terminations of the vapor densities, in order to check the purity of the samples. The results of the vapor density determinations are given in Table II. The first column gives the formula of the compound, the next two the pressure and temperature corresponding to the density (in mg./cc.) in the fourth column, and the fifth column gives the ratio of the apparent molecular weight to that calculated from the chemical formula. Gases of the type discussed here should give positive deviations up to several per cent.

TABLE II

VAPOR DENSITIES AND POLARIZATIONS OF FLUORINE COMPOUNDS

from ideal behavior. The sixth column gives the temperature at which the polarization was calculated; the polarization is given in the last column. The figure given is an average, based on the direct determinations and on the extrapolated values.

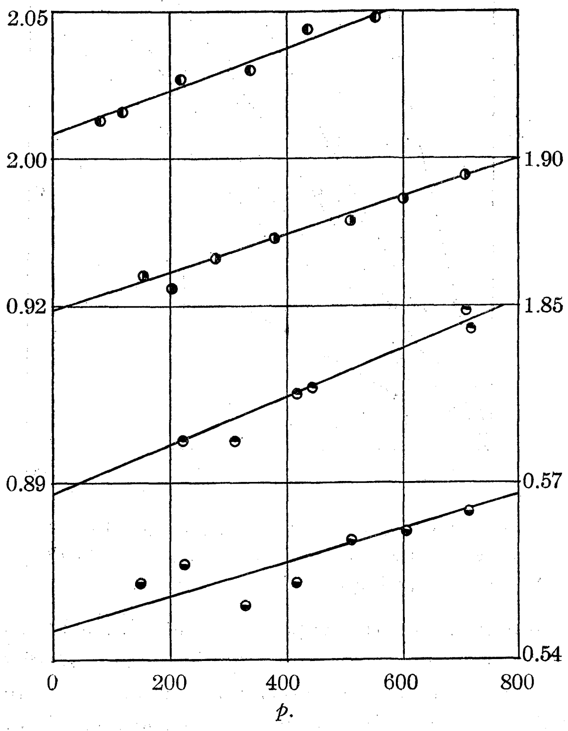

Fig. 2.—Variation of $(\epsilon' - 1)/p$ with pressure: ◐, CH_3CF_3; ◑, CH_3CClF_2; ◓, $CHFCl_2$; ◒, $C_2Cl_2F_4$.

IV. Discussion.—We begin by comparing the results of Table II with previously observed values for the cases where they are available. For SF_6, Watson, Rao and Ramaswany[3] find P_{25° = 16.51 cc. and for CF_4, Watson, Kane and Ramaswany[4] find P_{25° = 10.15 cc.

Four of the fluorinated chloromethanes have been studied by Smyth and McAlpine[5] at a series of temperatures, which permitted a direct determination of P_M, the part of the polarization due to orientation of permanent dipoles. Since the total polarization P is given by

$$P = P_E + P_A + P_M \tag{11}$$

we can calculate values of the moments from the data of Table II by using Smyth's values for P_A, the atomic polarization, together with calculated values for P_E, the electronic polarization. For the latter, the following values of atomic refractivities, extrapolated to infinite wave length by the Cauchy formula,[6] were used: C = 2.37, H = 1.07, Cl = 5.80, Br = 8.53, F = 1.00. The first four figures are conventionally accepted; for fluorine, whose atomic refraction varies with the compound containing it,[7] an average value was chosen which was derived from compounds of the type studied here.[4,7–10] An average value for P_A = 4.0 cc. was used for the fluoromethanes; Smyth and McAlpine's value 0.9 for $CHFCl_2$ seems low compared to the values they find for the other three compounds and to Watson's value of 2.86 for CF_4. We obtain the results given in Table III, where the moments are given in Debye units.

TABLE III

DIPOLE MOMENTS OF FLUOROMETHANES

Compound	(R. M. F.)	(S. and McA.)
CF_4	0.0	—
CF_3Cl	.47	—
CF_2Cl_2	.55	0.51
$CFCl_3$	.53	.45
CHF_2Cl	1.41	1.40
$CHFCl_2$	1.34	1.29
CHF_2Br	1.30	—
CF_2Br_2	0.72	—

It will be seen that the agreement is within the experimental error of the writer's method; the method of Smyth and McAlpine gives one more significant figure in the dielectric constant.

We can compare the result for CF_3Cl with that for the other fluorochloromethanes by the method of vector addition used by Smyth and McAlpine. Using their notation, in which the symbol for a radical or molecule in parentheses denotes its dipole moment corrected for induction,[11] we have

$$\begin{aligned}(CF_3Cl) &= 3(C - F)\cos 70^\circ - (CCl)\\ &= (CF) - (CCl) = 0.47 \text{ (obsd.)}\\ (CFCl_3) &= (CF) - 3(CCl)\cos 70^\circ\\ &= (CF) - (CCl) = 0.53 \text{ (obsd.)}\\ &= 0.45 \text{ (Smyth and McAlpine)}\end{aligned}$$

The moments of the last two compounds in Table III give a value for the difference (CCl) − (CBr). We shall assume an atomic polarization of 11.0 cc. for the bromo compounds; this value was chosen after considering the few data available on atomic polarization of bromoalkanes.

$$\begin{aligned}(CHF_2Br) &= (CH) + {}^1/_3(2CF + CBr) = 1.30\\ (CHF_2Cl) &= (CH) + {}^1/_3(2CF + CCl) = 1.41\end{aligned}$$

---

whence (CCl) − (CBr) = 0.33, and

$$(\mathrm{CF_2Br_2}) = (\mathrm{CF}) - {}^1/_3(\mathrm{CF} + 2\mathrm{CBr}) = 0.72$$
$$(\mathrm{CF_2Cl_2}) = (\mathrm{CF}) - {}^1/_3(\mathrm{CF} + 2\mathrm{CCl}) = 0.55$$

whence (CCl) − (CBr) = 0.26. When compared with Morgan and Lowry's[12] value for methyl bromide, it appears that the results for both the bromo compounds are high by about the same amount, as is shown by the following calculation

$$(\mathrm{CHF_2Br}) = (\mathrm{CH}) + {}^1/_3(2\mathrm{CF} + \mathrm{CBr}) = 1.30\ (\text{obsd.})$$
$$(\mathrm{CF_2Br_2}) = (\mathrm{CBr}) - {}^1/_3(2\mathrm{CF} + \mathrm{CBr}) = 0.72\ (\text{obsd.})$$
$$(\mathrm{CH}) + (\mathrm{CBr}) = 2.02$$
$$(\mathrm{CH_3Br}) = (\mathrm{CH}) + (\mathrm{CBr}) = 1.45\ (\text{Morgan})$$

The agreement could, of course, be improved by assigning a larger value to P_A for CF_2Br_2, which would also improve the agreement between the two determinations of the (CCl) − (CBr) difference. However, the available samples of these two compounds were quite small and did not permit a careful fractionation; judging from the vapor density, the CHF_2Br contained an impurity of low molecular weight. The value 11.0 cc. used above for P_A already seems large. If a smaller value is chosen, the following values are obtained: with $P_A = 4.0$ cc. $\mu(CHF_2Br) = 1.43$ and $\mu(CF_2Br_2) = 0.93$, which gives (CH) + (CBr) = 2.36, a value which seems entirely too large. Until data on the temperature coefficients of the polarizations of more bromo compounds are available, the value of their atomic polarizations will have to remain an open question.

The fluoroethanes present an interesting group. Two of them, CF_3CF_3 and $CClF_2CClF_2$, should be non-polar; this fact gives $P_A = 6.5$ for C_2F_6 and $P_A = 14.2$ for $C_2Cl_2F_4$. If we use $P_A = 6.5$ for CH_3CF_3 and CH_3CClF_2, we obtain $\mu(CH_3CF_3) = 2.27$ and $\mu(CH_3CClF_2) = 2.13$. We can compare these figures with the results for the methanes as follows

$$(\mathrm{CH_3CF_3}) = (\mathrm{CH_3C}) + 3(\mathrm{CF})\cos 70° = 2.27$$
$$(\mathrm{CH_3CF_2Cl}) = (\mathrm{CH_3C}) + {}^1/_3(2\mathrm{CF} + \mathrm{CCl}) = 2.13$$

whence (CF) − (CCl) = 0.42, in agreement with the earlier figures. For CF_3CF_2Cl, we have $(P - P_E) = 13.2$, which is smaller than the corresponding figure for the non-polar $C_2F_4Cl_2$. But within the experimental error, we can set $P_A = 12.8$ for CF_3CF_2Cl, which gives it a moment of 0.14, in agreement with the other moments

$$(\mathrm{CH_3CF_3}) - (\mathrm{CH_3CClF_2}) = 0.14$$
$$(\mathrm{CF_3CClF_2}) = 0.14$$

We could, in analogy with 1,1,2,2-tetrachloroethane, for which $\mu = 1.6$,[13] assume that $C_2Cl_2F_4$ had a finite moment, in which case the atomic polarizations for the fluorinated ethanes would be reduced from the values assumed here, and all moments would be correspondingly increased.

Finally, the compound $C_2H_2FCl_3$ will be considered. It was prepared by fluorination of $CHCl_2CHCl_2$ and one naturally would expect it to be $CHFClCHF_2$. However, the dipole moment agrees more closely with the structure CF_3CH_2Cl. If we use $P_E = 15.7$ and $P_A = 12.8$, we find $\mu(C_2H_2F_3Cl) = 1.64$. Then we have

$$(\mathrm{CF_3CH_2Cl}) = (\mathrm{CF_3C}) + {}^1/_3(2\mathrm{CH} - \mathrm{CCl}) = 1.64$$
$$(\mathrm{CF_3CH_3}) = (\mathrm{CF_3C}) + 3(\mathrm{CH})\cos 70° = 2.27$$

whence (CH) + (CCl) = 1.89, which agrees very closely with the value 1.85 used by Smyth and McAlpine for methyl chloride. The other isomer, CF_2ClCH_2F, gives (CH) + (CF) = 1.47, compared to the accepted value 1.81. The vapor density of the sample indicates a small amount of an impurity of higher molecular weight, but it hardly seems possible that the presence of an impurity could raise the moment from 0.1–0.2 expected for $CHFClCHF_2$ to the value observed. The only explanation which can be advanced on the basis of the present evidence is that rearrangement took place during fluorination.

Summary

The total polarization of a series of fluorine compounds has been determined by Schering bridge measurements on the gases. By making reasonable assumptions concerning the electronic and atomic polarizations, values for their dipole moments were obtained as follows: CF_4, 0.0; CF_3Cl, 0.47; CF_2Cl_2, 0.55; $CFCl_3$, 0.53; CHF_2Cl, 1.41; $CHFCl_2$, 1.34; CHF_2Br, 1.30; CF_2Br_2, 0.72; CF_3CF_3, 0.0; $CClF_2CClF_2$, 0.0; CH_3CF_3, 2.27; CH_3CClF_2, 2.13; CF_3CF_2Cl, 0.14; CF_3CH_2Cl, 1.64. These figures are in agreement with the theory of induction between dipole moments.

The Activity and Osmotic Coefficients of Trivalent Metal Chlorides in Aqueous Solution from Vapor Pressure Measurements at 25°

BY CHARLES M. MASON

In a previous communication[1] it was shown how the isotonic or isopiestic method of Robinson and Sinclair[2] could be adapted to the measurement of the vapor pressures of the aqueous solutions of the three-one electrolyte, lanthanum chloride. In the present investigation, with revised technique, this method has been extended to the determination of the vapor pressures of six more three-one electrolytes: namely, aluminum chloride, scandium chloride, yttrium chloride, cerous chloride, praseodymium chloride, and neodymium chloride. In the present work the previous data for lanthanum chloride were extended to higher concentrations and more accurate data obtained in the concentration range below 0.4 molal. All the data obtained in each case have been used to compute the osmotic and activity coefficients for the corresponding salt.

Experimental Details

Apparatus.—The apparatus employed was modified from that described by Mason and Gardner.[3] The brass desiccator used was supplemented by an additional one cast of monel metal. This metal was found to be freer of pinholes and easier to make vacuum tight. For this investigation the metal tee tube formerly used was replaced by a brass needle valve to which was soldered the female half of a brass union. The male half of the union was connected by rubber tubing to the vacuum line. Another male half of the union, interchangeable with the first, was soldered shut and served to keep water out of the needle valve during immersion in the thermostat. A diagram of the metal desiccator as used is shown in Fig. 1.

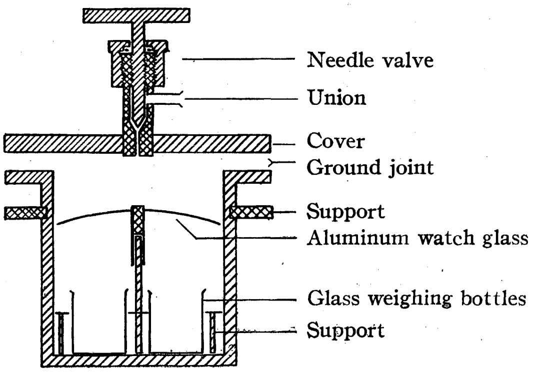

Fig. 1.—Metal desiccator.

With the more concentrated solutions it was found possible to obtain reproducible results using 30-cc. glass-stoppered weighing bottles in the apparatus. The solutions under investigation were weighed in these bottles. In order to ensure more rapid thermal and distillation equilibrium, platinum gauze was placed in the solutions in the glass bottles. This was done in the form of strips of gauze 1 cm. wide by 10 cm. long folded like a bellows and placed edgewise to stand up in the bottom of the weighing bottles. The strips were then about half in and half out of the solution, providing additional surface as well as thermal conduction. The platinum gauze was found to decrease by more than half the minimum time needed to obtain equilibrium. In order to prevent grease and other films from interfering with the wetting of the platinum they were ignited in the Meker burner before each run.

The glass bottles in the desiccator were immersed to a depth of about 0.3 cm. in potassium chloride or sodium chloride solution of the same concentration as that used in the reference bottles. They were held in place by a brass frame which kept them from tipping over and at the same time served as a shield to prevent any of the solution in the bottom from splashing into the bottles themselves. Attached to the frame above the bottles was a watch glass shaped disk of aluminum which acted as a shield to keep any spray from getting into the bottles when air was admitted at the end of a run.

Below 0.5 molal the accuracy obtained with glass bottles decreased rapidly with decreasing concentration. The glass bottles were therefore replaced in this range by similar bottles made of sterling silver and heavily gold plated. Stainless steel was tried but was found not to withstand corrosion. The design of the silver containers is shown in Fig. 2. They were made to fit tightly into recesses in a heavy copper block. A good thermal contact was secured by pressing them firmly against the bottom of the recess with a bakelite collar (to prevent wear) which was in turn forced down by a brass collar screwed into the top of the recess. It was found that equilibrium could be obtained without a contacting solution and so none was used. The air was removed from under the bottles and from under the copper block by putting a drop of water under each silver bottle and several drops under the block in the bottom of the desiccator. This evaporated when the desiccator was evacuated and swept the air out ahead

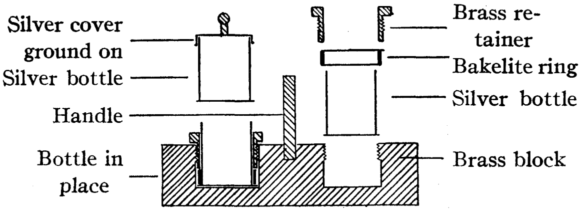

Fig. 2.—Brass block with silver bottles.

of it. No water was ever found in these places when a run was completed. In all cases the desiccator was evacuated slowly to prevent boiling and splashing, allowed to stand for one hour or more, and then reëvacuated to remove the last traces of air.

The concentration of the solution in all of the bottles was determined in the usual manner, namely, by weighing. Care was taken to wipe the bottles with a damp cloth before each weighing and thus the weights could always be reproduced within the error of the balance.

All measurements were carried out in a water thermostat at 25 ± 0.01°. The temperature was determined by thermometers checked against thermometers calibrated by the Bureau of Standards. The thermostat was equipped with a shaking device to rock the metal desiccators back and forth, about forty-five times a minute, thereby keeping the solutions in constant agitation.

Materials. (a) **Aluminum Chloride.**—The best commercial grade of hydrated aluminum chloride was dissolved in water, filtered, and recrystallized four times by shaking out of solution with hydrogen chloride gas at 0°. The hydrated salt so obtained was carefully dried in a current of warm air at 50–70° and then ground in an agate mortar to pass 20 mesh. This material was then placed for several weeks over potassium hydroxide in a vacuum desiccator to remove the last traces of hydrogen chloride. The product was analyzed gravimetrically for chloride ion by the usual methods and for the aluminum present by the method of Willard and Tang.[4] The results of the analysis indicated a purity better than 99.97%.

(b) **Cerous Chloride.**—The cerous chloride used had been prepared from a very pure sample of cerium oxalate by the method of Hönigschmid and Holch[5] and was found to be of high purity by spectroscopic analysis. The salt was recrystallized three times by shaking out of solution with hydrogen chloride gas at 0°. A pure white product was obtained entirely free from any trace of ceric cerium. This product was then purified as follows: The hydrated salt was dried in a current of warm air at 50–70° until all traces of hydrogen chloride appeared to be removed. The dried salt was then dissolved in a minimum amount of conductivity water, a few drops of concentrated hydrochloric acid added to prevent hydrolysis, and evaporated to a thick sirup on the steam-bath. This sirup was chilled to 0°, seeded if possible, and stirred vigorously with a motor stirrer. This action produced a mass of very fine crystals which were easily filtered onto a fritted glass plate, sucked free of mother liquor, and air-dried as before. The final drying was accomplished in a vacuum desiccator.

(c) **Hydrochloric Acid.**—All the hydrochloric acid used was obtained by distilling the best commercial grade of arsenic-free acid in an all-glass still and discarding the first and third portions.

(d) **Lanthanum Chloride.**—The lanthanum material had been prepared carefully by repeated crystallization as the oxalate and the hydroxide. The chloride was prepared by ignition of the oxalate to the oxide in an electric muffle furnace and solution of this oxide in hydrochloric acid. After filtering, the solution was evaporated and the chloride shaken out at 0° with hydrogen chloride. The product was purified by the same procedure as for cerous chloride.

(e) **Neodymium Chloride.**—This was prepared in a manner similar to that for cerous and lanthanum chloride.

(f) **Potassium and Sodium Chlorides.**—These salts were the best commercial material twice recrystallized from water and dried for twenty-four hours in an electric oven at 120°.

(g) **Praseodymium Chloride.**—Praseodymium oxalate was obtained from the estate of the late Charles James. It was purified by the method of Brauner[6] to remove cerium and lanthanum. The oxide so obtained was converted to the chloride and purified by the same method as that given for lanthanum and cerous chloride.

(h) **Scandium Chloride.**—Scandium oxalate was converted to the chloride and purified in a manner similar to the lanthanum chloride.

(i) **Yttrium Chloride.**—The yttrium oxalate was ignited to the oxide, dissolved in hydrochloric acid, and reprecipitated as the oxalate five times until all trace of the impurity, sodium, was removed. The chloride was then prepared and purified in a manner similar to that for lanthanum chloride.

Procedure.—In all the experimental work the analysis of the solutions under investigation was obtained from the weight of the bottles containing them. To make the standard reference solutions, enough potassium or sodium chloride, whichever was used, was weighed directly into the bottles to make between 1 and 2 cc. of solution of the concentration desired. The requisite amount of water was then added. Below 0.4 molal the weights of these salts became so small as to introduce weighing errors, and solutions of known concentration were weighed into the bottles instead. These were diluted with the proper amount of water before being placed in the desiccator.

It was not practical to weigh out the hydrated salts directly, so concentrated solutions in conductance water were prepared and carefully analyzed for chloride ion by the gravimetric method. These solutions were weighed directly into the bottles and diluted to the approximate concentration before being placed in the apparatus. All solutions were stored in Pyrex brand glass to prevent introduction of any dissolved material.

In several cases the solutions were also analyzed for rare earth content by precipitation of the oxalate and subsequent ignition to the oxide in the muffle furnace according to the standard procedure. The only divergence in the analyses was for cerium where the method outlined by Moore and Bonardi[7] and modified by Hillebrand and Lundell[8] was employed. In every case the concentration of the solutions checked that obtained from the chloride analysis within the known experimental error.

Density Measurements.—In the theoretical treatment it was necessary to know the concentration in moles per liter, which was calculated from the molality by means of the density. The densities of all these salts in aqueous solution were determined in duplicate at 25° using a 25-g.

Regnault specific gravity bottle. The usual precautions were observed and the results are given in Table IV.

Results and Discussion

In most of the experimental runs three samples of the salt solution were allowed to come to isotonic equilibrium with a like number of the standard reference solution. When the silver bottles were used two samples were in equilibrium with the two samples of standard solutions. In some experiments only two samples of the standard solution were used and these were opposed by two or four different salt solutions as the case might be. Ample time, usually more than forty-eight hours, was allowed in every case for the solutions to reach equilibrium with each other. No experiment was considered satisfactory if the deviation between identical samples was greater than one part per thousand.

Potassium chloride was used as a reference salt up to saturation and sodium chloride was used to extend the range of the three–one electrolytes beyond the concentrations which could be obtained with potassium chloride.

The silver bottles gave good results down to about 0.25 molal but below this concentration, although fair results were obtained down to about 0.06 molal, the results were inclined to be quite erratic and had about ten times the error of the results above 0.25 molal. In general, the results for all the salts are of about the same accuracy. The observed values of φ_2 did not, as a rule, deviate more than one per cent. from a smooth curve such as is shown in Fig. 3. The average deviation was about 0.2% in concentrated solutions and 0.5% in dilute. Scandium chloride was more erratic than the rest and gave larger

deviations. The isotonic data obtained are listed in Table I.

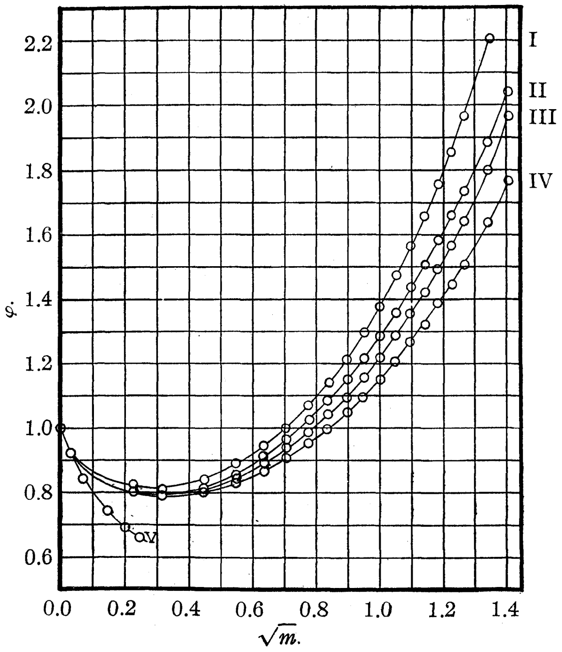

Fig. 3.—Osmotic coefficients of salts: I, $AlCl_3$; II, $ScCl_3$; III, YCl_3; IV, $LaCl_3$; V, φ_0, limiting law.

Table I includes the values of φ_1 and φ_2. The values of φ_1 were taken from those of Scatchard and Wood[9] which were given to me prior to publication by Professor Scatchard. These data represent the best possible evaluation of all the known data for potassium and sodium chlorides. The values of φ_1 in Table I were read from a large-scale plot of the data described above.

φ_2 is defined by the equation

$$\varphi_2 = (55.51/4\ m_2) \ln p_0/p \qquad (1)$$

and φ_1 by the equation

$$\varphi_1 = (55.51/2\ m_1) \ln p_0/p \qquad (2)$$

p_0/p is the same for both salts when at isotonic equilibrium and combining equations (1) and (2) we obtain

$$\varphi_2 = \frac{m_1}{2m_2}\varphi_1 \qquad (3)$$

By means of equation (3) the values of φ_2 in Table I were computed. These values have been smoothed graphically by plotting φ_2 against $m^{1/2}$ on a large scale as shown in Fig. 3. The data which were obtained are listed at round concentrations in Table II.

The activity coefficients have been computed from the osmotic coefficients by a modification of the method of Randall and White[10] using the equation

$$\log \gamma = -\frac{h}{2.303} - \frac{2}{2.303}\int_0^{m^{1/2}} \frac{h}{m^{1/2}}\, dm^{1/2} \qquad (4)$$

From the data of Wyman[11] the intercept on the $h/m^{1/2}$ axis was calculated to be 2.844. When the curve was constructed, as shown in Fig. 4, it was found that a large portion of the area was in the region below 0.25 molal where the data were least

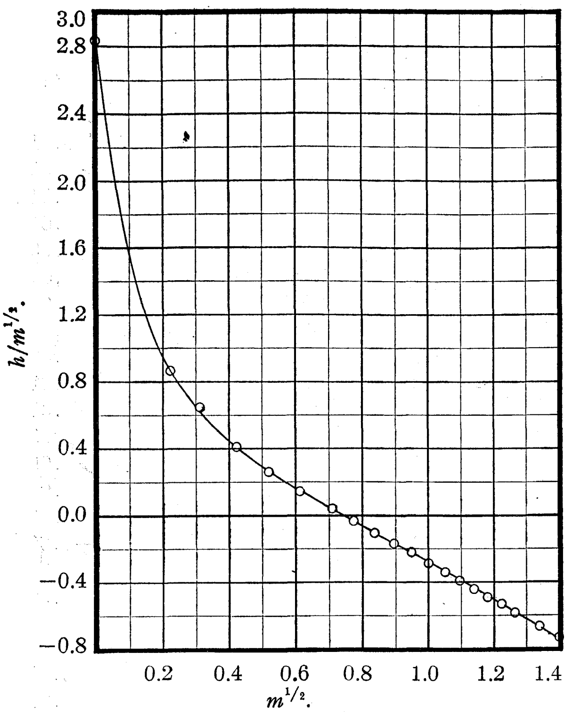

Fig. 4.—Plot of $h/m^{1/2}$ against $m^{1/2}$ for $ScCl_3$ to compute the graphical integration.

accurate and that there was probably a very long error in log γ resulting from this. Furthermore, there was the additional error in drawing this curve that it was impossible to determine how much of a hook or hump should be given to these data in considering their approach to zero concentration. Inasmuch as chlorides are peculiarly sensitive to the formation of complex ions, the area represented by such a hump may be considerable. The following method was adopted to correct this error. Equation (4) was rewritten in the form

$$\log \gamma = -\frac{h}{2.303} - \frac{2}{2.303} Y \qquad (5)$$

where Y represents the correct area under the curve at a given value of m. X was then defined as

$$X = Y + Z \qquad (6)$$

becoming equal to the measured area when Z represents the error introduced.

The right-hand term of equation (5) was then substituted for log γ in the equation of Hückel[12]

$$\log \gamma = -\frac{1.068\sqrt{12c}}{1 + A\sqrt{12c}} + B(12c) - \log(1 + 0.072\,m) \qquad (7)$$

where m is the molality and c is the concentration in moles per liter.

The constants A and B and the correction factor Z were then calculated by substitution of the numerical data for 0.5, 1.0 and 1.5 molal and simultaneous solution of the resulting equations. The numerical values obtained for the correction factors Z were larger than one would expect from an error in the linear extrapolation. This would show that a hook or hump of some sort must exist in the curve shown in Fig. 4 near zero concentration. The values obtained for these quantities are given in Table III.

TABLE III

CONSTANTS IN DEBYE AND HÜCKEL EQUATIONS

Salt	A	B	b	Z
$AlCl_3$	0.32953	0.08623	0.14560	−0.63409
$ScCl_3$	.47040	.06446	.11696	− .41977
YCl_3	.43836	.06186	.11067	− .50656
$LaCl_3$	.44919	.05506	.09413	− .43880
$CeCl_3$	.51556	.05115	.09663	− .45158
$PrCl_3$	.45350	.05485	.09500	− .46729
$NdCl_3$	.50930	.05118	.09771	− .40575

The values obtained for Z were used to calculate the correct areas, Y, in the graphical integrations. These values of Y were then used in equation (5) to compute the activity coefficients given as $\gamma_{\text{corr.}}$ in Table IV. In this same table $\gamma_{\text{obsd.}}$ refers to the values of the activity coefficients obtained directly from the graphical integration of Randall and White.[10] The constants A and B were used in Hückel's equation (7) to compute the values of γ_D recorded in Table IV. In order to compare the corrected activity coefficients with those obtained by equation (7), the values of $\Delta\gamma(\gamma_{\text{corr.}} - \gamma_D)$ have also been included in Table IV and one set for aluminum chloride have been

plotted against the square root of the ionic strength in Fig. 5. This plot in Fig. 5 is characteristic of all seven salts.

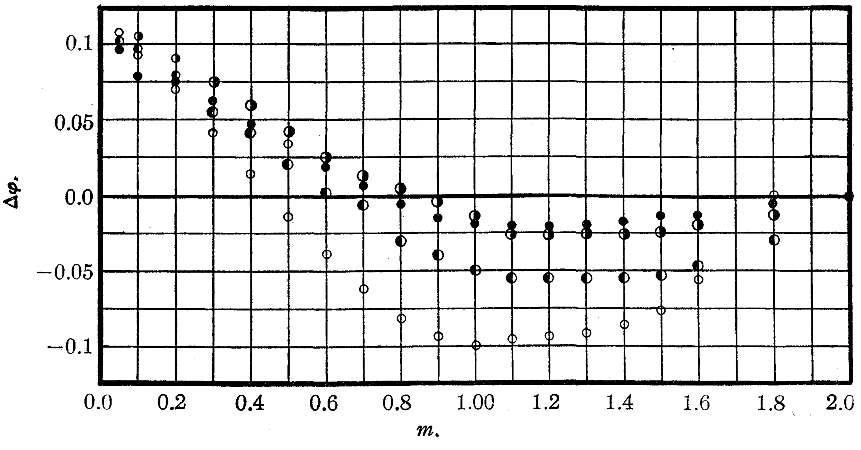

Fig. 6.—Deviations of osmotic coefficients: ○, $AlCl_3$; ●, $ScCl_3$; ◐, YCl_3; ◑, $LaCl_3$.

Examination of the values for $\Delta\gamma$ shows wide divergence in the dilute solutions. This is to be expected and the values for $\gamma_{\text{corr.}}$ are probably too low in this region, because of the increased error in the isotonic measurements at lower concentrations. The values of γ_D fall off above an ionic strength of ten but this is quite readily understood because the linear term in Hückel's equation may not be enough to correct for the variation of the dielectric constant in such concentrated solutions.

The smoothed osmotic coefficients given in Table II have been used to test the equation of Scatchard[13] for osmotic coefficients of salts in concentrated solutions. This equation was used in the form

$$\varphi_D = 1 + \frac{Az_1z_2}{\mu}\left[1 + \sqrt{\mu} - \frac{1}{1 + \sqrt{\mu}} - 2\ln(1 + \sqrt{\mu}\right] + b\mu \quad (8)$$

where μ is the ionic strength and b is the linear constant. The value −1.165 was used for A. b was calculated by fixing $\varphi_D = \varphi_{\text{exptl.}}$ at 2.0 molal and the values so obtained have been included in Table III. The values of φ_D were computed by

(13) Scatchard, *Chem. Rev.*, **19**, 309 (1936).

means of equation (8) and are given in Table IV. The corresponding values of $\Delta\varphi(\varphi_{\text{exptl.}} - \varphi_D)$ have also been calculated and are included in the same table (III). For some of the salts $\Delta\varphi$ has been plotted against m in Fig. 6. Cerium, praseodymium and neodymium chlorides were omitted from the plot because the values of $\Delta\varphi$ for these salts were so close to lanthanum chloride which has been included.

The values of $\Delta\varphi$ representing the deviation from Scatchard's equation are not proportionately large when compared to those given by him for the higher valence sulfates measured by Robinson and Jones.[14] In fact, the actual values of $\Delta\varphi$ found in this investigation are less than those for the sulfates.

I am indebted to Professor Scatchard and Dr. Wood for the use of their data for the osmotic coefficients of potassium and sodium chlorides prior to publication and for several suggestions regarding the use of equation (8). For these courtesies I wish to express thanks.

Summary

1. The osmotic coefficients of aluminum, scandium, yttrium, lanthanum, cerium, praseodymium and neodymium chlorides have been determined in aqueous solution at 25° by the isotonic method of Robinson and Sinclair.[2]

2. The activity coefficients of these salts have been computed from the osmotic coefficients.

3. The data obtained in both 1 and 2 have been compared with theory.

Ternary Systems. XXIV. Calcium Sulfate, Sodium Sulfate and Water

BY ARTHUR E. HILL AND JOHN H. WILLS[1]

Early study of this system by Fritsche[2] disclosed the existence of two double salts, glauberite ($CaSO_4 \cdot Na_2SO_4$) and a salt of the composition $CaSO_4 \cdot 2Na_2SO_4 \cdot 2H_2O$, which has been variously known as syngenite, from a mistaken reading of its composition, and as the labile double salt, from its metastable relationship to other double salts. Isotherms of the system have been studied at 22° by Cameron and Seidell,[3] and at 25° by Cameron and Breazeale,[4] in both cases without inclusion of double salts. Barre[5] compiled the concentrations of isothermally invariant solutions saturated with two salts, glauberite and each of the components of the system and the labile salt with each of the components, giving an outlined polytherm of the system from room temperature to 100°. D'Ans and Schreiner[6] discussed the two double salts and added a point of saturation by glauberite and gypsum at 60°. Van't Hoff[7] determined the invariant points of saturation by each of these double salts with gypsum and mirabilite (Glauber's salt) as 30.2° for the transition involving the labile double salt and 29° for that involving glauberite. The present research contains a repetition of the 25° isotherm and additional isotherms at 35, 50 and 75°, including in addition to the previously known double salts, anhydrite at the higher temperatures and a new double salt, sodium pentacalcium sulfate; these data permit the construction of a fuller polytherm than was previously possible.

In carrying out work in this system in which there occur so many degrees of metastability at any given temperature, much use has been made of van't Hoff's[8] generalization that the retardation of salts in coming to equilibrium with their solutions is related to the mean valence, calculated by dividing the total valence representing all the ions in the formula by the total number of such ions, giving each water molecule in a hydrate an arbitrary mean valence of 4/3; this rule guided us in this research, as in other related researches,[9] in deciding upon appropriate time of contact for

the different salts, for which periods as short as one or two minutes may sometimes not be exceeded without change, while in other cases weeks or months are necessary. The entire list of salts now known in this system, with the mean valence for each, is as follows:

Name	Formula	Mean valence
Mirabilite	$Na_2SO_4 \cdot 10H_2O$	1.33
(Unnamed)	$(Na_2SO_4 \cdot 7H_2O)$	(1.33)
Thenardite	Na_2SO_4	1.33
Labile salt	$2Na_2SO_4 \cdot CaSO_4 \cdot 2H_2O$	1.43
Gypsum	$CaSO_4 \cdot 2H_2O$	1.50
Glauberite	$Na_2SO_4 \cdot CaSO_4$	1.60
Pentasulfate	$Na_2SO_4 \cdot 5CaSO_4 \cdot 3H_2O$	1.64
(Hemihydrate)	$(CaSO_4 \cdot 0.5H_2O)$	(1.71)
Anhydrite	$CaSO_4$	2.00

Of this series, the second and the eighth, sodium sulfate heptahydrate and calcium sulfate hemihydrate, did not appear spontaneously in any of our experiments, and were omitted from consideration; the others have been considered in the appropriate isotherms. Special attention was paid to the labile salt, concerning which a number of points have apparently remained unsettled in the eighty years since its discovery and of course special attention was likewise given to the new pentasalt after it had appeared in one of the isotherms.

The Labile Salt, Sodium Hemicalcium Sulfate.—The composition of this salt as proposed by Fritsche and its condition as metastable with respect to glauberite as held by van't Hoff were disputed by Cameron, Bell and Robinson,[10] who believed the formula to be $2CaSO_4 \cdot 3Na_2SO_4$ (anhydrous) on the basis of indirect determination of composition in a sodium chloride solution, and also believed that their dilatometric experiments showed it to be stable. Experimental answer to this view appears in the four isotherms presented in this paper, which show by solubility curves that the labile salt is metastable with respect to glauberite between 25 and 75°, in accord with van't Hoff's conclusion based upon the transition temperatures. The matter of the composition of the salt was gone into by D'Ans and Schreiner,[6] who were able to obtain samples sufficiently freed from mother liquor, by use of a hydraulic press, to permit analyses, which agreed well with the formula $CaSO_4 \cdot 2Na_2SO_4 \cdot 2H_2O$. It is worth noting that each of the methods which led to the conflicting results is accompanied by unusual difficulties in the case of this salt, which forms from gypsum in sodium sulfate solution in the form of a network of fine spicules so knitted together that a weight of approximately 2% of the salt will hold the mass in suspension so rigidly that there is no movement upon inversion of the vessel. This condition obviously retards the attainment of equilibrium and may leave a considerable portion of gypsum unchanged, which is probably the cause of Cameron, Bell and Robinson's error. This network retains a large proportion of mother liquor even upon centrifuging at 1800 r. p. m., so that a direct analysis such as D'Ans and Schreiner made is not always possible. We are able, however, to confirm their findings, by the use of both methods; algebraic extrapolation of the tie lines for the labile salt in Table I gave (assuming the water content of the salt correct) agreement with the original formula of Fritsche with an average deviation of 0.75% for the six cases there tabulated, with a maximum deviation of 1.30%, in experiments in which the amounts of solid phase were usually less than 1% of the weight of the system. A sample was also prepared by washing out the mother liquor with alcohol–water mixtures, which was found to contain 29.75% $CaSO_4$ (theory 29.83), 61.57% Na_2SO_4 (theory 62.27), and 8.68% H_2O (theory 7.90), in agreement with the formula $CaSO_4 \cdot 2Na_2SO_4 \cdot 2H_2O$.

With respect to the metastability of the salt, our findings are in agreement with those of Barre and of D'Ans and Schreiner that the salt can be held unchanged for long periods of time in contact with its solutions at lower temperatures (25° *e. g.*), and that only at 75° and above does the change toward glauberite begin at once. The action of the salt when treated at 25° with pure water instead of a sodium sulfate solution with which it is in equilibrium (30–34%) is noteworthy; the decomposition cannot be better described than as explosive, both because of the astonishing speed at which the solid disappears, and also because of the unexpected concentration attained. A sample was treated with cold water and immediately filtered from a small residue of calcium sulfate; the solution was analyzed and found to contain 1.01% calcium sulfate. At 25° the solubility of gypsum is 0.208% and that of anhydrite[11] is 0.274%; the solubility of hemihydrate from the curve of Chassevent[12] is about 0.8%, all figures being considerably less than the value found.

This seems to be evidence that the mechanism by which the salt decomposes on treatment with water cannot be a simple change into dissolved sodium sulfate and solid calcium sulfate in one of the three forms noted, since a solution cannot supersaturate itself from a given solid phase; either a fourth solid calcium sulfate is formed (an amorphous body, perhaps, which may be the condition of the oft-quoted "soluble anhydrite") or else the primary change is into dissolved material which only later precipitates. Investigation of this phenomenon of decomposition is being continued.

Microscopic identification of the labile hemisalt is comparatively easy, by two of its properties: first, the unusual slimness of the long needles, which run quite uniformly between 1 and 2 μ in breadth, whatever be the length, and by their refractive index $\gamma = 1.510$ (± 0.003), which is sufficiently different from that of glauberite as given by Larsen[13] ($\gamma = 1.536$) as well as that of the pentasalt given later in this paper. The refractive indices in the other directions could not be determined accurately enough.

Sodium Pentacalcium Sulfate.—The new salt, resembling the pentacalcium sulfates found in the potash series and the ammonia series except as to extent of hydration, was first found at 75° when solutions of about 14% sodium sulfate content were treated with gypsum; in general, it may be prepared easily at temperatures of 60 to 75° in solutions of 10 to 14% sodium sulfate upon addition of gypsum, or more rapidly by introduction of gypsum and glauberite in proportions corresponding to the reaction $4(CaSO_4 \cdot 2H_2O) + CaSO_4 \cdot Na_2SO_4 \longrightarrow 5CaSO_4 \cdot Na_2SO_4 \cdot 3H_2O + 5H_2O$. The reaction is completed in four days or less; if the concentration of the solution is such that the salt is metastable only with respect to anhydrite (see Fig. 4), subsequent change to that solid is very slow and need hardly be taken into consideration, but operation in the concentration where the pentasalt is metastable with respect to glauberite will result in fairly rapid and eventually complete change into that salt. Samples of the pentasalt may be washed free of mother liquor without appreciable decomposition, and are found upon analysis to be in close agreement with the formula given; a sample gave $CaSO_4$ 77.59% (theory 77.63), Na_2SO_4 16.21 (theory 16.20), H_2O 6.20 (theory 6.17). This water content, which was confirmed by a number of analyses giving 6.2% of water or a few tenths higher, corresponds to a trihydrate, whereas the corresponding potassium and ammonium salts have been found by all investigators to be monohydrates.

The salt crystallizes in rather fine needles of an average diameter of about 7 μ, which under the microscope are seen to be prisms (or pinacoid faces) with pyramidal ends. They show oblique extinction; $Z \wedge c$ is 11° (± 2), which is quite close to that found for the corresponding potassium and ammonium salts by Gabriel;[14] the refractive indices found were $\alpha = 1.5557$ (± 0.003), $\gamma = 1.567$ (± 0.003).

Experimental Procedure

The materials used were precipitated gypsum and analyzed anhydrous sodium sulfate. Where salts were expected to form by reaction of these components, they were weighed accurately with weighed quantities of water, to give a known original complex as one of the points to be used in extrapolations for the composition of the solid phases. The materials were rotated in stoppered bottles in thermostats for appropriate times. For analysis, solution was filtered off and a part evaporated to constant weight, first at 100° and finally for a day at 200°; in the remainder of the solution, the calcium was precipitated as oxalate and weighed as oxide. It was found that the precipitated calcium oxalate occluded sodium sulfate in weighable amount, whereas occlusion of potassium sulfate did not occur in our previous work;[9] the most effective method of elimination was found to be the volatilization of the sodium salt from the bottom of the platinum crucible to the lid, which occurred at temperatures reached by a Meker burner or blast lamp, and subsequent volatilization from the lid by heating it in the open; failure to do this would leave the results one per cent. or more too high in calcium.

The 25° Isotherm.—The results at 25° are given in Table I and shown in Fig. 1.

The solubility curve for gypsum passes through a minimum at a concentration of about 1.5% of sodium sulfate, and through a maximum at about 20%. The figures of Cameron and Breazeale[4] are distinctly higher than found by us; the isothermally invariant point for gypsum and mirabilite

shows very little change in the solubility of mirabilite caused by the small amount of calcium sulfate present. It is not easy to explain Cameron and Breazeale's view that the solubility of mirabilite is considerably depressed. We have continued the measurements in the region of supersaturation with respect to mirabilite, which was accomplished by warming the systems above the transition temperature of mirabilite (32.4°) before immersion in the thermostat at 25°. The points on the curve for the labile salt were obtained by allowing the compound to form from gypsum, after seeding with the labile salt; the reaction required one to two weeks for completion, except where excess solid thenardite was present, in which case the change of gypsum to labile salt is quite rapid. Glauberite, however, did not seem to form at all at this temperature; the measurements were made, therefore, by addition of glauberite prepared at higher temperatures; equilibrium was reached in one day. Anhydrite was not included in the work at this temperature, because of the extreme difficulty in obtaining

equilibrium with that salt at low temperatures;[9,11] it is unquestionably metastable with respect to gypsum in water, with a solubility curve which crosses that for gypsum at a high concentration of sodium sulfate. The new pentacalcium sulfate was also omitted, since the isotherms at higher temperatures make it reasonably sure that it is metastable at 25° with respect to all other salts in the system.

The 35° Isotherm.—The isotherm at 35° was chosen to illustrate conditions just above the temperature at which mirabilite has disappeared. The results are shown in Table II and Fig. 2.

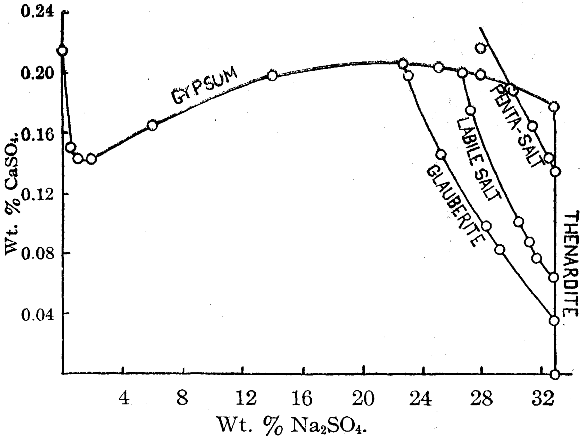

Fig. 2.—$CaSO_4$–Na_2SO_4–H_2O at 35°.

The gypsum curve again shows a maximum and a minimum, as it did at 25°. The salt comes to an equilibrium with its solution within a few minutes, but no need for rapid work resulted, as there was no spontaneous occurrence of double salts in eighteen hours' time up to a concentration of 30% sodium sulfate. In the presence, however, of solid thenardite at the invariant point (32.85%) the formation of labile salt begins immediately and the system becomes constant at the invariant concentration for labile salt and thenardite, the change toward glauberite being suspended. The change of labile salt to glauberite at this temperature is very slow under all conditions of concentration, for which reason some of the points on the glauberite curve were obtained with samples of that salt made at 75°. The labile salt formed from gypsum at 35°, upon seeding, within two to four days, but the extrapolations of the tie-lines fail to agree with the accepted formula by two to three per cent., which may be due either to the presence of unchanged gypsum or to that of glauberite, each of which is higher in calcium sulfate, that being the direction in which the experiments with the labile salt regularly err. Anhydrite was not included in the isotherm. The new pentasalt[15] is found to be metastable with respect to both labile salt and glauberite; the points on its curve were obtained by rotating the salt with sodium sulfate solution until the maximum content of calcium was found by analysis, which point was usually reached between five and twenty-four hours. During this period there was sometimes the appearance of a few glauberite crystals and more frequently formation of the labile salt set in.

The 50° Isotherm.—The isotherm at 50°, which includes a solubility curve for anhydrite in addition to the salts included at lower temperatures, is shown in Table III and Fig. 3. In this table and others which follow, the results in parentheses were obtained by interpolation.

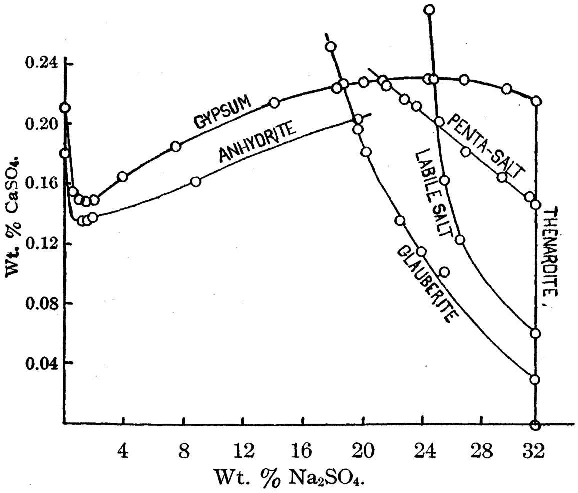

Fig. 3.—$CaSO_4$–Na_2SO_4–H_2O at 50°.

The gypsum curve again shows a minimum and maximum. No spontaneous formation of glauberite from gypsum occurred at any concentration of sodium sulfate; our observation is that it occurs only as a second step after labile salt (or pentasalt) has formed, according to the two equations

$$CaSO_4{\cdot}2H_2O + 2Na_2SO_4 \longrightarrow 2Na_2SO_4{\cdot}CaSO_4{\cdot}2H_2O$$

$$2Na_2SO_4{\cdot}CaSO_4{\cdot}2H_2O \longrightarrow Na_2SO_4{\cdot}CaSO_4 + Na_2SO_4 + 2H_2O$$

In obtaining the points on the gypsum curve any length of time was found possible up to about 25% sodium sulfate; beyond that concentration not more than ten minutes could be allowed

before the solubility began to drop, and at 31.77% (the invariant concentration) a still shorter time was necessary. The points on the curve for the labile salt were all obtained from undersaturation with material made at 35° and about 30% sodium sulfate; when the attempt was made to obtain results by formation of the labile salt from gypsum, the formation of glauberite began before the formation of the labile salt was complete. Glauberite, it will be observed, is the stable salt over a considerable range of concentrations; at about 25% sodium sulfate it could be formed completely in about two days from gypsum, via the labile salt, and from anhydrite in about two weeks. The invariant point with gypsum could be approached only from lower concentrations of sodium sulfate, that is, by decomposition of glauberite to gypsum, but not from the higher concentrations (change of gypsum to glauberite) because of the non-existence at this concentration of the apparently necessary intermediate compound, the labile salt. The curve for anhydrite was included, this being the lowest temperature at which it was thought feasible to work with that salt. It recently has been shown[11] that anhydrite is stable with respect to gypsum at temperatures down to 42°, as had previously been indicated in the systems containing potassium sulfate and ammonium sulfate.[9] The solid used was an artificial anhydrite made by dehydration of gypsum by sulfuric acid as previously described;[9] the solubility figures represent approach from undersaturation for one week's time, and were found constant for two months; approach from supersaturation did not prove feasible. Experiments were not successful in the region where the anhydrite is metastable with respect to glauberite or the labile salt. The points on the pentasalt curve are all obtained from undersaturation, using a sample of the salt made at 75° and periods of from two to eighteen hours, the time being limited usually by the spontaneous appearance of the labile salt.

The 75° Isotherms.—Table IV and Fig. 4 show the results at 75°, which include curves for the two forms of calcium sulfate and the three double salts.

The gypsum curve has apparently lost the maximum. In obtaining the curve, gypsum could be left in contact with solutions containing up to 12–13% of sodium sulfate for a half day without appearance of double salts; from that point on, there was almost immediate formation of double salts (probably pentasulfate, or labile salt at the higher concentrations) as shown by the extrapolation of the tie-lines; the last four points on the gypsum curve show the presence of double salt, although the filtrations were made within a minute or two. For this reason it is possible that the true solubility curve is slightly higher than we have found; Barre's[5] two figures are very much lower than ours, probably on this same account. The anhydrite figures were obtained from undersaturation, the time being a few days to a week; two points standing slightly above the curve represent approach from supersaturation by a month's decomposition of the pentasulfate. In the region in which anhydrite is metastable with respect to glauberite, it changes to that salt in surprisingly short time, so that the curve could not be continued to higher concentrations. The point on the glauberite curve at 25.78% sodium sulfate was obtained from anhydrite in two days. The points on the curve for the labile salt were obtained wholly from undersaturation, using material obtained at lower temperatures and were contaminated with excess sodium sulfate, for which reason the exact composition of the original complexes is not known; the time was restricted to one-half hour or less to avoid too extensive

formation of glauberite. The glauberite curve represents formation of the salt from gypsum, by way of labile salt, for periods of approximately one day. The figures for the pentasalt were obtained mostly by formation of the compound from gypsum and glauberite, in a few cases from undersaturation with pure pentasulfate. In general, the time allowed for formation was from two to five days at concentrations of sodium sulfate between 10 and 14%; in no case is any extensive decomposition of the pentasalt indicated by the extrapolation of the tie-lines, which show a solid with a sodium sulfate content of 10.84 to 17.7% (16.2 by theory). At higher concentrations, however, where it is metastable with respect to glauberite, its decomposition is very rapid, and the points on the curve were obtained in times of an hour or less.

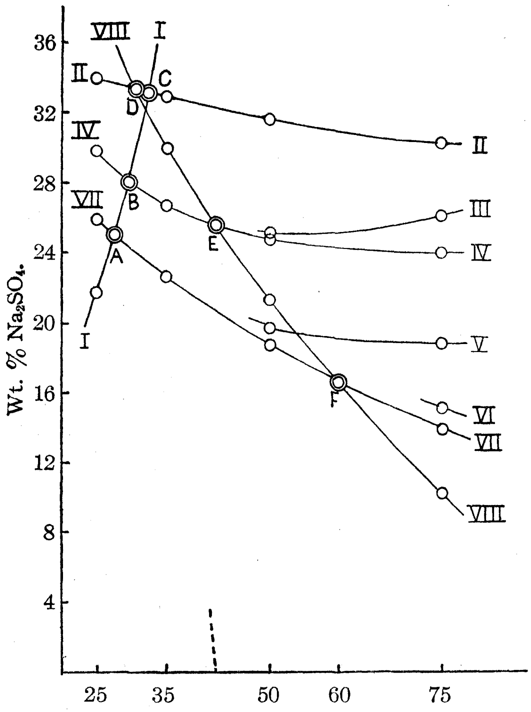

Fig. 5.—Polytherm of system $CaSO_4$–Na_2SO_4–H_2O. Curve I, gypsum and mirabilite; II, thenardite and any calcium salt; III, labile salt and pentasalt; IV, labile salt and gypsum; V, glauberite and anhydrite; VI, glauberite and pentasalt; VII, glauberite and gypsum; VIII, pentasalt and gypsum.

The Polythermal Diagram.—The results at the four temperatures are collected in Table V and in the polythermal diagram, Fig. 5, showing the concentration of sodium sulfate at each point and omitting the small concentrations of calcium sulfate. A corresponding diagram showing the concentrations of calcium sulfate can be constructed from the foregoing tables, but with less clarity.

In Fig. 5, the lines represent saturation with respect to the two salts indicated in each case by the Roman numeral in Table V, but it is to be noted that the areas between lines do not represent fields of saturation with respect to a single salt, as in the usual diagram, since the many degrees of metastability occurring in this system make impossible that simple method of representation. Curve I is the curve for mirabilite and gypsum. Curve II represents saturation with thenardite and any one of the calcium-containing salts; since their solubility is in all cases so slight, it is found that the solutions saturated with two salts show the solubility of thenardite within the errors of analysis. The curves for the labile salt with other salts make a pair (III and IV) running increasingly close together at lower temperatures; Barre's figures[5] for one of these pairs (gypsum and labile salt) are slightly above ours at the lower temperature and below ours at 75°, which we attribute to partial change of his salt to glauberite or pentasalt. The curves for glauberite with another salt make a trio (V–VI–VII) lower down in the diagram; Barre's figures for the gypsum–glauberite curve are above 2% higher than ours, as is also D'Ans' figure at 60°. The curve for gypsum and pentasalt (VIII) shows a markedly different direction, in accord with the fact that the solubility curve of the pentasalt (Figs. 2–4) does not parallel the curves for the other salts.

The system shows a relatively small number of invariant points of saturation with respect to three salts within the temperature range studied. That the number is small may be seen from the four isotherms, in which it appears that four of the seven salts considered change their relative solubility but slightly with change of temperature. The exceptions are anhydrite, mirabilite and pentasalt. With respect to anhydrite, it has been shown lately[11] that its transition temperature with gypsum is 42° instead of the higher temperature (63.5°) assigned at an earlier date by van't Hoff;[16] there must therefore be a series of invariant points below that temperature for anhydrite and gypsum with each of the other salts of the system. Because of the difficulty in obtaining saturation with anhydrite at these lower temperatures, this series of points has not been determined. Mirabilite increases its solubility greatly between 25° and its transition temperature to thenardite, 32.4°, so that its solubility curve (Fig. 1 and Fig. 5, curve I) passes through the solubility curves for gypsum–glauberite (VII), gypsum–labile salt (IV) and gypsum–thenardite (II), giving rise to invariant points A, B and C. A similar change in the solubility of the pentasalt gives rise to the invariant points D, E and F. The interpolated values of the temperature and the concentration of sodium sulfate are collected in Table VI.

TABLE VI

INVARIANT POINTS IN SYSTEM $CaSO_4$–$NaSO_4$–H_2O

Letter in Fig. 5	Saturating salts	Temp., °C.	Wt. % Na_2SO_4
A	Gypsum, Mirabilite, Glauberite	27.5	25.0
B	Gypsum, Mirabilite, Labile salt	29.5	28.0
C	Mirabilite, Thenardite, Gypsum	32.4	33.0
D	Pentasalt, Gypsum, Thenardite	31	33.2
E	Pentasalt, Gypsum, Labile salt	44	25.5
F	Pentasalt, Gypsum, Glauberite	60	16.6

The invariant points A and B of this table were determined previously by van't Hoff[7] and set at 29 and 30.2°, respectively; it is possible that the interpolated figures of Table VI from equilibrium experiments may be closer to the true values. The interpolated values which we have obtained for points D, E and F probably are less close to the true values, since they depend upon equilibria which were less clearly established.

Summary

The system $CaSO_4$–Na_2SO_4–H_2O has been studied and isotherms constructed at four temperatures, 25, 35, 50 and 75°, including solubility determinations for gypsum, anhydrite, glauberite, the labile salt and a new hydrated sodium pentacalcium sulfate, $Na_2SO_4 \cdot 5CaSO_4 \cdot 3H_2O$. The metastability and the composition of the labile salt, $2Na_2SO_4 \cdot CaSO_4 \cdot 2H_2O$, have been confirmed, and a polythermal diagram of the system sketched.

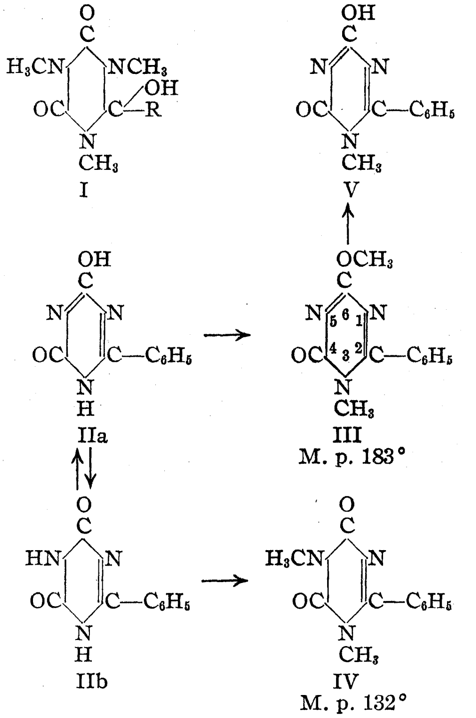
Studies on Triazines. II.
Lactim–Lactam Isomerism in Substituted Tetrahydrotriazines

BY EDITH BLOCH[1] AND HARRY SOBOTKA

In a previous communication[2] 1,3,5-trimethyl-2-phenyl(or -alkyl)-2-hydroxy-4,6-dioxohexahydrotriazines (I) were described. In order to corroborate this formulation it was attempted to arrive at a common derivative starting from 2-phenyl-4,6-dioxotetrahydrotriazine (II), the cyclization product of benzoyl biuret, a substance studied extensively by Ostrogovich.[3] In his later communications he ascribes mono-enolic structures to this product and to various homologs, as given in formula IIa. However, the result of catalytic hydrogenation seems to favor IIb, as only two hydrogen atoms can be introduced in the methyl homolog, yielding trigenic acid.[4]



The methylation of 2-phenyl-4,6-dioxotetrahydrotriazine with diazomethane in ether yields a mixture of two isomeric substances $C_{11}H_{11}O_2N_3$. One of them crystallizes in fine needles of m. p. 183°, whereas the other forms heavy, stout platelets of m. p. 132° and is generally more soluble in organic solvents and water. At first it was suspected that the two isomers differ from each other like isocyanurates from cyanurates, the former carrying the methyl groups on nitrogen, the latter on oxygen.

The constitution of the lower melting substance (IV) was confirmed by analysis of its decomposition products. After eight hours of digestion in alkaline solution, benzoic acid could be isolated from the mother liquors and methylamine hydrochloride, as well as ammonium chloride from the distillate, the methylamine hydrochloride definitely exceeding 1 equivalent.

Quantitative methoxyl determinations showed the absence of methoxyl in substance IV and the presence of only 1 methoxyl group in substance III. On treatment with dilute acid or alkali, substance III easily loses one methyl group and a monomethyl derivative (V) is formed. We therefore assign structure III with one methoxyl and one methyl imide group to this product. The location of the methyl groups in position 3 and 6 is not proved definitely, but seems more likely than in 4 and 5 or the highly improbable positions 3 and 4 or 5 and 6. The simultaneous occurrence of oxygen and nitrogen bound methyl groups in the molecule of this substance is the more remarkable, since no such "$^1/_3$ or $^2/_3$-isoesters" occur in the case of cyanuric acid. Hantzsch and Bauer[5] claimed the existence of such compounds, but Slotta and Tschesche[6] disproved their results and attribute the non-existence of such "mixed" esters–isoesters to the great trend toward symmetry in the molecule. In the present case there is, however, a far lesser degree of symmetry in the starting material which makes the unequal methylation more plausible. On treatment with diazomethane the monomethyl derivative V yielded again the mixed ester–isoester III in about 80% yield.[7]

[7] The methylation of imino nitrogen by diazomethane seems to depend upon its position in a ring between two CO groups, influencing the acidic character of the imino hydrogen. Cyanuric acid [Palazzo and Scelsi, *Gazz. chim. ital.*, **38**, 659 (1908)], phthalimide [Pechmann, *Ber.*, **28**, 859 (1895)], succinimide and the triazines in the present case react, whereas urea, methyl urea, benzoyl

Although the substances I and IV differ from each other only by the elements of methyl alcohol, it was not possible to convert one into the other. Neither the removal of CH_3OH from substance I nor the addition of the elements of water to the double bond in IV could be achieved. Aqueous or alcoholic sulfuric or hydrochloric acids of various concentrations were tried. However, in each case only the starting material could be recovered, even after heating to 100° in concd. sulfuric acid.

The similarity between substances I and IV is exemplified by their behavior on bromination. The tetrabromide $C_{11}H_{11}O_2N_3Br_4$ is very similar in appearance and properties to the substance $C_{12}H_{14}O_2N_3Br_3$ derived from substance I by bromination under identical conditions.[2] They differ from each other by one methyl group and the replacement of one hydrogen atom by bromine. Debromination of the new tetrabromide with alkali, zinc dust, or silver salts does not yield the starting material or any other crystalline substance.

The pharmacological action of these substances is under investigation.

Experimental Part

Benzoyl Biuret.—Forty grams of urea was dissolved in 120 cc. of dry pyridine and refluxed for two hours. The mixture was allowed to cool to about 80° and 38.5 cc. of benzoyl chloride was added dropwise under stirring, until a uniform solution was obtained, which occurs sharply on addition of the last drop. The solution was warmed for thirty minutes on a boiling water-bath, cooled to room temperature and kept in the refrigerator overnight. The resulting solid mass of crystals was extracted three times with 200 cc. of warm chloroform to remove benzamide and dibenzamide, formed as by-products of the reaction. The residue was heated for five minutes with 400 cc. of water and filtered hot through a Büchner funnel. This extraction with water was repeated twice. Then the residue was extracted twice with 200 cc. of hot methyl alcohol and filtered hot as above. After drying, the residue had a melting point of about 220° and was sufficiently pure for the following reaction; yield 11–12 g. After repeated recrystallization from ethyl alcohol the substance melted at 224–225° (all melting points corrected).

From the combined aqueous and alcoholic extracts and mother liquors a mixture of benzoyl urea and little benzoyl biuret was obtained. It was extracted with water in a Soxhlet extractor for forty-eight hours. A small amount of pure benzoyl biuret could be obtained from the residue in the thimble by recrystallization from ethyl alcohol. From the aqueous extracts benzoyl urea crystallized, which, after recrystallization from ethyl alcohol, melted at 214–216°; yield *ca.* 25 g.[8]

2-Phenyl-4,6-dioxotetrahydrotriazine (II).—Twelve grams of crude benzoyl biuret was dissolved in a solution of 7.5 g. of potassium hydroxide in 350 cc. of water and after standing for one hour the solution was saturated with carbon dioxide. The monopotassium salt crystallized and was redissolved by addition of more water. The solution was now made just acid to congo by addition of 50% acetic acid. On standing overnight the triazine crystallized in beautiful needles, which after recrystallization from ethyl alcohol melted at 297–300°; yield *ca.* 5 g.[8] The substance could be recovered unchanged after two hours of heating with concentrated sulfuric acid on a boiling water-bath.

Methylation of 2-Phenyl-4,6-dioxotetrahydrotriazine.—A solution of diazomethane in ether (from 8 g. of nitrosomethyl urea) was dried for one hour over pellets of potassium hydroxide and then poured over 3 g. of 2-phenyl-4,6-dioxotetrahydrotriazine, suspended in 500 cc. of dry ether. Slow reaction with gradual evolution of nitrogen occurred. After standing for two days at room temperature, the ether was filtered from a small amount of undissolved material and evaporated *in vacuo* to a volume of about 25 cc. After standing in the refrigerator overnight, the crystalline part was filtered on a Büchner, pressed well, to remove as much of the oily material as possible, then recrystallized twice from benzene: m. p. 183°; yield about 0.8–1.0 g. The ethereal and benzene mother liquors were combined and evaporated to dryness under reduced pressure. The partly oily residue was dissolved in 300 cc. of boiling water. On slow cooling and rubbing a small amount of fine needles appeared, which after recrystallization from benzene melted at 183° and were combined with the first lot; yield about 0.1 g The substance forms long fine white needles, very soluble in methanol, ethanol, hot benzene, soluble in chloroform, ether, glacial acetic acid; little soluble in water and in petrolic ether.

Anal.[9] Calcd. for $C_{11}H_{11}O_2N_3$: C, 60.83; H, 5.07; N, 19.30; OCH_3, 14.30. Found: C, 60.83; H, 5.11; N, 19.50; OCH_3, 14.18.

The aqueous mother liquors were extracted three times with 100 cc. of benzene in a separatory funnel, the combined extracts dried over sodium sulfate and evaporated *in vacuo*. The oily residue crystallized on rubbing with a few drops of petrolic ether. The substance was dissolved in 50 cc. of butanol on a hot water-bath. On cooling it slowly crystallized and after standing for several days was filtered on a Büchner funnel and washed several times with a mixture of 1 part of methyl alcohol and 4 parts of petrolic ether: m. p. 120–125°; yield *ca.* 0.5 g. Examination under the microscope proved that the substance still contained needles of the higher melting isomer. By repeated recrystallization from butanol it was finally obtained pure, in heavy, stout platelets melting at 132°. The substance is very soluble in organic solvents, except petrolic ether, also soluble in water. It is easily soluble in concd. hydrochloric acid and can be reprecipitated on neutralization with 10% ammonia.

---

urea, benzoyl biuret and glycine anhydride were found to remain unchanged in dry ether, also in wet ether suspension and in acetone-ether mixtures. For the reaction of amino acids see Kuhn and Brydowna, *Ber.*, **70**, 1333 (1937).

[8] Method adapted from A. Ostrogovich, *Bul. Soc. Stiinte Cluj*, **4**, 521, 528 (1929).

[9] We are indebted to Dr. S. A. Morrell for the methoxyl determinations.

Anal. Calcd. for $C_{11}H_{11}O_2N_3$: C, 60.83; H, 5.07; N, 19.30; OCH_3, 0. Found: C, 60.86; H, 4.92; N, 19.56; OCH_3, 0.

Monomethyl Derivative (V).—Five-tenths gram of substance III was heated with 2 cc. of normal sodium hydroxide for ten minutes. After cooling the solution was acidified with dilute sulfuric acid; the product separated at once and was recrystallized from dilute methanol or from a large amount of water, as prismatic glistening white needles, of m. p. 278–280°. The same product was also obtained by heating substance III in aqueous or alcoholic hydrochloric acid.

Anal. Calcd. for $C_{10}H_9N_3O_2$: C, 59.11; H, 4.43; N, 20.49; OCH_3, 0. Found: C, 59.02; H, 4.54; N, 20.22; OCH_3, 0.

Alkali Hydrolysis of Substance IV.—Hydrolysis was carried out in an apparatus similar to that described by Lieber and Smith:[10] 217 mg. of substance III was dissolved in 40 cc. of 25% sodium hydroxide and heated. After the given time intervals the receiver containing a measured amount of acid was changed and the liquid in the distilling flask each time filled up to the original volume The acid was titrated with 0.1 N alkali and from the amounts used by the distilled ammonia and methylamine the percentage hydrolysis was computed. It was 36.7, 56.3, 73.0, 83.2, and 84.6% after one, two, four, six, and eight hours, respectively.

After eight hours the alkaline solution was carefully acidified and the resulting precipitate filtered. After recrystallization from alcohol the substance formed shining plates which proved to be identical in melting point and gave no melting point depression with benzoic acid (122°). In order to determine the nature of the distilling amine, 1 g. of substance IV was hydrolyzed for eight hours with 50 cc. of 25% potassium hydroxide and the distillate absorbed in excess hydrochloric acid. The solution was evaporated to dryness and the residue carefully dried in a vacuum desiccator to constant weight; yield 460 mg. The material was extracted in a Soxhlet extractor with absolute alcohol for four hours. The alcoholic extract on evaporation yielded 350 mg. of methylamine hydrochloride. The residue in the thimble consisted of ammonium chloride.

Reaction of Substance IV with Bromine.—Forty-five hundredths gram of substance IV was dissolved in 2 cc. of glacial acetic acid and 2.5 cc. of an 8% solution of bromine in glacial acetic acid added dropwise. The bromide crystallized at once in beautiful red plates, which on filtering and washing with dry ether became yellow, apparently with loss of hydrobromic acid; yield 0.57 g. The substance was recrystallized from hot glacial acetic acid, containing bromine; it is very soluble in methanol, ethanol, soluble in hot chloroform and glacial acetic acid, insoluble in ether; it is readily debrominated by dilute alkali, also by silver salts in aqueous solution or etheric suspension.

Anal. Calcd. for $C_{11}H_{11}O_2N_3Br_4$: C, 24.58; H, 2.04; N, 7.82; Br, 59.59. Found: C, 24.84; H, 2.30; N, 7.73; Br, 59.87.

Summary

2-Phenyl-4,6-dioxotetrahydrotriazine, the cyclization product of benzoyl biuret, yields two isomeric dimethyl derivatives on methylation with diazomethane. The pair represents a case of lactam–lactim tautomerism involving one of the two methyl groups.

A New Synthesis of 3,4-Benzpyrene Derivatives

BY LOUIS F. FIESER AND E. B. HERSHBERG[1]

The only synthesis of the powerfully carcinogenic 3,4-benzpyrene heretofore achieved is that of Cook and Hewett,[2] consisting in the application to pyrene of the general method of constructing an additional ring with the use of succinic anhydride. With the technical improvements in the various steps introduced in this Laboratory,[3,4] by Winterstein, Vetter and Schön,[5] and by Vollmann, *et al.*,[6,7] 3,4-benzpyrene can now be prepared fairly readily by this method in over-all yield of about 36%.[3] The succinic anhydride synthesis, however, is not adaptable to the preparation of many derivatives of the important parent hydrocarbon, and the list of compounds thus far obtained by application of the general synthesis or by utilization of the same intermediates includes only the following substances: 4'-methyl-3,4-benzypyrene[3,8] (and its dihydride[3,8]), 3'(?)-methyl-3,4-benzpyrene,[5] 4'-hydroxy-3,4-benzpyrene,[4] 3,4-benzpyrene-3',4'-dicarboxylic anhydride[9] (and its dihydride[9]), 1',2',3',4'-tetrahydro-3,4-benzpyrene.[3,5,10]

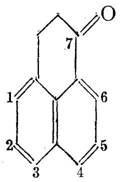
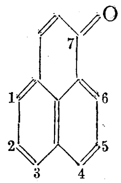
[10] The analytical sample of this hydrocarbon prepared with Mrs. Fieser[3] (by Clemmensen reduction) formed faintly yellow plates, m. p. 113°, whereas Winterstein, Vetter and Schön[5] subsequently

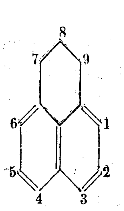
The synthesis of additional derivatives of known structure seemed to us of importance both for the purpose of exploring further the relationship between carcinogenic activity and structure and in order to provide reference substances for use in investigating the course of the oxidation,[6] diazo coupling,[11] and other substitutions[12] of the interesting hydrocarbon.[13] Because of the limitations in the succinic anhydride synthesis, a search was made for an alternate method of constructing the 3,4-benzpyrene ring system, and we can now report the development of a new synthesis which offers promise of considerable variation. An important step of the process involves a Scholl *peri*-condensation of a benzoylnaphthalene derivative, and in this respect the synthesis resembles that discussed but not tried by Cook and Hewett.[2] These authors expressed the view that 3,4-benzpyrene probably could be synthesized by application of the Scholl reaction to the benzoyl derivative of the ketone obtained by Mayer and Sieglitz[14] by the cyclization of β-(1-naphthyl)-propionic acid and regarded by them as having the structure I (for a discussion of the nomenclature of compounds I–III, see footnote[15]).



Perinaphthanone-7
I



Perinaphthenone
II



Perinaphthane
III

Cook and Hewett,[16] however, subsequently found that under certain conditions the cyclization gives a mixture of products, one of which is the unsaturated ketone II, apparently identical with the "pyrene ketone" obtained by Bamberger and Philip[17] in their degradation of pyrene.[17a] The English workers also observed in another connection that 4,5-benzhydrindone-3, a ketone somewhat analogous to I, failed to enter into a typical Friedel and Crafts reaction even at slightly elevated temperatures.[18] It was our plan to attempt to benzoylate not a ketone or diketone,[2] but the corresponding tricyclic hydrocarbon III.

peri-Trimethylenenaphthalene, for which we propose the new name perinaphthane,[15] was first isolated by Langstein,[19] who obtained a small amount of the crystalline hydrocarbon as a product of the degradation of pyrene. A synthesis was accomplished by Fleischer and Retze[20] from naphthalene and malonyl bromide, but the process involved reduction of the resulting diketone with hydrogen iodide and red phosphorus, followed by dehydrogenation of the over-reduced product, and the method is hardly practical for preparative purposes. In seeking a practical method we first considered the possibility of effecting a cyclization of 1-allylnaphthalene[21] into

---

reported obtaining colorless needles, m. p. 135°, from methanol. In an effort to account for this discrepancy the earlier experiment in this Laboratory has been repeated (L. F. F.). A pure sample (6.3 g.) of 4′-keto-1′,2′,3′,4′-tetrahydro-3,4-benzpyrene (crystallized from dioxane[4]) was reduced by the Clemmensen method with added dioxane and toluene. The crude, twice distilled product (3.7 g., pale yellow, m. p. 110.5–112°) was crystallized repeatedly from glacial acetic acid and from alcohol, further purified by chromatographic adsorption (E. B. H.), and again crystallized from alcohol, when it formed lustrous, colorless plates, m. p. 112.6–113.1°, corr. This material appears to be a pure individual, and our earlier observation concerning the melting point of the product of Clemmensen reduction is thus confirmed. High pressure hydrogenation of the ketone was reported[3] to give low-melting crude material which affords pure 3,4-benzpyrene on dehydrogenation. We may now add that this crude product, although it appears to contain a considerable quantity of the above tetrahydride, is not homogeneous and probably consists of a mixture of hydro derivatives.

(14) Mayer and Sieglitz, *Ber.*, **55**, 1835 (1922).

(15) *Note on Nomenclature.*—Cook and Hewett[16] have noted that three systems of naming these tricyclic compounds have been employed and that none of them is strictly correct. The ketone II has been referred to as pyrene ketone,[17] phenalone-9,[14,16] 1,8-naphthindenone[6] [see also Criegee, Kraft and Rank, *Ann.*, **507**, 177 (1933); Koelsch, This Journal, **58**, 1326 (1936); Wojack, *Ber.*, **71**, 1102 (1938)], and *peri*-naphthindone.[25,26] While we hesitate to add to the confusion of the literature, there is as yet so little agreement or precedent that we venture to propose a system which seems to us more satisfactory than any heretofore employed. For the parent hydrocarbon with a saturated alicyclic bridge, the name *peri*-trimethylenenaphthalene is lengthy and not well adapted to naming *ac*-substitution products, "dihydrobenznaphthene" imputes to the unsaturated hydrocarbon "benznaphthene" [v. Braun and Rath, *ibid.*, **61**, 960 (1928)] a completely aromatic character which it does not possess, "dihydrophenalene" implies a closer relationship to benzene than to naphthalene, and "*peri*-naphthindane" suggests the presence of an indane system and a five-membered ring. The hydrocarbon has been made reasonably easily available in the present work and may assume a position of importance comparable with acenaphthene. The name suggested, perinaphthane, calls to mind significant features of the structure and can be modified to include various possible *ac*-derivatives by the usual conventions (compare cholestane). It does not represent a wide departure from at least one of the names prevously employed, for perinaphthane may be regarded as a condensation of *peri*-naphthindane. A lack of correspondence with parallel compounds of the acenaphthene (ace, from acetic) series is regrettable, but hardly avoidable, since the common name for the latter hydrocarbon does not conform to modern usage with respect to the alicyclic part of the molecule. It would have been more appropriate to use "acenaphthane" for the hydrocarbon with the saturated bridge and "acenaphthene" for its dehydro derivative.

the 8-position, but the only smooth transformation discovered gave a different result. When the substance was passed over alumina at 500–550° there was produced a liquid hydrocarbon corresponding in properties to α-propenylnaphthalene.[22]

We next investigated as a possible starting point for the preparation of the desired hydrocarbon in quantity a process described in the patent literature for the synthesis of the unsaturated ketone, perinaphthenone (II). According to an early patent[23] a yellow substance (m. p. 152°) of this probable structure can be obtained by heating either α- or β-naphthol with glycerol and 82% sulfuric acid, the acid presumably functioning as a dehydrating, condensing, and oxidizing agent. Cook and Hewett[16] noted that the reported properties are similar to those of Bamberger and Philip's[17] "pyrene ketone" (m. p. 142°) and of the product (m. p. 153–154°) formed with other substances from β-(1-naphthyl)-propionic acid under the cyclizing and dehydrogenating influence of stannic chloride[16] (or of aluminum chloride, acting on the acid chloride[14]). Finally Vollmann, *et al.*,[6] made a direct comparison of the material prepared according to the patent with a purified sample of "pyrene ketone" (m. p. 152°) and found the two to be identical. Although the original process did not seem very promising, a more recent patent[24] includes a detailed description of an improved procedure in which sodium nitrobenzene sulfonate is employed as the oxidizing agent. Silbermann and Barkow[25] have employed this procedure with success and have recorded further observations concerning the reaction. In our hands the reaction proceeded essentially as described in the patent. After finding a convenient method for recovering the product from the tarry reaction mixture, no difficulty was experienced in preparing the ketone in quantity (200 g.), and although the yield of pure product is only 26% of the theoretical, based on the β-naphthol used, the starting materials are of such a nature that this is not a very important consideration. Our purified perinaphthenone (II) melts at 156–156.5°, corr.

The only recorded attempt to reduce perinaphthenone is an experiment by Silbermann and Barkow[25] in which the ketone was treated with zinc and hydrochloric–acetic acid and the resulting oil distilled over zinc dust. This gave a very small amount of an evidently impure sample of perinaphthane (III). We investigated the hydrogenation of the ketone in the presence of Raney nickel, platinum oxide, and copper chromite catalyst with quite different results. With Raney nickel at atmospheric pressure the ketone in ether–alcohol absorbed 2 moles of hydrogen and gave as the chief product the previously unknown saturated alcohol, perinaphthanol-7. With Adams catalyst there was a rapid initial absorption of gas and a yellowish reaction product soon separated from the alcoholic solution. This substance is very sensitive and decomposes rapidly in solution. Rapid recrystallization gave deep yellow material for which analyses and molecular weight determinations suggest the structure of a dimolecular product of either reduction or reduction and condensation. This was not investigated further.

On hydrogenating the unsaturated ketone in dioxane or ether at high pressure in the presence of copper chromite catalyst we invariably obtained a mixture of the saturated alcohol and the hydrocarbon. As the temperature was increased less alcohol was found in the reaction mixtures, and it seems likely that the alcohol is produced in any case and, at the higher temperatures, is converted into perinaphthane by a process of dehydration and hydrogenation. It appeared, however, that the temperature cannot be increased beyond a certain point without offering opportunity for hydrogenation of the naphthalene nucleus. In order to avoid such over-hydrogenation and still maintain dehydrating conditions, the amount of catalyst was reduced to a minimum. Using but 2.5 mg. of catalyst per gram of ketone, it was found possible to conduct the hydrogenation at 250–260° in a reasonable time and obtain hydrocarbon of high purity in 70–74% yield.

With a satisfactory method available for the preparation of perinaphthane in quantity, little difficulty was experienced in completing the remaining steps of the 3,4-benzpyrene synthesis indicated in the chart. Benzoylation of the hydrocarbon by the Perrier method proceeded smoothly to give a crystalline product which we assume to be 3-benzoylperinaphthane (IV). For conversion into 2,1′-trimethylenebenzanthrone-10 (V) by the Scholl reaction it was found best to

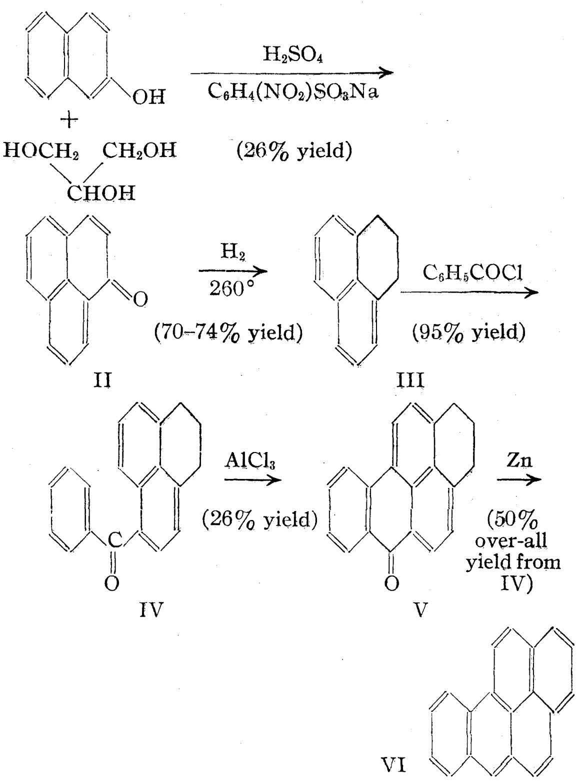
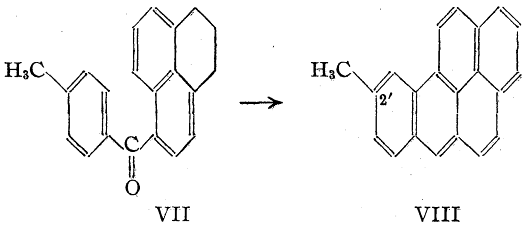
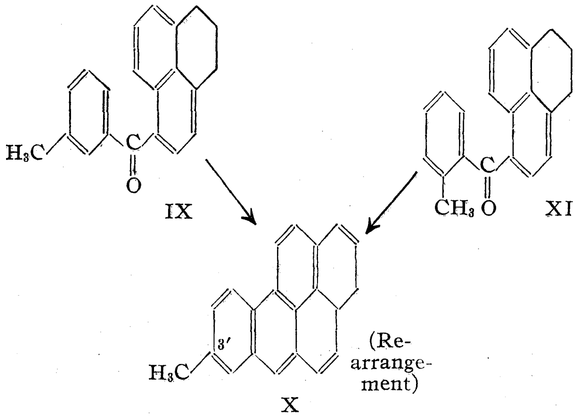
heat the ketone IV in a sodium-aluminum chloride melt at 155° in an atmosphere of oxygen. A pure product was then isolated from the reaction mixture fairly readily, if in low yield, and on distillation with zinc dust it yielded pure 3,4-benzpyrene (VI). It was thought that hydro derivatives of V are probably formed in the Scholl reaction along with the benzanthrone derivative, and indeed the mother liquor material from V gave an additional quantity of 3,4-benzpyrene on zinc dust distillation. It was then found that the over-all yield of the hydrocarbon can be improved greatly by carrying out the cyclization process at a lower temperature without undue exposure to air and submitting the total amount of moist, gummy reaction product to distillation from a mixture with zinc dust. Conducted in this way, the synthesis affords 3,4-benzpyrene in over-all yield of 34% from perinaphthenone, or 9% from β-naphthol. The process is rapid and compares favorably with the older synthesis as a practical method of preparing the carcinogenic hydrocarbon.



In extending the synthesis, we investigated the three ketones resulting from the condensation of the isomeric toluyl chlorides with perinaphthane. The Scholl reaction was conducted under conditions judged from the above experience to give material best suited for conversion into the hydrocarbon rather than for the isolation of the benzanthrone derivatives, and these intermediates were not examined. The hydrocarbons did not prove difficult to purify, and the homogeneity was checked carefully by conversion to the beautifully crystalline, brilliant red trinitrobenzene complexes and recovery of the hydrocarbons by chromatographic adsorption of the trinitrobenzene on alumina from benzene solution. The *p*-toluyl compound VII gave in 42% yield a hydrocarbon which we regard as 2′-methyl-3,4-benzpyrene (VIII), m. p. 140–140.2°, corr. The *m*-toluyl ketone IX and the *o*-toluyl ketone XI gave, in 14 and 22% yield, an identical hydrocarbon, m. p. 147.6–148.1°. This compound is definitely different from the 2′-isomer, for both the hydrocarbon and its picrate give a distinct depression in melting point (the trinitrobenzene derivatives show no depression on admixture). There is reason to believe that the second hydrocarbon is 3′-methyl-3,4-benzpyrene (X), formed normally from the *m*-toluyl ketone and produced in the case of the *o*-toluyl ketone as the result of a migration of the methyl group to the adjacent position in the course of the Scholl reaction. If the *o*-toluyl ketone had reacted normally the hydrocarbon would be identical with the known 4′-methyl-3,4-benzpyrene,[3] m. p. 219.5–220°, corr.,[8] which is not the





case. Since there is little likelihood that both reactions proceed abnormally and still yield the same product, it is safe to assume that the ketone IX undergoes normal cyclization. Furthermore, the hydrocarbon in question corresponds fairly closely in melting point with the methylbenzpyrene (m. p. 143–144°, corr.) synthesized by Winterstein, Vetter and Schön[5] from pyrene and methyl succinic anhydride. This synthesis must give either the 2′- or 3′-isomer and, in analogy with known cases, the 3′-position is the more probable point of attachment. The correspondence between the substances obtained in two syntheses which would be expected to yield the 3′-isomer strengthens the belief that this structure is correct. Further support is derived from the analogy with the behavior of the three isomeric toluyl-α-naphthyl ketones. In extending earlier work, Fieser and Martin[26] proved that the meta and para isomers condense normally to the expected methylbenzanthrone, while the ortho compound gives the same product as the meta isomer, corresponding exactly to the conclusions reached above. The structures assigned in the present work therefore are open to little question.

A number of ramifications of the new synthesis are being investigated, and we can report now the isolation of two additional methylbenzpyrenes resulting from the addition of methyl lithium to the benzanthrone derivative V.

Experimental Part[27]

Isomerization of α-Allylnaphthalene.—For preparation of the hydrocarbon,[21] the Grignard reagent from 207 g. of α-bromonaphthalene and 36 g. of magnesium in ether (600 cc.)–benzene was added in two hours, with stirring under reflux, to 121 g. of allyl bromide in 250 cc. of benzene. After refluxing further for two and one-half hours, the hydrocarbon fraction was separated and distilled, b. p. 220–235° (8 mm.); yield, 154 g. (92%). Fractionation through a 1-meter column gave 137 g. (81%) of material, b. p. 127.5–128.5° (8 mm.), n^{25}D 1.6089.

The picrate, obtained from a cold, concentrated methanol solution, formed orange needles, m. p. 68–69°.

Anal. Calcd. for $C_{13}H_{12}\cdot C_6H_3O_7N_3$: N, 10.59. Found: N, 11.00.

Fifteen grams of α-allylnaphthalene was distilled slowly through a tube of activated alumina at 500–550° at a pressure of 15 mm. The condensate consisted of a light yellow oil, b. p. 125–135° (8 mm.). Treated in alcoholic solution with two successive 5-g. portions of picric acid, the oil yielded 7.9 g. of picrate, m. p. 109–110°, and 6.2 g., m. p. 106–108°. Crystallized to constant melting point, the picrate formed orange needles, m. p. 110–111°.

Anal. Calcd. for $C_{13}H_{12}\cdot C_6H_3O_7N_3$: N, 10.59. Found: N, 10.99.

The hydrocarbon was recovered from the purified picrate by adsorption of the nitro compound on alumina from benzene and obtained as a yellow oil (4.9 g.), b. p. 139–140° (10 mm.), n^{20}D 1.6350. The constants given by Zal'kind and Zonis[22] for α-propenylnaphthalene are b. p. 105–106° (6 mm.), n^{20}D 1.6388. On oxidation of the hydrocarbon with sodium dichromate there was a strong odor of acetaldehyde and α-naphthoic acid, m. p. 158–159°, was isolated in good yield.

Perinaphthenone (II).—For the preparation of a quantity of the ketone the condensation was run conveniently in three lots, which were then combined for recovery of the product. In each lot the charge consisted of 460 cc. of water, 675 cc. of concentrated sulfuric acid, 250 g. of technical sodium nitrobenzene sulfonate, 500 g. of glycerol and 200 g. of β-naphthol. The reagents were mixed in this order in a 3-liter three-necked flask provided with a short condenser in the center opening, a mechanical stirrer (tantalum wire stirrer) working through the condenser, and a thermometer. The mixture was stirred and heated cautiously as required to maintain a temperature of 130–140° for one hour. (The reaction is exothermic and is apt to get out of control if a heating bath is used.) The dark solution was decanted while hot from a tarry residue through a pad of glass wool in a funnel onto 2–3 liters of ice in a series of beakers. After dilution to a total volume of about 6 liters, the mixtures were kept at 0° for one or two hours to allow the precipitated tar to agglomerate and the supernatant liquor was then decanted and discarded. The next two lots of reaction mixture were poured in succession onto ice in the same beakers, discarding the acid liquor and retaining the tar. The total tar, which becomes soft and mobile when warm, was then extracted with six 1-liter portions of benzene, heating the mixture on the hot-plate with mechanical stirring. The decanted extracts were filtered, combined, clarified with decolorizing carbon, and concentrated. After removing the solvent the product was distilled in vacuum, and there was obtained 209 g. of orange-yellow distillate boiling at 190–200° at 1–3 mm. For crystallization this was dissolved in 500 cc. of benzene and 500 cc. of ligroin (b. p. 80–86°) was added at the boiling point. This crystallization gave 196 g. (26%) of product in the form of yellow prisms, m. p. 154.5–155.5°. A sample recrystallized from benzene–ligroin formed elongated, diamond-shaped prisms, m. p. 156–156.5°.

The tar remaining from the benzene extraction dissolves fairly readily in hot water. The proportion of glycerol specified is considerably greater than that specified in the patent[24] and by Silbermann and Barkow,[25] for it was our experience in trial runs that this modification results in a definitely superior product. No advantage was found in increasing the proportion still further. Slow addition of the β-naphthol, as specified by Silbermann and Barkow, did not improve the result, nor did changes in the proportion of the oxidizing agent. In one trial with α-naphthol the yield was not as good as with the β-isomer.

Perinaphthane (III).—In the procedure found most satisfactory the charge consisted of 20 g. of perinaph-

---

(27) All melting points are corrected. Microanalyses by the Arlington Laboratories, Arlington, Virginia.

thenone, 25 cc. of peroxide-free dioxane, and 50 mg. of copper chromite catalyst 37 KAF. This was placed in the bomb in a glass liner and hydrogenation was conducted at an initial pressure of 1800 lb. (120 atm.) and a temperature of 250–260° for ten hours. On cooling, the solution separated into two layers and dioxane was added to make it homogeneous. After filtering from the catalyst the solvent was removed in vacuum and the product distilled at 8 mm. pressure. The fraction boiling at 140–165° (15.8 g.) consisted largely of the desired hydrocarbon, and the remaining distillate, b. p. 165–190°, was mainly perinaphthanol (see below).

Crystallization of the hydrocarbon fraction from 50–75 cc. of methanol diluted with a few cubic centimeters of water gave 11.7 g. (m. p. 63.5–64.5°) of perinaphthane in the first crop and 1.3 g. (m. p. 62–63°) in the second; total yield 70%. In a duplicate experiment the yield was 74%.

In pilot experiments hydrogenation was tried at temperatures below 200° with ether as solvent and without a solvent, but the yield of hydrocarbon was never better than 45%. It seems advantageous to use a solvent for there is then less gum left as a residue from the distillation. Yields of 45–58% were obtained in 20-g. runs at 200–230° using from 100 to 750 mg. of catalyst, and it was noticed that the use of a large amount of catalyst tended to give material of inferior melting point, possibly because of over-hydrogenation. This suggested the use of a very small quantity of catalyst, a higher temperature, and a pressure as low as possible, as specified in the procedure given above.

Further purification of perinaphthane by repeated crystallization from dilute methanol gave thin, colorless plates of the constant melting point 65.1–65.4°. We cannot confirm the melting point 68–69° reported by Langstein,[19] or 66–67° given by Fleischer and Retze.[20] Our hydrocarbon, like Langstein's, darkens on exposure to light.

The picrate forms fine orange-red needles from methanol and melts at 150–151°.

Anal. Calcd. for $C_{13}H_{12}\cdot C_6H_3O_7N_3$: N, 10.58. Found: N, 10.62.

It is doubtful whether previous investigators had the pure substance in hand, for melting points of 127° (Langstein[19]), 134–135° (Fleischer and Retze[20]), and 132–133° (Silbermann and Barkow[25]) are given, all with previous darkening.

The trinitrobenzene derivative formed long, yellow needles from methanol and melted at 160–161°, in agreement with the value 159–160° reported by Fleischer and Retze.[20]

Perinaphthanol-7.—This alcohol, formed in varying amounts in the above experiments, was obtained as the chief product of hydrogenation under the following conditions. A solution of 5 g. of perinaphthenone in 100 cc. of ether (distilled from a Grignard solution) and 25 cc. of absolute alcohol was shaken with hydrogen at atmospheric pressure in the presence of 0.5 g. of Raney nickel. There was a transient deep brown color at the start and the absorption of gas reached 2 moles in about five hours. After filtering from the catalyst and removing the solvent there was obtained on distillation in vacuum 3.2 g. of pale yellow distillate, b. p. 158–161° (1 mm.), and 0.9 g. of deep red distillate, b. p. 161–200° (1 mm.); considerable tar was left in the flask. The first fraction (solid) on crystallization from ligroin (b. p. 80–86°) gave 2.5 g. (49%) of colorless, crystalline product, m. p. 81–85°. After six further crystallizations the material formed glistening blades, m. p. 91.5–93°, and the picrate formed dull orange needles, m. p. 159–160°, from benzene–ligroin. This sample of the alcohol appears to be less satisfactory than those described below, and the substance seems to be very difficult to purify.

Crystallization from ligroin of the high-boiling fraction from the high-pressure hydrogenation gave a sample of the alcohol melting at 100.5–101.5° and showing no depression when mixed with the lower melting material. The picrate in this case melted at 163–165°. Surprisingly enough, the best sample was obtained from material recovered from an attempted dehydration. One gram of crude alcohol, m. p. 81–85°, was heated with a little potassium bisulfate at 180–200° for five minutes and the product distilled at 10 mm. pressure. There was considerable tarry residue, and the light yellow distillate afforded only 0.25 g. of crude, crystalline product from ligroin (b. p. 60–70°). After six recrystallizations, the sample melted at 105.5–106°. This sample was analyzed.

Anal. Calcd. for $C_{13}H_{12}O$: C, 84.75; H, 6.57. Found: C, 84.96; H, 6.38.

The picrate, prepared from the best sample and crystallized from benzene–ligroin, formed fine, dull orange needles, m. p. 163.5–164.5°.

Anal. Calcd. for $C_{13}H_{12}O\cdot C_6H_3O_7N_3$: N, 10.14. Found: N, 9.92.

Hydrogenation with Adams Catalyst.—A solution of 2 g. of perinaphthenone in 40 cc. of absolute alcohol with 30 mg. of platinum oxide catalyst quickly turned deep brown when shaken with hydrogen at slight positive pressure, and after a few minutes a yellowish solid began to precipitate. (The behavior was the same when a small amount of hydrochloric acid was added to the alcoholic solution.) After the absorption of 1 mole of gas (several hours), the solid was collected with the adhering catalyst and washed with dry ether (weight 1.75 g.). The material was dissolved in 40 cc. of hot dioxane and the solution was quickly filtered and diluted with 50 cc. of hot water. The first crop of crystals (0.25 g.) formed small, orange-yellow needles, m. p. 179–180°, dec. The substance decomposes rapidly in solution and recrystallization usually gives inferior material and is attended with heavy losses. Decomposition was evident in an attempted molecular weight determination in camphor.

Anal. Calcd. for $C_{26}H_{20}O_2$: C, 85.78; H, 5.54; mol. wt., 364. Calcd. for $C_{26}H_{18}O_2$: C, 86.18; H, 5.01; mol. wt., 362. Found: C, 86.06, 85.81; H, 5.41, 5.59; mol. wt. (ebullioscopic in acetone), 320, 348.

3-Benzoylperinaphthane (IV).—The Perrier complex from 45 g. of benzoyl chloride and 43.3 g. of aluminum chloride was dissolved in 500 cc. of carbon bisulfide and added with shaking to 52 g. of perinaphthane in 150 cc. of the same solvent. The clear, deep red solution was refluxed for one-half hour and decomposed with ice and acid. After evaporation of the solvent the oily product was extracted and washed in ether and distilled, giving 79.9 g.

(95%) of material, b. p. 210–215° (2 mm.) which slowly solidified. This was suitable for use in the next step. A sample recrystallized twice from ether–petroleum ether formed massive, faintly cream-colored prisms melting at 62–63°.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.21; H, 5.92. Found: C, 87.96; H, 5.95.

2,1′-Trimethylene-1,9-benzanthrone-10 (V).—The most satisfactory procedure found for preparing this intermediate, rather than utilize it in the synthesis, was as follows. A melt was prepared from 23 g. of sodium chloride and 80 g. of aluminum chloride, and 19.6 g. of benzoylperinaphthane was added. The mixture was heated for four hours in a bath maintained at 150–155°, while stirring mechanically and passing oxygen over the surface of the melt. The hot melt was then poured onto ice and hydrochloric acid and the brown, gummy precipitate was collected and taken into glacial acetic acid while still wet. Four crystallizations from this solvent, with the liberal use of decolorizing carbon each time, gave in all 5.0 g. (26%) of iridescent golden-yellow leaflets, m. p. 217–218°. The substance is readily soluble in benzene, rather sparingly soluble in glacial acetic acid, and only slightly soluble in alcohol. In very dilute alcoholic solution it exhibits a striking yellow-green fluorescence. The solution in concentrated sulfuric acid shows a brilliant red-yellow fluorescence.

Anal. Calcd. for $C_{20}H_{14}O$: C, 88.86; H, 5.22. Found: C, 89.05; H, 5.24.

The material precipitated from the mother liquors of the above experiment by dilution with water was distilled with zinc dust as described below and yielded 2.2 g. (12%) of 3,4-benzpyrene. A small sample of the pure benzanthrone derivative was converted in the same way into the hydrocarbon.

3,4-Benzpyrene.—A melt was prepared from 23 g. of sodium chloride and 80 g. of aluminum chloride in a 125-cc. Erlenmeyer flask, 15.1 g. of 3-benzoylperinaphthane was added, and the flask was stoppered loosely and heated with occasional shaking in an oil-bath held for three hours at 130–140° and for two hours longer at 145–150°. The ketone dissolves readily in the melt giving at the outset a deep red solution which turns brown as the reaction proceeds. At the end of the time specified this was poured onto ice and acid and the gummy precipitate was collected on a filter, washed with water, and sucked well. The crude, moist material, which darkens appreciably during the washing, was shredded and mixed with 250 cc. of zinc dust in a 300-cc. round-bottomed flask sealed directly to a distilling flask with a sealed-on receiver. The distillation was conducted from a sodium–potassium nitrate bath at a dull red heat and was continued as long as distillate collected in the distilling flask (one-half to one hour). The crude product was then distilled into the second receiver at a pressure of 1–2 mm. This eliminated entrained zinc dust and a tarry residue and gave a clean distillate easily purified by dissolving it in ether, concentrating, and adding successive portions of petroleum ether until crystallization was complete. The first crop (5.8 g.) consisted of light yellow needles, m. p. 176–177°, and the second (1.2 g.) melted at 172–175°; total yield, 50%. When the zinc dust distillation was conducted at too low a temperature, or too rapidly, the product often crystallized in the form of leaflets of lower melting point; this probably is due to contamination with hydro derivatives. When the Scholl reaction was conducted with stirring in the presence of oxygen as above and the crude product put through the zinc dust distillation the yield of hydrocarbon was about half that obtained by the process described.

The hydrocarbon was fully identified by comparison with known material.[3] For further characterization, and for comparison with the new derivatives described below, the hitherto unknown **3,4-benzpyrene–trinitrobenzene** was prepared. It formed glistening, bright red blades from benzene, m. p. 226–227°.

Anal. Calcd. for $C_{20}H_{12} \cdot C_6H_3O_6$: N, 9.03. Found: N, 9.00.

Unlike the corresponding complex from methylcholanthrene,[28] this trinitrobenzene derivative can be cleaved effectively with full recovery of the hydrocarbon by selective adsorption of the nitro component on alumina from benzene solution. The recovered hydrocarbon after crystallization melted at 178.5–179°.

The Isomeric 3-Toluylperinaphthanes.—These were prepared as above from the reaction of the Perrier complex of the appropriate toluyl chloride and perinaphthane (from 8 to 13 g.) in carbon bisulfide solution, distilled in vacuum for use in the syntheses, and crystallized for analysis from ether–petroleum ether or from ether. The properties and yields are given in the table. They all form massive prismatic clusters and were obtained in either a colorless or pale yellow condition.

2′-Methyl-3,4-benzpyrene (VIII).—A solution of 16.9 g. of 3-(*p*-toluyl)-perinaphthane in a melt from 23 g. of sodium chloride and 80 g. of aluminum chloride was heated in a stoppered flask at 140–150° for four and one-half hours. The crude, moist product was mixed with 150 cc. of zinc dust and distilled slowly as before, except that the pressure was reduced to 200–250 mm. to allow for a higher boiling point of the methylated hydrocarbon. Crystallization of the distillate gave in all 6.8 g. (42%) of material melting in the range 130–136°. This was converted into the trinitrobenzene complex, which was crystallized to a constant melting point of 212–213° and then passed in benzene solution through an adsorption tower of alumina. The regenerated hydrocarbon collected from the filtrate was crystallized once from benzene–ligroin and three times from methanol. It forms fluffy, light yellow needles and has a double melting point. When heated slowly it melts almost completely at 138–139°, and after solidification by cooling it remelts at 140–140.2°. It is readily soluble in benzene and ether, moderately soluble in metha-

3′-Methyl-3,4-benzpyrene (X). (a) Normal Reaction.—3-(*m*-Toluyl)-perinaphthane (9.4 g.) was heated with sodium–aluminum chloride in a closed flask at 135–150° for four and one-half hours and the product distilled from zinc dust at atmospheric pressure. The once crystallized distillate melted at 138–142°; yield, 1.3 g. (14%). A benzene solution of this material was passed through a tower of alumina and the recovered product was crystallized six times from ether–ligroin and ether–absolute alcohol. This gave small, faintly greenish-yellow needles. The hydrocarbon apparently exists in two forms of slightly different melting point. When heated slowly the sample melted at 146.5–147°, but when inserted in a bath at 145° it melted at once. The resolidified material melts at 147.6–148.1°. The melting point and appearance remained unchanged on further passage through an adsorption tower and on regeneration from the purified trinitrobenzene derivative. The hydrocarbon is somewhat less soluble than the 2′-isomer.

Anal. Calcd. for $C_{21}H_{14}$: C, 94.70; H, 5.30. Found: C, 94.52; H, 5.04.

The trinitrobenzene complex forms long, brilliant red needles from benzene–ligroin, m. p. 210.5–211°.

Anal. Calcd. for $C_{21}H_{14}\cdot C_6H_3O_6N_3$: N, 8.77. Found: N, 8.55.

The picrate separated from benzene–ligroin as fine brownish-red needles, m. p. 179.5–180°.

Anal. Calcd. for $C_{21}H_{14}\cdot C_6H_3O_7N_3$: N, 8.48. Found: N, 8.42.

Mixtures of the hydrocarbon with the 2′-isomer were found to melt as low as 123–128°, and a depression to 171–173° was noted with a mixture of the two picrates. The trinitrobenzene derivatives melt at practically identical temperatures and no depression was observed with mixtures.

(b) By Rearrangement.—The Scholl reaction was conducted as above with 12 g. of 3-(*o*-toluyl)-perinaphthane (four hours at 150–160°) and the distillation from zinc dust carried out at 100–200 mm. pressure. The redistilled and once crystallized product formed straw-yellow needles, m. p. 143–145°; yield, 2.6 g. (22%). After further crystallization from ether–petroleum ether it melted at 146.5–147.5° and gave no depression when mixed with the first sample (a). The melting points and mixed melting points of the picric acid and trinitrobenzene complexes were also identical with those of the above samples.

Summary

The first step in the synthesis consists in condensing β-naphthol with glycerol essentially as described in a patent. The resulting unsaturated ketone, for which the name perinaphthenone is proposed, can be reduced satisfactorily to the hydrocarbon (perinaphthane, in the suggested system of nomenclature) by high pressure hydrogenation. The benzoyl derivative of the hydrocarbon undergoes the Scholl cyclization fairly smoothly, and 3,4-benzpyrene is obtained in good over-all yield by zinc dust distillation of the product.

Of the isomeric toluyl derivatives of perinaphthane, the meta and para compounds undergo normal cyclization and give as final products of the synthesis 3′- and 2′-methyl-3,4-benzpyrene, respectively, while with the ortho isomer there is methyl migration leading to the ultimate formation of 3′-methyl-3,4-benzpyrene. These results parallel those obtained in the application of the Scholl reaction to the preparation of the corresponding methylbenzanthrones.

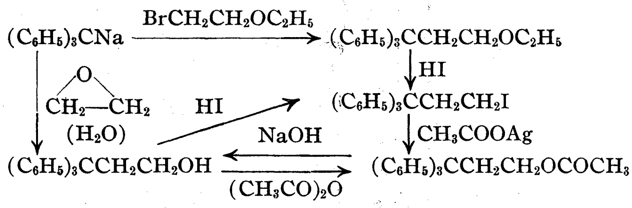
γ,γ,γ-Triphenylpropyl Derivatives

BY CHARLES BUSHNELL WOOSTER, H. D. SEGOOL AND T. T. ALLAN, JR.

The reaction between sodium in liquid ammonia solution and γ,γ,γ-triphenylpropyl iodide which results in the formation of sodium triphenylmethide was reported in a previous paper.[1] Because of the interesting nature of this reaction and of the observed tendency of compounds of the type R_3C-C-CX to undergo unusual reactions,[2] it appeared desirable to establish more thoroughly the constitution of the triphenylpropyl iodide which was used. This has now been accomplished by carrying out the reactions indicated in the flow sheet.



The iodide was prepared originally by cleavage of γ,γ,γ-triphenylpropyl ethyl ether the constitution of which appeared to be reasonably well established by the method of its synthesis. Furthermore, the available evidence demonstrated the presence of a triphenylmethyl group in the iodide. There remained, however, the possibility of molecular rearrangement during the action of hydriodic acid on the ether which might have led to the formation of a triphenylisopropyl iodide instead of the expected triphenyl-*n*-propyl iodide. Accordingly, the synthesis of the same iodide from triphenyl-*n*-propyl alcohol and the regeneration of this alcohol, by conversion to the acetate and hydrolysis, furnish the necessary link in the chain of evidence which shows that the iodide actually has the primary structure.

Experimental Part

The Preparation of γ,γ,γ-Triphenylpropyl Alcohol.—Sodium triphenylmethide was prepared by slowly adding 50 g. of triphenylchloromethane to a solution of 8.3 g. of sodium dissolved in about 500 cc. of liquid ammonia in a one-liter three-necked flask equipped with a mercury-sealed stirrer, a dropping funnel and an outlet for gaseous ammonia. A large excess of ethylene oxide was then added gradually in small portions. This reacted vigorously with the excess sodium, but at first the deep red solution of sodium triphenylmethide showed no evidence of reaction. However, after several hours a voluminous pink precipitate had appeared in the reaction vessel, although the red color of the solution indicated the presence of some unreacted sodium triphenylmethide. These observations suggest that ethylene oxide may form an intermediate, unstable oxonium complex with the organo-alkali compound similar to those which are formed with Grignard reagents.

The addition of water to the reaction mixture discharged the red color and precipitated a yellow plastic mass which solidified on standing in contact with water after it had been washed free of most of the aqua ammonia. The product was recrystallized from commercial hexane and obtained in the form of light yellow crystals, m. p. 106.5–107.5°; yield about 30 g.

Anal. Calcd. for $C_{21}H_{20}O$: C, 87.5; H, 6.94. Found: C, 87.9, 87.7; H, 7.07, 7.05.

Attempts to oxidize this product to tritylacetic acid were unsuccessful, but its structure seems to be sufficiently well established by its thermal stability and the method of preparation. Although "abnormal" reactions with the Grignard reagent (involving isomerization to the aldehyde or ketone structures) have been reported with isobutylene oxide, styryl oxide and *sym*-dimethylethylene oxide[3] no such results have ever been observed with ethylene oxide itself. Furthermore, the triphenylisopropyl alcohol, $(C_6H_5)_3CCHOHCH_3$, which is the only likely alternative structure, would be expected to be thermally unstable since its next lower homolog $(C_6H_5)_3CCH_2OH$, decomposes smoothly into triphenylmethane and formaldehyde when heated slightly above its melting point (107°)[4] and the corresponding decompositions of triphenylacetic acid and triphenylacetaldehyde indicate the generality of such behavior. However, the reaction product was recovered unchanged after heating to 150–170° for an hour and failed to give a test for even a trace of triphenylmethane with a solution of potassium amide in liquid ammonia which instantly produces a deep red solution of potassium triphenylmethide when treated with this hydrocarbon.

Preparation of Triphenylpropyl Iodide from the Alcohol.—Five grams of the alcohol was refluxed for five hours with 40 cc. of constant boiling hydriodic acid. After cooling, the product was separated and purified as previously described[1] and identified by a mixed melting point; yield 1.6 g.

Preparation of Triphenylpropyl Acetate from the Alcohol.—The alcohol seems to be quite unreactive toward many of the usual reagents; it was recovered unchanged after refluxing for one hour with acetyl chloride and thionyl chloride although a product of m. p. 134° (presumably the benzoate) was obtained by refluxing with benzoyl chloride.

---

[1] Wooster and Morse, THIS JOURNAL, **56**, 1735 (1934).

[4] Schlenk and Ochs, *Ber.*, **49**, 610 (1916).

The determining factor seems to be the boiling point of the reagent since the acetate was obtained in satisfactory yield by the use of acetic anhydride.

Seven and three-tenths grams of the alcohol was refluxed for one hour with excess acetic anhydride, the solution poured into water and, after the hydrolysis of the anhydride was complete, the product was separated by filtration and recrystallized from alcohol: yield 6.4 g., m. p. 114–115°.

Anal. Calcd. for $C_{23}H_{22}O_2$: C, 83.6; H, 6.67. Found: C, 83.3, 83.1, 83.7; H, 6.72, 6.70, 6.75.

Hydrolysis of the Acetate.—Two grams of the acetate was dissolved in 50 cc. of alcohol in which 3 g. of sodium had been dissolved and 10 cc. of water was added. After refluxing for two hours the solution was poured into water, neutralized with hydrochloric acid and filtered. After crystallization from commercial hexane the product was identified as the triphenylpropyl alcohol by a mixed melting point.

Preparation of Triphenylpropyl Acetate from the Iodide.—An attempt to prepare the acetate by refluxing a solution of the iodo compound in glacial acetic acid with silver acetate for ten and one-half hours proved unsuccessful, possibly because the initially formed silver iodide coated over the sparingly soluble silver acetate. The reaction proceeded satisfactorily, however, when an excess of silver acetate was placed in the filter thimble and the acetic acid solution of 1.88 g. of triphenylpropyl iodide was placed in the flask of a Soxhlet apparatus to prevent precipitation of the silver iodide from occurring in the presence of solid silver acetate. After the Soxhlet apparatus had been operated for about twenty hours, the solution in the flask was cooled, filtered, evaporated to small volume, diluted with water, neutralized with sodium carbonate and filtered again. The black gummy solid was crystallized from alcohol by seeding with a sample of the previously prepared acetate. After recrystallization from alcohol it was found to be halogen free and identical (by mixed melting point) with the acetate obtained from γ,γ,γ-triphenylpropyl alcohol and acetic anhydride.

Summary

The product previously obtained by the action of hydriodic acid on γ,γ,γ-triphenylpropyl ethyl ether has been shown to be γ,γ,γ-triphenylpropyl iodide. Evidently no molecular rearrangement occurs during this reaction.

Semiquinone Radicals in the Indamine and Indophenol Groups

BY G. SCHWARZENBACH[1] AND L. MICHAELIS

The original task of this paper was to extend the search for semiquinone radicals as intermediate steps of reversible oxidation–reduction, to the indamine and indophenol groups. The result not only was successful but in addition presented an excellent opportunity for developing the general principles concerned with the degree of stability of such radicals.

In none of the many representatives of the indophenol dyes investigated by W. M. Clark[2] and associates, was there any evidence for the existence of an intermediate step of reduction. On the contrary, these authors took just these dyestuffs as models to prove their assumption that in reversible bivalent oxidations the two electrons always go on and off in pairs. The experimental results can be confirmed entirely for the dyestuffs selected by these authors and for the *p*H range covered by their experiments. Yet it would be unjustifiable to consider this state of affairs as general. We shall demonstrate for two dyestuffs rather closely related to the group investigated by these authors, that semiquinone radicals are formed in fairly large concentrations as intermediate steps. These two dyestuffs are phenol blue and Bindschedler's green, the formulas of which are given by the T-forms in the table of formulas (Fig. 7). The experimental material will be presented first, and the cause for the different behavior will be treated in the discussion.

The formulas shown in the table are electronic formulas, each stroke representing an electron pair. The totally oxidized forms T, the semiquinone forms S, and the fully reduced forms R are given in the different possible states of ionization. T, R, and S, themselves, denote the forms existing only in very alkaline solutions, where all removable protons are removed. The order represented in this scheme corresponds to the order of the ionization steps as derived from the experiments.

An open structure has been chosen for the T-forms in which the central nitrogen appears surrounded by only six electrons. The fourth electron pair can be said to be delivered by the auxochromic groups $N(CH_3)_2$, OH, and O. These have

---

[2] Hygienic Laboratory Bulletin, No. 151, United States Public Health Service, Washington, D. C., 1928.

unshared electron pairs, which can form a double bond with the neighboring carbon atom, whereby the benzene ring, of which this carbon is a part, is converted into a quinoid ring. Both auxochromic groups take part in this electron delivery, the molecule is a resonance system. The valence chemistry and its connection with the absorption spectra and the acidimetric behavior of systems like these have been described by Schwarzenbach and co-workers.[3] In the S-form the odd electron is represented as a dot attached to the central atom, but this should not be regarded as an expression of a definite position of the odd electron.

A. Experimental Part

1. Preparation of the Dyestuffs

Phenol blue was prepared by the method described by Heller,[4] by oxidation of freshly prepared *p*-aminodimethylaniline and phenol with sodium hypochlorite in acetate buffer and at zero temperature. The dye was filtered off and crystallized three times from 95% ethanol. It then forms dark crystals, m. p. 167°.

Bindschedler's green was prepared by the method given by Wieland.[5] *p*-Aminodimethylaniline and dimethylaniline are oxidized with bichromate in acid solution and in the presence of zinc chloride. The zinc double salt forms a beautifully crystallized green product which was not further purified. Recrystallization cannot be accomplished without some decomposition and the recrystallized product is rather less pure than the original material. In concentrated aqueous solutions this green salt is converted partially into red crystals, the longer known of the two modifications of Bindschedler's green, which behave in solution exactly like the green product. Both modifications have been described already by Wieland. Titrations have been carried out mainly with the green crystals, which show certain advantages owing to their greater solubility.

Phenolindophenol was prepared according to the method described by Clark[2] and recrystallized five times from a solution of sodium chloride. It was obtained in beautifully crystalline state of great purity and stability. All these specimens were kept constantly in the ice box to prevent decomposition.

2. The Titrations.—The titrations were mostly reductive. As reductant, reduced rosindulin GG, and in a few cases in the acid *p*H range, where rosindulin becomes insoluble, titanous chloride was used. These reductive titrations were controlled in some cases by a corresponding oxidative titration, the dyestuff being reduced previously by means of hydrogen on colloidal palladium, and bromine or ferricyanide was used as oxidant.

The technique of the titration has been described before. The only modification consisted in adding the dyestuff to the buffer solution just before the titration began. This makes the effect of a possible slow decomposition of these dyestuffs, which are not very stable, almost negligible. Two microburets were introduced through the stopper of the titration vessel which contained 50 cc. of the buffer solution. One of the burets contained a strong solution of the dye (concentration about 4×10^{-3} *M*) in alcohol (in the case of phenol blue) or water (in the case of Bindschedler's green) and the other the reductant or oxidant in the same molar concentration. The air in the titration apparatus was then replaced by hydrogen. Colloidal palladium ensured the removal of the oxygen dissolved and produced a hydrogen potential, which made possible the measurement of the *p*H of the buffer. In the case of an oxidative titration 2 cc. of the dyestuff solution was now added and immediately reduced. After replacement of the hydrogen by nitrogen the titration was started. In the case of a reductive titration, the buffer was bubbled with nitrogen before adding the dyestuff and the titration begun immediately after its addition. After the titration was finished more colloidal palladium was added, hydrogen was passed through the vessel and the hydrogen potential measured. It was found that the change of *p*H value during the reduction was negligible in all titrations of Bindschedler's green, except for some few titrations with titanous chloride. In the experiments with phenol blue the final *p*H value was always somewhat lower than the value before the beginning of the titration. This difference of about 0.07 *p*H unit is due to the addition of alcohol to the buffer solution and not to a change caused by the oxidation–reduction process. In the following tables only the final *p*H value is registered.

In the case of phenol blue we could get excellent titration curves between *p*H 3.7 and 9.1. The potentials could be measured in this *p*H range with the same accuracy achieved in the case of lactoflavin,[6] the limits of error being about ±0.2 mv. In more acid solutions we had difficulties in the determination of the starting point of the reduction and end-point of the oxidation. The potentials at these points are very unsteady due to an irreversible decomposition of phenol blue. But even in solutions of a *p*H of 2 or 3 it could be shown definitely that the titration curve is much too steep for a two-electron process without intermediate. The semiquinone in these solutions could also be detected visually by its color, especially distinctly visible in a nearly completely reduced solution. At *p*H 10 the potentials were again unstable. This is due most probably to a hydrolytic elimination of the dimethylamino group, as can be inferred from the fact that the potentials dropped slowly to the potential range of phenolindophenol which is produced by this process.

Bindschedler's green is more stable in acid solutions and less stable in alkaline solutions in comparison with phenol blue. The potentials were perfectly stable between *p*H 3 and 7, the limits of error being not greater than in the case of phenol blue. At *p*H 7.5 and 8.0 fairly reliable titration curves were still obtained, but at *p*H 9 the dye stuff was hydrolyzed rather quickly to form phenol blue, a well-known reaction for Bindschedler's green. In the acid range fairly good curves were obtained down to a *p*H of 1.5. Here titanous chloride had to be applied as a reductant because rosindulin forms a precipitate. The strong acidity of the titanous chloride solutions impaired some-

what the reliability of the measurements around *p*H 2 due to a change in *p*H during the reduction. Below *p*H 1 Bindschedler's green begins to become very unstable, the green solution being decolorized in a few hours. In phosphate buffer solutions which were used in the *p*H range around 7, zinc phosphate was precipitated, because the zinc double salt was used directly. In some cases this precipitate was filtered off, but it was found that it did not affect the potential measurements at all.

The final concentration of the dye in the titration experiments was usually between 2 and 4 × 10^{-4} mole per liter. The slight solubility of phenol blue did not allow of higher concentrations. Below a concentration of 1 × 10^{-4} the establishment of the potentials was no longer satisfactory.

In Table I the normal potentials E_m against the standard hydrogen electrode in volts and the index potentials E_i against the corresponding E_m value in millivolts are registered for the different buffer solutions. The values are mean values of several duplicate titration experiments at 30°.

TABLE I

Buffer	*p*H	Titration	E_m	E_i

Phosphate	8.03	Reductive (rosindulin)	.1853	16.2

The E_i values in brackets are not certain. Here the titration curves were not very reliable because the dye was not quite stable or the *p*H during the titration could not be kept quite constant.

The results indicate clearly that in both dyes the reduction leads through an intermediate product on an oxidation level of a quinhydrone, since the index potentials are distinctly greater than 14.3 mv. In the case of phenol blue below *p*H 5 the index potentials are so high as to indicate the formation of the quinhydrone in large quantities.

This quinhydrone may be a radical or its dimeric form, a hydrazine derivative. To decide between these alternatives, we carried out some titration experiments with various concentrations of the dyestuff, keeping the *p*H value constant. Table II gives information about these.

TABLE II

Phenol blue *p*H 4.60		Bindschedler's green *p*H 4.58		Bindschedler's green *p*H 6.78	
C	E_i	*C*	E_i	*C*	E_i
0.9 × 10^{-4}	19.8	2.2 × 10^{-4}	16.4	2.8 × 10^{-4}	17.2
1.8 × 10^{-4}	19.5	4.0 × 10^{-4}	16.4	5.6 × 10^{-4}	17.2
3.5 × 10^{-4}	19.5	7.6 × 10^{-4}	16.4	9.0 × 10^{-4}	17.3

These figures show clearly that the quinhydrone is a radical and not a dimeric compound, since the index potential is independent of concentration. This result is not unexpected. The intermediate form of phenol blue has a definite blue color which would not be expected of a valence saturated hydrazine. Furthermore, Wieland states that the radical *bis*-(dimethylaminophenyl)-hydrazine at a concentration of 2 × 10^{-2} *M* in benzene solution is 10% dissociated into radicals. We may expect that the dimerization constant in water is even smaller, but even if this be not the case, the dimeric form could not be formed in the low concentration range used in our titration experiments.

3. The Absorption Spectra.—Phenol blue is a base, which takes up a proton at *p*H 4.9 giving rise to a color change from pure blue to violet. There can be no doubt about the constitution of the molecules involved in this acidity equilibrium: namely, T and HT. The color of the ion and the neutral molecule indicate that both are resonance systems, the quinoid double bonds shifting from one nucleus to the other. This is only possible if we place the added proton in the indicated position. An addition to the electron pair of the dimethylamino nitrogen would destroy the resonance and give rise to the formation of a quinone of a very slight, probably yellow, color.[7] Furthermore the order of magnitude of 10^{-5} must be expected for a dissociation constant of a phenolic hydroxide group which is acidified through a slightly asymmetrical resonance. The addition of the proton to the central nitrogen would give rise to a much smaller change in color as we will see in the case of Bindschedler's green. The absorption spectra of T and HT have been determined with König and Martens' spectrophotometer and are given in Fig. 1, together with the spectra of two forms of Bindschedler's green. It can be seen that the absorption maxima of phenol

---

(7) G. Schwarzenbach and co-workers, *Helv. Chim. Acta*, **20**, 490, 627 (1937).

blue in its T and HT state are separated far enough to make a spectrometric determination of the acidity constant possible. It was found by this method that in an acetate buffer solution of a *p*H of 4.55 the ratio of HT/T is 1.81 at 30°, a wave length of 6620 Å. being used for the measurements of the extinctions. This corresponds to a dissociation constant of $K_t = 10^{-4.81}$.

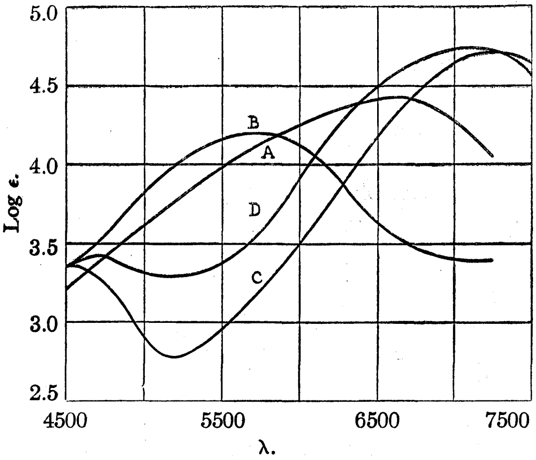

Fig. 1.—The logarithm of the molar extinction coefficient: Curve A, phenol blue *p*H 5.5 (T); Curve B, phenol blue *p*H 3.5 (HT); Curve C, Bindschedler's green *p*H 4.5 (T); Curve D, Bindschedler's green *p*H 2 (HT).

Bindschedler's green gives yellowish-green solutions which on acidifying turn to a more bluish-green. Both solutions have a strong absorption band at the infrared border of the visible part of the spectrum. The maximum of the absorption lies so far in the red that its determination with the visual method (König and Martens' apparatus) is scarcely possible. Photographs on infrared sensitized plates revealed, however, the exact position of the bands. Their maximum is in the infrared quite close to the visible red. The color change on acidifying takes place between *p*H 3 and 4. From Fig. 1 it can be seen that the change in the absorption spectrum is not very pronounced, making a colorimetric determination of the acidity constant difficult. But this acidity constant shows up clearly if we plot the E_m potentials against *p*H. From this curve it follows that this dissociation constant has a value of about $10^{-3.4}$. The place of addition of the proton can only be the central nitrogen atom of the molecule so that the molecules T and HT, with the formulas in the table of formulas, are involved in this acidity equilibrium. An addition to the free electron pair of the dimethylamino nitrogen would give rise to the formation of a strongly asymmetrical structure, which would have a yellow color. Such a color change takes place only at much lower *p*H values, namely, in about 40% sulfuric acid.

Both forms of Bindschedler's green and of phenol blue have two more absorption bands in the region of shorter wave lengths. One lies in all cases in the neighborhood of 2900 Å. The other lies in the case of the acid form of phenol blue also in the ultraviolet at about 3550 Å., whereas in the case of Bindschedler's green and the neutral form of phenol blue this second band which is rather weak lies in the violet and blue region of the visible spectrum (Fig. 1). The whole absorption spectrum has therefore in all cases three bands showing a pronounced similarity to the spectra of the sulfonphthaleins.[8] This is not surprising because the indophenols and indamines represent a resonance system very similar to that of the dyes of the Döbner's violet and benzaurin type (2). On reduction the bands in the visible part of the spectrum and in the nearer ultraviolet disappear, whereas the band at 2900 Å. is strongly increased in intensity.

It has been mentioned that the presence of the semiquinone of phenol blue can be demonstrated by its definite color. If small amounts of bromine are added to a solution of reduced phenol blue in an acid solution (HCl = 0.005 *N*), the color of the solution turns blue, not violet, which in acid solution is the color of the fully oxidized form. Also an absorption appears in the far red which disappears again on further oxidation and is replaced by the band of the fully oxidized substance HT. The absorption in the far red has to be attributed to the radical. Curve A in Fig. 2 represents the extinction of a solution in which 16% of the phenol blue has been reoxidized (concentration of the dyestuff = 10^{-5}). From the semiquinone formation constant, derived from the titration experiments, the concentration of the fully oxidized form HT has been calculated and the absorption due to its presence introduced as curve B in Fig. 2. Curve C is the difference between the curves A and B and represents the absorption of the semiquinone. In the other regions of the spectrum, including the ultraviolet, the presence of the semiquinone does not show up by any specific absorption.

---

[8] Mohler, Forster and Schwarzenbach, *Helv. Chim. Acta*, **20**, 654 (1937).

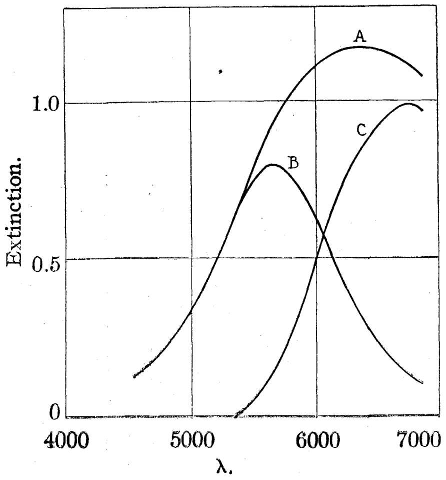

Fig. 2.—A, the extinction of a solution of 10^{-5} molar leuco-phenol blue in 5×10^{-3} molar hydrochloric acid of which 16% has been oxidized; B, the extinction due to the form HT; C, the extinction due to the form H_2S (the free radical).

It is somewhat surprising that the oxydimethylaminodiphenyl nitrogen, the radical derived from phenol blue, has a completely different color from *bis*-(dimethylaminophenyl-)-nitrogen derived from Bindschedler's green, which has been prepared by Wieland[5] and which is yellow. Since the absorption bands of Bindschedler's green are shifted toward the red in comparison with phenol blue, we think it likely that this will be the case also in the two corresponding radicals and we predict for the yellow radical of Wieland another absorption band in the infrared region.

4. The Acid–Base Constants of Reduced Phenol Blue.—The curve of E_m as a function of pH which is shown in Figs. 4 and 5, shows different points where it changes its direction owing to the dissociation of the reduced and oxidized forms. To confirm the exact positions of these bends, the direct determination of the acidity constants of the reduced forms also was desirable. In the case of Bindschedler's green this was not possible because the reduced form is very sparingly soluble, but it could be accomplished easily in the case of leuco-phenol blue, which is a phenol and an aniline at the same time

$$\mathrm{HR^-} \underset{K_r''}{\leftrightarrows} \mathrm{H_2R} \underset{K_r'''}{\rightleftarrows} \mathrm{H_3R^+}$$

K_r''' was derived from an acid titration curve of the leuco-base which is shown in Fig. 3 and K_r'' was computed from the shift of the potential of a hydrogen electrode in a sodium hydroxide solution by addition of phenol blue. The results are

$$K_r''' = 10^{-5.99} \qquad K_r'' = 10^{-10.00}$$

Both figures hold for 30° and an ionic strength of about 0.1.

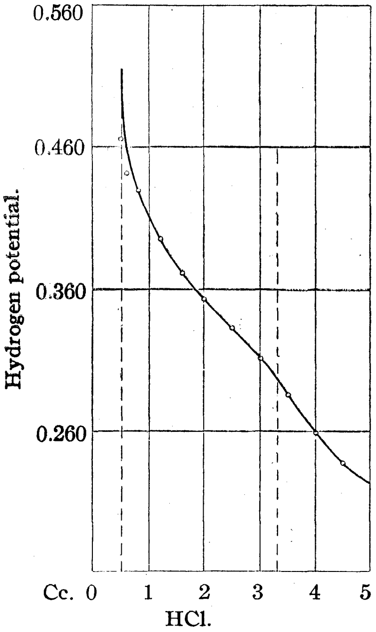

Fig. 3.—Titration of leuco-phenol blue with acid at the hydrogen electrode.

B. The Interpretation of the Potential Measurements

1. The Mean Potentials E_m as a Function of pH and the Dissociation Constants of T and R.—The curve drawn through the experimental points in Fig. 4 for phenol blue shows a bend at pH 4.8 and 6.0 owing to the acid dissociations of T and R described above. At pH 10 there must be another bend indicating K_r'' and then the curve will have, in the more alkaline range, a slope of 30 mv. per pH unit and can be extrapolated safely. In the acid range, where experimental points no longer can be obtained, the extrapolation is not so safe. We will probably soon reach another constant of the T form, a proton being attached to the central nitrogen.

The curve of Bindschedler's green represented in Fig. 5 has a slope of 30 mv. per pH unit in the alkaline solution. The reduced form contains, therefore, one proton more than the oxidized form in this pH range and must be represented by formula HR. The curve will extend with this slope far into the alkaline range, where the proton attached to the central nitrogen atom finally will be lost, the potential becoming independent of *p*H. At *p*H 6.4 and 5.1 the reduced form takes up two more protons, obviously forming the ions H_2R and H_3R. The constants $K_r'' = (H^+) \times (HR)/(H_2R)^+ = 10^{-6.4}$ and $K_r''' = (H^+) \times (H^+) \times (H_2R^+)/(H_3R^{++}) = 10^{-5.1}$ are very reasonable for aromatic dimethylamino groups and also the ratio of K_r''/K_r''', corresponding to 1.3 *p*H units is compatible with the expected value as influence of the ionic charge of the first proton on the acidity constant of the second in this distance. In the case of leuco-phenolindophenol about the same ratio between K_r'' and K_r'' has been observed, the constants being $10^{-9.4}$ and $10^{-10.6}$. Unfortunately the solubility of the base HR is so slight that no good acidimetric titration curves could be obtained in a titration experiment with the hydrogen electrode to confirm the constants above.

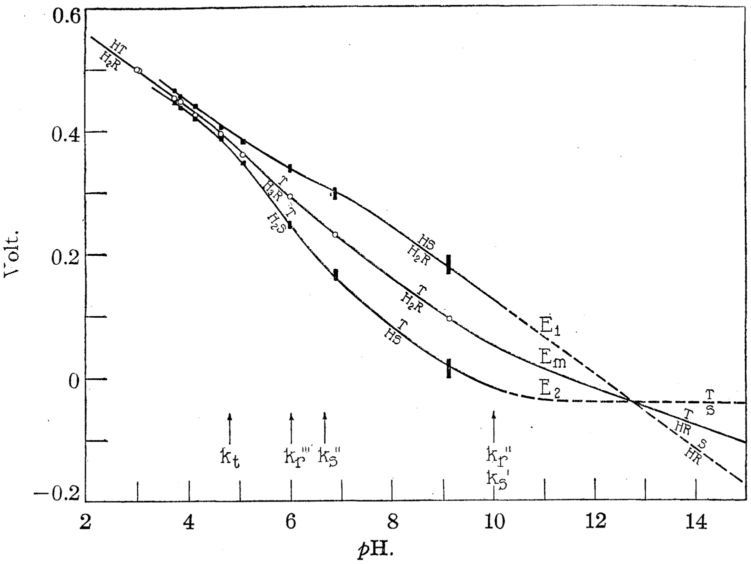

Fig. 4.—Phenol blue: the normal potentials E_m for the system T, R; E_2 for the system T, S; and E_1 for the system S, R. K_t, K_s, and K_r denote the acidity constants of the T, S, and R forms.

At *p*H 3.4 the E_m curve bends from the 90 mv. slope back to the 60 mv. slope owing to the dissociation constant of the T-form described above.

At *p*H 1.5 there is once more a bend indicating a third constant of the reduced form. This is somewhat surprising. Only the ion H_4R can be formed here with salt formation of the weakly basic diphenylamino nitrogen. This constant lies so far in the acid range that a confirmation by means of an acidimetric titration is impossible.

2. The Index Potentials, E_i, the Normal Potentials of the Lower and the Higher Step of Oxidation, E_1 and E_2, and the Semiquinone Formation Constant, k.—From the index potentials we can calculate[9] the semiquinone formation constant k and the maximum ratio of semiquinone to the total dye $(s/a)_{max}$. Table III contains these figures in solutions of different *p*H, as computed from the curves E_1 and E_2 which will be discussed later. Obviously both dyestuffs form free radicals to a large extent. One of these radicals, the one derived from Bindschedler's green, is identical with the *bis*-(dimethylaminophenyl)-nitrogen obtained by Wieland from the corresponding hydrazine.[5] Wieland states that this radical is very sensitive toward water. We can confirm this result but Wieland's viewpoint should be corrected somewhat. The radical does not disappear entirely in the presence of water. There is an equilibrium established according to $2S \rightleftarrows$

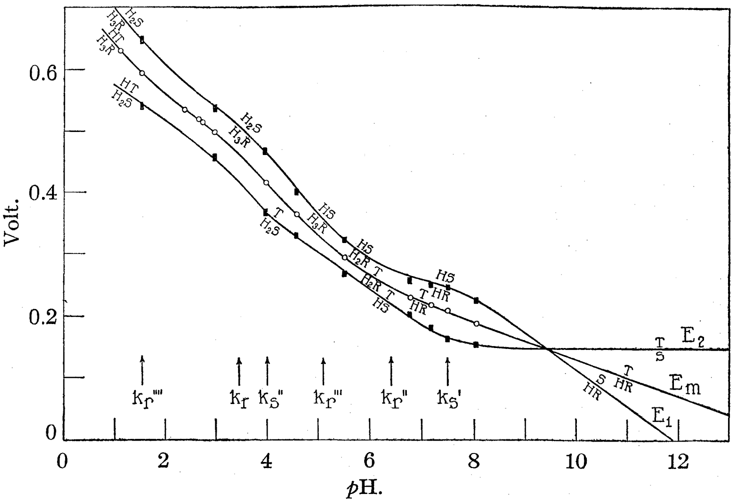

Fig. 5.—Bindschedler's green: The normal potentials E_m for the systems T, R; E_2 for the system T, S, and E_1 for the system S, R. K_t, K_s and K_r denote the acidity constants of T, S, and R.

---

[9] The methods of calculation as developed previously will be summarized in *Chem. Rev.*, in press (1938).

TABLE III

$k = s^2/rt$, where s, r and t denote the activities of the S, R and T-forms. $(s/a)_{\text{max.}}$ = maximum ratio of $s:a$, that is to say the ratio $s:a$ in the half-reduced state.

*p*H		1	2	3	4	5	6	7	8	9	10	11	12
Bindschedler's green	k	0.0087	0.030	0.040	0.023	0.100	0.146	0.059	0.059	0.40	4.00	36	1550
	$100 \times (s/a)_{\text{max.}}$	4.5	8.0	9.1	7.0	13.7	16.0	10.8	10.8	24	50	75	95
Phenol blue	k			0.48	0.48	0.25	0.027	0.0041	0.0022	0.0022	0.0047	0.022	0.18
	$100 \times (s/a)_{\text{max.}}$			26	26	20	7.6	3.1	2.2	2.2	3.3	6.9	17.5

R + T, the constant of this equilibrium depending on *p*H. At *p*H 6 as much as 16% of the whole dyestuff is still present in the form of the radical.

It is worth while mentioning that this is the first case in which a radical of the semiquinone type is identical with a radical previously prepared by the classical method, by spontaneous dissociation of its dimeric form in an organic solvent.

If we compare the figures of Table III with the behavior of phenolindophenol we find at first sight a pronounced difference. As can be inferred from the data obtained by W. M. Clark,[2] the latter compound does not form a radical between *p*H 5 and 13. We also have found in these *p*H ranges an index potential not differing from the theoretical minimum value 14.3. But there is an indication that in very strongly alkaline solutions the formation of an intermediate does occur. Satisfactory titration curves could not be obtained owing to an instability of the system, but by reducing a very pure sample of phenolindophenol in strong alkali (> 2 *m* sodium hydroxide) with glucose, a pink color can be observed easily just before the solution decolorizes on forming the fully reduced compound. On re-oxidation with air, the pink color appears again before the solution becomes blue. We do not believe that this phenomenon is due to a decomposition product, but to the formation of a radical as intermediate product. It is analogous in appearance and behavior to the intermediate form of the indigosulfonate as described by Shaffer.[10]

We also have an indication that a semiquinone is formed in more acid solutions. Below *p*H 4 the dye is very unstable, the potentials always drift toward the positive side, probably because quinone-imide is formed with a normal potential above phenolindophenol. This decomposition has the effect of compressing the titration curve (potential plotted against degree of reduction), causing the index potentials to appear lower than they would be without secondary decomposition occurring. So at *p*H 3.7 a curve was obtained with an index potential of only 11.0, but at *p*H 4.6 an index potential of 14.7 and at *p*H 4.02 even one of 15.2 was observed. The corrected values, therefore, would be distinctly greater than 14.3 although accurate figures cannot be given. This is a clear indication that a semiquinone is formed in these *p*H ranges.

We shall discuss the semiquinone formation in terms of the E_1 and E_2 values which, in addition to E_{m}, are plotted in Figs. 4 and 5. These potentials are the normal potentials of the systems T, S and S, R and defined by the equations

$$E = E_2 + \frac{RT}{F} \ln (t/s) = E_1 + \frac{RT}{F} \ln (s/r)$$

where E is the potential observed.

It is comparatively easy to give the correct E_1 and E_2 curves although the index potentials may not be absolutely certain, for these curves can only have a slope of 0.06 or 0.12 v. per *p*H unit. This restriction makes it possible to compute a mean value of the measured index potentials at different *p*H. The slope of the curve informs us about the number of protons by which the semiquinone differs from the t or r forms. We are therefore definitely sure about the state of ionization of the half reduced form. In the *p*H range investigated, the semiquinone formation constant, k, is in the case of both dyestuffs, and of course also in the case of phenolindophenol, so small, that $E_2 - E_1$ becomes negative, the E_1 curve being above the E_2 curve. Here, a wide separation of E_2 and E_1 is equivalent to a small k.

Figure 4 shows that between *p*H 7 and 10 the semiquinone of phenol blue has the form HS and that below *p*H 6.6 the form H_2S exists. These two forms will have the structures given in the table of formulas because it is reasonable to assume that the dissociation constant for an acidic group in the semiquinone lies between the corresponding constants for the T and R forms.

The last value experimentally obtained for phenol blue on the alkaline side is that for *p*H 9. Nevertheless we know, as has been pointed out, the course of the E_{m} curve beyond 10, because the

---

[10] P. A. Shaffer, *J. Biol. Chem.*, *Proc.* **105**, lxxviii (1934); *cf.* also L. Michaelis, *Chem. Rev.*, **16**, 243 (1935), on p. 282.

dissociation constant $H_2R \rightarrow HR$ has been measured. At *p*H 10, where the parallel course of these three curves is broken by the constant just mentioned, the semiquinone has still the central proton to lose. The semiquinone formation constant in very alkaline solutions depends on the magnitude of this unknown constant $HS \rightarrow S$. It is certain that this constant must be much greater than the corresponding one for the reduced form $RH \rightarrow R$, and reasonable to assume that it has to lie in the neighborhood of 10^{-10}. As we will see, we have in the case of Bindschedler's green a clear indication that this constant $HS \rightarrow S$ lies below *p*H 8. If we take account of all these arguments, we come to the extensions for the curves in the high *p*H ranges as indicated in Fig. 4, and reach the conclusion that in very strong alkaline solutions we must expect a very large semiquinone formation. The same holds true for the very acid range. At *p*H 3, where the last experimental points could be obtained, we have as semiquinone the form H_2S and a new constant will soon be due, addition of the proton taking place at the dimethylamino nitrogen. Such a constant makes the E_1 and E_2 curves again bend toward the E_m curve, producing an increase in the semiquinone formation.

The case of Bindschedler's green is very similar, but the conclusions reached for the behavior in very alkaline solutions are more certain because the constant of the semiquinone $RS \rightarrow S$ is indicated clearly at *p*H 7.5. It is clearly seen that the semiquinone formation in very alkaline solutions must be very large as indicated also in Table III.

The observations on all three dyestuffs, Bindschedler's green, phenol blue and phenolindophenol, indicate the following general behavior: strong semiquinone formation in alkaline and acid range and comparatively small semiquinone formation in the middle *p*H range. In the case of phenol blue the acid range of large semiquinone formation is reached exceptionally early and already begins at *p*H 4.

The above statement for the very alkaline range is not astonishing. We know that the formation of R and T forms in non-aqueous solutions, from a free radical, is generally negligible and that we find only the equilibrium between the dimeric compound and the radical. Such solutions are similar to a solution of very high *p*H, because the R form has not the possibility of taking up a proton. The sensitivity of these equilibria toward water now becomes quite clear. The addition of water, a proton donator, has an effect equivalent to that of a strong lowering in *p*H by converting the R form into HR

$$R + H_2O \longrightarrow RH + OH'$$
$$2S + H_2O \longrightarrow T + RH + OH'$$

This is the main reason for the dismutation which has been found in many cases by addition of water to the radicals and has been especially described for the case of the radical derived from Bindschedler's green by Wieland. If we dissolve small quantities of the semiquinone or its dimeric product in water, Bindschedler's green is produced immediately and by the action of the OH ions, formed by the reaction just mentioned, hydrolyzed to phenol blue.

C. Discussion

The general treatment of oxidations and reductions of organic compounds has to take account of the following equilibria

$$\begin{tikzcd} R \arrow[r, shift left, "\epsilon"] & S \arrow[l, shift left] \arrow[r, shift left, "\epsilon"] \arrow[d, shift left] & T \arrow[l, shift left] \\ & {}^1/_2D \arrow[u, shift left] & \end{tikzcd} \qquad (1)$$

The reaction $D \rightleftarrows 2S$ has been the classical one to prepare radicals and has been investigated always in non-aqueous solutions. On the other hand, oxidations and reductions $R \rightleftarrows T$ have been investigated extensively in aqueous solution by means of the potentiometric method. The general belief was that the bivalent reversible oxidation–reduction in organic compounds would occur in a single bivalent step. There was no reason to link the reversible oxidation with the problem of free organic radicals, until almost simultaneously Friedheim and Michaelis[11] and Elema[12] found that in some cases during such reductions and oxidations free radicals are formed even in aqueous solutions. Later on, Michaelis and Fetcher[13] also found the dimeric form of the radical to exist in the equilibrium. Thus the complete picture of the scheme (1) was revealed.

The semiquinones, however, still seemed to have little connection with the substances commonly known as free radicals. As pointed out by Michaelis, the semiquinones were in all cases compounds which contained two equal atoms (other

---

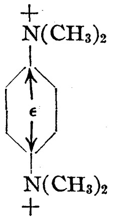
[13] L. Michaelis and E. S. Fetcher, This Journal, **59**, 2460 (1937).

than carbon), symmetrically located in the molecule, as in the case of Wurster's blue



These two atoms could be regarded as carriers of the odd electron, ε, which was assumed to resonate symmetrically between the two positions. The older free radicals, on the other hand, contained one atom which might be considered as the carrier of the odd electron, so that it was reasonable to speak of trivalent carbon, or divalent nitrogen or univalent oxygen. These latter radicals were found to be very sensitive toward water.

The present paper has filled the gap between the two groups of radicals: radicals of the second type, with so called divalent nitrogen, have been found to exist in aqueous solution in equilibrium with the oxidized and reduced forms. These findings are quite in agreement with the theory of stability of the free radicals. As Hückel[14] and Pauling[15] have shown, all free radicals owe their existence to resonance energy. The odd electron and the π electrons of the aromatic nuclei cannot be placed in a definite position, rather their charge is on a time average distributed over a wide range of the molecule.[16]

The equilibria constants of the above scheme are of course dependent on pH. The equilibrium R $\rightleftarrows$ T is expressed in the potential E_m and the equilibria R $\rightleftarrows$ S and S $\rightleftarrows$ T in the potentials E_1 and E_2. To understand their magnitude, we must know something about the relative stability of the molecules involved in the equilibrium, this is to say, of all the molecules whose formulas are given in the table of formulas (Fig. 7) for the T-, R- and S-forms.

This stability cannot yet be calculated by quantum mechanical methods. Even in simpler cases, where the molecules contain no other atoms than carbon and hydrogen, different approximation methods (Hückel and Pauling) yield widely differing results. We will try here to express the stability of a molecule in terms of the more qualitative valence chemistry, starting from the concept of an ideal state of a molecule exhibiting maximum stability. The instability of a molecule is then measured in terms of the tendency of its atoms to reach this ideal state.

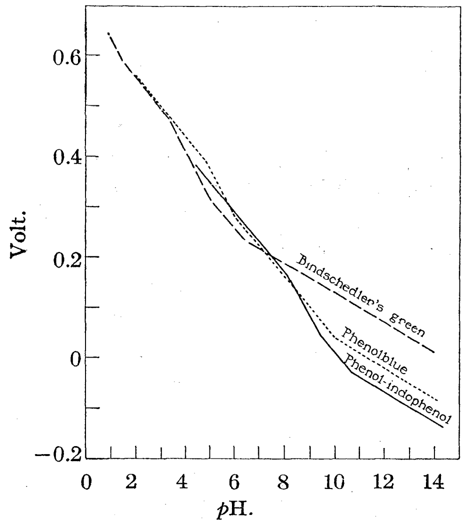


Fig. 6.—The mean normal potentials of Bindschedler's green, phenol blue and phenolindophenol.

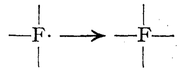
An atom in the ideal state would be surrounded by four electron pairs which are all equal and indistinguishable. For example, the C-atom in methane or the helium atom can be regarded as being in this ideal state. Any reactivity can be attributed to one of the two following reasons:

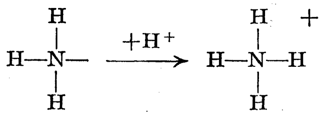
1. A deviation from the stable electron number 8, giving rise to a tendency for oxidation or reduction as for instance in the fluorine atom



$$\text{—F·} \longrightarrow \text{—F—}$$

This kind of instability will be called oxidation–reduction instability.

2. A deviation from the ideal state of equality of the four electron pairs, giving rise to acid–base reactions as in ammonia



$$\text{H—}\overset{\text{H}}{\underset{\text{H}}{\text{N}}}\text{—} \xrightarrow{+\text{H}^+} \text{H—}\overset{\text{H}}{\underset{\text{H}}{\text{N}}}\text{—H}^{+}$$

We will call this instability an acid–base instability.

Both tendencies must be regarded as equally important, because the free energies of acid–base reactions and oxidation–reduction reactions are of the same order of magnitude.

Phenolindophenol.

Fig. 7.

If we regard the stability of all the ions and molecules involved in the equilibrium $R \rightleftarrows S \rightleftarrows T$ in all possible pH ranges, we arrive at the following conclusions.

1. **The Stability of the R-Forms.**—The R-forms of our dyestuffs show primarily an acid–base instability, all atoms being surrounded by an electron octet. (In the formulas in the table of formulas (Fig. 7) 4 strokes belong to every atom.) The instability is manifested in the basic character of these molecules, the central N-atom and the auxochromic groups having unshared electron pairs. It is easily understood that the instability will be great in strongly alkaline solution, where even the central N atom has lost a proton and is strongly basic. In extremely acid solutions a maximum stability is reached. This means that all equilibria will be displaced in favor of the R form on decreasing the pH.

2. **The Stability of the T-Forms.**—The fact that the R-forms can be oxidized to the S- and T-forms even in acid solutions, is due to the fact that the oxidized forms exhibit a new type of resonance, which is missing in the R forms. The nature of this resonance is different for the S and for the T forms. In the T forms we have resonance between the two moieties of the molecule, one of quinoid structure, the other of benzenoid structure. Their acid–base instability is much decreased in comparison with the R forms, but instead an oxidation–reduction instability arises. In these substances the fourth electron pair of the central nitrogen is delivered by the auxochromic groups. The stability will therefore depend on the tendency of these groups to share their electron pairs with the neighboring carbon atom, in other words, to form a double bond with this carbon atom. This tendency is strongly related to the basicity of the auxochromic groups. The stability will be great if the auxochromic groups are strongly basic. We have, therefore, the maximum stability in solutions of a high pH. As we go

to more acid solutions we block the unshared electron pairs of the auxochromic groups ($T \rightarrow HT$) and the central nitrogen is more and more deprived of its electrons, giving rise to an increased tendency to take up an electron pair from outside. It has to be assumed that all symmetrical forms, in which the two auxochromic groups are equal, have a greater stability than the corresponding unsymmetrical forms. This is due to the larger resonance energy of the symmetrical forms.

The stabilities of the R and T-forms change, therefore, in just the opposite sense as we change the *p*H. In acid solutions R is especially stable and in alkaline solutions T is especially stable. This corresponds to the general fact that the normal potentials all become more negative as we raise the *p*H. A more positive potential means that T is more easily reduced to R and a more negative potential means that R is more easily oxidized to T.

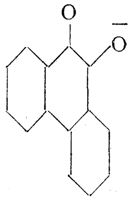
In this respect a comparison of the E_m values of phenolindophenol, phenol blue and Bindschedler's green, as demonstrated in Fig. 6, is of interest. Above *p*H 10, the three curves are parallel, the value for Bindschedler's green being the most positive and the one for phenolindophenol the most negative. The same must hold true for still more alkaline solutions, where the potentials become independent of *p*H. The relative values of the three normal potentials can be understood easily, because the instability (basicity) of the three R forms will increase in the following sequence

Bindschedler's green < Phenol blue < Phenolindophenol

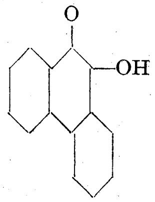
whereas the instability of the T forms will increase in just the opposite order, the more basic ionic oxygen group forming a more stable resonance system than the less basic amino group. This brings about the sequence in the normal potentials of these three dyestuffs.

3. The Stability of the Radical S.—It is much more difficult to predict the stability of a radical even qualitatively. Quite generally it must be assumed that a valence-unsaturated compound is less stable than R or T. The S form arises from the reaction $R + T \rightleftarrows 2S$ only if R and T are relatively unstable; this means, in general, in very acid and in very alkaline solution. We have shown experimentally that this really is the case in our examples. However, although it is difficult to make any statement about the stability of a radical in a general way, there may exist one quite obvious electronic structure in a radical which greatly enhances its existence. We may say that the semiquinones, which are radicals stable to a well measurable extent even in an aqueous solution, show this type of electronic arrangement. This is a resonance phenomenon, which differs essentially from the resonance of the T form mentioned above. It is not concerned necessarily with a resonance between two rings, but may be confined entirely within one single ring which contains two atoms of the same kind, either two N atoms, or two O atoms in symmetrical positions—that is to say, either in ortho or in para positions; either attached to, or within this ring. They are within the ring in phenazine, attached to the ring in Wurster's dyes. Instead of one ring, it may be the double ring of the biphenyl type, as in benzidine and γ,γ'-dipyridyl. The experience with the Wurster's dyes shows that the atom groups attached to each of the two N atoms need not necessarily be alike. They are alike in Wurster's blue, which has a very great stability. They are not alike in Wurster's red, which still has a fair stability. Also the semiquinone of phenol blue may be considered as comparable to Wurster's red, symmetrical with respect to the two N atoms at one ring, but not symmetrical with respect to the groups attached to the two N atoms. Phenolindophenol does not show this type of symmetry at all, but Bindschedler's green does.

This type of resonance furthermore is greatly influenced by *p*H, as was formerly explained on several occasions, *e. g.*, for the semiquinone of phenanthrenequinone,[13] and for the purple radical prepared by partial reduction of benzil.[17]



I



II

So, in alkaline solution (I), there is resonance with respect to the negative charge which may be at the one or the other O atom. But in acid solution (II), the attachment of the proton fixes the electron in one of the two possible positions thus decreasing the resonance and so the stability.

---

[17] L. Michaelis and E. S. Fetcher, THIS JOURNAL, **59**, 1246 (1937).

These considerations convey, at least qualitatively, an understanding about the stability of the radicals as depending on the constitution of the particular dye and on *p*H. We may emphasize once more, at this occasion, that practically none of the organic radicals that had been known prior to the discovery of the semiquinones, exhibit that particular type of strongly symmetrical resonance structure which has just been described as characteristic of the semiquinones. Correspondingly, those older radicals are usually not stable enough to be capable of any appreciable existence in the presence of water, in contrast to the semiquinone radicals.

Summary

Potentiometric oxidative and reductive titrations of Bindschedler's green and phenol blue at various *p*H's have been carried out. The slope of the titration curves indicates that an intermediate semiquinone radical is formed. The ionization constants for the reduced, half-oxidized, and oxidized forms of these dyes as well as the semiquinone formation constant have been determined. The latter depends on *p*H.

The ionization constants have been checked by spectrophotometric measurements. The absorption bands of all the three forms of each of these two dyestuffs are shown.

The discussion correlates the stability of the three forms, and especially that of the free radical, with general ideas about molecular stability derived from the electronic theory of the chemical bond and the principle of resonance. The type of resonance stabilizing the free radical is very different from the type of resonance stabilizing the oxidized form of the dye itself. The relative stability of the three forms of a dyestuff (oxidized, half-reduced radical, and reduced) is accounted for, qualitatively at least. The results are summarized in Figs. 4, 5, 6.

Potentiometric and Magnetometric Study of the Duroquinone System

By L. Michaelis, M. P. Schubert, R. K. Reber,[1] J. A. Kuck[1] and S. Granick

Among the numerous reversible bivalent two-step oxidation–reduction systems studied so far only a few cases of simple quinones have been subjected to an experimental study. They are concerned with orthoquinones. This paper adds an example of a paraquinone. A suitable representative avoiding the difficulties due to the instability of most quinones in alkaline solution, is duroquinone (tetramethylbenzoquinone). Although there is a limit to the stability of duroquinone also, no observable irreversible alteration by alkali occurs at all, during the period of time necessary for the experiments, at the temperature, 30°, even at the highest *p*H that reasonably may be used for experiments of this type. Because of its slight solubility, the experiments were performed with buffer solution containing 20 volume per cent. of pyridine, which, though reacting chemically with other quinones, serves only as a solvent for duroquinone. The process of reduction was studied both by the potentiometric and the magnetometric methods. Both methods agree in the final result. In sufficiently alkaline solution a free semiquinone radical of brown color is formed as intermediate step of the reversible reduction. This radical is strongly paramagnetic. In contrast to the semiquinone of phenanthrenequinonesulfonate, which is a representative of the orthoquinones, the semiquinone of duroquinone has no measurable tendency to form a valence-saturated, dimeric form in the dissolved state.

1. Potentiometric Experiments

Reductive titration with leuco-rosinduline G G was used. In sufficiently alkaline solutions, *p*H >9, the potentials are instantaneously and reproducibly established at concentrations down to 6×10^{-5} molarity. At lower *p*H values, the establishment of the potentials in low concentrations, about 10^{-4} *m*, is relatively sluggish, though eventually leading to definite and reproducible values. For this reason titration curves for duroquinone at *p*H < 9 are somewhat less accurate than those at *p*H > 9. This uncertainty has no

noticeable bearing on the values of E_m, the mean normal potential, but it affects somewhat the values for E_1 and E_2, the normal potentials of the lower and the higher steps of oxidation, since at $p\text{H} < 9$ the index potential E_i is very close to its minimum value 14.3 mv., and under these circumstances a small error in E_i involves a distinct error in E_1 and E_2. It will be seen, however, that no uncertainty in the construction of the curve (Fig. 1) ensues herefrom, except for the fact that the ionization constant of the radical cannot be determined with accuracy. All that we can say is that it is greater than 10^{-11}. Probably it is very much greater than 10^{-11}, by analogy with the semiquinone of phenanthrenequinonesulfonate.[2] The titration experiments are summarized in Table I, and the normal potentials, plotted against pH according to calculations from these experiments, are shown in Fig. 1. The bend correlated to the acid dissociation of the radical has been located tentatively at pH 11; it may be in reality at a much smaller pH value. In any case, it can be seen that the radical is practically incapable of existence in neutral or acid solution.

The initial concentration of duroquinone has been varied in these experiments in the ratio 1:16 without producing any variation in the shape of the titration curve at any given pH, in contrast to the case of phenanthrenequinonesulfonate.[3] This clearly indicates that there is no measurable tendency to dimerization of the radical. This result is confirmed by the magnetic method up to much higher concentrations.

One striking difference of this paraquinone from the two orthoquinones previously investigated is this. An *o*-quinone shows an acidic ionization, at pH around 9, due to the addition of an *OH⁻ ion* in alkaline solution. A *p*-quinone does not show this type of ionization, obviously because the acidifying influence of one CO group upon another is distinct only if the two CO groups are in close proximity. In any case, within the pH range experimentally available no ionization is noticeable. A consequence of this fact is that the E_1 and the E_2 curves do not run parallel in strongly alkaline solution, and hence the maximum ratio of semiquinone to total dye $(s/a)_{\text{max.}}$ continuously increases with increasing pH, whereas in the two orthoquinones investigated[2,4] it reaches a maximum value constant for any $p\text{H} > 11.5$.

Magnetometric Measurements

The method used was what may be called the slow-reduction method as described in a previous paper[5] with the magnetic balance of Wills and Boeker, modified by Woodbridge.[6] The change of magnetic susceptibility of the solution was measured during the period of reduction. The duration of this reductive period depends on *p*H and on the concentrations. The concentration of glucose was usually adjusted so as to stretch the time of reaction approximately over one hour.

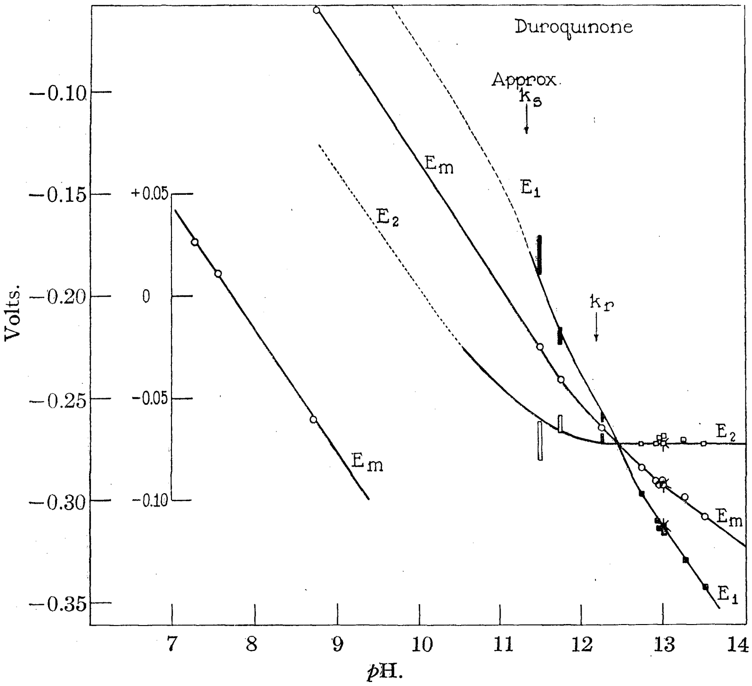

Fig. 1.—The mean normal potential, E_m; the normal potential of the lower step of oxidation, E_1, and the normal potential of the higher step of oxidation, E_2, of duroquinone plotted against *p*H. The left-hand curve is an extension of the main curve. The point designated ȯ- corresponds to three separate experiments with coinciding results.

In order to compare these measurements with those obtained potentiometrically one has to know the *p*H of the solution. In general, the *p*H will not be constant during the reduction. First, from the non-acid duroquinone the acidic semiquinone and the acidic hydroquinone are formed gradually. Since in these experiments the concentration of the quinone has to be taken much higher than in the potentiometric experiments, this fact has to be taken into consideration. Second, as the sugar acts as a reductant it is oxidized to various acids. So a sufficient excess of sodium hydroxide has to be added in order to minimize the effect of these acidic molecular species on the *p*H during the reduction. The following experiments will show that the experimental conditions chosen were such as to render any change of *p*H during the reduction negligible. All of these experiments were carried out by measuring the potential of the platinum electrode after adding some drops of 1% colloidal palladium, and while bubbling with hydrogen until the reduction was complete and the hydrogen potential was constant. (1) A solution just as used for the magnetic experiments no. 12 to 15, containing sodium hydroxide and pyridine, but without duroquinone and without glucose, showed *p*H 13.05. (2) The same solution, containing glucose, showed *p*H 13.01. (3) After adding in addition the duroquinone and rapidly reducing it by PdH_2 in the electrode vessel to the hydroquinone, *p*H was 12.99. (4) The same solution, containing glucose and the duroquinone as in (3) was allowed to stand at 30° in a closed bottle until the reduction by glucose was complete. Then the solution was poured into the electrode vessel, and after addition of colloidal palladium the potential in hydrogen was measured. This showed *p*H 13.00.

These experiments show that addition of glucose slightly shifted the *p*H of the sodium hydroxide solution, as may be expected, but that the effect on *p*H of any chemical reaction during the reduction is within the limits of error in the measurement of *p*H in such strongly alkaline solutions.

So we may put for experiments 12, 13, 14, and 15, *p*H = 13.00. For this *p*H we derive from the curve Fig. 1, $E_2 - E_1$ = 40 mv. Hence the semiquinone formation constant k = 4.64; and $(s/a)_{\text{max.}}$ = 0.517 ± 0.01. The limits of error are based on the assumption that the limit of error in the index potential, E_i, from which $E_2 - E_1$ has to be calculated, is ± 0.5 mv. The magnetic measurement yields $(s/a)_{\text{max.}}$ = 0.519 as average for the four parallel experiments, 12

to 15. The agreement is satisfactory. The calculation of $(s/a)_{\max.}$ is based on the difference in the value of susceptibility of its maximum point in the half reduced state, and the final, time-independent value after the completion of the reduction, and on the principle set forth in the previous paper[5] by assuming that the contribution of one mole of the free radical to the total susceptibility, in the direction of paramagnetism, amounts to $2.94/T$ units, where T is the absolute temperature. According to Van Vleck, "all odd polyatomic molecules should presumably conform to this formula."[7] Certainly this radical does.

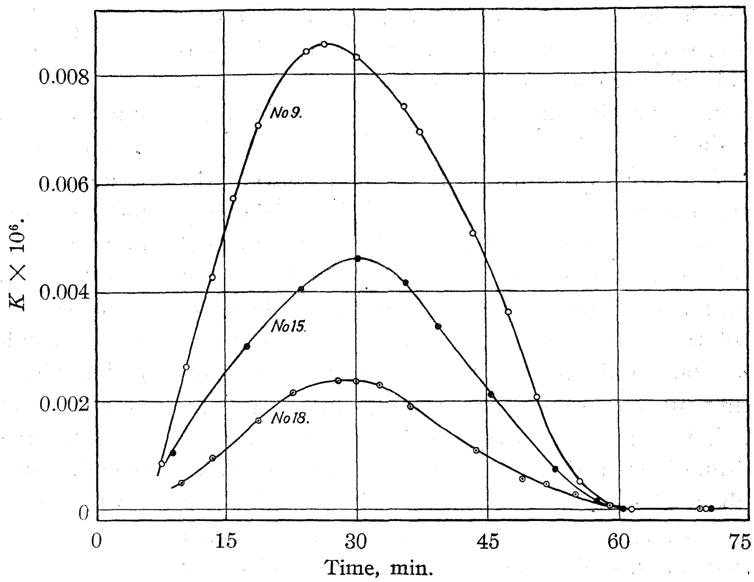

Fig. 2.—Magnetic susceptibility of duroquinone plotted against time, for three of the experiments tabulated in Table II. The time-independent diamagnetic susceptibility after the completion of the reduction is taken as zero point.

It should be ascertained also that the oxidation of glucose itself does not entail any measurable change in magnetic susceptibility. This was proved in the following experiment.

P = ml. of pyridine in 10 ml. of solution.
G = mg. of glucose in 10 ml. of solution.
S = ml. of 2.00 N NaOH in 10 ml. of solution.
s = calculated molar concentration of the semiquinone radical.
a = molar concentration of duroquinone added.
K = difference between the susceptibility at the maximum point and the time independent value at the end of the reaction.

[a] The exceptionally low value of $(s/a)_{\max.}$ in experiment no. 2 is due to the fact that the amount of glucose in comparison with that of sodium hydroxide is so high that pH is considerably lower than in experiment no. 1.

A fresh solution just as in the magnetic experiment, but without duroquinone, was measured in the magnetic balance. Another portion of this solution was bubbled for five hours with air under conditions such as to avoid any evaporation and to keep the volume unchanged, and was then put in the magnetic balance. The oxidation of the sugar had not been allowed to proceed too far in order to ensure the absence of dissolved oxygen during the magnetic observation. The result was that the diamagnetic susceptibility was the same as without previous oxidation, within the limits of error ($\pm$ 0.0002 $\times$ 10^{-6} unit).

Discussion of the Problem of Dimerization

With regard to the formation of either a paramagnetic free semiquinone radical or a dimeric, valence-saturated, non-paramagnetic molecular species on the oxidation level of a quinhydrone, the following statements may serve as actual material for the discussion.

(1) For the benzoquinone system, no statement can be made for alkaline solution because of the instability of benzoquinone in alkali. In acid solution, on mixing benzoquinone and hydroquinone, the solid crystals of quinhydrone are precipitated, and the remaining mother liquor contains practically nothing but a mixture of quinone and hydroquinone. The crystals of

---

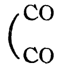
[7] J. H. Van Vleck, "Electric and Magnetic Susceptibilities," Oxford University Press, 1932, p. 274.

quinhydrone are diamagnetic[8] and so are representatives of a dimeric form, which may be considered as a compound of quinone and hydroquinone with the same justification as a dimerized radical.

(2) For duroquinone in alkaline solution the free paramagnetic semiquinone radical is the only form in which the quinhydrone arises. In acid solution, no quinhydrone can be detected at all on mixing duroquinone and durohydroquinone in solution. It is extremely difficult also to obtain a solid quinhydrone. When a mixture of duroquinone and durohydroquinone, say in methanol, is evaporated even to dryness, no quinhydrone is formed. On heating the dry residue to about 200°, a dark brown mass is formed which on cooling again becomes yellow. If it is cooled very rapidly, dark brown crystalline specks may survive, which disappear either spontaneously or on gently warming. If the hot brown mass is cooled down sufficiently slowly, all the brown color may disappear. It is formed over again on heating strongly. Obviously the formation of duroquinhydrone is a strongly endothermic reaction. The substance is not capable of existence at room temperature except in a metastable or transient state.

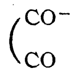
(3) Phenanthrenequinone-3-sulfonate, an orthoquinone, forms a paramagnetic radical in alkaline solution, which, when present in not too low a concentration, is in equilibrium with its non-paramagnetic dimeric compound. In acid solution, the free radical cannot be detected in any safely measurable concentration at all, whereas the dimeric compound is easily formed to a great extent in solutions of sufficiently high concentration of the parent substances.

These facts may be interpreted as follows: Let (I) be the symbol for any quinone. Then (II) is the semiquinone radical in a sufficiently alkaline solution, and (III) the same in a sufficiently acid solution. In (II) there is a strong symmetrical resonance, one electron oscillating from the one O atom to the other. This is not the case in (III) where the fixed proton fixes the electron, too. So (II) should be more stable than (III). This greater stability may find its expression in two ways: (a) the tendency of dismutation is smaller in (II) than in (III). This accounts for the fact that the semiquinone radical is more stable in alkaline than in acid solution, indicated by the fact that the semiquinone formation constant increases with increasing pH for all quinones that have been amenable to measurement yet. (b) The tendency toward dimerization is smaller in (II) than in (III). This explains why the dimerization constant should be greater in acid than in alkaline solution.[2]



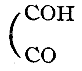
$\left(\begin{matrix}\text{CO}\\ \text{CO}\end{matrix}\right.$

(I)



$\left(\begin{matrix}\text{CO}^-\\ \text{CO}\end{matrix}\right.$

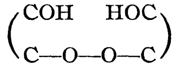
(II)



$\left(\begin{matrix}\text{COH}\\ \text{CO}\end{matrix}\right.$

(III)

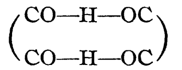
As regards the structure of the dimeric compound, one suggestion is the peroxide structure (IV).



$\left(\begin{matrix}\text{COH} & & \text{HOC}\\ \text{C—O—O—C}\end{matrix}\right)$

(IV)

The peroxide of Goldschmidt and Steigerwald[9] derived from chlorophenanthrol is colorless; the color appears only when the radical is formed by dissociation of the peroxide. So, one has to resort to the meriquinone structure proposed long ago by Willstätter and Piccard.[10] Expressing their idea in modern terms, one may assume two hydrogen bonds as in (V) for the dimeric form in the solid state. This hydrogen bond involves a resonance between two fictitious structures, in which alternately the one and the other half of the molecule is in the quinoid or in the benzenoid state, in the same way as is the case for any quinoid dyestuff, say of the indophenol type. This accounts for the deep color much more plausibly than does a peroxide structure.



$\left(\begin{matrix}\text{CO—H—OC}\\ \text{CO—H—OC}\end{matrix}\right)$

(V)

The same structure will hold for the soluble dimeric quinhydrone of phenanthrenequinonesulfonate, which represents the quinhydrone practically as it exists in acid solution, and as it exists in equilibrium with the free radical in alkaline solution. This dimeric molecule (V) is such a weak acid that it can exist, to a certain extent, even in rather strongly alkaline solution, provided it can exist in an acid solution.

So we have to discuss on what the existence of this dimeric form depends. The answer is that there must be no steric hindrance for a sufficiently close approach of each pair of atoms which are to be bridged by the hydrogen bond. If the quinone

---

[8] Some time ago Dr. C. D. Coryell in Professor L. Pauling's laboratory, at our request, measured the susceptibility of crystalline benzoquinhydrone and found it to be diamagnetic, in confirmation of unpublished experiments of several physicists about which we had personal information.

[9] St. Goldschmidt and Ch. Steigerwald, *Ann.*, **438**, 202 (1924).

[10] R. Willstätter and J. Piccard, *Ber.*, **41**, 1458 (1908).

is an orthoquinone, there is no steric restriction on forming these bonds. In a paraquinone, however, the two bonds can be formed only by putting the planes of the two six-carbon rings flatly one upon the other. This will be easily possible in benzoquinone, but in duroquinone the voluminous side chains prevent a sufficiently close approach. It may be briefly and preliminarily mentioned that the ease with which a solid quinhydrone is formed by mixing a quinone with the corresponding hydroquinone, decreases with the number of CH_3 groups which substitute the H atoms. In the tetramethyl compound, duroquinone, no quinhydrone is formed at all at room temperature.

The authors are deeply indebted to Columbia University for the use of their facilities.

Summary

Duroquinone in a strongly alkaline solution forms a free paramagnetic semiquinone radical of brown color as intermediate step of the reduction. There is no dimeric form of this radical; in other words, no compound corresponding to the ordinary crystalline benzoquinhydrone, which is a dimeric diamagnetic molecule, is formed from duroquinone and durohydroquinone either from alkaline or acid solutions. Solid benzoquinhydrone is a compound formed from quinone and hydroquinone by two hydrogen bonds. These bonds cannot be formed in duroquinone due to steric hindrance.

The maximum percentage of the duro-semiquinone radical in equilibrium with its parent substances continuously increases with increasing *p*H. At *p*H 13 this maximum is about 50%, a result which is the same whether derived from potentiometric or magnetic observations.

The Influence of Surface Tension on the Measurement of Viscosity
The Viscosity of Methanol

BY GRINNELL JONES AND HOLMES J. FORNWALT

Introduction

In recent years many measurements of viscosity of solutions of salts in water and in methanol have been carried out in this Laboratory by an improved technique.[1] The various sources of experimental error in determining the measurement of the viscosity of dilute solutions have been studied and discussed in an earlier paper. When measurements were extended to concentrated solutions and especially when the viscosity of methanol was compared with that of water it became apparent that the possibility of two additional sources of error which are negligible for relative measurements of dilute solutions should be considered, namely, errors due to unequal drainage and errors due to surface tension. The drainage error has recently been studied by Jones and Stauffer[2] with results which show that this source of error may be disregarded safely in measurements on methanol.

Surface tension can influence the measurement of viscosity by the Ostwald viscometer because the effective hydrostatic head which drives the liquid through the capillary is not solely determined by the dimensions and mounting of the instrument and the volume of liquid contained therein but is influenced by the capillary rise of the liquid in the two arms of the viscometer. Since this capillary rise is a function of the surface tension divided by the density, it will be different for the solutions and for the pure solvent.[3]

In this paper is given a mathematical analysis of the problem that has led to the development of a method of estimating the magnitude of the correction which should be applied to the results obtained with the Ostwald viscometer. This analysis guided the design of another instrument in which the error due to surface tension was minimized as much as other considerations of design permitted. The viscosity of methanol was then measured with reference to water in both the old and new instruments. The results are compared

before and after applying the computed corrections for surface tension.

Experimental

The source of the methanol was the same as that previously described[4] and the treatment similar except that it was more thorough. Lund and Bjerrum's method[5] of dehydration by distillation from magnesium methylate was carried out twice on each batch and in some cases there was an additional treatment with metallic sodium. The methanol was distilled through a good fractionating column 75 cm. long. The maximum range in the boiling point of the portions collected and used was only 0.04°. The four different batches which were used for the viscosity measurements gave the following densities, respectively: $d^{25}{}_4$, 0.786527, 0.786523, 0.786527, 0.786525. These results are slightly lower and more consistent than had been obtained with many batches which had been given a single treatment with magnesium methylate. The average density of these earlier batches was 0.786545. A comparison with the best results which have been found in the literature is given in Table I.

The freezing point of this methanol was determined by Mr. Edwin E. Roper in this Laboratory by the use of a platinum resistance thermometer to be −97.68 ± 0.02° (see the succeeding paper).

The first viscometer (designated herein as instrument T) was originally built for and used by S. K. Talley. The quartz-blower was instructed to make the surfaces connecting the constrictions and the cylindrical part of the upper bulb as nearly conical with a 60° angle as possible. Except for some necessary rounding at the line of contact with the cylinders above and below, he accomplished this objective approximately. In the calculations given below, the conical form is assumed. The values used for the angles are based on measurements made on the finished instrument. The lower reservoir was a vertical cylinder of much larger radius than the upper bulb. This larger radius was chosen in order to minimize the error due to variations in the working volume.

In the new instrument (designated here as F) there were three changes in design for the purpose of minimizing the surface tension correction: (1) the lower reservoir was made a cylinder of the same radius as the cylindrical part of the upper bulb; (2) the hydrostatic head was increased; (3) the quartz blower was instructed to make the upper dome and lower bowl as nearly hemispherical as he could. It is easier to meet this specification than to make the surfaces conical. The essential dimensions in centimeters which were used in the calculations are given below. The significance of the symbols will be understood by reference to Fig. 1.

TABLE II

DIMENSIONS OF THE VISCOMETERS IN CENTIMETERS

	w	*r*	*R*	*J*	*a*	*b*	*c*	*e*	*f*
T	0.05	0.90	3.58	24.3	23.8	22.3	18.5	17.5	16.5
F	.05	.848	0.848	28.5	27.43	26.59	21.95	21.1	20.7

T: Upper dome, $\tan\theta = -0.567$; $\theta = -29°30'$: lower bowl, $\tan\psi = +0.85$; $\psi = +49°38'$.

F: Radius of hemisphere, $r = 0.848$.

The first erratic results for the relative viscosity of methanol obtained with the new instrument were traced to the fact that variations in working volume have a greater effect on the hydrostatic head and, therefore, on the time of flow in the new instrument owing to the narrow lower reservoir. It was found by suitable independent experiments that in the old T viscometer a variation of 0.01 ml. in the working volume of methanol will cause an error of 0.007 second in the total time of 417 seconds; in the new F viscometer a variation of 0.01 ml. causes an error of 0.191 second in 682 seconds. The usual practice of delivering the working volume from a special pipet and determining the weight delivered by the loss of weight of the pipet is adequate when using water even with the F viscometer. However, due to the greater volatility of methanol the results with the old technique were erratic. A technique of transferring by distillation in a vacuum was developed. The methanol was placed in a suitable flask provided with a stopcock and a ground joint beyond the stopcock, and weighed. The flask and the viscometer were then connected by means of their ground joints to the same wide tube, which was also connected to a vapor trap and a stopcock leading to a good mechanical vacuum pump. The ground joints were not greased but were made vacuum tight by an external mercury seal. The vapor trap was chilled with a mixture of solid carbon dioxide and ether, and then the entire system was evacuated through the trap without losing any methanol. After a good vacuum had been established the stopcock to the pump was closed, the viscometer chilled by solid carbon dioxide and ether, and the weighing flask and trap warmed gently, thus distilling the methanol completely into the vis-

cometer. The empty flask was then weighed, which gave the amount of methanol transferred to the viscometer. This method of transfer by distillation in a vacuum gave more consistent results with methanol and was used in all of the experiments recorded in Table III. With water there was no significant difference between the results obtained by the old and new methods of transfer to the viscometer.

TABLE III

VISCOSITY OF METHANOL RELATIVE TO THAT OF WATER AT 25° UNCORRECTED FOR SURFACE TENSION EFFECTS

Batch	d^{25}_4	Relative Viscosity T	F
35	0.786527	0.60554	0.60831
		.60539	
36	.786523	.60571	.60798
		.60567	.60849
37	.786527	.60562	.60877
		.60584	
38	.786525	.60576	.60794
		.60582	
Average	0.786525	0.60567	0.60830
Probable error of mean		± .00004	± .00010
Ratio F/T = 1.0043			

This table shows that the two instruments give results which differ in the ratio of 1.0043. This difference is substantially greater than the "probable error" of the mean for each instrument, which proves that there is a systematic error in the results obtained with one or both instruments.

The next step is to attempt to compute the correction which must be applied for the error due to surface tension in order to determine whether or not it is large enough to account for the systematic difference.

Computation of the Error in Viscosity Measurements with the Ostwald Viscometer Due to Surface Tension.—The effective hydrostatic head in the Ostwald viscometer will be the geometric head minus the capillary rise in the upper bulb plus the capillary rise in the lower bulb. The capillary rise will depend on the liquid used, and will also depend on the shape of the upper and lower bulbs. The effective hydrostatic head will vary continuously during the flow. It will, therefore, be necessary to derive a differential equation for the time of flow and integrate it over the total volume.

Poiseuille's law of flow may be put in the form

$$\mathrm{d}t = \frac{8l\eta \mathrm{d}V}{\pi s^4 g\rho H} = \frac{A\eta \mathrm{d}V}{\rho H} = \frac{B\mathrm{d}V}{H} \qquad (1)$$

where s is the radius and l the length of the capillary, g the acceleration of gravity, η the viscosity, ρ the density, and H the effective hydrostatic head (geometric head minus the capillary rise) and $\mathrm{d}V$ is the differential volume which flows in the time $\mathrm{d}t$; and for the sake of abbreviation we write $A = 8l/\pi s^4 g$; and $B = A\eta/\rho$. A will have a definite numerical value for any given instrument. B will depend both on the instrument and on the viscosity and density of the liquid used, but will be independent of the surface tension. H will depend on the dimensions of the instrument and the ratio of surface tension to density σ/ρ, but will be independent of the viscosity.

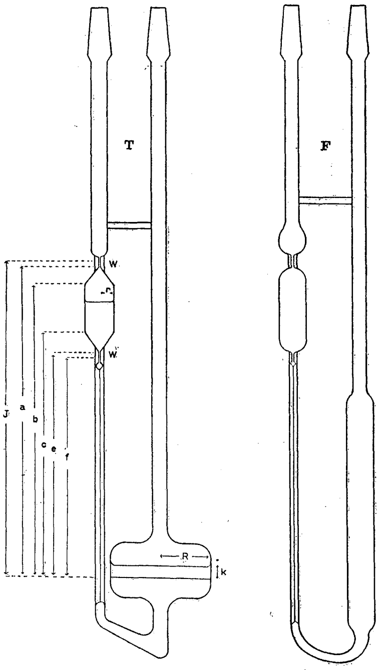

Fig. 1.

The definite integral obtained from Equation (1) should express the time of flow as a function of the instrumental constants which determine A and influence H, and the viscosity, density and surface tension of the fluid. The total time is determined experimentally and the density is also determined independently as a routine part of the viscosity measurements. The surface tension can be measured independently and therefore in mathematical theory may be regarded as a known quantity. However, if it can be shown that with a suitable design of the viscometer the surface tension correction becomes negligible or can be estimated sufficiently well without a precise knowledge of the surface tension, then the precise measurement of viscosity will be greatly simplified.

The absolute measurement of viscosity is an experimental problem of great difficulty. However, for the many theoretical purposes values of the viscosity of solutions relative to that of pure water are sufficient. By making measurements of the total time of flow of water in the same instrument, the instrumental constant A may be eliminated, thus making it unnecessary to measure the length and radius of the capillary.

The definite integral of Equation (1) may be expressed

$$t_c = B_c \int_0^V \frac{\mathrm{d}V}{H_c} = A\,\frac{\eta_c}{\rho_c} \int_0^V \frac{\mathrm{d}V}{H_c}$$

for methanol or for the solution of concentration c, and

$$t_0 = B_0 \int_0^V \frac{\mathrm{d}V}{H_0} = A\,\frac{\eta_0}{\rho_0} \int_0^V \frac{\mathrm{d}V}{H_0}$$

for water. Hence the relative viscosity is given by the expression

$$\frac{\eta_c}{\eta_0} = \frac{t_c\rho_c}{t_0\rho_0}\,\frac{\int_0^V \frac{\mathrm{d}V}{H_0}}{\int_0^V \frac{\mathrm{d}V}{H_c}} \qquad (2)$$

It has been commonly assumed in this and other laboratories that $\int_0^V \frac{\mathrm{d}V}{H_0} = \int_0^V \frac{\mathrm{d}V}{H_c}$, which amounts to the assumption that the effect of surface tension is negligible. The magnitude of the error caused by this assumption will be considered in the succeeding pages.

In order to integrate the equation $\mathrm{d}t = B\mathrm{d}V/H$ it is necessary to know the shape and dimensions of both the upper and lower bulbs. To facilitate this integration it is practically necessary to assume that the geometric form is a comparatively simple one. It is assumed that the working part of the lower reservoir, the upper and lower constrictions where the transits are timed at the beginning and end of the flow, and the central part of the upper bulb are all right circular cylinders having the internal radii R, w and r, respectively, and that the axes of these cylinders are vertical. The upper dome (from a to b) and the lower bowl (from c to e) of the upper bulb may be assumed to be either cones or hemispheres. Although a good quartz blower can make these portions of the instrument approximately hemispherical or conical as desired, the actual geometrical form of the instrument will not correspond exactly to the assumed geometrical form, especially near the lines of contact with the cylindrical parts of the instrument, and, therefore, these assumptions unavoidably introduce some error in the resulting calculations. Moreover, there will be some experimental error in the measurement of the essential dimensions after the instrument has been constructed. The calculations are, therefore, at best only approximations and they are so laborious that they are entirely impractical as a regular part of the routine of viscosity measurements.

In the integration of the fundamental equation $\mathrm{d}t = B\mathrm{d}V/H$ the geometrically distinct parts of the instrument must be treated separately and the definite integrals for the several parts added together.

In the operation of the viscometer a standard working volume of the liquid is added. The liquid is sucked above the mark in the upper constriction and then allowed to fall under the influence of gravity. The timing is started at the instant the meniscus passes the upper mark. The origin from which all vertical or horizontal distances are measured is in the axis of the upper bulb and at the level of the liquid in the lower reservoir when the instrument contains the standard volume and the upper meniscus is at the reference mark on the upper constriction assuming that there is no distortion of the surfaces by surface tension effects. Let J represent the height of the upper mark above this base level. J as thus defined depends solely on the dimensions of the instrument and the standard working volume and is independent of the liquid used.

Now consider a particular instant of time when the meniscus has passed the upper mark and is flowing downward through the upper constriction at a height y above the base level. We may then write

$$\mathrm{d}V = -\pi w^2\mathrm{d}y \qquad (3)$$

and

$$H = +y - h + j - k \qquad (4)$$

where

$$h = 2\sigma/gw\rho \qquad (5)$$

is the capillary rise in the upper constriction; and

$$j = 2\sigma/gR\rho \qquad (6)$$

is the capillary rise in the lower reservoir; and

$$k = \frac{w^2}{R^2}(J - y) \qquad (7)$$

is the increase in height of the liquid in the lower reservoir, because a volume of liquid equal to that in the constriction between the initial mark and the height y has entered the lower reservoir.

When

$$y = a \qquad k = k_a = \frac{w^2}{R^2}(J - a) \qquad (7a)$$

The correction, j, must be applied even if the lower reservoir is so wide that it has a flat portion at its center because the instrument is filled with a standard volume of liquid and the withdrawal of a part of this volume into the meniscus lowers the effective hydrostatic level in the reservoir and thus increases the effective head.

Substituting these values in (1) gives

$$\mathrm{d}t = \frac{B\mathrm{d}V}{H} = \frac{-\pi B w^2 \mathrm{d}y}{y - \frac{2\sigma}{gw\rho} + \frac{2\sigma}{gR\rho} - \frac{w^2}{R^2}(J - y)} \qquad (8)$$

Now integrate between the initial limit of $y = J$ and the final limit $y = a$, which gives

$$t_J^a = \frac{B\pi w^2}{1 + w^2/R^2} \ln \frac{J - \frac{2}{g}\left(\frac{1}{w} - \frac{1}{R}\right)\frac{\sigma}{\rho}}{J - \frac{2}{g}\left(\frac{1}{w} - \frac{1}{R}\right)\frac{\sigma}{\rho} - \left(1 + \frac{w^2}{R^2}\right)(J - a)} \qquad (9)$$

It is evident from this equation that in order to minimize the effects of variations in σ/ρ, J should be made large, and $(J - a)$ and w small. Since $\frac{2}{g}\left(\frac{1}{w} - \frac{1}{R}\right)\frac{\sigma}{\rho}$ is small in comparison with J and with $J - (1 + w^2/R^2)(J - a)$, the error due to the neglect of the surface tension will be almost a linear function of σ/ρ.

The upper dome of the upper bulb may be constructed so that it may be treated either as a cone or as a hemisphere. We have not found an equation for the capillary rise in a conical tube in the literature. An exact solution of this problem would require an exact knowledge of the shape of the meniscus expressed as an equation for the surface. The problem of finding such an equation has not been fully solved even for cylindrical tubes, much less for conical tubes. However, we have succeeded in deriving an approximate equation for the capillary rise in conical tubes which is sufficiently good for the present purpose by a method which is similar to that commonly used to derive the equation for the rise in a cylindrical tube. The details of this derivation are omitted for the sake of brevity. Assume that a conical tube open at both ends is dipped with its axis vertical into a large surface of liquid (see Fig. 2), then the rise of liquid inside the cone above the free surface will be approximately

$$h = \frac{2\sigma(1 - \sin\theta)}{gx\,\rho\cos\theta} \qquad (10)$$

where x is the radius of the circle formed by the intersection of the cone with the horizontal plane at the height h above the free surface, and θ is the angle between the vertical axis of the cone and the sides. By substituting $\theta = 0$ this reduces to the correct form for a cylinder. If the narrow end of the cone is upward the angle θ must be taken as negative and therefore will have a negative sine and a positive cosine, therefore

$$0° > \theta > -90°$$

$$1 > \frac{1 - \sin\theta}{\cos\theta} > +\infty$$

The capillary rise in the cone with the tip upward is greater than in a cylinder of the same effective diameter.

If the narrow end of the cone is downward the equation has the same form but the angle which is called ψ in Fig. 2 is in the first quadrant and is taken as a positive angle; therefore if

$$0° < \psi < 90°$$

$$1 > \frac{1 - \sin\psi}{\cos\psi} > 0$$

Therefore the capillary rise in a cone with the narrow end downward is less than in a cylinder of the same effective diameter.

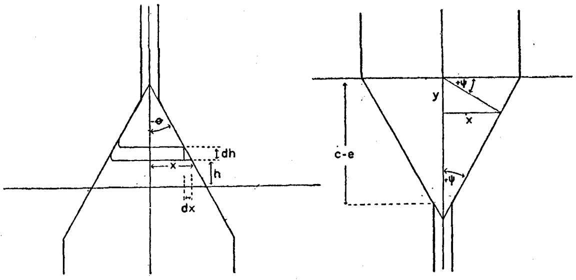

Fig. 2.

The differential equation for the time of flow of the meniscus from a to b in the upper conical dome may now be derived in a manner similar to that given above. The first step is to compute J_a, the geometrical head at the beginning of the conical part of the tube without allowance for surface tension effects. This will be the height, a, above the base level minus the increased level in the lower reservoir, k_a, owing to the transfer of the liquid from the upper constriction to the lower reservoir.

$$J_a = a - k_a = a - \frac{w^2(J - a)}{R^2} \qquad (11)$$

Now consider the particular instant of time when the meniscus is in the cone at a distance y above the base level and let x be the radius of the circle formed by the intersection of the cone with a horizontal plane at the height y.

$$H = y - h + j - k - k_{\mathrm{a}} \qquad (12)$$

$$(x - w)/(y - a) = \tan \theta \qquad (13)$$

here $a > y$ and θ is negative

$$y = a + (x - w) \cot \theta \qquad (14)$$

$$\mathrm{d}y = \cot \theta \, \mathrm{d}x \qquad (15)$$

$$\mathrm{d}V = -\pi x^2 \mathrm{d}y = -\pi x^2 \cot \theta \, \mathrm{d}x \qquad (16)$$

$$\pi R^2 k = \int \mathrm{d}V = -\pi \cot \theta \int_w^x x^2 \mathrm{d}x \qquad (17)$$

$$k = -\frac{(x^3 - w^3) \cot \theta}{3R^2} \qquad (18)$$

When $y = b$, then $x = r$, and

$$k = k_{\mathrm{b}} = -\frac{(r^3 - w^3) \cot \theta}{3R^2} \qquad (18a)$$

h is given by Equation (10) and j by Equation (6) as before, therefore

$$\mathrm{d}t = \frac{B\mathrm{d}V}{H} = \frac{-B\pi x^2 \cot \theta \, \mathrm{d}x}{J_{\mathrm{a}} + (x - w)\cot \theta - \frac{2\sigma(1 - \sin \theta)}{\rho g x \cos \theta} + \frac{2\sigma}{gR\rho} + \frac{(x^3 - w^3) \cot \theta}{3R^2}} \qquad (19)$$

then an algebraic rearrangement gives

$$\frac{\mathrm{d}t}{3R^2B\pi} = \frac{-x^3\mathrm{d}x}{x^4 + 3R^2x^2 + (3R^2J_{\mathrm{a}} \tan \theta - 3R^2w - w^3)x + \frac{6R\sigma x}{g\rho} \tan \theta - \frac{6R^2\sigma \sin \theta}{g\rho(1 + \sin \theta)}} \qquad (20)$$

This equation must now be integrated between the lower limit $x = w$ and the upper limit $x = r$. It has not been found possible to integrate this equation in general terms, but if numerical values are assigned to w, r, R and θ for any particular instrument, and to σ/ρ for any particular liquid, the integration is then possible, although laborious. By a purely algebraic device this equation can be transformed into an equation of the form

$$\frac{\mathrm{d}t}{3R^2B\pi} = \frac{M\mathrm{d}x}{x - m} + \frac{N\mathrm{d}x}{x - n} + \frac{P(2x + p)dx + Q\mathrm{d}x}{x^2 + px + q} \qquad (21)$$

with known numerical values for all of the quantities except B. The integral of this equation has the form

$$\frac{t_{\mathrm{a}}^{\mathrm{b}}}{3R^2B\pi} = \Bigg[M \ln (x - m) + N \ln (x - n) + P \ln (x^2 + px + q) + \frac{2Q}{\sqrt{4q - p^2}} \tan^{-1} \frac{2x + p}{\sqrt{4q - p^2}}\Bigg]_{x = w}^{x = r} \qquad (22)$$

From this equation (22) a numerical value of $t_{\mathrm{a}}^{\mathrm{b}}/B$ can be computed for each special case.

The calculation of $t_{\mathrm{b}}^{\mathrm{c}}$ for the cylindrical part of the bulb between b and c is so similar to that for the cylindrical upper constriction that it is only necessary to write down the equation similar to Equation (9).

$$t_{\mathrm{b}}^{\mathrm{c}} = \frac{B\pi r^2}{1 + \frac{r^2}{R^2}} \ln \frac{J_{\mathrm{b}} - \frac{2}{g}\left(\frac{1}{r} - \frac{1}{R}\right)\frac{\sigma}{\rho}}{J_{\mathrm{b}} - \frac{2}{g}\left(\frac{1}{r} - \frac{1}{R}\right)\frac{\sigma}{\rho} - (b - c)\left(1 + \frac{r^2}{R^2}\right)} \qquad (23)$$

where J_{b} is the geometric head at the beginning of the flow through the cylinder;

$$J_{\mathrm{b}} = b - k_{\mathrm{a}} - k_{\mathrm{b}} = b - \frac{w^2}{R^2}(J - a) + \frac{(r^3 - w^3) \cot \theta}{3R^2} \qquad (24)$$

Here it should be pointed out that if the instrument is so designed that $r = R$, then the term involving the surface tension drops out entirely so that the time of flow through this part of the apparatus is not influenced by the surface tension regardless of the magnitude of $b - c$. This is because the capillary rise in the upper bulb is exactly compensated by the capillary rise in the lower bulb. The lower bowl, like the upper dome, may be assumed to be either a cone or a hemisphere. If it is assumed to be a cone, the derivation is similar to that given for the dome, except that the half angle, ψ, is to be taken as a positive angle, and of course the initial geometric head J_{c} is different.

$$J_{\mathrm{c}} = c - k_{\mathrm{a}} - k_{\mathrm{b}} - k_{\mathrm{c}} = c - \frac{w^2}{R^2}(J - a) + \frac{(r^3 - w^3) \cot \theta}{3R^2} - \frac{r^2}{R^2}(b - c) \qquad (25)$$

$$H = y - h + j - k - k_{\mathrm{a}} - k_{\mathrm{b}} - k_{\mathrm{c}} \qquad (26)$$

$$y = e + (x - w) \cot \psi \qquad (27)$$

$$h = \frac{2\sigma}{gx\rho} \frac{(1 - \sin \psi)}{\cos \psi} \qquad (28)$$

$$k = \frac{(r^3 - x^3) \cot \psi}{3R^2} \qquad (29)$$

Making these substitutions followed by a purely algebraic transformation gives the equation

$$\frac{\mathrm{d}t}{3R^2B\pi} = \frac{-x^3\mathrm{d}x}{x^4 + 3R^2x^2 + (3R^2J_{\mathrm{c}} \tan \psi - 3rR^2 - r^3)\, x + \frac{6R\sigma x \tan \psi}{g\rho} - \frac{6R^2\sigma \sin \psi}{g\rho\, (1 + \sin \psi)}} \qquad (30)$$

This equation must be integrated between the initial limit of $x = r$ and the final limit of $x = w$. To accomplish this numerical values are substituted and the procedure described above for Equation (20) is carried out.

The equation for the lower constriction is similar to that for the upper constriction. If the dome and bowl are conical

$$J_{\mathrm{e}} = e - k_{\mathrm{a}} - k_{\mathrm{b}} - k_{\mathrm{c}} - k_{\mathrm{e}} = e - \frac{w^2}{R^2}(J - a) - \frac{(r^3 - w^3)(\cot\psi - \cot\theta)}{3R^2} - \frac{r^2}{R^2}(b - c) \qquad (31)$$

$$t_{\mathrm{c}}^{\mathrm{b}} = \frac{B\pi w^2}{1 + \frac{w^2}{R^2}} \ln \frac{J_{\mathrm{e}} - \frac{2}{g}\left(\frac{1}{w} - \frac{1}{R}\right)\frac{\sigma}{\rho}}{J_{\mathrm{e}} - \frac{2}{g}\left(\frac{1}{w} - \frac{1}{R}\right)\frac{\sigma}{\rho} - (e - f)\left(1 + \frac{w^2}{R^2}\right)} \qquad (32)$$

If the upper dome and lower bowl are blown so as to make them as nearly as possible hemispheres instead of cones, the calculation is similar to that for a cone but different in detail. The time of flow through the upper constriction, $t_{\mathrm{j}}^{\mathrm{a}}$, is computed by Equation (9) just as before. The upper dome is considered to be a hemisphere of radius, r, whose center has the coördinates $y = b$ and $x = 0$ cut by a vertical cylinder of radius w. It is convenient to introduce an abbreviation $z = y - b$. Then $x^2 + z^2 = r^2$ and $\tan\theta = -z/x$; $\sin\theta = -z/r$; and $\cos\theta = x/r$. The minus signs are due to the fact that θ must be taken as a negative angle but z is a positive quantity.

$$\mathrm{d}V = -\pi x^2 \mathrm{d}y = -\pi(r^2 - z^2)\mathrm{d}z \qquad (16')$$

$$H = y - h + j - k - k_{\mathrm{a}} \qquad (12)$$

$$h = \frac{2\sigma}{\rho g x}\,\frac{(1 - \sin\theta)}{\cos\theta} = \frac{2\sigma}{\rho g x^2}(r + z) = \frac{2\sigma}{\rho g(r - z)} \qquad (10')$$

$$\pi R^2 k = \int \mathrm{d}V = -\int_{(a-b)}^{z} \pi(r^2 - z^2)\mathrm{d}z \qquad (17')$$

$$k = \frac{1}{R^2}\left[r^2(a - b) - \frac{(a - b)^3}{3} - r^2 z + \frac{z^3}{3}\right] \qquad (18')$$

When $y = b$, $z = 0$ and

$$k = k_{\mathrm{b}} = \frac{r^2(a - b)}{R^2} - \frac{(a - b)^3}{3R^2} \qquad (18'a)$$

$$J_{\mathrm{b}} = b - k_{\mathrm{a}} - k_{\mathrm{b}} = b - \frac{w^2}{R^2}(J - a) - \frac{r^2}{R^2}(a - b) + \frac{(a - b)^3}{3R^2} \qquad (24')$$

$$\mathrm{d}t = \frac{B\mathrm{d}V}{H} = \frac{-B\pi(r^2 - z^2)\mathrm{d}z}{J_{\mathrm{b}} + z - \frac{2\sigma}{\rho g(r - z)} + \frac{2\sigma}{\rho g R} + \frac{3r^2 z - z^3}{3R^2}} \qquad (19')$$

Then a purely algebraic transformation gives

$$\frac{\mathrm{d}t}{3R^2 B\pi} = \frac{-(r^2 - z^2)(r - z)\mathrm{d}z}{z^4 - rz^3 - 3(R^2 + r^2)z^2 + (3R^2 r + 3r^3 - 3R^2 J_b)z - \frac{6R\sigma z}{g\rho} - \frac{6R(R - r)}{g}\sigma/\rho + 3R^2 r J_b} \qquad (20')$$

This equation must be integrated between the initial limit of $z = (b - a)$ and the final limit of $z = 0$. This cannot be done except by introducing numerical values. A numerical value of $t_{\mathrm{a}}^{\mathrm{b}}/B$ can then be computed by introducing the appropriate numerical values for R, r, J_{b} and integrating between the initial limit of $z = b - a$ and the final limit of $z = 0$.[6]

The equation for the time of flow in the cylindrical part of the upper bulb, $t_{\mathrm{b}}^{\mathrm{c}}$, is the same as Equation (23) above except that J_b is given by Equation (24′) above instead of by Equation (24).

The differential equation for the time of flow in the lower bowl considered as a hemisphere has the same form as Equation (20′) above except that in place of J_{b} we must insert

$$J_{\mathrm{c}} = c - k_{\mathrm{a}} - k_{\mathrm{b}} - k_{\mathrm{c}} = c - \frac{w^2}{R^2}(J - a) - \frac{r^2}{R^2}(a - b) + \frac{(a - b)^3}{3R^2} - \frac{r^2}{R^2}(b - c) \qquad (25')$$

The integration must be carried out between the initial limit of $z = 0$ and the final limit of $z = e - c$.

The equation for the time of flow through the lower constriction has the same form as Equation (32) above except that J_{e} is given by

$$J_{\mathrm{e}} = e - \frac{w^2}{R^2}(J - a) - \frac{r^2}{R^2}(a - e) + \frac{(a - b)^3 + (c - e)^3}{3R^2} \qquad (31')$$

Table IV gives the results of the numerical calculations carried out by the use of these equations for the instrument T using the dimensions

---

(6) There is one disturbing subtlety in these calculations which deserves a footnote: the assumption that the shape of the upper dome is a hemisphere of radius $r = 0.848$ cm., intersected by a vertical cylinder of radius $w = 0.05$ cm., and that the equation (10) holds for values of θ which are near $-90°$ gives a value of $h > J_{\mathrm{a}}$ which makes $H < 0$ and the time of outflow infinite. But as a matter of fact the actual instrument does empty itself, which shows that the conditions mentioned above do not prevail. This means that as a matter of practical quartz blowing the vertical cylinder is somewhat flared before it meets the hemisphere, so that there is in effect a short conical tube inserted between the cylinder and the hemisphere so that values of θ which are nearly $-90°$ do not occur in the actual instrument. At the level where the hemisphere starts x is large enough and θ sufficiently different from $-90°$ so that $h < J_{\mathrm{a}}$ and $H > 0$. The calculations of the results shown in Table V are based on the assumption that there is a truncated cone with $\theta = -45°$ and a height of 0.07 cm. between the vertical cylinder of radius, $w = 0.05$ cm., and the hemisphere of radius, $r = 0.848$ cm. This makes the initial limit for the integration of Equation 20′, $z = \sqrt{0.848^2 - (0.05 + 0.07)^2} = 0.8394665$, which avoids the mathematical paradox described above. Essentially the same result may be obtained in a much less laborious manner by arbitrarily taking as the initial limit for z a value which is slightly smaller than the value which would make $H = 0$, and $t = \infty$.

Total	t_J^f/B	0.593530	0.593097	0.592667	0.590924
	$\frac{\int dV/H_0}{\int dV/H_c}$		1.0007_3	1.0014_6	1.0044_1

given in Table II. These calculations have been carried out for water, assuming that $\sigma = 71.97$ dynes per centimeter at 25° and $\rho = 0.99707$, giving $\sigma/\rho = 72.18$; and for two hypothetical aqueous solutions for which σ/ρ is taken as 0.9 and as 0.8 of that of water, or 64.962 and 57.744, respectively; and for methanol[7] assuming that $\sigma = 22.17$ dynes per centimeter, and $\rho = 0.78652$, giving $\sigma/\rho = 28.19$.

The experimental data recorded in Table III for methanol with viscometer T give $t_c\rho_c/t_0\rho_0 = 0.60567$ and therefore, according to Equation (3), we have $\eta_c/\eta_0 = 0.60567 \times 1.0044_1 = 0.6083_4$ as the value for the relative viscosity of methanol corrected for the surface tension as determined with the old T viscometer.

Similar calculations have been carried out with the new F viscometer and the results are recorded in Table V. The dimensions used in the calculations are given in Table II.

TABLE V

ERRORS IN VISCOSITY MEASUREMENTS DUE TO SURFACE TENSION

Values of the definite integral $\int dV/H$ for parts of the viscometer F for water and for methanol.

		Water	Methanol
	σ/ρ	72.18	28.19
Upper constriction	t_J^a/B	0.000377	0.000356
Upper dome	t_a^b/B	.048368	.048125
Upper cylinder	t_b^c/B	.498199	.498199
Lower bowl	t_c^e/B	.078955	.079115
Lower constriction	t_e/B	.000254	.000224
Total	t_J^f/B	0.626153	0.626019

$$\frac{\int dV/H_0}{\int dV/H_c} = 1.0002_1$$

A comparison of Tables IV and V shows clearly the effectiveness of the new design in reducing the error due to surface tension. One important result of making the radius of the lower reservoir equal to that of the cylindrical part of the upper bulb is that for this part of the apparatus $\int dV/H_0 = \int dV/H_c$, thus completely eliminating the correction for a large fraction of the total time. Moreover, another result is that the effect in the lower bowl partly compensates the effect in the upper dome. For the upper dome $\int dV/H_0 - \int dV/H_c = +0.000243$, whereas for the lower bowl $\int dV/H_0 - \int dV/H_c = -0.000160$.

The experimental data recorded in Table III for methanol with viscometer F give $t_c\rho_c/t_0\rho_0 = 0.60830$, and, therefore, according to Equation (2), we have $\eta_c/\eta_0 = 0.60830 \times 1.0002_1 = 0.6084_3$.

The values obtained with the two different instruments agree much better after applying the surface tension correction (0.60834 with viscometer T, and 0.60843 with viscometer F) than they did before the correction was applied (0.60567 and 0.60830). Averaging the results, giving greater weight to the F instrument because the correction is so much smaller, gives $\eta_c/\eta_0 = 0.6084$. If the absolute viscosity[8] of pure water at 25° is taken as 0.008949 poise, then the absolute viscosity of methanol is 0.005445 poise.

At least sixteen different determinations of the viscosity of methanol at 25° are recorded in the literature, but the references and results are not given in detail. In most cases the results are quite discordant because the measurements were incidental to some other purpose and the technique was crude, or the density of the methanol was so high that it is evident that the sample contained water. The best of the previous results are given below.

The data given in Table IV show that the cor-

recting factor for viscometer T is very nearly a linear function of σ/ρ so that

$$\int\frac{dV}{H_0}\Big/\int\frac{dV}{H_c} = 1 + 0.0074\,\frac{(\sigma_0/\rho_0 - \sigma_c/\rho_c)}{\sigma_0/\rho_0} = 1.0074 - \frac{0.0074\,\sigma_c\rho_0}{\rho_c\sigma_0}$$

However, no systematic attempt will be made at this time to estimate the corrections which should be applied to the viscosity data which have been published from this Laboratory, because the surface tension data are not available in most cases. An improved method of measuring surface tension has been developed[9] and data on a few salts obtained, but it is necessary to postpone a general revision of the data for the viscosity of concentrated solutions until the surface tensions of these solutions have been measured. One illustrative example, in which the correction is exceptionally high, must suffice for the present. Jones and Talley,[10] who used our instrument T, report that the relative viscosity of a 2.962 normal potassium chloride solution at 25° is 1.03211. From the data of Jones and Ray the value of $\sigma_c\rho_0/\rho_c\sigma_0$ may be found by a slight interpolation to be 0.9445. This gives a correcting factor of 1.00041 or a relative viscosity corrected for the effect of surface tension of 1.03253.

The Design of the Ostwald Viscometer

With an Ostwald viscometer, where the liquid depends on its own hydrostatic head for driving pressure, an approximate value for the viscosity relative to that of water is computed by the simple equation $\eta = \eta_c/\eta_0 = t_c\rho_c/t_0\rho_0$, but to obtain the maximum precision it may be necessary to apply one or more of the following corrections unless the instrument can be designed so as to make the corrections negligible. The four corrections are (1) the drainage correction; (2) the working volume correction; (3) the kinetic energy correction; (4) the surface tension correction.

It is obvious that the first requirement for precise viscometry is accuracy in the timing and in the determination of the densities. However, the technique of making these measurements has been developed so that the real precision depends on the reliability of the corrections.

The instrument should be designed so as to make the corrections negligible if possible, or at least to minimize them as much as other considerations of design, such as convenience and speed of operation, permit. Unfortunately, details of design which may be helpful in minimizing one of the corrections may increase some other correction or cause trouble in operation or other errors so that the best design is a matter of compromise.

It has been shown in a recent paper from this Laboratory[2] that if the design is suitable in other respects the drainage correction is negligible except for extremely viscous liquids or for viscometers of a very short time of efflux.

The correction for variations in working volume can be applied with most confidence because its theoretical basis is beyond criticism, and the experimental determination of the magnitude with sufficient precision is easy in the case of aqueous solutions if the lower reservoir is not too narrow.

In the case of the kinetic energy correction there is some doubt, or at least a difference of opinion among the authorities, as to the proper way to compute the correction. Some authorities even deny that the correction should be applied at all. Although we believe that the correction should be applied, we also believe it wise to use every feasible artifice of design to reduce the magnitude of the correction, and thereby reduce the error due to inaccuracy in its computation. In designing the viscometer it is possible to control within practical limits the length and radius of the capillary, the hydrostatic head, the volume and shape of the measuring bulb, and the radius of the lower reservoir. The kinetic energy correction is diminished by any change in design which increases the time of outflow, except increasing the volume of the measuring bulb. The correction in principle always can be made negligible by using an instrument with a sufficiently long time of outflow, but this may cause serious inconvenience and delay in making measurements. Reducing the radius of the capillary and reducing the hydrostatic head both increase

---

(9) Grinnell Jones and W. A. Ray, THIS JOURNAL, **59**, 187 (1937).

(10) Grinnell Jones and S. K. Talley, *ibid.*, **55**, 624, 4124 (1933).

the time of flow and hence reduce the kinetic energy correction proportionally to the increase in time of flow. However, reducing the radius of the capillary has the disadvantage that it may increase the number of erratic results due to dust particles. Reducing the hydrostatic head will increase the error due to surface tension and make the reproducibility of the mounting more critical. The most useful and unobjectionable way to reduce the kinetic energy correction is to increase the length of the capillary. The time of flow increases proportionally with the length but the correction varies inversely as the square of the length. Variations in volume and shape of the upper bulb and variations in the radius of the lower reservoir have no direct influence on the kinetic energy correction.

Similarly, it is desirable to make the surface tension correction negligible by suitable design of the instrument if feasible. Although the theory of the correction as developed above seems to be mathematically logical and the correction clearly should be applied, nevertheless, it has the weakness that (1) the actual instrument does not have the exact shape and dimensions assumed in the calculations; (2) the equation for the capillary rise in conical or hemispherical tubes used in the calculations is an approximation; (3) the surface tension of the solution may not be known with sufficient accuracy; (4) the calculations are so laborious that they can never become popular.

As has been pointed out above the effective way to minimize the surface tension correction is to design the upper bulb so that as large a part of its volume as is feasible is in the cylindrical portion, and to make the radius of the lower reservoir the same as the radius of the cylindrical part of the upper bulb. If this common radius is too small, the correction for the variation of working volume will be troublesome, especially when dealing with volatile liquids, which may make it difficult to determine the actual volume added with sufficient precision. On the other hand, if, in order to avoid this difficulty, the common radius is made larger, the time of outflow may be made inconveniently long. If the attempt is made to remedy this difficulty by increasing the radius of the capillary there will be an increase in the kinetic energy correction. The best radius will, therefore, be a compromise.

For use with dilute aqueous solutions having a viscosity and surface tension and density nearly the same as water, the compromise can favor the working volume correction by choosing a larger radius for the lower reservoir than for the upper bulb. If the liquids to be studied differ substantially from water, then it will be advisable to make the radius of the lower reservoir the same as that of the upper bulb, to minimize the surface tension correction; and if this common radius is made large in an effort to minimize the working volume correction, then either the kinetic energy correction will be large or the time of outflow inconveniently long.

Similarly, increasing the hydrostatic head will lower the surface tension correction and the working volume correction, but increase the kinetic energy correction by lowering the time of outflow. However, the latter effect can be compensated by a decrease in the radius of the capillary without introducing any other unfavorable result except more trouble from dust particles. Therefore the hydrostatic head should be made as great as mechanical considerations permit without undue inconvenience.

Viscometer T, which was originally designed for dilute aqueous solutions, has proved in the light of our experience to be well designed for this purpose, except that the original specification that ends of the bulb should be made as nearly conical as possible has been found to be unnecessary. Hemispherical ends would be slightly better. Viscometer F, which was designed for methanol, a volatile liquid differing substantially from water in viscosity, surface tension and density, is satisfactory for such liquids and for concentrated aqueous solutions, except that it would have been better to have made the areas of the cross section of the lower reservoir and upper bulb 1.5 or 2 times as great as they actually are.

Summary

1. It is demonstrated by mathematical analysis and by experiments on methanol and water that surface tension effects may influence the measurement of viscosity with the Ostwald viscometer.

2. A method of computing the error due to surface tension for an instrument of known dimensions is given.

3. The viscosity of methanol at 25° relative to that of water is 0.6084.

4. The principles of design of the Ostwald

viscometer to give high precision without unnecessary sacrifice of convenience and speed in operation are discussed.

The Freezing Point of Methanol; A Simple Type of Cryostat Applicable to Freezing Point Determinations

BY EDWIN E. ROPER

A very pure sample of methanol had been prepared by Jones and Fornwalt[1] for their work on the relative viscosity and on the density. It appeared desirable to determine some physical constants as accurately as possible. Since a cryostat had been constructed by the author and a standardized resistance thermometer was available, Professor Jones requested a determination of the freezing point of their best samples of carefully purified methyl alcohol. The reported physical constants in the literature for methanol appear to be somewhat erratic and, in view of the difficulty involved in thoroughly freeing this material from water, in all probability the main cause of the discrepancies may be assigned to the presence of this impurity.

Experimental Procedure

Temperature Measurement and Standardization.—The temperature of the alcohol sample was measured by means of a four-lead coiled-filament 25-ohm platinum resistance thermometer.[2] The thermometer resistance was measured by a standardized Mueller type Wheatstone bridge, which was thermostated (25.0 ± 0.1°) in an oil-bath. The reproducibility of the measurements was *ca.* 0.0001 ohm, corresponding to 0.001°. The thermometer was standardized by accepted methods[3] at the sulfur boiling point, the steam point, the ice point and compared against the vapor pressure thermometers of carbon dioxide and of oxygen. The temperatures of the fixed points above 0° were taken as recommended by the International Temperature Scale specifications[3] and below 0° as given by Heuse and Otto.[4] The temperature of the ice point on the thermodynamic temperature scale was taken as 273.16°K.[5] The thermometer constants fulfilled all specifications[3] for pure platinum. The absolute accuracy at −100° is probably ±0.02° and the precision ±0.001°. A single junction copper–constantan thermel was used as an aid in adjusting the cryostat. This thermel was standardized at the same fixed points as was the resistance thermometer, with the exception that the freezing point of a National Bureau of Standards sample of tin replaced the sulfur boiling point. The e. m. f. of the thermel was determined with a special type K potentiometer to one microvolt. The e. m. f. was converted into temperature by the accepted method of constructing a deviation curve[6] in conjunction with the reference tables of Southard and Andrews.[7] The accuracy is about ±0.05°.

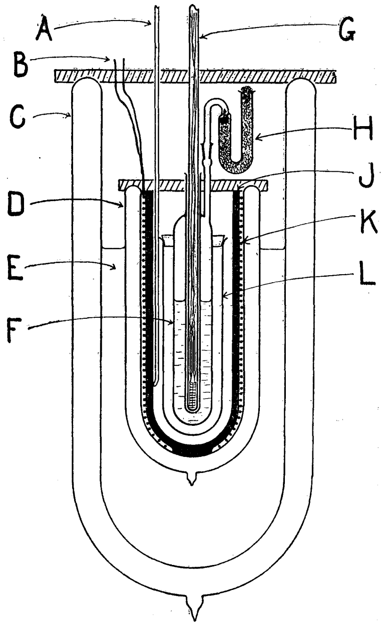

Fig. 1.—Freezing point apparatus showing details of cryostat. A is the environment thermel, B the heater leads, C the outer Dewar containing the refrigerant, D is the inner Dewar, E is the refrigerant, F is the freezing point tube, G the resistance thermometer, H a protective tube of Dehydrite, J is the copper tube, K is the heater wound on the surface of J, L is a glass jacket about the freezing point tube. Not drawn to scale.

Temperature Control.—The cryostat, somewhat similar to the one of Southard and Andrews,[7] is shown diagrammatically in Fig. 1. The copper shell J was 4 mm. wall thickness, 52 mm. outside diameter and 200 mm. long. The outer surface was so machined that after the heater winding was in place, the assembly fitted quite closely

into the Dewar tube D. The heater winding K consisted of 14.1 meters (136 ohms) of number 30 D. S. C. constantan wire wound non-inductively on the tube J, a good thermal contact being ensured by coating the completed winding with Bakelite lacquer, which was subsequently baked. Two slide resistances and an 0–150 milliammeter in series with the heater served to control the energy input. A lag of but a few seconds was found between the heater and the thermel. A glass test tube L about F served to damp out sudden temperature changes in J; this baffle introduced a thermal lag of sixty to eighty seconds between J and F. The outer Dewar tube C was 13 × 52 cm., while the smaller Dewar was 5.4 × 21 cm., both inside dimensions. Liquid air was placed in the outer Dewar to serve as a cold reservoir; the rate of cooling could be controlled within limits by varying the liquid air level. Approximately 100 milliamperes (1.36 watts) d. c. in the heater was sufficient to maintain the assemply at −100°. A given temperature setting could be held constant for several hours, but during this time the decrease in the liquid air level had to be compensated by a manual decrease in the energy input to the cryostat. However, this type of cryostat is particularly suited to freezing point determinations below 0°, where a slow but steady decrease in the environment temperature is required.

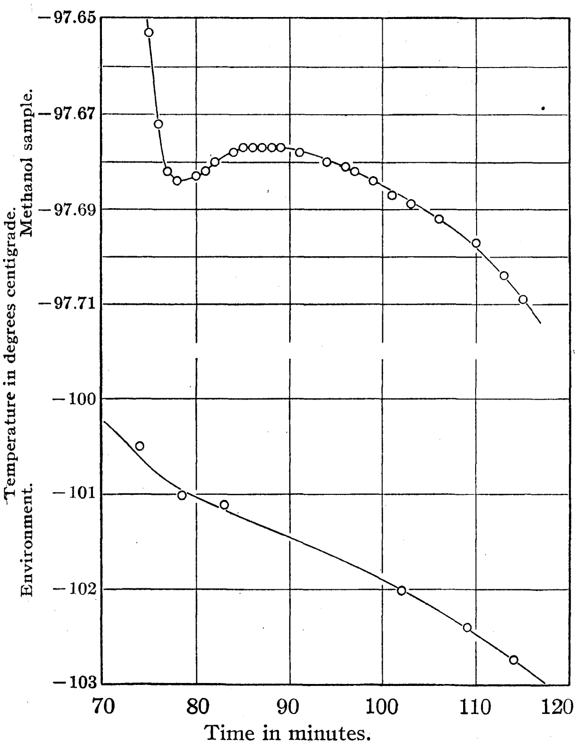

Fig. 2.—Typical freezing point data obtained. The upper curve shows the temperature of the sample of methanol as measured by the resistance thermometer while the lower curve is the course of the environment temperature measured by means of the thermel.

Methanol Samples.—The freezing point of two different portions was investigated. The data on the original samples as determined by Jones and Fornwalt are presented in Table I. The sample no. 31 contained some water as shown by means of the relative viscosity and the density. The sample no. 37 was classed as anhydrous by these investigators. The alcohol was distilled directly into the freezing point tube through the ground joint at the top and then the protective tube of Dehydrite immediately placed in position. Fifty cc. of alcohol was used in the freezing point tube F; this covered the thermometer with 5 cm. of alcohol, which should be sufficient to eliminate heat conduction down the thermometer leads.

TABLE I

Sample	Relative viscosity	Density, d^{25}_4, g./ml.
31	0.6094	0.786 65
37	.6084	.786 53

Procedure.—The alcohol was precooled to *ca.* −90° and the freezing point tube placed in position in the cryostat, which was at about the same temperature. The energy input to the heater was then decreased so that an approximately constant rate of cooling ensued. The temperature of the environment as indicated by the thermel was closely followed. Upon nearing the freezing point, readings of both the thermel and the resistance thermometer were taken at suitable intervals of time. If the environment temperature is not known and carefully controlled, there is no means of predetermining (if no supercooling takes place) whether the freezing point "flat" has been reached or whether the sample is merely approaching the temperature of the environment.

Results Obtained

Figure 2 gives a typical set of data obtained for one particular determination of the freezing point. It can be seen that the temperature of the alcohol sample is constant to 0.01° for twenty-four minutes, while during the same interval the environment temperature dropped 1.1°. The temperature of the alcohol sample does not fall off as abruptly as would be expected, and this might indicate slight traces of water. However, this falling off is a function of the thermal head and conductivity between J and F. Mair[8] takes as the principal criterion of purity the slope of the approximately horizontal portion of the freezing point curve. Table II gives the freezing points found for the two samples and also rough calculations of the amount of water present in sample no. 31 on the assumption that sample no. 37 is anhydrous. The value based on the relative viscosities was calculated on the basis of an estimate made by Jones and Fornwalt[9] on the effect of water upon the viscosity of methanol. The value obtained from the difference in densities was calculated on the basis of a linear relationship be-

tween density and composition, while the value calculated from the observed freezing point depression was obtained by the application of the approximate thermodynamic equation connecting the mole fraction of impurity, the true freezing point, the freezing point depression and the heat of fusion, the latter value being taken from the calorimetric work of Kelley.[10]

TABLE II

Sample	Freezing point, °C.	Percentage of water in sample from: rel. vis.	density	f. p. dep.
31	−97.75 ±0.02	0.04	0.06	0.05
37	−97.68 ± .02	(.00)	(.00)	(.00)

Discussion

It is very probable that the value −97.68° represents the true freezing point of anhydrous methanol to within the thermometric accuracy in relation to the thermodynamic temperature scale, namely, ±0.02°. An attempt has been made to correlate the freezing point with the density of methanol. Table III gives data taken from three other precision researches and Fig. 3 shows the data plotted, a rough estimate of the estimated accuracy being shown by the diameters of the plotted points. It can be seen that the results of Parks and of Timmermans and Hennaut-Roland are not in agreement with the data of Kelley and of this research. The latter two appear to be the more precise measurements and the density–freezing point curve has been passed through the data as shown.

[a] Calculated value from that given for 22°.

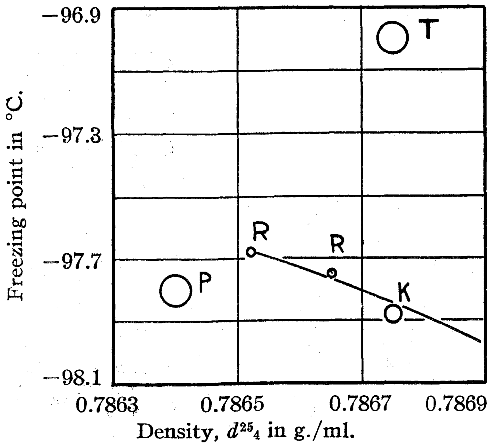

Fig. 3.—Data of different investigators plotted in order to attempt to determine the course of the freezing point–density of the liquid curve: K, Kelley; P, Parks; R, Roper; T, Timmermans.

Acknowledgments.—The author wishes to express his appreciation to Professor Arthur B. Lamb, in whose laboratory the cryostat was developed, for the use of the resistance thermometer, the cryostat and other apparatus and facilities. Professor Grinnell Jones and Dr. H. J. Fornwalt kindly supplied the methanol samples and furnished data concerning their respective relative viscosities and densities. Dr. Fornwalt filled the freezing point tubes with the samples and aided in measuring the environment temperatures in part of the determinations.

Summary

A simple cryostat is described which is applicable to the determination of freezing points below 0° and data are appended describing the operation of the cryostat during the freezing point determination of a methyl alcohol sample. The freezing point of a particularly pure sample of methanol prepared by Jones and Fornwalt was determined to be −97.68 ± 0.02°. A short discussion is given of the freezing point–density relationship.

The Solubility Curves of the Systems Carbon Tetrachloride–Branched Chain Alkyl Acids–Water at 25°

BY HILTON A. SMITH AND HAROLD TAYLOR

In an earlier paper[1] the effect of the length of the carbon chain of normal organic acids on the solubility curves of the systems carbon tetrachloride–*n*-alkyl acids–water was demonstrated. The present paper gives the results of investigations concerning the effect of branched chain acids on the solubility curves of similar systems.

Experimental

All acids used were the best grade of Eastman chemicals. C. P. carbon tetrachloride was used without further purification since the solubility of water in pure carbon tetrachloride is not great enough to affect the results within the limit of experimental error.

As in the earlier investigation, the limits of mutual solubility of the three components were determined by titration of mixtures of two of the components with the third until two phases merged into a single phase or, when the two starting components were miscible, until a second phase separated. In the case of acids which were only partially miscible with water, the mutual solubility of each in the other was also determined by titration methods.

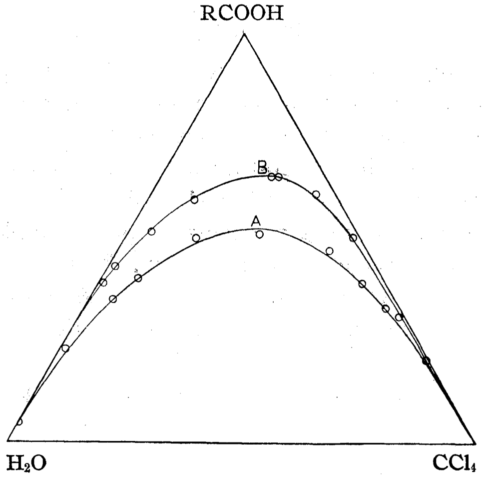

Fig. 1.—Solubility curves of the systems CCl_4–C_3H_7COOH–H_2O at 25°: A, *n*-butyric acid; B, isobutyric acid.

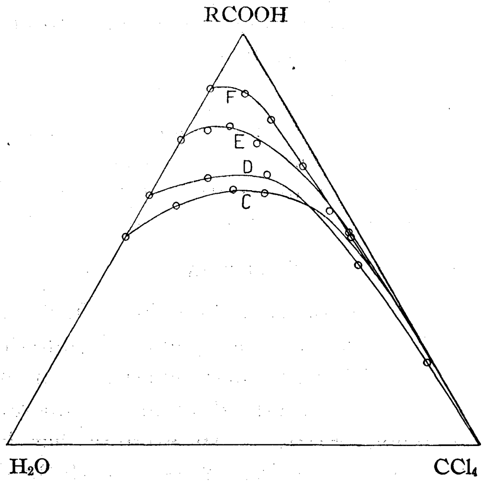

Fig. 2.—Solubility curves of the systems CCl_4–C_4H_9COOH–H_2O at 25°: C, *n*-valeric acid; D, isovaleric acid; E, methylethylacetic acid; F, trimethylacetic acid.

Results and Discussion

The results of the determinations are given in Table I. The values represent the maximum mole per cent. of carbon tetrachloride which may be dissolved in the indicated mixtures of acid and water. As in the earlier paper, the solubility of water in carbon tetrachloride and that of carbon

tetrachloride in water were calculated from the data of Clifford,[2] Rosenbaum and Walton[3] and Gross and Saylor.[4]

Figure 1 shows the solubility curves of the systems carbon tetrachloride–acid–water at 25° for butyric and isobutyric acids. The curve for *n*-butyric acid was taken from the data of Smith and Berman.[1] Figure 2 shows the diagrams for similar systems using *n*-valeric acid, isovaleric acid, methylethylacetic acid, and trimethylacetic acid. Again the curve for *n*-valeric acid was taken from the data of Smith and Berman.[1]

An examination of these curves shows that in all cases the mutual solubility area is decreased by substitution of a branched chain acid for a normal acid. The curves for isovaleric acid and methylethylacetic acid indicate that a methyl group substituted in the alpha position is more effective in decreasing the mutual solubility area than a methyl group substituted in the beta position.

Summary

The solubility curves at 25° of the systems CCl_4–RCOOH–H_2O have been studied for the following acids: isobutyric, isovaleric, methylethylacetic, and trimethylacetic. The curves show that the mutual solubility area decreases with increased chain branching.

The Action of Aluminum Chloride on Fluorinated Compounds

BY ALBERT L. HENNE AND MELVIN S. NEWMAN

In an effort to establish the orientation effect of a CF_3 group by the synthesis of $CF_3C_6H_4COCH_3$, benzotrifluoride was allowed to react with acetyl chloride and aluminum chloride. Instead of the expected products, the reaction gave benzotrichloride and aluminum fluoride in excellent yield and purity. In the absence of acetyl chloride, the reaction was not clean-cut and produced a large amount of tar; only a small quantity of benzotrichloride was isolated. In neither reaction was there a copious evolution of hydrogen halide; in the first case only hydrogen chloride came off, while in the second case a small amount of hydrogen fluoride was present in the hydrogen chloride.

From these results, it is concluded that the principal reaction is an exchange of halogen atoms between the organic fluoride and the inorganic chloride. In the presence of acetyl chloride, a complex presumably is formed between this compound and the aluminum chloride, and the exchange of halogen atoms is smooth because it occurs between the complex and the organic fluoride. In the absence of acetyl chloride, the exchange occurs directly and the benzotrichloride produced is subjected to the action of free aluminum chloride. This is known to cause tar formation.[1] The fact that some hydrogen fluoride comes off indicates that either benzotrifluoride or the intermediate benzofluorochloride is also involved in the condensation.

The replacement of organically bound fluorine by chlorine in the presence of aluminum chloride suggests a reason for the repeated failures[2] to effect Friedel–Crafts condensations between organic fluorides and chlorinated ethylenes or benzene.[3] The reactions involving only aliphatic compounds always gave tarry materials, which were abandoned. The reactions involving benzene were tried with the following fluorides: CCl_2FCCl_2F, CCl_2FCClF_2, $CClF_2CClF_2$, $CHClF_2$ and CCl_2F_2. In the last two cases, the fluorinated compound was passed as a gas through benzene containing aluminum chloride. In the other cases, aluminum chloride was dropped in small portions into a cooled solution of the fluoride in an excess of benzene. In general, a vigorous but controllable reaction started at once but soon stopped; it was started again every time a portion of aluminum chloride was added. The gas evolved was mostly hydrogen chloride which contained only a very small amount of hydrogen fluoride. After completion of the reaction, and decomposition with water in the usual way, the

[3] The use of metalloid fluorides instead of aluminum chloride is now under investigation.

products were tarry, somewhat elastic masses which were either fluorine-free, or almost so. From these masses, only fluorine-free substances were isolated by extraction with benzene, chloroform or dioxane, followed by precipitation with alcohol, ether or acetic acid. These substances had molecular magnitudes of about one thousand. The aluminum salt separated from the aqueous portion invariably tested very strongly for fluorine.

Even in the absence of benzene, the effect of aluminum chloride on stable aliphatic fluorides is apparent after a relatively short period of heating. After forty-eight hours of refluxing over aluminum chloride, CCl_2FCClF_2 generated a small quantity of CCl_3CClF_2, which was isolated, and some higher boiling material which no longer contained any fluorine. In a similar experiment with $CHCl_2$-$CClF_2$ the fluorine was more easily removed, hydrogen fluoride was evolved slowly and steadily and tar formation was more pronounced. In both cases, the aluminum salt tested positively for fluorine.

It is fitting to recall an old experiment[4] which was performed in order to establish the structure of $CHCl_2CHF_2$. This derivative was exposed to the action of chlorine in sunlight, in the presence of aluminum chloride, and from 60 g. of product only 4 g. of impure CCl_3CClF_2 was isolated, while the remainder was predominantly hexachloroethane. More recent work[5] has established that chlorination in sunlight follows a perfectly normal course if the aluminum salt is omitted, and pure CCl_3CClF_2 is obtained quantitatively from $CHCl_2CHF_2$. In the older experiment, the mechanism of the reaction was not well understood. It is probable that an exchange of halogens between the organic fluoride and the aluminum salt took place first, and that the small amount of CCl_3-CF_2Cl obtained owed its formation to the fortuitous fact that an insufficient quantity of aluminum chloride was present to take care of all the organic fluorine.

From this series of experiments it is concluded that it would be futile to use aluminum chloride to effect condensations between a fluorinated derivative and either an aliphatic or an aromatic compound.

Experimental

Benzotrichloride from Benzotrifluoride.—To a solution of 78 g. (1 mole) of acetyl chloride in 540 g. (450 cc.) of benzotrifluoride was added 140 g. (1.05 mole) of powdered anhydrous aluminum chloride over a period of one-half hour, the reaction flask being cooled to prevent the temperature from rising above 40°. A greenish solid seemed to form on the surface of the aluminum chloride at first. After the mixture had been stirred at 30–40° for one hour and then slowly heated to 70° during another hour, the solid gradually dissolved to give a deep red solution. During this latter period a slow steady stream of hydrogen chloride was evolved. A test for hydrogen fluoride was negative and the glass apparatus was not etched during the reaction. After stirring for two hours more at 65–70° the mixture was cooled, poured on ice (very little heat evolved) and steam distilled. By observing the distillate a crude separation of benzotrifluoride and benzotrichloride was effected. Upon fractional distillation there was obtained 135 g. (0.69 mole) of pure benzotrichloride, f. p. −4.4°, b. p. (10 mm.) 89.0–89.5°, $d^{20}{}_4$ 1.3741, $n^{20}{}_D$ 1.55789, *MR* calcd. 45.54, found 45.67. *Anal.* Calcd. for $C_7H_5Cl_3$: C, 43.01; H, 2.58; Cl, 54.41. Found: C, 43.02; H, 2.62; Cl, 53.02, 53.07. In addition, about 20 g. (0.165 mole) of benzoic acid was isolated, which resulted from hydrolysis of the benzotrichloride during steam distillation (benzotrifluoride is not hydrolyzed[2] under similar conditions). Thus the total yield based on the aluminum chloride amounted to 86%. The analysis of the aluminum salt proved it to be aluminum fluoride slightly contaminated by chloride.

Summary

The condensation of fluorinated substances with aliphatic or aromatic compounds cannot be obtained with aluminum chloride, because an exchange of halogen atoms takes place between the organic fluoride and the aluminum salt. A particularly clean-cut exchange was observed when benzotrifluoride reacted with a mixture of aluminum chloride and acetyl chloride. Benzotrichloride of unusual purity was thus obtained in good yield.

NOTES

The Catalyst in the Gattermann Reaction

By Richard T. Arnold and Joseph Sprung

The modification of Gattermann's synthesis for aromatic aldehydes has greatly increased the popularity of this reaction as a synthetic method.[1] It is noteworthy, however, that the zinc cyanide usually prepared in the laboratory is not pure, but it is stated that the material "contains no impurity that interferes with the Gattermann synthesis." We have reason to believe that these impurities are essential to the successful use of this method. An attempt to use pure zinc cyanide (prepared by Eimer and Amend, New York) for the preparation of 4-hydroxy-α-naphthaldehyde resulted in complete failure and after five hours the only product which we could isolate was the starting substance α-naphthol. We have shown repeatedly, however, that the addition of potassium chloride (0.33 mole) to this zinc cyanide will cause the reaction to take place as described when the zinc cyanide was prepared just before using. If the potassium chloride is added at the beginning of the reaction, the mixture may be decomposed after seventy minutes to give the reported yield. It also has been shown that the zinc cyanide usually employed for this reaction will not function if it is thoroughly washed with water before being dried. We have found one sample of commercial zinc cyanide (Eimer and Amend) which did not require an additional salt and gave good yields in seventy minutes. This material was partially leached with water and filtered. The filtrate gave a strong test for chloride ion. The residue after drying underwent the Gattermann reaction in one hundred minutes. The addition of sodium chloride cut this reaction time to seventy minutes.

The Stability of Chlorine–Water Vapor Mixtures in Light

By James E. Cline and George S. Forbes

The photochemical reaction involving chlorine and liquid water has been the subject of many papers since its discovery by Berthollet in 1785. The most definite results are those of Allmand, Cunliffe and Madison.[1,2] They found that solutions of hypochlorous acid as well as those of chlorine yield hydrochloric acid, oxygen and chloric acid in the same relative amounts. For each quantum absorbed, two molecules of chlorine or of hypochlorous acid are decomposed.

A search of the literature failed to disclose any investigation of the photochemical behavior of mixtures of chlorine and water vapor. Allmand, Cunliffe and Madison[1] concluded merely that the reaction, if any, in 3 cc. of vapor phase was negligible in comparison with that in 220 cc. of liquid phase.

The apparatus and method used by us to detect and measure a minimal amount of oxygen photochemically evolved from mixtures of chlorine and water vapor was a modification of that previously used for investigation of the photolysis of hydrogen sulfide.[3] Purified chlorine and water were distilled separately into the quartz reaction cell. The pressure of water vapor was read on a mercury manometer and the pressure of chlorine estimated from its volume as a liquid in a calibrated tube. Capillary seals which could be broken by magnetic hammers were used consistently instead of stopcocks. Several distillations under high vacuum served effectively to remove gases not condensable at liquid air temperature. After long exposure of the cell to radiation the extremely small amount of non-condensable gases was determined by use of a McLeod gage as previously described.[3]

Each value of ϕ in the last column was calculated upon the assumption that the radiation considered was the sole effective one. The small amounts of non-condensable gases found might have escaped from the walls of the cell, so that the values of ϕ may be considered as upper limits.

Schwab[4] found that oxygen does not react perceptibly with chlorine atoms, so that oxygen once formed in our reaction mixture could scarcely have been eliminated. The experiments described above therefore indicate the absence of any photo-

COMMUNICATIONS TO THE EDITOR

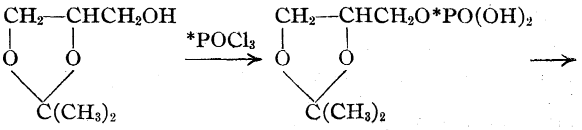
SYNTHESIS OF A RADIOACTIVE ORGANIC COMPOUND: α-GLYCEROPHOSPHORIC ACID

Sir:

The use of radioactive elements as labels in the study of metabolic processes, as initiated by G. Hevesy, already has given highly significant results in a number of cases. Most of the biochemical work accomplished so far has made use of the unstable phosphorus isotope $^{32}_{15}P$. The usual experimental procedure involves the administration to animals of a sodium phosphate solution containing a minute amount of radioactive sodium phosphate and the study of the distribution of the radioactive phosphorus in various organs or chemical fractions isolated from them. While valuable results may be obtained in this manner, it is obvious that the application of organic derivatives of radioactive phosphorus offers even greater possibilities. The development of methods for the synthesis *in vitro* of such compounds is therefore of interest. Biochemical synthesis, while theoretically possible, would be expected to yield products of lower activity and less definitely controllable composition.

For these reasons the synthesis of radioactive phosphorus oxychloride, $*POCl_3$,[1] was carried out, which, as is well known, is an excellent reagent for the introduction of phosphoric acid into organic compounds. The radioactive phosphorus was obtained by the action of fast neutrons liberated by a radon-beryllium source on carbon disulfide. For this material we are indebted to Dr. J. R. Dunning of the Department of Physics of Columbia University. To the reddish residue remaining after the evaporation of the carbon disulfide [*cf.* O. Chievitz and G. Hevesy, *Kgl. Danske Videnskab. Selskab., Biol. Medd.*, **13,** 9 (1937)] a small amount of dry red phosphorus was added and the mixture converted into the chlorides which were sublimed at a pressure of 10^{-5} mm. The sublimate was converted into $*PCl_3$, diluted with ordinary PCl_3 and rectified by distillation. The radioactive PCl_3 obtained was oxidized to $*POCl_3$ by means of potassium chlorate [F. Ullmann and A. Fornaro, *Ber.*, **34,** 2172 (1901)], and the *radioactive phosphorus oxychloride* was purified by fractionation.

With this material the synthesis of *radioactive α-glycerophosphoric acid* was carried out according to E. Fischer and E. Pfähler [*Ber.*, **53,** 1606 (1920)]. The synthesis involved the following steps:



Isopropylidene glycerol

Radioactive isopropylidene α-glycerophosphoric acid

$CH_2(OH)CH(OH)CH_2O{*}PO(OH)_2$

Radioactive α-glycerophosphoric acid

The barium salts of the radioactive α-glycerophosphoric acid and of its acetone derivative were both obtained in crystalline form, the former

---

[1] In writing formulas, analytical figures, etc., for compounds containing an unstable isotope it is proposed to express this fact by using an asterisk before the letter symbol for the particular element, *e. g.*, *P, *S.

crystallizing from hot water as clusters of fine needles (calcd. for $C_3H_7O_6PBa$: P, 10.1; Ba, 44.7; found: P, 9.8; Ba, 44.3).

The radioactivity of the various samples was measured by means of a sensitive Geiger–Müller counter; the substances, in aqueous solution, being contained in a standardized glass cell. This technique, in contrast to the usual method of ignition and measurement of the activity of the ash, makes it possible subsequently to manipulate the radioactive substances unchanged. It leads, however, to considerably lower activity counts than those obtained with the ashed residues. Representative solutions of sodium glycerophosphate and of phosphoric acid (from the phosphorus oxychloride originally employed), containing 84.8 and 70.9 mg. of phosphorus, respectively, yielded respective counts of 0.797 and 0.815 impulses per minute per mg. of phosphorus when examined under strictly comparable conditions. As was to be expected, the ratio ${}^{32}_{15}P$: ${}^{31}_{15}P$ was constant in all compounds prepared, after allowance had been made for the natural decay of the unstable isotope.

This work has been made possible by a grant from the John and Mary R. Markle Foundation.

THE TRANSIENT INHIBITION OF THE THERMAL DECOMPOSITION OF BUTANE BY NITRIC OXIDE

Sir:

It has been shown by the writers [Echols and Pease, THIS JOURNAL, **59,** 766 (1937)] that the decomposition of butane is inhibited by nitric oxide. Subsequent study of the reaction has clearly indicated that the inhibition by nitric oxide is a *transient effect.* Careful analysis of the reacted gases has shown that this is not the result of removal of the nitric oxide by reaction.

For example, with 200 mm. of butane and 20 mm. of nitric oxide at 520° it is found that the initial slope of the reaction curve is nearly zero, but that the slope slowly rises with time until at 20% reaction it is very nearly that of the uninhibited reaction at the same percentage decomposition. Under these conditions less than 10% of the nitric oxide has reacted.

It has been found that these facts, together with all of the data so far obtained on the phenomenon, may be very nearly quantitatively explained by the assumption that the nitric oxide forms an unstable compound with chain carriers leading to an equilibrium of the form:

$$R + NO \rightleftarrows NOR$$

where R is the chain carrier, presumably a free radical.

This equilibrium is slowly established in the initial stages of the reaction and as the equilibrium is approached the "feed-back" of radicals neutralizes the inhibition, producing a normal rate of the butane decomposition. A detailed discussion of the facts will be presented shortly.

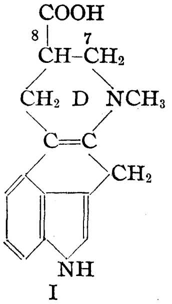
THE POSITION OF THE CARBOXYL GROUP IN LYSERGIC ACID

Sir:

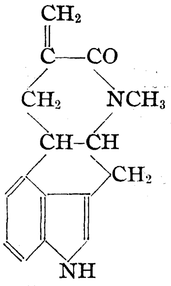
We have reported previously [*J. Biol. Chem.,* **113,** 760 (1936)] that dihydrolysergic acid, contrary to lysergic acid which loses carbon dioxide and methylamine somewhat above 200°, can be sublimed at 25 mm. from a bath heated at 300°. *Anal.* Calcd. for $C_{16}H_{18}O_2N_2$: C, 71.06; H, 6.72. Found: C, 71.3; H, 6.61.] However, more recent investigation of the sublimation of α-dihydrolysergic acid has shown that a chemical change accompanies such sublimation which is accentuated by raising the temperature to 350°. A neutral substance was isolated from the chloroform solution of the sublimate after extraction of dihydrolysergic acid with dilute potash. After recrystallization from methyl alcohol, the substance was obtained in a yield of 33% (m. p. 305–307° with decomposition) $[\alpha]^{25}_{D} -219°$ (*c,* 0.48 in pyridine). Analysis showed that its formation involved loss of water. [*Anal.* Calcd. for $C_{16}H_{16}ON_2$: C, 76.15; H, 6.40; N, 11.11; (N)CH_3, 5.96. Found: C, 76.10; H, 6.58; N, 11.02; CH_3, 5.04.] Contrary to dihydrolysergic acid, it no longer dissolved in dilute acid or alkali, but it still gave the characteristic Keller color reaction unimpaired. Also contrary to the dihydro acid, it was found to be unsaturated since on catalytic hydrogenation it absorbed 1 mole of hydrogen with the formation of a neutral dihydro derivative which melted with decomposition at 336°. [*Anal.* Calcd. for $C_{16}H_{18}ON_2$: C, 75.54; H, 7.14. Found: C, 75.50; H, 7.12.]

In a communication by L. C. Craig, T. Shedlovsky, R. G. Gould, Jr., and W. A. Jacobs which is now in press, an investigation of the dissociation constants of lysergic acid and its derivatives has been reported, which has made it necesssary to revise our previous tentative conclusion that the COOH group of lysergic acid is in position 7, *i. e.*, on the carbon atom adjoining the N atom of Ring D. Such an arrangement would place it in the category of a substituted α-amino acid like proline. Instead, the evidence indicates a β-amino acid derivative and that the point of attachment of the COOH group is the carbon atom β to the N atom or position 8 as shown in formula I.

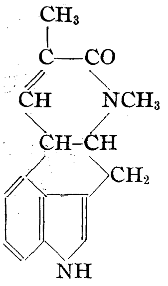
The formation of the above neutral pyrolysis product from dihydrolysergic acid fits in well with such β-substitution of the COOH group and must be interpreted as an unsaturated cyclic amide possessing either formula II or III.



I



II



III

It is well known that β-amino acids, in contradistinction to the α-acids, decompose readily into unsaturated acids and ammonia. For instance, β-alanine gives readily ammonia and acrylic acid. In accordance with this property, dihydrolysergic acid should cleave between the N atom and carbon atom 7 to give an unsaturated complex secondary amino acid which would at once lactamize. Model experiments with the various piperidine carboxylic acids are now in progress to verify the nature and formation of this pyrolysis product of dihydrolysergic acid.

ENOL ETHERS OF STEROID KETONES

Sir:

The following is a report of the synthesis of enolic ethers of unsaturated ketonic sterols. For the preparation of these compounds the modification of Arbuzov and Mikhailova [*J. Gen. Chem.* (*U. S. S. R.*), **6**, 390 (1936)] of the classical Claisen method was used. Instead of obtaining the expected ketal, the reaction yielded directly the enol ether, one molecule of alcohol having been split out.

As a class, these compounds are stable in a solid state, but quite unstable in solution. From Table I it may be seen that in chloroform solution at room temperature the rotation changes rapidly from a negative to a positive one, the final rotation in each case being that of the free ketone. Very probably the traces of hydrochloric acid in the chloroform are the cause of the rapid splitting of the ethoxyl group, since in pyridine solution the rotation remained practically unchanged. By hydrolyzing the testosterone enol ether propionate with alcoholic potash it was possible to remove the propionic acid group without splitting the ethoxyl out of the molecule.

TABLE I

Time, hours	Specific rotation of enol ethyl ethers Cholestenone[a]	 Testosterone benzoate[b]	 Testosterone propionate[c]
0	−102.3	− 42.5	−140
0.5	− 33.8	+130	−114
1	+ 18.2	+142	
2	+ 67.6	+143	+60
24	+ 87.7		+88 (48 hours)

[a] 1.1% in chloroform. [b] 1.01% in chloroform. [c] 1.2% in chloroform.

In pyridine solution the specific rotations were −96.0° for cholestenone enol ethyl ether, and −67.5° for testosterone benzoate enol ethyl ether. These values changed only slightly after standing for several hours.

The fact that all the new substances show initially a negative rotation would indicate that one of the double bonds is in ring A, the other in ring B [Ulrich Westphal, *Ber.*, **70**, 2128 (1937)].

These substances are prepared by dissolving 5 g. of the ketone in 10 cc. of ethyl orthoformate and 1 cc. of formic acid. The solution is cooled to 20° and one drop of concentrated sulfuric acid added. The mixture is warmed on the water-bath to 50° with constant stirring, held at this temperature for ten minutes. After standing overnight at room temperature, ether is added and the solution washed with water, soda and finally with water until neutral. After drying, the ether is evaporated and the residue recrystallized from acetone or ligroin.

Table II gives the physical constants of these compounds as well as the substances isolated from the solutions on which the rotations were determined. Table III summarizes the analytical results.

THE QUANTITATIVE DETERMINATION OF AMINO ACIDS

Sir:

One of the methods frequently employed for the estimation of individual amino acids in protein hydrolysates involves the selective precipitation of the respective amino acids in the form of salts. It is the object of such methods to precipitate as much of the salt as possible, 100% isolation being the ultimate goal. Unfortunately, most of the salts that are precipitated selectively are not precipitated quantitatively. Such an incomplete precipitation may be used to advantage, however, in a newly developed analytical principle which permits a rather precise determination of individual amino acids. It depends upon the fact that the amount of an amino acid salt precipitated at equilibrium is a function of the concentration of its ions in solution.

In order to demonstrate this, let us assume that an acidic reagent, RH, forms, with an amino acid, A, the binary salt, AH·R. In many cases the so-called solubility product of the participating ions was found to be approximately a constant.

$$[AH^+] \times [R^-] = \text{const.} \qquad (1)$$

Figure 1 illustrates an experiment in which increasing amounts r', r'', r''' of the reagent are added to several equal portions of a solution, each containing Y moles of amino acid. In each sample a precipitate is formed. Were it completely insoluble, the course of precipitation would follow the straight line OB. In reality, however, the precipitation follows a hyperbolic curve passing through the points C', C'', C''', C''''.

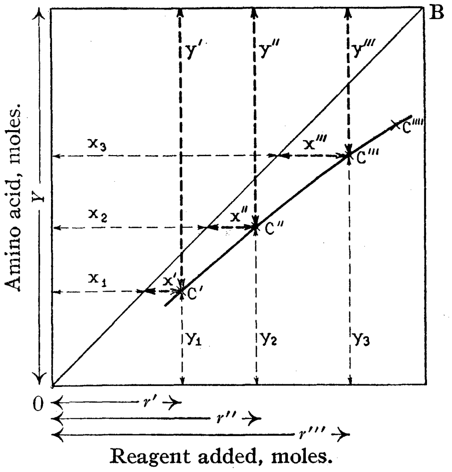

Fig. 1.—Determination of amino acids by means of the solubility product.

The precipitate obtained with an amount of reagent r' contains equivalent amounts x_1 of the reagent, and y_1 of the amino acid; the amounts x' of the reagent and y' of the amino acid remain in solution. Similarly, in a precipitation with an amount of reagent r'' the amounts x'' and y'' remain in solution. From equation (1) it follows that

$$x' \times y' = x'' \times y'' = x''' \times y''' \qquad (2)$$

Experimentally we have found the requirements of equation (2) to be fulfilled satisfactorily for the precipitation of proline by rhodanilic acid [M. Bergmann, *J. Biol. Chem.*, **110**, 471 (1935)], of glycine, alanine and leucine by dioxpyridic acid [M. Bergmann, *ibid.*, **122**, 569 (1938)], and of tyrosine by dioxanilic acid. In all cases where equation (2) is valid, the amount Y of an amino acid can be determined in a solution of unknown content. For this purpose equation (2) may be written in the following manner:

$$x'(Y - y_1) = x''(Y - y_2) = x'''(Y - y_3) \quad (3)$$

In equation (3) all values, with the exception of Y, may be determined experimentally.

In order to demonstrate the precision of such determinations, we report the following analyses:

	Present, mole	Found, mole
Glycine	0.0100	0.0103
l-Alanine	.00297	.00300
l-Leucine	.00255	.00269
l-Proline	.00420	.00435

The results obtained by the application of this type of analysis to protein hydrolysates will be reported elsewhere.

NEW BOOKS

Fortschritte der Photographie. (Progress in Photography.) Edited by E. STENGER, Berlin-Charlottenburg, assisted by H. STAUDE, Berlin-Tempelhof. Vol. V. of "Ergebnisse der angewandten physikalischen Chemie." Akademische Verlagsgesellschaft m. b. H., Sternwartenstrasse 8, Leipzig, Germany, 1938. xiv + 415 pp. 78 figs. 16.5 × 24 cm. Price, RM. 33; bound, RM. 35.

Modern photography dates back to the introduction of the silver bromide–gelatin emulsion in the eighth decade of the last century. Since that time, there has been no basic change in the photosensitive material of the plate, film and paper—silver halides dispersed in gelatin. During the sixty years that the silver bromide–gelatin emulsion has been known, no substitute has been found which in any way approaches it in sensitivity to light, adaptability to varied purposes, and ability to reproduce tones satisfactorily.

The study of the photographic process by the methods of scientific research received its first important impetus in England in the hands of Hurter and Driffield in 1890, and Sheppard and Mees in the first decade of the present century. These investigators laid the foundations for the quantitative interpretation of the action of light on the plate and film. At the same time, the pioneer work on spectral sensitization was done in Germany, and extensive study of the development process was made in Germany and France. It was not until the years following 1918, however, that systematic research in Europe and the United States produced information which permitted clarification of the basic principles governing the action of light on the emulsion. These studies were made largely in the research laboratories of the photographic manufacturing concerns, particularly the Eastman Kodak Company in this country, the Agfa Company in Germany, and the British Photographic Research Association in England.

In Germany alone has the photographic process been the object of much research in the Universities. In reading the book under review, one is struck by the opportunities offered by photography as a subject for research in the Universities of this country. Even in those fields where the plate or film is used as an instrument for research on other subjects, many of the results are open to doubt because the investigator displayed lack of knowledge of the capabilities and limitations of his tools. With the increasing use of photography as an instrument, there is growing need for courses of study in its principles. If these were associated with research on some of the infinity of unsolved problems, much of the misuse of photography in its applications to science and industry would eventually be avoided, and the results could not fail to be applied to an improvement of the product.

The photographic literature is singularly diluted by a large proportion of perfectly useless papers, written by people having no broad appreciation of the field, or no scientific training to guide their practical approach. It is very difficult for those not closely associated with scientific research in the subject to select the valuable material from that of doubtful basis. The book under review should provide a reliable guide for them. It is edited by Dr. Erich Stenger, head of the photographic and photochemical department of the Berlin Technische Hochschule, with particular assistance from Dr. H. Staude, who was trained at Dresden under Dr. Robert Luther, dean of German photographic research, and aided by a number of other competent co-workers. The book aims at surveying recent progress in the important fields of photographic research, and has succeeded singularly well. It is the most useful of the photographic textbooks which have appeared in recent years, considered from the point of view of those interested in the scientific aspects. It presupposes a moderate chemical and physical knowledge on the part of the reader. Its perusal will provide an excellent understanding of the state of knowledge of the subject up to the summer of 1937, for it covers not only the scientific and photographic publications, but the patent literature as well.

The first Chapter, compiled by W. Meidinger, treats of the photolysis of crystals of the alkali and silver halides, and of the latter in the presence of gelatin, as in the photographic emulsion, and closes with a survey of theories of the latent image. Progress in the technique of making photographic emulsions is handled by H. Socher, while H. Staude deals with the nature of developers and the theories of their action, and the problems of hypersensitizing, desensitizing, fixing, washing and drying. There is a very comprehensive survey by K. Meyer of recent research in photographic sensitizing dyes, in which field so much progress has been made in the past ten years, and which has been largely responsible for the recent outstanding advances in photographic plates and films, and particularly in color photography. W. Falta writes of the manufacture, properties and handling of photographic papers, W. Petzold of exposure meters, and M. P. Schmidt of diazotype papers and films. The important subject of color photography is treated in two chapters by F. Lührig and K. Räntsch. The chemical and optical aspects are considered, although not so fully as the remaining subjects in the book. This is deliberate on the part of the editor, for the fundamental principles are not new, whereas the practical development of the art is undergoing such rapid changes at the moment, that a useful evaluation of it is not yet possible. There is adequate material provided, however, for a fair basis for understanding developments likely to occur in the near future. In any case, the chapters give the fullest general survey of current trends in color photography which has yet been published.

The book is an indispensable reference source for those concerned with a knowledge of the present state of the theory and practice of photography. The material is critically selected, and its study will give an excellent idea of the ramifications of photography in the fields of physics, and physical and organic chemistry, and of its suitability as a subject for research.

The work is most appropriately dedicated to Professor Robert Luther, outstanding son of the Ostwald school, and leader of German photographic research, who attained his seventieth birthday on January 2nd of this year.

Walter Clark

Piezoelektrizität des Quarzes. (Piezoelectricity of Quartz.) By Dr. Adolf Scheibe, Physikalisch-technische Reichsanstalt. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1938. xii + 233 pp. 175 figs. 15.5 × 22.5 cm. Price, RM. 20; bound, RM. 21.

This book is volume 45 of the "Wissenschaftliche Forschungsberichte, Naturwissenschaftliche Reihe," edited by Liesegang. The author, a member of the Physikalisch-technische Reichsanstalt, was associated with Dr. E. Giebe in a number of important investigations on piezoelectric crystals. In recent years in collaboration with U. Adelsberger he has designed the extraordinarily precise quartz clocks at the Reichsanstalt, which exceed in constancy the best astronomical clocks. As is to be expected, his own contributions are described in considerable detail. That the book is not for this reason one-sided is attested by the fact that the bibliography at the end contains three hundred and eleven references from foreign as well as German journals, all of which are at least mentioned in the text, while many are fully discussed.

In the main, the book deals exclusively with the piezoelectric properties of quartz and their applications in high-frequency circuits. It is only to a slight extent mathematical, but is considerably broader in scope than Vigoureux's "Quartz Resonators and Oscillators," which is now the only book on this subject in the English language.

Part A, on the static piezoelectricity of quartz, contains an excellent account of the various methods of measuring the piezoelectric constants, which should provide future investigators in this field with sufficient guidance without recourse to the original sources. Ten pages are also devoted to a very complete classified list of all known piezoelectric crystals. The relation of piezoelectric to elastic properties and their dependence on temperature also receives fairly full consideration, although the general vibration equations are not derived.

Part B, on the quartz crystal as resonator, occupies the greater part of the book. The treatment includes full discussions of quartz resonators in the form of bars, plates and rings, their modes of vibration, overtone frequencies, temperature coefficients of frequency, construction of thermostats, methods of mounting, and devices for the detection and measurement of resonance. The luminous resonators developed by Giebe and Scheibe are minutely described and well illustrated. The space given to the equivalent electric constants of the resonator and to the analysis of the resonator as a circuit element, while adequate for a general survey, is hardly complete enough to be of much value to the research worker. The same remark may be made with respect to the brief treatment of the quartz filter. This part closes with an account of various optical methods for the investigation of vibrating crystals. It is to be regretted in this connection that nothing is said in regard to the use of polarized light for the detection of twinned regions in quartz crystals.

Part C deals with the construction and performance of the quartz piezo-oscillator, including various forms of the quartz clock.

Part D, on miscellaneous piezoelectric effects, contains a very brief account of the use of quartz as a source of ultrasonic waves and for a few other special purposes, and of the effect of vibration upon the Laue X-ray patterns of quartz crystals. It is to be regretted that this portion of the book is not sufficiently complete to be as useful as it might for purposes of reference.

Presswork and diagrams are uniformly excellent. Among the few errors noted may be mentioned the statement on page 35 that of the 32 crystal classes 21 are piezoelectric (instead of 20); the assertion on page 50 that β-quartz is not piezoelectric; wrong numbering of an equation on page 57; reference (279) on page 71 should apparently be (284); on page 129 the words "äusseren" and "inneren" should be interchanged. At a few points such matters as notation, the orientation of crystals shown in illustrations, and directions of vibration are either not specified or are ambiguous.

These are minor criticisms. As a whole this book is probably the most complete and authoritative treatment of the piezoelectric properties and applications of quartz that has yet appeared.

Walter G. Cady

Principles of Organic Chemistry. By H. P. Starck, M.A., The Technical College, Kingston-on-Thames, England. Chemical Publishing Company of New York, Inc., 148 Lafayette Street, New York, N. Y., 1938. viii + 664 pp. 14 × 20.5 cm. Price, $5.00.

This new textbook of organic chemistry offers enough new and significant features to justify its intrusion into a field that may, at first thought, seem to be supplied adequately with good texts. The author's approach has been largely experimental and a much larger amount of theoretical and practical information is included than is usually found in such volumes.

"The present work originated," according to the author, "in connection with the author's teaching of organic chemistry to students reading for Pre-medical, First M. B., National Certificate, Pharmaceutical and General examinations in Chemistry. The theoretical sections cover the syllabuses of the Higher School Certificate courses of the Universities of Oxford, Cambridge, and London, and of various professional bodies." The introduction of complex compounds at an early stage in the text, before their methods of preparation and characteristic properties have been described, has been avoided. The treatment does not claim to be exhaustive. The author has sought to present the underlying principles as clearly as possible, in the hope of giving the student a sound foundation which will enable him to take full advantage of his further studies, whether in Chemistry, Biochemistry, Pharmacy, or Medicine. The first 486 pages are devoted to theoretical items, and the remaining 150 pages to practical work including tests for the elements, qualitative and quantitative analysis, and laboratory preparations. The appendix includes numerous tables, logarithms, first aid directions, a description of the Svedberg Ultracentrifuge, and answers to numerical questions.

The reviewer regrets that certain portions of this book, which otherwise might have been a valuable and unique addition to the list of organic textbooks, have not been somewhat modernized. The formulas frequently used for glucose, fructose, and other carbohydrates do not conform to the best modern usage, and the author on page 373 admits as much and yet seeks to justify this discrepancy on the basis of simplicity for the student. The references to the Grignard reagents and to the acetoacetic ester synthesis are again of the traditional, orthodox type, even though these explanations have now been proved to be either inadequate or incorrect. The directions for carbon and hydrogen determinations, as outlined beginning on page 497, might be improved by the use of "Ascarite" and "Dehydrite" and more modern absorption tubes. The naming of compounds might profitably be made to coincide more nearly with the Geneva system.

The valences of carbon, as shown on pages 53 and 62, may be confusing to beginning students. The index might logically and profitably be extended. The portions of the text devoted to organic qualitative analysis are not organized so as to permit of any systematic identification of unknown compounds. The preparation of 3,5-dinitrobenzoates might be superior to that of *p*-nitrobenzoates as derivatives for alcohols. Some twenty-six laboratory preparations and experiments are scattered throughout the first 486 pages or theoretical portion of the text. While they seem to be well organized, they are not of a suitable type, length, or number to constitute a complete laboratory program. Neither are they listed at any point in the index or table of contents. This number of experiments is, however, greatly supplemented by numerous additional exercises in Part II or the practical portion of the text. The reviewer also questions the wisdom of the preparation of hydrocyanic acid by students as outlined on page 331.

However, in spite of these adverse criticisms, the desirable features of this book far outweigh any objections that might be cited. The amounts and arrangement of theoretical and practical material is unique and far greater than usually found in elementary organic texts. Every chapter is concluded with a long list of splendid review and study questions. Important and related facts and properties are frequently summarized in convenient tables. There is a greater intermingling of the aliphatic and aromatic compounds than is usually found in such texts, thereby making the transition from one series to the other much easier and more logical. Important facts and conclusions are emphasized with large bold-faced type. The book is neatly and attractively printed and well bound. It is remarkably free from typographical errors.

The volume can be recommended to instructors who desire a new type of organic textbook that develops the subject largely from an experimental and theoretical standpoint, and then points out numerous organic applications to industrial and home activity.

RALPH E. DUNBAR

The Biological Standardisation of the Vitamins. By KATHARINE H. COWARD, D.Sc., Reader in Biochemistry, University of London. William Wood and Company, Mt. Royal and Guilford Avenues, Baltimore, Maryland, 1938. viii + 227 pp. 44 figs. 15 × 22.5 cm. Price, $4.50.

The author, who is Head of the Nutrition Department of the Pharmaceutical Society of Great Britain, is a recognized authority on methods of vitamin assay. It is fitting, therefore, that the first book to be published in English covering all essential details of biological determinations of vitamins, should come from the pen of one who has contributed so much to the establishment of our present international standards of vitamin unitage.

As the title suggests, the book is devoted exclusively to questions involving the quantitative accuracy of vitamin assays. She has confined her discussion to those vitamins (A, B_1, C and D) the methods for which have been standardized and which have received the approval of the International Vitamin Standards Committee of the League of Nations.

The book is divided into two parts. Part I is devoted to practical phases of vitamin work and may be used without reference to Part II. The latter has to do with the biometrical phases of vitamin work and emphasizes the value of statistical treatment of assay data.

Part I contains seven chapters dealing with such topics as "General Principles which Govern the Biological Methods for the Determination of the Vitamins," "Animals Suitable for the Determination of Vitamins by Biological Methods," "The Determination of Vitamin A, B_1, C and D" (one chapter devoted to each vitamin) and "The Interdependence of the Vitamins."

Each chapter which deals with the determination of a vitamin is preceded by an outline of the material which is to be discussed. The following outline of Chapter III, "The Determination of Vitamin A," is typical of the plan and treatment followed in discussing vitamin assay problems:

1. The International Standard of Reference and Unit of Vitamin A Activity.
    A. The dilution of the standard of reference for dosing.
    B. The need for a simultaneous test of the Standard whenever a determination of vitamin A is made.
    C. The general arrangement of the test for a determination of the vitamin A potency of a substance in terms of the International Standard.
2. The Preparation of Rats for Vitamin A Determinations.
    A. Animals suitable for the test.
    B. Housing of the animals.
    C. Vitamin A-free diet.
3. Criteria for the Measurement of the Response of Rats to Doses of Vitamin A.
    A. Increase in weight.
    B. Occurrence of xerophthalmia.
    C. Changes in the vaginal contents.
    D. Comparison between prophylactic and curative methods.
    E. Comparison between (a) the "increase in weight" method, (b) the "xerophthalmia" method and (c) the "vaginal contents" method.
4. Physical Properties of Vitamin A by means of which it may be Measured.
5. References.

Part II consists of five chapters dealing with "The Standard Deviation" and "The Accuracy Obtainable in Determinations of Vitamin A, B_1, C and D." An appendix consisting of ten pages contains a report of the Second International Conference on Biological Standardisation and a table of Vitamin Content of Some Common Foods, expressed in International Units.

The author shows remarkable familiarity with the various methods and laboratory practices prevailing in the best European and American laboratories. Even the experienced worker will find Part I (practical) of great value and it is the reviewer's opinion that every vitamin assay laboratory should have the book available, since Dr. Coward has brought together material which is widely scattered in the literature.

Part II, however, contains information that is even less readily available than that referred to in Part I. Furthermore, most workers are not familiar with the use of statistical methods. Dr. Coward has the happy faculty of making statistical methods usable and understandable for the average worker.

The author has shown excellent judgment in her choice of photographs, tables and charts which illustrate the points emphasized in the text. No worker in vitamin research can afford to be without this very useful book

R. Adams Dutcher

The Economics of the Sulfuric Acid Industry. By Theodore J. Kreps, Stanford University Press, Stanford University, California, 1938. xiii + 284 pp. 20 figs. 16 × 23 cm. Price, $5.00.

Announced as the first of a series of four volumes in the field of chemical economics, this work deals preëminently with the sulfuric acid industry in the United States. The author has collated and arranged, in this volume, a vast array of statistics and other data relating to the sulfuric acid industry. With unstinted labor he has delved into the archives of Government bureaus and into the files of technical periodicals, and has made conveniently accessible a mass of figures which might otherwise have been lost in oblivion.

The sulfuric acid industry is here displayed in an unusual light, interesting to both the economist and the technician. After the Introduction and two chapters tracing historical developments, the current status of the industry, including the dominance therein of the United States, is presented in Chapter IV. Then ensue eight chapters on different phases of competition, concluding with a chapter on Intercommodity Competition, and the "Outlook for Sulfuric Acid." The presentations of all these different aspects are interesting, and one must admire the painstaking care with which the author has handled his data, and the conscientious manner in which he has drawn his inferences. However, the experienced technician will be unable to agree that the premises are always adequate, or the conclusions always right.

The chapter on Interprocess Competition might well have been expanded to include some subdivisions of this title, such as Intercatalyst Competition and Competition between Tower- and Chamber-Processes. The "idealized" table of comparative operating costs of chamber and contact plants (p. 72) may be objected to as established on incorrect data and forced into balance. Chapter VI contains an interesting account of the struggle between brimstone and pyrite, but why do the statistical tables stop with the year 1934? The discussion of the minor and potential sources of sulfur in Chapter XII seems to belong in Chapter VI.

Quite inadvertently, no doubt, some elements of unfairness seem to have crept into the text here and there. A good deal of publicity is given to one firm of contact-plant contractors to the exclusion of its competitors. In fact the influence of the intense pressure for business on the part of competing vanadium-mass contact-plant builders on (1) the displacement of platinum catalysts; (2) the relative decline in the production of chamber-plant acid; and (3) the creation of an over-supply of acid-plant capacity in the United States, has been omitted altogether. In the last chapter, the tendencies toward curtailment in sulfuric acid demand in certain industries are detailed without any mention of offsettnig new uses and expanding consumption in certain other industries.

The author, Associate Professor of Business Economics at Stanford University, shows a remarkable grasp of many of the technicalities of sulfuric acid manufacture. It is true, however, that some inaccuracies and debatable statements have been included. The solution of the "vanadium mass problem" is ascribed to the wrong man (p. 54); the chamber process is erroneously said to have completely lost the market for oil of vitriol (p. 65); copper ores are said to enter the United States free of duty (p. 79), whereas a duty has been imposed since 1932; it is incorrectly implied (pp. 110 and 264) that vanadium mass can use pyrite gas without gas-purification; for the recent progress of America in contact-process technique, too much credit is given to vanadium mass, and too little to other developments (p.

55); and on p. 187 it is stated that many manufacturers of joint-cost products "do not even attempt to find particular costs for particular products, but are quite happy when the receipts from the totality of their operations show a profit over the totality of their outlays," which is in direct conflict with the practice of all manufacturers of joint-cost products with whose accounting methods the reviewer is familiar.

Several misprints (such as "turbo-dispenser" for turbo-disperser, pp. 60 and 264; "niter coke" for niter cake, p. 61; "carts" for cars, p. 90; and "767 caustic soda" for 76% caustic soda, p. 261), besides faulty English on p. 192 (line 14) and at the top of p. 215, escaped the proofreaders. It seems probable that a pre-publication critical review by a competent sulfuric acid engineer would have served to avoid most of these errors, as well as to guide the author to better sources of information and to bring the data more nearly up to date.

On the whole, this book, the first of its kind, is a valuable contribution to the literature of sulfuric acid, and will be welcomed in the libraries of the economist, the business executive and the technologist.

ANDREW M. FAIRLIE

Annual Tables of Constants and Numerical Data. N. THON, Editor-in-Chief. Vol. XI. Published for the International Union of Chemistry by Hermann et Cie.: McGraw-Hill Book Company, Inc., 330 West 42d Street, New York, N. Y., 1937. 17 × 25.5 cm.

This volume, No. XI, Part 1, is the first to be issued by the Managing Board appointed at the Twelfth Conference of the International Union of Chemistry at Lucerne in 1936. It contains numerical data which have been published during the years 1931–1934 classified in twenty-five sections and in addition a list of forty-four sections in which the other numerical data to be included in subsequent volumes will be classified. It is printed in a smaller and therefore more convenient size than the previous volumes of these Tables. Two other sections, namely, No. 26, Raman Effect, and No. 27, Rotatory Power, printed in the older, larger format, are available as separate monographs.

The Editors state that in this new series of Annual Tables emphasis will be placed on the selection and critical examination of the numerical data without abandoning the ideal of complete presentation to which Annual Tables have adhered in the past. Quantitative data are often divergent because of the different methods employed in, or the different conditions prevailing during, their determination; also because of the different methods of computation or different standard values which have been employed. It is very difficult to assign proper weights to these various factors and it would be unwise to select one single determination and discard the rest. The Editors believe that the best results will be obtained if, after elimination of data which are clearly inaccurate or are dependent upon uncertain factors, the remaining data are simultaneously tabulated and adequate information as to the attendant conditions and the methods or hypotheses involved in their determination is added.

The Editors consider it impossible to include all the data relative to industrial materials, so that in this field a few typical examples will have to suffice.

Data for the years 1935–1936 belonging in the above twenty-seven sections will be included in the forthcoming Volume XII, Part 1; data for the years 1931–1936 belonging in the remaining forty-four sections will appear in Parts 2 and 3 of the forthcoming combined Volumes XI–XII. The Managing Board states that the preparation and printing of these three volumes are progressing rapidly. Prior to their publication the separate sections will be issued in the form of monographs containing one to three sections.

Finally, the Managing Board points out that the publication of these volumes has been possible only because of a substantial grant received from the French Government.

Workers in the physical sciences everywhere will be gratified not only at this continuation of Annual Tables but particularly at the prospect of prompt publication of future volumes.

ARTHUR B. LAMB

The Chemistry of Plant Constituents. By OLE GISVOLD and CHARLES H. ROGERS. Burgess Publishing Company, Minneapolis, Minn., 1938. 309 pp. $3.50.

The authors state in the preface to the first (present) edition that the subject matter deals with the chemistry of plant constituents, with various possible reactions involved in their formation, and that "a rather complete bibliography is presented." When a book covers a vast field, the reviewer's critical competency must be limited to the topics with which he is intimately acquainted. His approval or disapproval of the book as a whole depends upon the thoroughness of his sampling of these topics.

The synthesis of hexoses *in vitro* by Baly (p. 6) is complete to 1928. No mention is made of the work of Ramsperger and Porter, nor of the work of Dhar and associates. The criticisms of Barton Wright (1930), the detailed discussion by Spoehr (1933), the Cold Spring Harbor Symposium (1934) are all ignored. Credit is given (p. 30) to Ehrlich for our "quite complete knowledge about the pectin molecule." Yet Norris and Resch (1937) point out the difficulty of distinguishing the essential structure from incidental adjunct. The authors make no reference to the work of Nanji, Paton and Ling, Carré, nor to the review by Bonner (1936). The work of Myers and Baker (1931, 1934), of Stoep (1928) and the important contributions of Link are all ignored. They suggest (p. 32) that the name pectin should be retained for substances now known as "urpectin" and "protopectin." This is contrary to the A. C. S. committee nomenclature (1927). The suggestion is made (p. 33) that the "definite ratio of calcium and magnesium in the pectin molecule might well explain the necessity of a balanced calcium and magnesium supply for normal plant development." A perusal of Norman ("Biochemistry of Cellulose, the Polyuronides and Lignin," 1937) shows how grossly inadequate is the present treatment.

The carotenoids (chapter X) were next examined. Reviews of this topic tend to conform to a set pattern but, in the reviewer's opinion, this chapter does not compare with the extremely readable account contributed by

Bogert to Gilman's "Organic Chemistry" (1938). Loose statements are frequent. Although Bogert uses xanthophyll synonymously with lutein (to the reviewer's regret, as it has for long been associated with the non-hydrocarbon carotenoids of the leaf), the present authors (p. 178) devote brief paragraphs to (1) *xanthophyll* and (2) *lutein or leaf xanthophyll.* This they state has been isolated from Dotter (sic) pigments. (*Egg-yolk*, Eidotter, or *Dodder?*) Strain has shown that leaf xanthophyll is not synonymous with lutein. They point out (p. 178) that rhodoxanthin does not have a double bond in the center of the molecule and therefore has a different type of symmetry. Application of Pauling's discussion on resonance (Gilman) to a conjugated system of double bonds indicates this to be illusory. On p. 184 they offer a confused discussion of water-soluble yellow pigments, carotenoids, and the autumnal coloring of leaves. "Some of the red colors are developed by the oxidation of the yellow ones. In the tomato, the yellow pigments are masked by the predominating red pigment, lycopin." The sentences, in juxtaposition, entirely unrelated, illustrate the confusion. The contribution of the late K. W. Hausser (1934) to color and bond conjugation might well have been mentioned. The improved method for isolating carotene by Homes (Holmes) and Leicester is hardly their most important contribution, and it has not found wide application because of the re-introduction of the Tswett column, of which but brief mention is made.

Russell's spectrographic evidence in favor of flavpinacol formation in phlobatannins might well have been stressed, and his lucid review (1934) should have settled the undesirability of including caffetannins and chlorogenic acid with the true tannins. The term *leucocyanin* has been substituted (p. 166) for leuco-*antho*cyanin. The development of color was first noted by Willstätter, explained by Rosenheim (1920), but this is not mentioned.

A discussion of chlorophyll is wedged (p. 272) into the chapter on enzymes. The sole reference to chlorophyll chemistry is Hans Fischer's review (1937). Willstätter and Conant are to be remembered, not for their positive chemical contributions, but by less valuable suggestions as to the photosynthetic mechanism. The theory of Muller (p. 272) is put forward, though it has no widespread acceptance, while the views of van Niel on assimilation, and of Emerson and Arnold, Gaffron, on a possible photosynthetic unit are ignored.

Let us set to one side the irritations caused by numerous typographical errors, the indifference to accepted spelling, (carotinoid, lycopin interchangeably with carotenoid, lycopene), the innovations on nomenclature. Limitations of space necessitate compression and even omission. Instead of a highly incomplete bibliography, a critically selective one is required. A further ground for uneasiness lies in the general framework into which the facts are set. Let us examine pp. 1–4 in some detail. "In general, the greater the water supply, the smaller the root system. Too much water will result in the death of most plants." Solution culture technique is overlooked, and no hint is given that oxygen supply is an essential factor. "(Leaves) are the laboratories in which 'nuclear' or simple materials are synthesized." When did chemist or biologist use nuclear in this sense? "Fruits...have the lowest percentage of ash, and leaves have the highest. The latter is probably due to the fact that the water leaves the ash behind as it evaporates from them in transpiration." There is no differentiation of constituents immobilized to a great extent, notably iron and calcium, and those of great mobility, particularly phosphorus and potassium, and we are told the ash is left behind as the water evaporates.

The book shows evidence of uncritical compilation, typographical errors are inexcusably numerous, the style is in places too staccato, and many expressions are both irritating and unscientific, (*e. g.*, p. 1 "a myriad number," p. 5 "a myriad of organic reactions," p. 14 "a myriad of plant products"). It is fair to add that these remarks apply to five of the fifteen chapters, and to slightly less than one-third of the book. The residue is certainly much more free from irritating or obvious defects, and appears to be more carefully reasoned. Unfortunately the reviewer has already limited his field of critical competency, but drastic changes must be made if this book is to survive.

G. Mackinney

Handbuch der Lebensmittelchemie. A. Bömer, A. Juckenack and J. Tillmans. Dritter Band. **Tierische Lebensmittel.** (Handbook of Food Chemistry. Vol. III. Animal Foodstuffs). Edited by A. Bömer. Verlag von Julius Springer, Linkstrasse 22-24, Berlin W 9, Germany, 1936. xvi + 1049 pp. 174 figs. 17.5 × 26 cm. Price, RM 129; bound, RM 132.60.

The first two volumes of this series are devoted to those constituents of the plant and animal world which constitute, or are a part of, man's food. Reviewed and described, also, are the relevant analytical procedures. In the third volume, and so to continue in the others which are contemplated, individual foods are treated. Unlike the practice followed by others, for example König, volume I and supplements of his "Chemie der Menschlichen Nahrungs- und Genussmittel," no attempt has been made at compiling the voluminous data on the proximate composition of foods which have appeared within the past century. Claimed as a novel feature which has been introduced to extend the serviceability of the work for the (German) food chemist in official or private practice is the inclusion of a digest, written by members of the profession (Holthöfer and Bames), of the legal aspects, both domestic and foreign, of the regulations under which the various substances are sold.

An excellent monograph of some 540 pages on milk and milk products, the work of A. Gronover and R. Strohecker who had the assistance of several others on certain special topics; similarly one on meats and meat products (359 p.) by A. Beythien and others; and a 74-page section by J. Grossfeld on the subject of eggs represent the major points of emphasis in this volume. Of lesser interest, although not without value, are the following topics: proprietary foods (23 p.) and sampling and preparation of material for analysis (17 p.) by A. Beythien; a brief discourse on foods and nutritive values (4 p.) by A. Bömer; and German food and food label laws (18 p.) by H. Holthöfer (18 p.).

References to the German literature on all of the topics are rather complete. That apparent ignoration of the world literature against which criticism was directed in respect to an earlier volume (This Journal, 57, 2017

(1935)) appears to have been avoided by the present authors, who have gone beyond their own frontiers in their attempts to bring into the picture the work of other scientists. Keeping pace with the advances in a field as large as that defined by the term food chemistry is, indeed, a large task. The authors have simplified this task for the many by bringing together in condensed form the vast amount of information now extant on this subject. The fact that methods of analysis have not been presented critically may perhaps disappoint some. Inasmuch as the reviewer does not understand that this work was to be primarily a treatise of this kind, he is of the opinion that the project has not missed its mark; rather that it should prove to be an invaluable aid to the worker in these fields.

Halogenation of 1-Hexyne in Methanol[1]

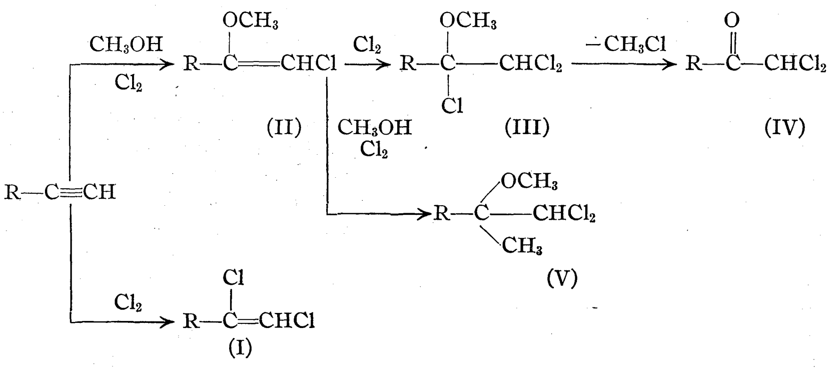
BY J. J. VERBANC AND G. F. HENNION

Introduction

Relatively little attention has been directed toward the halogenation of alkylacetylenes. It is generally accepted that di- and tetrahalogen addition products result from such reactions when conducted in inert solvents. However, there are numerous synthetic possibilities if a third reagent is present, *e. g.*, a reactive solvent such as methanol.

Goldschmidt, Endres and Dirsch[2] treated phenylacetylene with ethyl hypochlorite in carbon tetrachloride solution. They obtained dichloroacetophenone and not the anticipated diethoxydichloro addition product. Jackson[3] chlorinated phenylacetylene in methanol and obtained 1-phenyl-1,1-dimethoxy-2,2-dichloroethane. Similar studies with aliphatic acetylenes have not been reported. In the present investigation 1-hexyne has been chlorinated under a variety of conditions using both methanol and carbon tetrachloride as solvents. All likely addition products have been isolated or prepared by independent methods.

Chlorination of 1-hexyne in methanol at 0–5° yielded a mixture of 1,2-dichloro-1-hexene (I) and 1,1-dichloro-2,2-dimethoxyhexane (V). At 25–30°, 1,1-dichloro-2-hexanone (IV) was obtained in addition to the above products. The formation of these compounds may be represented by the following scheme of reactions (R is n-C_4H_9).



Compounds (II) and (III) were not isolated. The reactivity of (II) precludes the possibility of isolation from the chlorinated mixture. Compounds of type (III) spontaneously decompose, as has been shown previously.[4] During these experiments the formation of methyl chloride was observed, confirming the mechanism of dihaloketone (IV) formation.

The absence of (II) and the monochloro analogs of (IV) and (V) prompted us to synthesize these in another manner. The following reactions were employed, starting with 1-hexyne.

The 1-chloro-2-methoxy-1-hexene (II) thus obtained was dissolved in methanol and treated with chlorine at 25°. Compound (V) was ob-

tained in 60% yield, thereby confirming, in part, the mechanism proposed above.

Chlorination of 1-hexyne in carbon tetrachloride yielded only the anticipated 1,2-dichloride.

Bromination of 1-hexyne yielded the 1,2-dibromide, irrespective of whether the reaction was conducted in carbon tetrachloride or methanol. Neither methoxy bromides nor bromo ketones could be prepared under the conditions employed.

Experimental

Reagents.—1-Hexyne[5,6] and 1-chloro-1-hexyne[7] were prepared as previously described. All other materials were c. p. stock reagents.

Reaction of Chlorine with 1-Hexyne in Methanol.—Into a two-liter three-necked flask with a reflux condenser, mechanical stirrer and a gas inlet tube, was placed 400 cc. of anhydrous methanol and 82 g. of 1-hexyne. A moderately rapid stream of chlorine, measured by a flowmeter, was introduced over the surface of the rapidly agitated mixture. The absorption of chlorine was quite rapid and the reaction was accompanied by a moderate rise in temperature. The initial temperature, 25–30°, was maintained by moderate cooling. After the theoretical amount of chlorine had been added the mixture was allowed to stir for an additional hour after which it was washed with water, dilute carbonate solution and again with water. The organic layer was dried over calcium chloride and fractionated. Distillation through an efficient column yielded the following compounds listed in order of increasing boiling point.

1,2-Dichloro-1-hexene (I).—Obtained 29 g. (18% yield); b. p. 60–61° at 34 mm.; d^{28} 1.0511; $n^{28}\text{D}$ 1.4535; *MR* (calcd.), 39.17; *MR* (obsd.), 39.10.

Anal. Calcd. for $C_6H_{10}Cl_2$: Cl, 46.4; mol. wt., 153.0. Found: Cl, 46.1; mol. wt., cryoscopic in benzene, 151.3.

1,1-Dichloro-2-hexanone (IV).—Obtained 60.3 g. (37% yield); b. p. 64–66° at 10 mm.; d^{26} 1.1344; $n^{26}\text{D}$ 1.4533; *MR* (calcd.), 39.65; *MR* (obsd.), 40.0.

Anal. Calcd. for $C_6H_{10}Cl_2O$: Cl, 42.0; mol. wt., 169.0. Found: Cl, 42.2; mol. wt., cryoscopic in benzene, 167.7.

1,1-Dichloro-2,2-dimethoxyhexane (V).—Obtained 75 g. (35% yield); b. p. 76–78° at 2 mm.; d^{29} 1.120; $n^{29}\text{D}$ 1.4530; *MR* (calcd.), 52.1; *MR* (obsd.), 51.8.

Anal. Calcd. for $C_8H_{16}Cl_2O_2$: Cl, 32.81; mol. wt., 216. Found: Cl, 32.7, 32.55, 32.50; mol. wt., cryoscopic in benzene, 215, 218.

A similar experiment was carried out employing a reaction temperature of 0–5°. This reaction resulted in a 20% yield of 1,2-dichloro-1-hexene and a 30% yield of 1,1-dichloro-2,2-dimethoxyhexane. Approximately 24% of 1-hexyne was recovered.

Bromination of 1-Hexyne in Methanol.—Into a two-liter three-necked flask with a reflux condenser, mechanical stirrer, and a gas inlet tube, was placed 500 cc. of anhydrous methanol, and 82 g. of 1-hexyne. Two hundred and forty grams of bromine was placed in a 250-cc. wide-mouthed bottle equipped with an inlet and outlet tube. The bromine bottle was connected by means of rubber tubing to the reaction flask and to a nitrogen tank. A slow stream of nitrogen was bubbled through the liquid bromine for four hours, sufficient to transfer all the bromine. The reaction flask was cooled in an ice-bath during the addition. The mixture was stirred for an additional hour, after which it was washed with water, dilute carbonate solution and again with water. The organic layer was dried over calcium chloride and distilled through an efficient column. The yield of 1,2-dibromo-1-hexene was 223 g. (92.5% yield). The compound had the following characteristics: b. p. 89–91° at 30 mm.; d^{22} 1.608; $n^{22}\text{D}$ 1.5080; *MR* (calcd.), 44.97; *MR* (obsd.), 44.80.

Anal. Calcd. for $C_6H_{10}Br_2$: Br, 66.1; mol. wt., 242. Found: Br, 65.9; mol. wt., cryoscopic in benzene, 239.

Chlorination of 1-Hexyne in Carbon Tetrachloride.—Into a one-liter three-necked flask with a reflux condenser, motor driven stirrer, and a gas inlet tube, was placed 82 g. of 1-hexyne and 500 cc. of carbon tetrachloride. An additional 100 cc. of solvent to which had been added 3 cc. of antimony pentachloride was added slowly to the agitated mixture. A moderate stream of chlorine was passed over the surface until the theoretical amount had been added. The reaction mixture was stirred for an additional hour after which it was washed with water, dilute carbonate solution and again with water. The organic layer was dried over calcium chloride and distilled. The yield of product was 38 g. (25% of the theoretical). Considerable polymer (tar) was also obtained. The 1,2-dichloro-1-hexene had the following characteristics: b. p. 62–65° at 36 mm.; d^{27} 1.0525; $n^{27}\text{D}$ 1.4540; *MR* (calcd.), 39.17; *MR* (obsd.), 39.10.

Proof of Structure of 1,1-Dichloro-2-hexanone.—Ten grams of 1,1-dichloro-2-hexanone and 20 g. of calcium hypochlorite were mixed with 100 cc. of distilled water. The mixture was refluxed for thirty minutes after which it was subjected to distillation. The following compounds were obtained: 3.5 g. of chloroform, b. p., 57–58° at 746 mm.; d^{25} 1.481; $n^{25}\text{D}$ 1.4438, and 1.5 g. of *n*-valeric acid, identified by its characteristic odor and *p*-bromophenacyl ester, m. p. 63°.

Identification of Methyl Chloride.—A solution of 82 g. of 1-hexyne in 500 cc. of methanol was chlorinated at 40–50° as described above. The exit gas was passed through two wash bottles containing 25% sodium hy-

(7) McCusker and Vogt, THIS JOURNAL, **59**, 1307 (1937).

droxide solution, then through a calcium chloride drying tube, and finally into a 500-cc. flask cooled to −75° with carbice and acetone. About 20 cc. of condensate was obtained, identified as methyl chloride by conversion to methylmagnesium chloride, then to acetic acid (b. p. 118–119°), in turn converted to acetanilide (m. p. 114°). The chlorinated methanol solution yielded 39 g. of 1,2-dichloro-1-hexene and 38 g. of 1,1-dichloro-2-hexanone.

Addition of Methanol to 1-Chloro-1-hexyne.—This reaction was carried out using the method previously reported.[8] From 116.5 g. of 1-chloro-1-hexyne there was obtained 150 g. (83% yield) of 1-chloro-2,2-dimethoxyhexane: b. p. 77–80° at 14 mm.; d^{25} 0.9873; $n^{25}\text{D}$ 1.4305; *MR* (calcd.), 47.30; *MR* (obsd.), 47.20.

Anal. Calcd. for $C_8H_{17}O_2Cl$: Cl, 19.65; mol. wt., 180.5. Found: Cl, 19.40; mol. wt., cryoscopic in benzene, 179.8.

Preparation of 1-Chloro-2-methoxy-1-hexene.—Employing the general procedure already reported,[9] 90.3 g. of 1-chloro-2,2-dimethoxyhexane was desaturated using *p*-toluenesulfonic acid as a catalyst. The yield of 1-chloro-2-methoxy-1-hexene was 68.5 g. (92.5% yield). The following characteristics were determined for this compound: b. p. 90–91° at 65 mm.; d^{23} 0.9725; $n^{23}\text{D}$ 1.4460; *MR* (calcd.), 40.57; *MR* (obsd.), 40.65.

Anal. Calcd. for $C_7H_{13}OCl$: Cl, 24.9; mol. wt., 148.5. Found: Cl, 24.8; mol. wt., cryoscopic in benzene, 147.1.

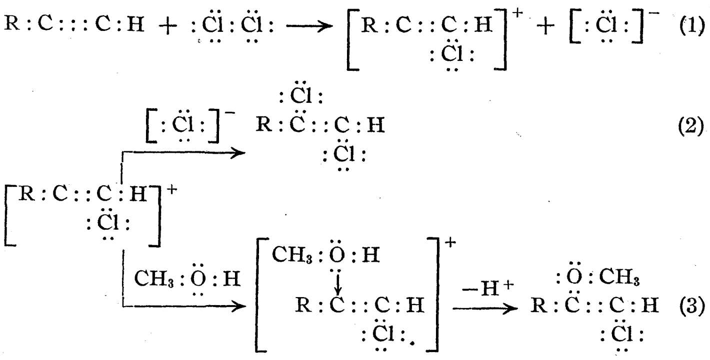
Chlorination of 1-Chloro-2-methoxy-1-hexene.—Forty grams of 1-chloro-2-methoxy-1-hexene was added dropwise (below the surface) to 200 cc. of methanol, while chlorine was passed over the surface. The temperature was maintained at 25–30°. At the completion of the reaction the excess chlorine and hydrogen chloride formed were exactly neutralized with sodium methylate–methanol solution, using phenolphthalein as an indicator. The sodium chloride was filtered off and the filtrate distilled. There was obtained 35 g. (60% yield) of 1,1-dichloro-2,2-dimethoxyhexane.

Hydrolysis of 1-Chloro-2-methoxy-1-hexene.—Fifteen grams of 1-chloro-2-methoxy-1-hexene was added to a mixture of 15 cc. of water and 50 cc. of methanol to which had been added 0.2 g. of *p*-toluenesulfonic acid. The solution was placed in a 250-cc. flask equipped with a reflux condenser and heated for a period of two hours. The excess water was removed by addition of anhydrous sodium sulfate and the clear supernatant liquid fractionated. The yield of 1-chloro-2-hexanone was 11 g. (82%). The ketone had the following properties: b. p. 73–74° at 20 mm.; d^{24} 1.007; $n^{24}\text{D}$ 1.4370; *MR* (calcd.), 34.79; *MR* (obsd.), 34.80.

Anal. Calcd. for $C_6H_{11}ClO$: Cl, 26.38. Found: Cl, 26.3.

Discussion

It is extremely unlikely that methoxychloro addition products of 1-hexyne result through direct addition of methyl hypochlorite. In accord with modern electronic concepts, we prefer to consider a series of repeated fragmentary additions as shown below with electronic formulas.



Equations (1) and (2) represent the normal course of halogenation in inert solvents. Equation (3) shows how a reactive solvent may coordinate with the "positive fragment" from (1), the complex then stabilizing by rejection of a hydrogen ion.

While direct proof of such mechanisms cannot be offered, these electronic concepts have proved extremely useful in predicting a number of other mixed addition reactions now under investigation.

Summary

1-Hexyne has been chlorinated in methanol and in carbon tetrachloride. Chlorination in methanol yielded 1,2-dichloro-1-hexene, 1,1-dichloro-2,2-dimethoxyhexane, and 1,1-dichloro-2-hexanone. In carbon tetrachloride 1,2-dichloro-1-hexene was formed. Bromination in methanol gave exclusively the 1,2-dibromide.

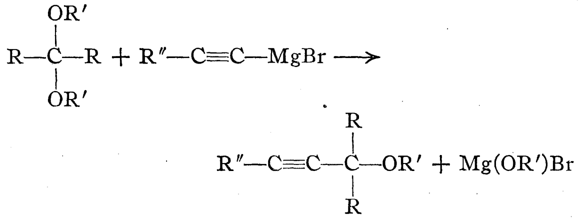
Reactions of Dialkoxyalkanes with Alkynylmagnesium Bromides[1]

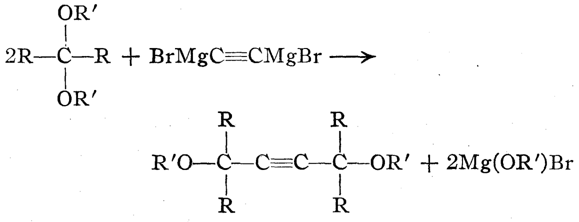
BY A. L. KRANZFELDER AND R. R. VOGT

Introduction

It has been shown by Spaeth[2] and by Tschitschibabin and Jelgasin[3] that several common acetals react with certain alkyl- and arylmagnesium halides to yield various amounts of ethers through replacement of one alkoxyl group by the hydrocarbon radical. This reaction has been applied in the present research by utilizing the acetylenic magnesium bromides and acetal-type compounds for the synthesis of alkyl ethers of alkynyl carbinols and glycols, according to the following type equations, in which (R′) and (R″) represent alkyl groups and (R) may be an alkyl radical or hydrogen atom



$$\mathrm{R{-}\overset{OR'}{\underset{OR'}{C}}{-}R + R''{-}C{\equiv}C{-}MgBr \longrightarrow R''{-}C{\equiv}C{-}\overset{R}{\underset{R}{C}}{-}OR' + Mg(OR')Br}$$



$$\mathrm{2R{-}\overset{OR'}{\underset{OR'}{C}}{-}R + BrMgC{\equiv}CMgBr \longrightarrow R'O{-}\overset{R}{\underset{R}{C}}{-}C{\equiv}C{-}\overset{R}{\underset{R}{C}}{-}OR' + 2Mg(OR')Br}$$

Several ethers of acetylenic glycols as well as certain methoxybutynes have been prepared previously by the action of halomagnesium or sodium compounds of acetylenes on various haloethers, as shown below[4–7]

$$\mathrm{CH_3OCH_2Cl + BrMgC{\equiv}C{-}CH_3 \longrightarrow CH_3OCH_2{-}C{\equiv}C{-}CH_3 + MgBrCl}$$

$$\mathrm{CH_3OCH_2CH_2Br + NaC{\equiv}CH \longrightarrow CH_3OCH_2CH_2{-}C{\equiv}CH + NaBr}$$

$$\mathrm{2ROCH_2Cl + BrMgC{\equiv}CMgBr \longrightarrow ROCH_2C{\equiv}CCH_2OR + 2MgClBr}$$

By treating propargylic acetal, obtained from acrolein, with methyl-, ethyl- and phenylmagnesium bromides, Grard[8] prepared the corresponding 3-ethoxy-1-alkynes. The methyl ethers of some acetylenic carbinols also have been synthesized from methyl sulfate and the sodium alcoholates.[9]

The object of this investigation was to study the reactivity of different types of dialkoxyalkanes toward acetylenic Grignard reagents, and to determine the practicability of the reaction as a general method for the synthesis of various classes of acetylenic ethers. The method lends itself particularly well since the intermediate acetals and ketals are readily prepared directly from acetylene and the alkylacetylenes

$$\begin{tikzcd}
\mathrm{HC{\equiv}CH} \arrow[r, "+2\mathrm{ROH}"] \arrow[d, "\mathrm{Na\ +\ RBr}"] & \mathrm{CH_3{-}CH(OR)_2} \\
\mathrm{RC{\equiv}CH} \arrow[r, "+2\mathrm{ROH}"] & \mathrm{R{-}C(OR)_2CH_3}
\end{tikzcd}$$

The reactions carried out are listed in Table I, along with the physical constants of the acetylenic ethers obtained. Table II shows the analysis of the ethers not reported in the literature. All compounds distilled as water-white liquids having very pleasant odors.

Experimental

Reagents.—1-Hexyne and 1-heptyne were prepared by a modification of the Picon synthesis.[10] Ethyl orthoformate was synthesized according to the method described in the literature.[11] Ethylal and *n*-propylal were Eastman Kodak Company products, and were purified by distillation before use.

Preparation of 1,1- and 2,2-Dialkoxyalkanes.—1,1-Diethoxyethane and 2,2-dimethoxyhexane were obtained by the addition of ethanol and methanol to acetylene[12] and to 1-hexyne,[13] respectively, by means of a mercuric oxide–boron trifluoride catalyst.

The preparation of 1,1-diethoxypropane was effected by the addition of an ether solution of 1.0 mole ethylmagnesium bromide to a solution of 222 g. (1.50 moles) of ethyl orthoformate in dry ether. The method employed was similar to the general procedure described below. Special precautions were taken, however, to use an excess of ester to ensure reaction of only one alkoxyl group. Hy-

[a] Cryoscopic in benzene. [b] Zeisel method. [c] *Anal.* Calcd. for $C_{10}H_{18}O$: C, 77.92. Found: C, 77.17. (By wet combustion method.)

drolysis was carried out by the careful addition of dilute acetic acid, and the product was neutralized immediately to minimize conversion to the aldehyde. The yield amounted to 100 g. (75% of the theoretical), b. p. 122–123°.

Ethyl orthoformate, treated in a similar manner with phenylmagnesium bromide, gave a 55% yield of benzylidene acetal, b. p. 92–93° at 10 mm.

1,1-Diethoxy-2-heptyne (not previously reported) was obtained analogously, utilizing hexynylmagnesium bromide. The yield was 69%, b. p. 97–98° at 10 mm.; n^{27}_D 1.4320; d^{25}_4 0.8668.

Preparation of 1,2-Dimethoxyethane.—A modification of the reported method[14] was employed, which resulted in increased yields and a purer product.

Seventeen grams (0.75 mole) of metallic sodium was added in small portions to 228 g. (3.0 moles) of ethylene glycol monomethyl ether (Methyl Cellosolve) after which 94.5 g. (0.75 mole) of methyl sulfate was added dropwise, with stirring, during thirty minutes. After heating for an additional fifteen minutes at 85–90° on an oil-bath, the product was distilled through a short Vigreux column. All material boiling below 100° was collected and this fraction redistilled. The amount of product boiling at 82–83° was 54.5 g. (81% yield).

Reaction of Dialkoxyalkanes with Hexynylmagnesium Bromide.—The following represents the general procedure employed for all reactions.

Ethylmagnesium bromide was prepared in the usual manner, using 12 g. (0.50 mole) of magnesium turnings in anhydrous ether, and sufficient ethyl bromide to react with all the metal. To this solution was added dropwise and with stirring 41 g. (0.50 mole) of 1-hexyne, diluted with an equal volume of dry ether. The reaction mixture was allowed to stand for twelve hours, and was then stirred and refluxed vigorously for two hours longer. After allowing to cool, this solution was transferred to a dropping funnel and added slowly to 0.55 mole of the dialkoxyalkane dissolved in 100 cc. of anhydrous ether. The 1-liter, 3-necked flask used for preparation of the Grignard reagent was employed and constant agitation was effected by means of a sealed mechanical stirrer. Throughout the addition the reaction mixture was kept at a temperature sufficiently high, by heating on a water-bath, to distil off the ether at a constant rate. It was found advantageous to add the Grignard reagent through a short, upright water-cooled condenser to prevent evaporation of the ether and solidification in the funnel stem. Stirring was continued for one hour with the water-bath at 95°, after which the semi-solid mixture was hydrolyzed in the cold with dilute hydrochloric acid. The organic layer was dried and distilled under reduced pressure. It was found that merely refluxing the reactants in dry ether with stirring for two to three hours gave lower yields of acetylenic ether than those obtained by removing the ether continuously and heating as described above.

In the reaction involving 1,2-dimethoxyethane, the reaction mixture was heated on a near-boiling water-bath for three hours after the ether had been removed. The remainder of the procedure was the same as that given.

Reaction of Dialkoxyalkanes with Ethynylmagnesium Bromides.—Acetylene dimagnesium bromide was obtained by bubbling acetylene gas, purified by passing through concentrated sulfuric acid and a calcium chloride tower, through a solution of ethylmagnesium bromide in anhydrous ether during the course of eight to ten hours with constant stirring. After refluxing to remove ethane and excess acetylene, the Grignard reagent was added to twice its molal quantity of dialkoxyalkane in the usual manner. In addition to the ethers shown in Table I, 0.50 mole of the reagent, when treated with ethyl orthoformate, gave 69 g. of the diacetal, 1,1,4,4-tetraethoxy-2-butyne, b. p. 107° at 4 mm.; n^{30}_D 1.4315; d^{22}_4 0.9525.

By adding bromobenzene to magnesium turnings in dry ether and simultaneously passing acetylene gas into the solution, as above, with vigorous refluxing, a Grignard reagent was obtained which, by its reactions with acetals proved to be mainly ethynylmonomagnesium bromide.

---

[14] Clarke, *J. Chem. Soc.*, **101**, 1802 (1912).

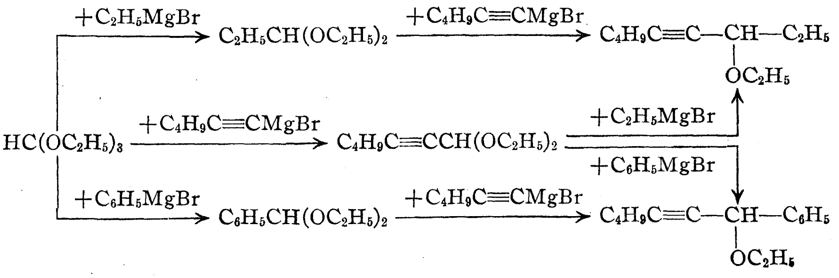
With orthoformic ester, 0.50 mole of the reagent gave 24 g. of the monoacetal, 3,3-diethoxy-1-propyne, b. p. 35° at 10 mm.; $n^{22}D$ 1.4139; $d^{22}{}_4$ 0.8942.

Reaction of 1,1-Diethoxyethane with Sodium Acetylides.—Ninety-six grams (1.0 mole) of 1-heptyne was added slowly to a solution of approximately 1.0 mole of sodamide in liquid ammonia. When most of the ammonia had evaporated, the solid acetylide was suspended in 600 cc. of anhydrous ether. To this solution was added 147 g. (1.25 moles) of ethyl acetal and the mixture refluxed with stirring for two hours. After hydrolysis the organic layer was purified, and distillation yielded 7 g. of 2-ethoxy-3-nonyne, b. p. 108° at 40 mm.

Since liquid ammonia was found to be an excellent solvent for ethyl acetal, the reaction with sodium amyl acetylide was carried out in this medium as well as in *m*-xylene at 120°. In one case the solid acetylide was treated with excess acetal and heated for three hours. In each instance some 2-ethoxy-3-nonyne was obtained, but the yields were quite low. No acetylenic ether could be identified among the reaction products when sodium acetylide was employed in the above media.

Discussion of Results

That the reaction studied in this investigation proceeds through replacement of one alkoxyl group of the acetal or ketal by the acetylenic radical was clearly demonstrated by synthesizing 1-phenyl-1-ethoxy-2-heptyne and 2-ethoxy-3-nonyne by two independent methods, involving the use of different intermediates. Such a mechanism accounts for the formation of identical products when the following reactions were carried out



Each reaction of dialkoxyalkane with hexynylmagnesium bromide was carried out under identical conditions of time, temperature and concentration of reactants, and a very marked variation in the reactivity of the different types of alkoxy compounds was noted. 1,2-Dimethoxyethane, given a longer reaction period, produced only 15% of acetylenic ether. Under the standard conditions, the acetals of formaldehyde yielded 31 to 35% of ether, acetaldehyde and propionaldehyde, 46 to 49%, 2-hexanone, 57%, *n*-butylpropiolaldehyde, 62% and benzaldehyde, 66%.

This method of acetylenic ether synthesis is a very general one, in so far as alkyl ethers of primary, secondary or tertiary acetylenic carbinols may be obtained, depending on whether acetals of formaldehyde, higher aldehydes or ketones are used as starting materials. In addition, the intermediates needed for the secondary and tertiary acetylenic ethers are obtainable directly from acetylene and the alkylacetylenes, thus obviating the use of haloethers or acetylenic carbinols as such.

Summary

Various acetals and ketals have been found to react with alkynylmagnesium bromides to yield ethers of primary, secondary and tertiary acetylenic carbinols and glycols. The latter two types of acetylenic ethers were synthesized from intermediates obtained from acetylene and alkylacetylenes.

Acetals of formaldehyde, higher alkyl aldehydes, ketones and benzaldehyde exhibited a definite increase in reactivity, in the order named, which is explainable electronically.

Sodium acetylides have been shown to react only to a slight extent with acetals in various solvents.

Several new acetylenic ethers have been reported.

A convenient method for the synthesis of 1,2-dimethoxyethane in good yields has been described.

Some Reactions of Dialkylacetylenes[1]

BY EDWARD A. BRIED AND G. F. HENNION

Introduction

A previous communication[2] in this series reported a rapid preparation of dialkylacetylenes involving the simultaneous interaction of sodium acetylide, sodamide and alkyl halides in liquid ammonia. This work has been extended with three objectives in mind: (1) to study the behavior of higher alkyl halides in the dialkylacetylene synthesis; (2) to study reactions of dialkylacetylenes; and (3) to prepare dialkylacetylene derivatives suitable for rapid identification. Definite results have been obtained only with regard to the first two objectives. A number of noncatalytic addition reactions have been investigated, but in no case have solid derivatives been found suitable for ready identification.

The rapid dialkylacetylene synthesis[2] is limited definitely to the usage of alkyl halides of moderate molecular weight and appreciable solubility in liquid ammonia. Whereas *n*-butyl bromide gave a 70% yield of dibutylacetylene, *n*-amyl bromide gave a 30% yield of diamylacetylene[2] and *n*-hexyl bromide a 38% yield of dihexylacetylene. *n*-Octyl bromide, when treated with sodium acetylide and sodamide in liquid ammonia at atmospheric pressure, gave a 57% yield of octylacetylene and a 15% yield of dioctylacetylene. At 120 lb. per sq. in. (8 atm.) the yield of dioctylacetylene increased to 27%, while the yield of octylacetylene amounted to 15%. Decyl bromide gave decylacetylene and decylamine.

Oxidation of dibutylacetylene with 68% nitric acid in the presence of mercuric nitrate resulted in good yields of *n*-valeric acid. Dibutylacetylene rapidly absorbed hydrogen quantitatively at 55 lb. per sq. in. (3.7 atm.) in the presence of Raney nickel to give *n*-decane. In this connection it seems the hydrogenation of dialkylacetylenes may well serve as a source of pure long chain paraffin hydrocarbons. Addition of bromine to dibutylacetylene yielded a dibromide boiling over a 20° range and therefore likely a mixture of *cis* and *trans* isomers. Hydration of dibutylacetylene, using the method recently reported,[3] gave 5-decanone in excellent yield. Catalytic addition[4] of methanol, ethylene glycol and acetic acid to dibutylacetylene proceeded readily.

Addition of thiocyanogen to diphenylacetylene yielded a crystalline addition compound previously reported by Söderbäck.[5] Treatment of dibutylacetylene under identical conditions failed to give a derivative. Addition of iodine monobromide to dioctylacetylene in ether yielded a brownish-black solid which decomposed upon heating.

Experimental

Reagents.—Octyl alcohol and decyl bromide were kindly supplied for this work by the du Pont Company.

Reaction of Hexyl Bromide with Sodium Acetylide and Sodamide.—Hexyl bromide (124 g., 0.75 mole) was added dropwise to a mixture of 0.69 mole of sodium acetylide and 0.78 mole of sodamide[2] in three liters of liquid ammonia during the course of forty-five minutes. The mixture was evaporated to dryness. Ether (200 ml.) and one liter of crushed ice were added, the organic layer separated and treated in the usual manner. Fractionation *in vacuo* through a 30-cm. Vigreux column yielded 27.5 g. (38% yield) of dihexylacetylene boiling at 132–134° at 21 mm. Redistillation gave a product with the following physical constants: b. p. 124° (15 mm.), 140° (25 mm.), 144° (30 mm.); $n^{25}\text{D}$ 1.4330; d^{25} 0.7991; *MR* (calcd.), 64.85; *MR* (obsd.), 64.5.

Anal. Calcd. for $C_{14}H_{26}$: C, 86.51; H, 13.49. Found: C, 85.66; H, 13.46.

Reaction of Octyl Bromide with Sodium Acetylide and Sodamide.—The same procedure was employed as described above. The yield of dioctylacetylene was 14.2 g. (15% yield). There was a recovery of 59.5 g. (57% yield) of octylacetylene and 5.6 g. of octyl bromide. The addition of 100 ml. of dry ether, when half of the octyl bromide had been introduced, did not increase the yield of dioctylacetylene. Octylacetylene (61.6 g., 59% yield) and dioctylacetylene (7 g., 7% yield) were recovered. Preparation of dioctylacetylene in the autoclave at 120 lb. per sq. in. (8 atm.), using the general method previously described,[2] yielded 25 g. (27% yield) of dioctylacetylene and 15 g. (15% yield) of octylacetylene. Distillation gave dioctylacetylene with the following physical constants: b. p. 163–164° (7 mm.); $n^{25}\text{D}$ 1.4488; d^{25} 0.8022; *MR* (calcd.), 83.32; *MR* (obsd.), 83.71.

Anal. Calcd. for $C_{18}H_{34}$: C, 86.31; H, 13.69. Found: C, 85.76; H, 13.15.

Reaction of Decyl Bromide with Sodium Acetylide and Sodamide.—Two experiments were performed, using 27.6

[5] Söderbäck, *Ann.*, **443**, 142 (1925).

g. (0.125 mole) of decyl bromide with 0.075 mole of sodium acetylide and 0.082 mole of sodamide in each case.

An experiment at atmospheric pressure gave 15 g. of a decyl bromide–decylacetylene mixture, b. p. 72° (3 mm.).

An experiment conducted in the autoclave at 120 lb. per sq. in. (8 atm.) gave 12 g. of decylacetylene and 6 g. of decylamine, weighed as the hydrochloride, m. p. 193°, confirming that reported by Komppa.[6]

Oxidation of Dibutylacetylene.—Seventy-nine grams of 68% nitric acid was placed in a 500-ml. three-necked flask equipped with a dropping funnel, mercury-sealed motor-driven stirrer and water condenser. One gram of mercuric nitrate was dissolved in the nitric acid and 34.5 g. (0.25 mole) of dibutylacetylene added dropwise. The reaction was highly exothermic and it was found possible to maintain a temperature of 80° by controlling the rate of addition of the dialkylacetylene. Stirring was continued for one hour. Benzene (100 ml.) was added, the organic layer separated, washed with water, and fractionated through a 50-cm. Vigreux column. The yield of *n*-valeric acid, after the first distillation, was 34.5 g. (68%). Redistillation gave 30 g. (60% yield) of product boiling at 90–91° (19 mm.). The neutralization equivalent was 100 (molecular weight, calcd., 102).

Hydrogenation of Dibutylacetylene.[7]—A catalytic reduction machine similar to the apparatus described by Adams and Voorhees[8] was used. A solution of dibutylacetylene (24.2 g., 0.175 mole) in 100 ml. of methanol with 3 g. of Raney nickel catalyst, prepared according to the method of Covert and Adkins,[9] was shaken in an atmosphere of hydrogen for a period of ninety minutes. The pressure rapidly fell from 55 to 20 lb. per sq. in. (3.7 to 1.3 atm.), corresponding to the absorption of approximately 0.4 mole of hydrogen. The product was washed with 100 ml. of water, the organic layer separated and dried over powdered anhydrous potassium carbonate. Fractionation through a 30-cm. column gave 15.3 g. of product boiling at 62–63° (15 mm.). Successive treatments with concentrated sulfuric acid, water, dilute sodium carbonate and finally with distilled water, followed by distillation, yielded *n*-decane, b. p. 66–67° (17 mm.); $n^{25}\text{D}$ 1.4093; d^{25} 0.7269; *MR* (calcd.), 48.39; *MR* (obsd.), 48.4.

Bromination of Dibutylacetylene.—Bromine (40 g., 0.25 mole) was added dropwise at reflux temperature to a solution of 34.5 g. of dibutylacetylene (0.25 mole) in 200 ml. of dry chloroform. After stirring for one hour, the product was washed successively with water, dilute sodium carbonate, finally with distilled water and dried over calcium chloride. Distillation through a 30-cm. Vigreux column gave a product (50.2 g.) boiling at 113–132° (17 mm.). Repeated fractionation *in vacuo* gave two fractions: (a) b. p. 123–124° (17 mm.); $n^{25}\text{D}$ 1.4975; d^{25} 1.3473; *MR* (calcd.), 63.45; *MR* (obsd.), 64.8; (b) b. p. 127–128° (17 mm.); $n^{25}\text{D}$ 1.5005; d^{25} 1.3749; *MR* (calcd.), 63.45; *MR* (obsd.), 63.8.

Anal. Calcd. for $C_{10}H_{18}Br_2$: Br, 53.67. Found: for fraction (a), Br, 53.91; for fraction (b), Br, 53.94.

Hydration of Dibutylacetylene.—Using the general procedure previously described,[3] dibutylacetylene (69 g., 0.5 mole) was added dropwise to 225 g. of 70% isopropyl alcohol, in the presence of mercury catalyst, at 80°. Distillation through a 30-cm. column gave 62.4 g. (80% yield) of 5-decanone: b. p. 106–108° (27 mm.); $n^{24}\text{D}$ 1.4225; d^{24} 0.8115; *MR* (calcd.), 48.92; *MR* (obsd.), 48.6.

Anal. Calcd. for $C_{10}H_{20}O$: C, 76.84; H, 12.91. Found: C, 76.48; H, 12.77.

It was found impossible to prepare any of the common ketone derivatives from 5-decanone.

Addition of Methanol to Dibutylacetylene.—Dibutylacetylene (34.5 g., 0.25 mole) was added dropwise to 32 g. (1 mole) of anhydrous methanol, containing the usual catalytic mixture of mercuric oxide, boron fluoride, and trichloroacetic acid.[4] The product was isolated in the usual manner. The 5,5-dimethoxydecane was found to decompose slowly on distillation. After one distillation the following constants were obtained: b. p. 98–99° (10 mm.); $n^{25}\text{D}$ 1.4245; d^{25} 0.8549; *MR* (calcd.), 60.91; *MR* (obsd.), 60.4.

The decomposition of the dimethoxy compound was accelerated by distillation with a trace of *p*-toluenesulfonic acid.[10] In this manner 32 g. of 5,5-dimethoxydecane gave 27 g. of 5-methoxy-5-decene: b. p. 94–95° (20 mm.); $n^{25}\text{D}$ 1.4310; d^{25} 0.8212; *MR* (calcd.), 54.18; *MR* (obsd.), 53.6. Analysis indicated that the product was impure.

Anal. Calcd. for $C_{11}H_{22}O$: C, 77.57; H, 13.03; CH_3O, 18.2. Found: C, 75.0; H, 11.8; CH_3O, 12.0.

Addition of Acetic Acid to Dibutylacetylene.—Using the general procedure and catalyst described above, 69 g. (0.5 mole) of dibutylacetylene was added dropwise to 36 g. (0.6 mole) of glacial acetic acid containing 5 g. of acetic anhydride. The product was extracted with 150 ml. of ether and the extract washed successively with water, dilute sodium carbonate, finally with distilled water and dried over calcium chloride. Fractionation gave 59 g. (60% yield) of 5-acetoxy-5-decene boiling at 95–97° (10 mm.). The following physical constants were obtained: $n^{25}\text{D}$ 1.4320; d^{25} 0.8663; *MR* (calcd.), 58.81; *MR* (obsd.), 59.3.

Anal. Calcd. for $C_{12}H_{22}O_2$: C, 72.66; H, 11.19. Found: C, 72.04; H, 11.08.

This ester was very resistant both to saponification with alcoholic potassium hydroxide and to hydrolysis with dilute sulfuric acid.

Addition of Ethylene Glycol to Dibutylacetylene.—Dibutylacetylene (69 g., 0.5 mole) was added dropwise to 37.2 g. of ethylene glycol (0.6 mole) according to the general method previously described.[4] The two liquid phases, which originally prevailed, gradually became homogeneous as the reaction progressed. After distillation the fraction boiling at 105–106° (10 mm.) was retained. Redistillation gave 86.5 g. (86% yield) of 2-butyl-2-amyl-1,3-dioxolane: b. p. 103–105° (10 mm.); $n^{25}\text{D}$ 1.4339; d^{25} 0.8862; *MR* (calcd.), 58.71; *MR* (obsd.), 58.8.

Anal. Calcd. for $C_{12}H_{24}O_2$: C, 71.93; H, 12.08. Found: C, 71.98; H, 12.04.

Hydrolysis with a small quantity of sulfuric acid gave 5-decanone, b. p. 106–107° (27 mm.); $n^{25}D$ 1.4225.

Reaction of Thiocyanogen and Iodine Monobromide with Dialkylacetylenes.—A benzene solution of thiocyanogen was prepared according to the method of Söderbäck.[5] To one-half of this solution was added 1.3 g. of diphenylacetylene in 25 ml. of dry benzene, while to the other was added a comparable quantity of dibutylacetylene. The two solutions were placed in the dark for twenty hours. The diphenylacetylene deposited a crystalline product melting at 192–193°, as previously reported by Söderbäck.[5] Dibutylacetylene failed to give a derivative.

Dioctylacetylene (2 g.) was added to an ether solution of iodine monobromide (4 g.). After twenty-four hours at room temperature a brownish-black solid was obtained which decomposed upon heating.

Acknowledgment.—The authors acknowledge the kind assistance of Messrs. H. I. Lipsie and C. J. Kelley in a number of experiments.

Summary

1. The action of hexyl bromide, octyl bromide and decyl bromide on mixtures of sodium acetylide, and sodamide in liquid ammonia is described.

2. Oxidation, hydrogenation, bromination, hydration and the addition of methanol, acetic acid and glycol to dibutylacetylene are described.

3. No solid addition compound of dialkylacetylenes, suitable for identification purposes, has been found to date.

Pyrimidine Research: The Molecular Rearrangement of 4-Methyl-5-*n*-butyl-2,6-dimethoxypyrimidine[1]

BY YUOH FONG CHI, CHI WEI AND NAW SHAUNG PAN

It has long been known that lactim ethers of configuration I will undergo rearrangement to their isomeric and stable lactam form II. These transformations are irreversible and can be brought about by the application of heat with or without the presence of special catalytic agents, and have been observed to take place in both acyclic and cyclic compounds.

$$\underset{\text{I}}{\overset{|}{N}=\overset{|}{C}-OCH_3} \qquad \underset{\text{II}}{CH_3\overset{|}{N}-\overset{|}{C}=O}$$

This interesting rearrangement recently has been illustrated by Hilbert and Johnson[2] in the pyrimidine series. They showed that 2,6-dialkoxypyrimidines and 2-oxy-3-alkyl-6-alkoxypyrimidines easily undergo rearrangement on heating without catalytic reagents, at an elevated temperature to form the corresponding 1,3-dialkyl-uracils. Nevertheless, 2,6-dialkoxypyrimidine, containing two lactim configurations within the same pyrimidine molecule, will only undergo partial rearrangement by treatment with methyl iodide at a much lower temperature to form 2-oxy-3-alkyl-6-alkoxypyrimidines.

In this paper, the authors have extended this study and describe the conditions under which 4-methyl-5-*n*-butyl-2,6-dimethoxypyrimidine III, rearranges to (a) 1,3,4-trimethyl-5-*n*-butyl-uracil IV, and (b) 2-oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine V. Thus far, it has been found that the 2,6-dimethoxypyrimidine III easily undergoes transformation into its isomeric and stable lactam configuration, 1,3,4-trimethyl-5-*n*-butyl-uracil IV, by merely heating at 250–270° for three hours. On the other hand, it was only transformed into 2-oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine V, under the catalytic influence of methyl iodide at 50 or at 100°. Such partially rearranged pyrimidines like 2-oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine V, were only stable, however, at this lower temperature, and undergo further transformation into the isomeric and completely rearranged modification IV by heating. These respective changes are expressed by the formulas.

1,3,4-Trimethyl-5-*n*-butyl-uracil, IV, was identical with the pyrimidine prepared by methylation of 4-methyl-5-*n*-butyluracil. 2-Oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine very easily underwent hydrolysis by treatment with dilute hydrochloric acid yielding 3,4-dimethyl-5-*n*-butyl-uracil. The dimethoxypyrimidine III required for this research was synthesized by the action of

(a) C_4H_9 = *n*-butyl

sodium methylate upon 4-methyl-5-*n*-butyl-2,6-dichloropyrimidine, which was obtained by treating its corresponding uracil precursor previously described by Chi,[3] with a mixture of phosphorus oxychloride and phosphorus pentachloride.

Experimental Part

4-Methyl-5-*n*-butyl-2,6-dichloropyrimidine.—One hundred and ten grams of 4-methyl-5-*n*-butyluracil was dissolved in a cold mixture of 500 cc. phosphorus oxychloride and 50 g. of phosphorus pentachloride. This was then heated in an oil-bath at 120° until hydrogen chloride gas ceased to be evolved. This required about ten hours. The excess of phosphorus oxychloride was distilled off under diminished pressure at water-bath temperature, when there was left behind a dark brown, resinous residue. In order to decompose any phosphorus compounds, this product was cooled by an ice–salt mixture, and then treated with cracked ice. Care must be taken to add a very small piece of ice at each time and to observe that the temperature does not rise above 20°. This precaution must be observed in order to avoid hydrolysis of the dichloro compound to the corresponding uracil derivative. After this treatment, the mixture was extracted with ether, the ethereal solution washed with water and dried over calcium chloride. After distilling off the solvent there was left an oil which was distilled under diminished pressure whereupon we obtained the pure dichloropyrimidine boiling at 171° at 23 mm. pressure. The yield was 106 g. or 80% of the theoretical.

Anal. Calcd. for $C_9H_{12}N_2Cl_2$: N, 12.79. Found: N, 12.87, 12.84.

4-Methyl-5-*n*-butyl-2,6-dimethoxypyrimidine.—Four and six-tenths grams of sodium was dissolved in 50 cc. of absolute methyl alcohol. To this cold alcoholic solution of sodium methylate 21.9 g. of 4-methyl-5-*n*-butyl-2,6-dichloropyrimidine dissolved in 50 cc. of absolute methyl alcohol was added slowly. There separated immediately solid sodium chloride. After allowing to stand for one hour to complete the reaction, the sodium chloride was filtered off and washed thoroughly with methyl alcohol. The excess of alcohol was then removed by heating when we obtained an oil. This was shaken with 30 cc. of 30% sodium hydroxide solution, in which the required pyrimidine-2,6-dimethyl ether is insoluble and separated as the upper layer of the solution and was extracted with ether. 4-Methyl-5-*n*-butyl-2,6-dimethoxypyrimidine distilled as a colorless oil, boiling at 159° at 29 mm. The yield was 20 g. or 95% of the theoretical.

Anal. Calcd. for $C_{11}H_{18}O_2N_2$: N, 13.33. Found: N, 13.28, 13.21.

Further alkoxypyrimidines of this type that we prepared according to this procedure are recorded in Table I.

TABLE I

DIALKOXYPYRIMIDINES

4-Methyl-5-*n*-butyl-2,6-	B. p., °C.	Yield, %	Formula	Analyses, % N Calcd.	Found	
Diethoxy-pyrimidine	174 at 27 mm.	87.6	$C_{13}H_{22}O_2N_2$	11.76	11.80	11.82
Di-*n*-propoxy-pyrimidine	193–4 at 23 mm.	98.8	$C_{15}H_{26}O_2N_2$	10.52	10.56	10.74
Di-*n*-butoxy-pyrimidine	219 at 29 mm.	86.5	$C_{17}H_{30}O_2N_2$	9.52	9.71	9.60

The Molecular Rearrangement of 4-Methyl-5-*n*-butyl-2,6-dimethoxypyrimidine, III. A. Rearrangement to 1,3,4-Trimethyl-5-*n*-butyluracil, IV.—Five grams of the pyrimidine III was heated in an oil-bath at 250–270° for three hours. At first there was a vigorous ebullition which gradually subsided and finally ceased as the proportion of the rearranged compound increased. On cooling, the pale brown reaction product completely solidified. This was purified by dissolving in hot benzene, to which petroleum ether was gradually added to turbidity. After cooling a solid amorphous mass separated. After filtering, this reaction product was dissolved in dry benzene, and then petroleum ether added just to turbidity. On cooling, more amorphous material separated. The clear combined filtrates were then heated at 100° to expel the solvents when an oil was obtained which solidified on cooling. It was purified by recrystallization from a benzene–petroleum ether mixture (1:40), whereupon a compound melting at 54–55° separated in colorless needles.

Anal. Calcd. for $C_{11}H_{18}O_2N_2$: N, 13.33. Found: N, 13.8.

This compound, melting at 54–55°, proved to be identical with 1,3,4-trimethyl-5-*n*-butyluracil, IV, which has not been described previously in the literature. It was prepared as follows.

Synthesis of 1,3,4-Trimethyl-5-*n*-butyluracil, IV.—Five grams of 4-methyl-5-*n*-butyluracil was dissolved in 150 cc. of a sodium hydroxide solution containing 2.6 g. of sodium hydroxide. To this cold solution, 6.9 g. of dimethyl sulfate was then added slowly from a dropping funnel, and during its addition the fluid was stirred vigorously. It was then heated to boiling for one hour. After cooling, the product was extracted with benzene and the solution dried over calcium chloride. After distilling off the benzene we obtained an oil which solidified on cooling. It was purified by crystallization from a mixture of benzene and petroleum ether, from which pure 1,3,4-trimethyl-5-*n*-butyluracil separated. It melted at 54–55° and its melting point was not depressed on mixing with 1,3,4-trimethyl-5-*n*-butyluracil described in the preceding experiment.

Anal. Calcd. for $C_{11}H_{18}O_2N_2$: N, 13.33. Found: N, 12.86, 13.17.

---

[3] Chi, THIS JOURNAL, 58, 1151 (1936).

Rearrangement of 4-Methyl-5-*n*-butyl-2,6-dimethoxypyrimidine, III, to 2-Oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine, V. Method A.—Five grams of 4-methyl-5-*n*-butyl-2,6-dimethoxypyrimidine, III, was mixed with 14.2 g. of freshly distilled methyl iodide and the solution was heated in a sealed tube at 100° for six hours. The excess of methyl iodide was removed by a blast of air and the residue distilled under a vacuum. Pure 2-oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine boiled at 235–236° at 31 mm. pressure with slight decomposition and at 183–184° at 1 mm. pressure without decomposition. This compound is a light yellow and very viscous oil which showed no signs of solidifying.

Anal. Calcd. for $C_{11}H_{18}O_2N_2$: N, 13.33. Found: N, 13.48.

Method B.—Five grams of 4-methyl-5-*n*-butyl-2,6-dimethoxypyrimidine was heated with 14.2 g. of freshly distilled methyl iodide in a sealed tube at 50° for ten hours; from which the partially rearranged pyrimidine 2-oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine was isolated as described above. It boiled at 183–184° at 1 mm. pressure.

Anal. Calcd. for $C_{11}H_{18}O_2N_2$: N, 13.33. Found: N, 13.22.

The structure of this compound was established by its behavior on hydrolysis.

Hydrolysis to 3,4-Dimethyl-5-*n*-butyluracil.—2-Oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine was heated with dilute hydrochloric acid for one hour. The solution was then evaporated to dryness on a water-bath. The residue dissolved in hot water, whereupon 3,4-dimethyl-5-*n*-butyluracil crystallized on cooling in long needles melting at 151–152°.

Anal. Calcd. for $C_{10}H_{16}O_2N_2$: N, 14.28. Found: N, 14.21, 14.75.

In another experiment, 4-methyl-5-*n*-butyl-2,6-dimethoxypyrimidine was exposed to freshly distilled methyl iodide in the presence of methyl alcohol at room temperature for two weeks, from which a trace of 3,4-dimethyl-5-*n*-butyluracil was isolated. Probably it was produced due to the secondary hydrolytic effect of methyl alcohol upon the partially rearranged product, 2-oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine, first formed in the reaction.

Method C. Rearrangement of the Pyrimidine V into the Uracil Compound IV.—2-Oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine, V, was heated at 300–360° for three to four hours. The above reaction mixture was dissolved in benzene, to which a large volume of petroleum ether was then added. After cooling, the benzene–petroleum ether solution was decanted from the insoluble portion. The solvent being removed from the benzene–petroleum ether solution, there remained an oil which solidified on cooling. It was recrystallized from benzene–petroleum ether and melted at 54–55°. This proved to be identical with 1,3,4-trimethyl-5-*n*-butyluracil, IV, obtained by heating 4-methyl-5-*n*-butyl-2,6-dimethoxypyrimidine, III.

Summary

1. 4-Methyl-5-*n*-butyl-2,6-dichloropyrimidine has been prepared by the action of phosphorus oxychloride and phosphorus pentachloride upon its corresponding uracil compound.

2. 4-Methyl-5-*n*-butyl-2,6-dialkoxypyrimidines are formed smoothly by interaction of 4-methyl-5-*n*-butyl-2,6-dichloropyrimidine with sodium alcoholates.

3. 4-Methyl-5-*n*-butyl-2,6-dimethoxypyrimidine and 2-oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine are found to undergo a transformation into their isomeric and stable lactam modification, 1,3,4-trimethyl-5-*n*-butyluracil, on heating at an elevated temperature. On the other hand, 4-methyl-5-*n*-butyl-2,6-dimethoxypyrimidine will rearrange only partially on heating with methyl iodide at 50 or 100° giving 2-oxy-3,4-dimethyl-5-*n*-butyl-6-methoxypyrimidine.

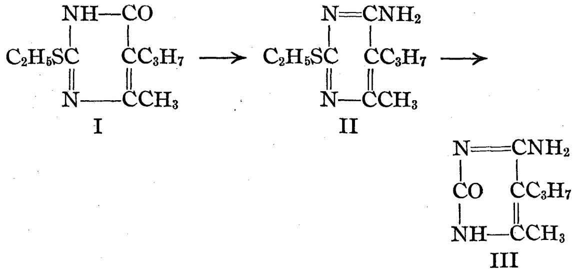
Pyrimidine Research. Synthesis of 4-Methyl-5-*n*-propylcytosine[1]

BY YUOH FONG CHI AND KOU-JEN CHANG

In this short paper is described a method for synthesizing 4-methyl-5-*n*-propylcytosine III. Starting with 2-thio-4-methyl-5-*n*-propyl-6-oxypyrimidine, which is prepared by condensing ethyl *n*-propylacetoacetate with thiourea, the corresponding 2-ethylmercapto compound I is obtained by alkylation in the usual manner, and the resulting mercapto derivative is then treated with phosphorus oxychloride to give 2-ethylmercapto-4-methyl-5-*n*-propyl-6-chloropyrimidine. This new chloropyrimidine derivative reacts with alcoholic ammonia in a normal manner giving the corresponding 6-amino compound II. On digesting the latter with concentrated hydrobromic acid 4-methyl-5-*n*-propylcytosine hydrobromide is formed. The free cytosine base III is liberated by treatment with a slight excess of ammonia.

---

[1] The authors wish to express their thanks to Mr. Yao-Tseng Huang for his assistance in making micro-analyses of the compounds described in this paper. They are also indebted to Professor Treat B. Johnson of Yale University for his personal help in the preparation of this report for publication.



Experimental Part

2-Thio-4-methyl-5-*n*-propyl-6-oxypyrimidine.—Twenty-three grams of metallic sodium was dissolved in 400 cc. of absolute alcohol. One hundred and seventy-two grams of ethyl *n*-propylacetoacetate and 84 g. of thiourea were then added to the solution. The mixture was heated on a water-bath for four hours. After distilling off the solvent the residue remaining behind was dissolved in cold water. This was acidified with dilute acetic acid, when the desired thiopyrimidine separated. After being recrystallized from boiling water, it separated in needles and melted at 209–209.5°. The yield was 103 g. For analysis, the compound was dried over phosphorus pentoxide in a vacuum at 80°.

Anal. Calcd. for $C_8H_{12}ON_2S$: N, 15.21. Found: N, 15.5, 15.5.

2-Methylmercapto-4-methyl-5-*n*-propyl-6-oxypyrimidine.—Twenty-three hundredths gram of sodium was dissolved in 20 cc. of absolute alcohol. To this solution, 1.84 g. of the above thiopyrimidine and 1.55 g. of methyl iodide were added and the mixture heated on a water-bath for four hours. On cooling, the methylmercapto compound separated in needles. It was recrystallized from absolute alcohol and melted at 180–181° to a clear oil. The yield was 1.2 g. The substance was dried over phosphorus pentoxide in a vacuum at 80°.

Anal. Calcd. for $C_9H_{14}ON_2S$: N, 14.14. Found: N, 14.5, 14.1.

2-Ethylmercapto-4-methyl-5-*n*-propyl-6-oxypryrimidine I.—One hundred and fifteen grams of sodium was dissolved in 1 liter of absolute alcohol and 92 g. of the thiopyrimidine and 60 g. of ethyl bromide were added to the solution. The mixture was heated on a water-bath for four hours and the solution then filtered from the insoluble sodium chloride. After distilling off the excess of alcohol the residue was triturated with cold water and filtered. The pyrimidine was recrystallized from dilute alcohol, and melted at 92–93°. The yield was 87.5 g. The substance was dried for analysis over phosphorus pentoxide in a vacuum at 80°.

Anal. Calcd. for $C_{10}H_{16}ON_2S$: C, 56.55; H, 7.60. Found: C, 56.55; H, 7.68.

2-*n*-Propylmercapto-4-methyl-5-*n*-propyl-6-oxypyrimidine.—Twenty-three hundredths gram of sodium was dissolved in 20 cc. of absolute alcohol, to which 1.84 g. of thiopyrimidine and 1.55 g. of *n*-propyl bromide were then added. The experiment was carried out as described above, whereby the *n*-propylmercaptopyrimidine was obtained melting at 89–90°. It was recrystallized from dilute alcohol and separated in needles. The substance was dried over phosphorus pentoxide in a vacuum at 80°.

Anal. Calcd. for $C_{11}H_{18}ON_2S$: N, 12.39. Found: N, 12.6, 12.2.

$\overline{NHCONHC(CH_3)=C(C_3H_7)CO}$, **4-Methyl-5-*n*-propyluracil.**—This pyrimidine is formed quantitatively by digesting any one of the preceding mercaptopyrimidines with hydrobromic or hydrochloric acid. It is also easily prepared by digesting the corresponding 2-thiopyrimidine described above with chloroacetic acid in aqueous solution. The uracil derivative crystallizes from hot water in the form of needles melting at 247–248°.

Anal. Calcd. for $C_8H_{12}O_2N_2$: C, 57.10; H, 7.20. Found: C, 57.36, 57.04; H, 7.17, 7.26.

Ethyl 4-Methyl-5-*n*-propyl-6-oxypyrimidine-2-thioglycolate was obtained easily by alkylation of the above 2-thiouracil derivative in alcohol solution with ethyl chloroacetate. It was purified by crystallization from dilute alcohol and melted at 100–101°.

Anal. Calcd. for $C_{12}H_{18}O_3N_2S$: C, 53.29; H, 6.71. Found: C, 53.40; H, 7.04.

4-Methyl-5-*n*-propyl-6-oxypyrimidine-2-thioglycolic Acid was prepared by saponification of the above ethyl ester with alcoholic potash solution. The acid crystallized from hot water as plates melting at 105–106°. The compound contained water of crystallization.

Anal. Calcd. for $C_{10}H_{14}O_3N_2S$: N, 11.57; H_2O, 6.92. Found: N, 11.4, 11.45; H_2O, 6.74.

2-Ethylmercapto-4-methyl-5-*n*-propyl-6-chloropyrimidine.—Twenty-one and two-tenths grams of 2-ethylmercapto-4-methyl-5-*n*-propyl-6-oxypyrimidine was dissolved in cold phosphorus oxychloride. The solution was heated for twelve hours at 120–130°. After the excess of phosphorus oxychloride was removed, the residue was then treated with cracked ice, the solution extracted with ether and the ether solution dried over calcium chloride. After distilling off the ether the pyrimidine chloride distilled at 165–166° at 11 mm. pressure.

Anal. Calcd. for $C_{10}H_{15}N_2SCl$: C, 52.02; H, 6.56. Found: C, 52.26; H, 6.47.

2-Ethylmercapto-4-methyl-5-*n*-propyl-6-aminopyrimidine II.—Six grams of the above 6-chloropyrimidine was heated with alcoholic ammonia at 160–170° for three hours. The solution was evaporated to dryness and the residue triturated with cold water. The crude pyrimidine dissolved in petroleum ether, from which the 6-amino compound separated in needles, melting at 86–87°.

Anal. Calcd. for $C_{10}H_{17}N_3S$: N, 19.90. Found: N, 20.01, 19.9.

4-Methyl-5-*n*-propylcytosine, III.—The above 6-aminopyrimidine was digested with concentrated hydrobromic acid for sixteen hours, and the solution then evaporated to dryness. After dissolving the residue in boiling water and cooling, the hydrobromide of 4-methyl-5-*n*-propylcytosine separated in prisms. It melted at 253–254°. The salt was dried over phosphorus pentoxide in a vacuum at 80°.

Anal. Calcd. for $C_8H_{13}ON_3 \cdot HBr$: C, 38.70; H, 5.69. Found: C, 38.90; H, 5.79.

The free base was obtained by treating the aqueous solution of the above hydrobromide with ammonia. It was recrystallized from water and melted at 317–318° with decomposition. The substance was dried over phosphorus pentoxide in a vacuum at 80°.

Anal. Calcd. for $C_8H_{13}ON_3$: C, 57.44; H, 7.84. Found: C, 57.81; H, 7.92.

Hydrochloride.—The above cytosine derivative dissolved in dilute hydrochloric acid, and on cooling the hydrochloride separated in prisms, melting at 235°.

Anal. Calcd. for $C_8H_{13}ON_3 \cdot HCl$: C, 47.15; H, 6.93. Found: C, 46.78; H, 6.65.

Summary

1. Ethyl *n*-propylacetoacetate condenses with thiourea in alcohol solution in the presence of sodium ethylate to give 2-thio-4-methyl-5-*n*-propyl-6-oxypyrimidine.
2. 2-Thio-4-methyl-5-*n*-propyl-6-oxypyrimidine is alkylated on sulfur by treatment with methyl iodide, ethyl bromide, *n*-propyl bromide and ethyl monochloroacetate to form the corresponding 2-mercaptopyrimidine derivatives, respectively.
3. 2-Ethylmercapto-4-methyl-5-*n*-propyl-6-chloropyrimidine is obtained from its corresponding 6-oxypyrimidine compound by heating the latter with phosphorus oxychloride.
4. This chloropyrimidine interacts with alcoholic ammonia to form 2-ethylmercapto-4-methyl-5-*n*-propyl-6-aminopyrimidine.
5. Treatment with concentrated hydrobromic acid converts 2-ethylmercapto-4-methyl-5-*n*-propyl-6-aminopyrimidine into 4-methyl-5-*n*-propylcytosine hydrobromide, from which the free base is obtained by neutralization with ammonia.

The Alkaloids of Chinese Gelsemium, Kou Wen[1]

BY YUOH FONG CHI, YEE-SHENG KAO AND YAO-TSENG HUANG

Chou[2] has isolated the following alkaloids from the plant Kou Wen: (A) koumine $C_{20}H_{22}N_2O$, m. p. 170°, (B) kouminine, (C) kouminicine and (D) kouminidine. Of these four alkaloids, koumine only was obtained in a good crystalline state and kouminidine was probably not very pure on account of small traces of impurity present, while kouminine and kouminicine were only obtained in an amorphous condition. Recently, Chou[3] isolated the following alkaloids from Ta-Cha-Yeh: (Z) koumine $C_{20}H_{22}N_2O$, m. p. 170°; (B) kouminine in the form of its hydrochloride; (C) gelsemine, $C_{20}H_{22}N_2O_2$, m. p. 178°; and kounidine $C_{21}H_{24}N_2O_5$. In this short paper the authors give a report of their investigation of the alkaloids of Kou Wen. Besides koumine, m. p. 168°, they succeeded in separating Chou's kouminine into gelsemine and other impure bases. From the kouminidine fraction, they isolated a base, m. p. 299° (instead of 200°), to which the original name, kouminidine, was assigned.

Experimental Part

Twenty-two and seven-tenths kilograms of Kou Wen in the form of stems, roots and leaves was powdered and percolated with cold 95% alcohol. The alcoholic extract was evaporated under diminished pressure, and the resin left over was taken up with a sufficient quantity of 2% hydrochloric acid. When the insoluble resinous matter was filtered off the acid extract was allowed to stand for about two weeks, when there deposited a further quantity of neutral resinous material. The clear solution, obtained after removing the insoluble non-basic resinous matter, was finally neutralized with sodium carbonate and extracted thoroughly, first with ether several times (A), and then with chloroform (B).

Isolation of Koumine.—After removing the solvent from the ethereal solution (A), the crude basic residue weighed 38 g. This was dissolved in a small quantity of acetone, and the solution allowed to stand in an ice-box for several days; whereupon koumine deposited in the form of colorless prisms. This was recrystallized from acetone several times or until the melting point became constant at 168°. It was readily soluble in alcohol, chloroform and benzene and slightly soluble in hot water.

Anal. Calcd. for $C_{20}H_{22}N_2O$: C, 78.38, H, 7.24; N, 9.15. Found: C, 78.52, 78.37; H, 7.31, 7.39; N, 9.37, 9.35.

Acetylation of Koumine.—When Koumine was treated with acetic anhydride, the original alkaloid melting at 168° was recovered.

Isolation of Gelsemine.—The acetone mother liquid, from which the base, koumine, had been separated, was evaporated to dryness. The residue was dissolved in ethyl alcohol and acidified with the desired amount of alcoholic hydrochloric acid. The solution was then allowed to stand for several days, whereupon the mixed hydrochlorides separated in the form of a crystalline pow-

der. They were repeatedly purified by recrystallization from ethyl alcohol, and melted at 303°.

The free base was liberated from an aqueous solution of the crystallized mixed hydrochlorides by adding sodium carbonate just to neutrality. The resulting amorphous base was then filtered off and dried in a vacuum desiccator. It was soluble in most of the common organic solvents with the exception of petroleum ether and water, and refused to crystallize from any of the common solvents tried. This amorphous base, melting approximately at 108°, was extracted with hot benzine (b. p. 80–90°), and after filtering off the insoluble part and cooling, the benzine solution deposited a colorless amorphous solid. This amorphous base was then digested with petroleum ether (b. p. 40–60°) for twenty-four hours, whereupon the base gradually changed into a crystalline condition. It was then filtered and the base purified further by recrystallization from acetone. It separated in the form of long shining needles, melting at 176–178°. It contained acetone of crystallization. When 0.0735 g. of the substance was dried in a vacuum over phosphorus pentoxide at 117°, it was found that the weight lost was equal to 0.0111 g., where from the percentage of acetone of crystallization was 15.1, the calculated value for $C_{20}H_{22}O_2N_2 \cdot CH_3COCH_3$ being 15.27. A sample dried at room temperature was used for analysis.

Anal. Calcd. for $C_{20}H_{22}O_2N \cdot CH_3COCH_3$: C, 72.58; H, 7.42; N, 7.37. Found: C, 73.41, 73.10; H, 7.52, 7.67; N, 7.56.

Color Test.—A few crystals of the base were dissolved in a small quantity of concentrated sulfuric acid, to which a few crystals of potassium dichromate were then added. The solution first became violet, and then turned to a red color. On standing it changed to green.

Nitrate.—The pure base was dissolved in dilute nitric acid, and the solution evaporated to dryness in a vacuum desiccator. The residue was then recrystallized from ethyl alcohol and melted at 288°.

Anal. Calcd. for $C_{20}H_{22}O_2N_2 \cdot HNO_3$: C, 62.31; H, 6.02; N, 10.91. Found: C, 62.17, 62.70; H, 6.28, 6.17; N, 10.42.

Methiodide.—The pure base dissolved in warm acetone, to which an excess of methyl iodide was then added and the mixture heated for about one to two hours. The methiodide separated on cooling in colorless shining scales and melted at 284°.

Anal. Calcd. for $C_{20}H_{22}O_2N_2 \cdot CH_3I$: C, 54.29; H, 5.43. Found: C, 54.17, 53.91; H, 5.46, 5.59.

The alcoholic mother liquid, from which the crude gelsemine hydrochloride had been separated, was evaporated to dryness, and the residue dissolved in 1% hydrochloric acid. This acid solution was repeatedly washed with chloroform, and then made alkaline with sodium carbonate. The resulting solution was first extracted with ether to remove koumine and gelsemine, and then extracted with chloroform. When the solvent was distilled off an amorphous basic product was obtained and nothing crystalline could be isolated.

Isolation of Kouminidine.—The chloroform extract (B) was evaporated to dryness, and the crude base left over weighed 22 g. It dissolved in warm acetone, from which a small quantity of a neutral substance, melting at 62–64°, separated. The mother liquid was concentrated and allowed to stand for several days, whereupon a small quantity of a basic substance separated. This was then purified by recrystallization from a methyl alcohol–ethyl ether mixture and separated in colorless prisms, melting at 299° with decomposition. It was soluble in water and most organic solvents.

Anal. Calcd. for $C_{19}H_{25}N_2O_4$: C, 66.04; H, 7.30; N, 8.12. Found: C, 66.88, 66.42; H, 7.18, 7.29; N, 8.20.

Summary

1. The authors have repeated the work of Chou and have isolated from Kou Wen the alkaloid koumine, $C_{20}H_{22}N_2O$.

2. The alkaloid kouminine obtained from Kou Wen by Chou has been separated by the authors into gelsemine, $C_{20}H_{22}N_2O_2$, and other impure bases.

3. Gelsemine is also found in the plant Ta-Cha-Yeh.

Sterols. XL. The Origin and Interrelationships of the Steroidal Hormones

BY RUSSELL E. MARKER

In the thirty-nine papers which have been reported from this Laboratory, we have described the progress made in our investigations of the steroid content of urines. Heretofore, our results have not been discussed from the broader standpoint of the origin and interrelationships of the steroidal hormones, but now sufficient information is at hand to make such a correlation desirable.

The isolation and synthesis of sex hormones, and more recent work on the isolation of steroids from the adrenal cortex, have led biochemists to the increasing realization of the important role played by steroids in the animal. It appears to be generally assumed that these various steroids arise from cholesterol.[1] This hypothesis has many more or less obvious difficulties. It is hard to understand how oxygen atoms such as occur at C-11 in cortical derivatives, or at C-12 in bile acids, could be introduced into the cholesterol molecule. Attempts to show that cholesterol may be converted by biochemical methods into sex hormones have been inconclusive.[2] Moreover, the assumption that sex hormones are derived from cholesterol through the intermediate formation of Δ^5-pregnenol-3β-one-20 and dehydroisoandrosterone leads to contradictions when the relative physiological activities of the hormones are considered. Thus it is not apparent, if progesterone is derived from Δ^5-pregnenol-3β-one-20, why the latter should show no progestational activity. The inactivity of this unsaturated hydroxy ketone suggests that it is a product of the utilization of progesterone and not a precursor. Moreover, the drastic conditions which must be employed in the laboratory to oxidize the cholesterol side chain to yield carbonyl and acetyl groups at C-17, and the fact that phytosterols are not utilized in the animal organism,[1] throw grave doubt on the possibility of a biochemical oxidation of the cholesterol side chain. Although Shimizu[3] has suggested that the isolation of trihydroxybufosterocholenic acid indicates a genetic relationship between sterols and bile acids, experiments by Schoenheimer and co-workers[4] on the deuterium content of bile acids of dogs injected with an emulsion of coprostanone-4,5d_2 show that the conversion of cholesterol to bile acids is extremely unlikely.

In the course of comprehensive studies in this Laboratory of the numerous steroids present in urine from various animals, a number of substances have been isolated which, we believe, cannot be accounted for satisfactorily on the assumption of an oxidative degradation of cholesterol in the animal. It now appears that sex hormones and the cortical substances may be derived from another precursor.

Before considering the nature of this precursor it seems desirable to attempt a correlation between the various urinary steroids that have been isolated. The isolation from urines of numerous reduction products of progesterone such as pregnanediol-3α,20α,[5,6] *allo*-pregnanediol-3α,20α,[6,7] *allo*-pregnanol-3α-one-20,[8] pregnanol-3α-one-20,[9] *allo*-pregnanedione.[10] pregnenediol-3β,20-α,[11] pregnanetriol-3α,4-β,20α,[12] pregnanedione,[10] *allo*-pregnanol-3β-one-20,[10] and *allo*-pregnanediol-3β-20α,[11] suggests that these are all formed by the biochemical reduction of progesterone, possibly according to the scheme of Fig. 1.

According to this hypothesis, most of the substances isolated are formed from progesterone either by initial reduction of the $\Delta^{4,5}$-double bond (Type I reduction), or by reduction of the carbonyl group at C-3 to a 3-β-OH with simultaneous migration of the double bond to the 5,6-position (Type II reduction). It is supposed that in the initial biochemical reduction of the double bond of progesterone according to Type I, both regular and *allo* series compounds are formed, in complete agreement with the course of reduction

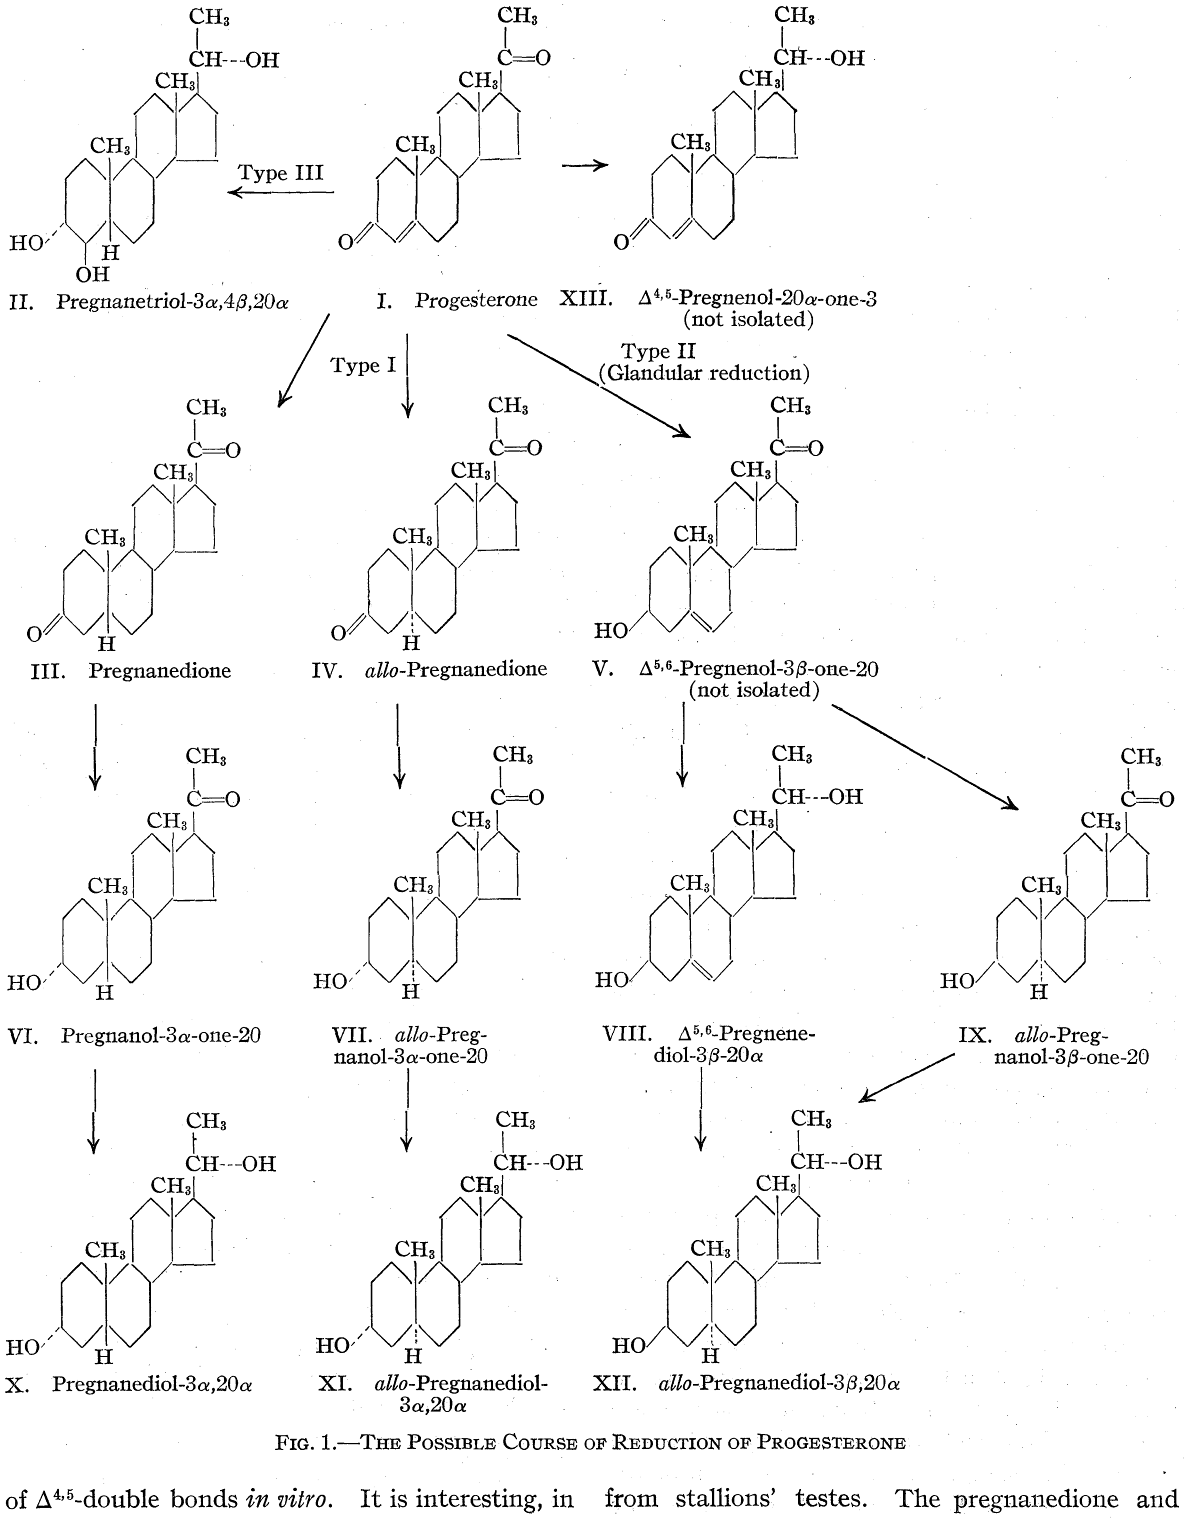

FIG. 1.—THE POSSIBLE COURSE OF REDUCTION OF PROGESTERONE

of $\Delta^{4,5}$-double bonds *in vitro*. It is interesting, in this connection, to note that Ercoli and Mamoli[13] have obtained aetiocholanedione-3,17, XVI, in 65% yield from Δ^{4}-androstenedione-3,17 by biochemical hydrogenation with an enzyme obtained from stallions' testes. The pregnanedione and *allo*-pregnanedione thus formed then probably suffer further reduction, first at the 3-carbonyl group, and then at the 20-carbonyl group. While the order of attack of these ketonic groups parallels the corresponding reactions under laboratory

---

[13] Ercoli and Mamoli, *Ber.*, **71**, 156 (1938).

conditions,[14] the stereochemical relationships involved are entirely different *in vivo* from those *in vitro*. The steric arrangement of the 3-OH formed by *in vitro* reduction of steroids is determined by the Skita rule,[15] so that under like conditions of acidity or alkalinity pregnanedione and *allo*-pregnanedione yield 3-OH groups which have opposite configurations. The configuration of 20-OH groups formed on *in vitro* catalytic hydrogenation of 20-carbonyl groups under the most varied conditions is always found to be of the β-type.[16] In contrast to these rules, *in vivo* reduction of 3- and 20-keto-steroids appears always to give α-OH groups.

In the Type II reduction of progesterone steroids of the cholesterol type (3-βOH, $\Delta^{5,6}$) are assumed to be first formed. This reaction has not yet been performed in the laboratory. The suggestion that the reduction of cholestenone to cholesterol is unlikely since it has not yet been achieved in the laboratory, loses its force because, as Schoenheimer, Rittenberg and Graff[17] have suggested, cholestenone and cholesterol probably constitute a reversible biochemical oxidation–reduction system. These workers showed that the nature of the intestinal flora, which can be controlled by a suitable choice of diet, determines the nature of the sterols excreted in the feces of test dogs. When cholestenone was fed to a dog the sterol output in its feces was increased, and depending on whether the dog's basal diet was meat or dog biscuit, the major constituent of the excreted sterols was coprostanol or cholesterol, respectively. These results strongly suggest that cholestenone may be reduced biochemically to cholesterol.

The second stage of the Type II reduction may result in the formation of either VIII or IX. Judging from the products isolated, reduction of the double bond in the 5,6-position to form IX yields only substances of the *allo* series, in complete agreement with the results of the corresponding reaction in the laboratory; for example, the hydrogenation of cholesterol yields only β-cholestanol. (A careful search for carbinols of the 3-βOH type of the regular series from mares' pregnancy urine has revealed the presence of only uranediol-3β,11-β.[36]) Finally, the further reduction of either VIII or IX gives XII, *allo*-pregnanediol-3β,20α.

At least two other modes of reduction of progesterone seem possible. Pregnanetriol-3α,4β,20α (II), which was first isolated by Marrian,[12] and later studied by Marker,[18] may arise either by hydration of the double bond of progesterone followed by subsequent reduction of the pregnanedione-3,20-ol-4 thus formed, or by the hydration of the 3-enol form of pregnanedione. The latter mechanism, which is analogous to the mechanism by which oestriol is supposed to arise from oestrone, would suggest that *allo*-pregnanetriol-2,3,20 might also be found in mares' pregnancy urine. No other compounds which might throw light on this type of reduction have yet been found. By analogy with the formation of testosterone from androstenedione in the testes, we may expect the formation of XIII, $\Delta^{4,5}$-pregnenol-20α-one-3 from progesterone in the corpus luteum. This substance, however, probably can be found only in corpus luteum extracts, just as testosterone is found only in testicular extracts. The prolonged alkaline treatment which is necessary to hydrolyze urines probably destroys all α,β-unsaturated ketones so that, even if present originally, substances of this type cannot be isolated from urines. Further reduction of $\Delta^{4,5}$-pregnenol-20α-one-3, which has been prepared by Butenandt and Schmidt,[19] can proceed according to Type I or II, giving rise to pregnanediol-3α,-20α(X), *allo*-pregnanediol-3α,20α (XI), $\Delta^{5,6}$-pregnanediol-3β,20α, (VIII), and *allo*-pregnanediol-3β,20α (XII).

In contrast to the large number of reduction products of progesterone found in human and mares' pregnancy urine, relatively few reduction products of the corresponding parent male hormone, androstenedione (XIV), have been found, probably because of the very low steroid content of male urines. As would be expected, stallions' urine apparently contains no reduction products of progesterone,[20] and it is likely that none are present in human male urine. According to the present hypothesis the course of reduction of androstenedione (Fig. 2) is supposed to be similar to that of progesterone, so that most of the ex-

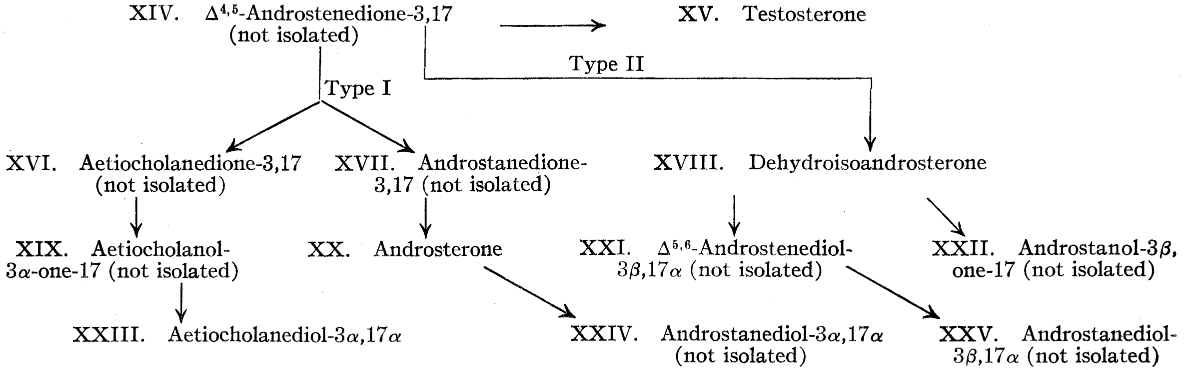

FIG. 2.—THE POSSIBLE COURSE OF REDUCTION OF ANDROSTENEDIONE

pected products would arise by Type I or Type II reduction, following the scheme indicated in Fig. 2. We have used the conventions of Ruzicka in regard to the stereochemistry of the 17-OH groups, except that we designate the configuration of the 17-OH group found naturally as α rather than *trans*. This is in agreement with the customary usage in regard to the configuration of hydroxyl groups at C-3 or C-20. Of the products listed in Fig. 2, only a few have been isolated. However, it should be noted that no C_{19} compounds have been isolated which are not predicted by the theory under discussion. The compounds isolated are androsterone,[21] dehydroisoandrosterone,[22] and aetiocholanediol-3α,17α[23] from human male urine, and testosterone[24] from testicular extracts.

In the foregoing discussion of the course of the reduction of progesterone and androstenedione to yield various steroids, most of the steroids mentioned have been found only in urines, although a few have been found only in the extracts from glands. Although our studies of the steroid content of various urines have not yet been completed, the large number of the possible reduction products of progesterone which have already been isolated suggests to us that all the reduction products possible according to the mechanism discussed in this paper occur in urine or glandular extracts.

At this point it may be profitable to compare briefly the types of compound which one may expect to isolate from urines and glandular extracts. It may be assumed that the parent hormones such as androstenedione and progesterone will exist as such in glandular extracts, but perhaps not in urines. However, it should be borne in mind that these parent substances are α,β-unsaturated ketones, and, even if present, may not survive the rigorous hydrolytic treatment to which the urines must be subjected, a treatment which is usually unnecessary to apply to glandular extracts. Besides the parent hormone such as androstenedione, progesterone, or cortin, the glandular extracts contain compounds which appear to be of only two types, corresponding in Rings A and B to cholestenone and β-cholestanol. Thus *allo*-pregnanol-3β-one-20 accompanies progesterone in corpus luteum extracts[25] and testastalone (*allo*-pregnanol-3β-one-20-al-21) accompanies testosterone in testicular extracts,[26] while numerous substances all of either the β-cholestanol or cholestenone type[27] have been found to accompany cortin in cortical extracts. The fact that only compounds of these two kinds are found in glandular extracts may indicate that glandular reduction occurs exclusively according to Type II. Although steroids of the cholesterol type have not yet been found in glandular extracts, they may be present; on the other hand, it may be that glandular reduction is so complete that no unsaturated sterols of the cholesterol type survive. The generalization that only substances of the cholestenone, β-cholestanol, and possibly of the cholesterol type, appear in glandular extracts, although it seems to be sound in view of the information now available, should of course be verified by a deliberate search

for compounds of other types. It is perhaps to be expected that glandular extracts will contain few types of steroids, for primarily the glands are the sources of the hormones, which are then passed to other localities for utilization, with the formation of reduction products. These reduction products of varied types all will be excreted ultimately in the urine so that the latter must be expected to be a source of a much wider variety of steroid types than can be found in glandular extracts. Thus the reduction products of progesterone, androstenedione, and cortin which may be expected to occur in urine will conform, in the structure of rings A and B, to all of the types indicated in Fig. 1.

From these considerations it was suspected that cortical derivatives which we regard as reduction products of the as yet unknown cortical hormone, would be found to occur in urines, and, furthermore, it was anticipated that these reduced cortin derivatives would be found present in both male and female urines. During the last year the isolation from urines of a number of steroids containing oxygen atoms at C-11 has been reported from this Laboratory, and the presence of other such substances has been indicated. These new steroids proved to be derived not from pregnane or *allo*-pregnane, but from a new hydrocarbon, urane (9β-pregnane). While the inversion of the asymmetric center at C-9 might be expected to occur in the isolation of a pregnanone-11 derivative, no such inversion could be expected to have occurred with a pregnanol-11 derivative. Therefore the uranetriol-3,11,20 isolated from mares' pregnancy urine[28] must have been present originally as such in the urine. This occurrence of steroids inverted at C-9 (β-type), of which numerous other examples have been found since, would lead one to suspect that the cortical compounds isolated in the laboratories of Reichstein, Kendall, and Wintersteiner and Pfiffner may not possess the skeleton of *allo*-pregnane, as they assumed, but the skeleton of the corresponding hydrocarbon *allo*-urane, in which the hydrogen at C-9 is inverted (β-type).[28a]

The assignment of a cholestane configuration to the cortical steroids is due mainly to the splendid work of Reichstein, who obtained androstane and *allo*-pregnane by the reduction of cortical derivatives. Since experimental details of his conversion of corticosterone to *allo*-pregnane are not yet available,[28a] it is not possible to comment on this work, but it appears that his conversion of the saturated triketone, $C_{19}H_{26}O_3$, obtained from his compounds A, C, and D, to androstane may not give conclusive information in regard to the configuration at C-9 in the cortical steroids. When this triketone was reduced by the Clemmensen method, the hydrocarbon fraction obtained was highly unsaturated. Since the unsaturation would probably be at C-11, his subsequent hydrogenation may have yielded androstane even though the original triketone had a 9β-configuration. Such a conversion from a 9β to a 9α-configuration has been observed by Tschesche and Bohle[29] in the course of their investigations of the structure of sarmentogenin and digoxigenin (Fig. 3).

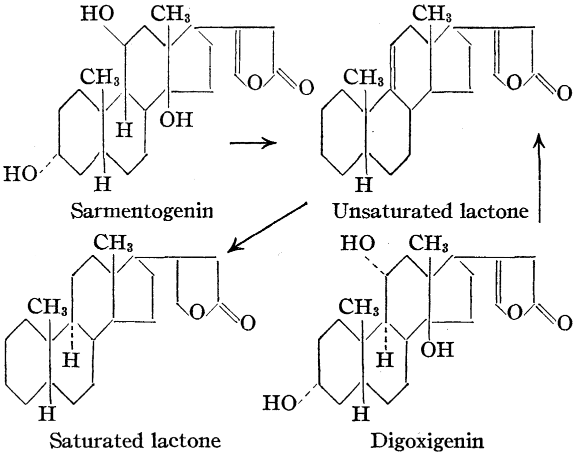

FIG. 3.—THE CORRELATION OF SARMENTOGENIN AND DIGOXIGENIN

Recent work in this Laboratory seems to support the idea that cortical steroids may be *allo*-urane derivatives. When uranetrione was reduced by the Clemmensen method in acetic acid and hydrochloric acid, the saturated hydrocarbon produced was urane. Yet when uranetrione was reduced by other means[30] with elimination of the carbonyl group at C-11 or C-20, pregnandione and uranedione were obtained. In the former case there was an inversion at C-9.

Another indication that cortical steroids may be of the *allo*-urane rather than of the *allo*-pregnane type is the apparently anomalous course of

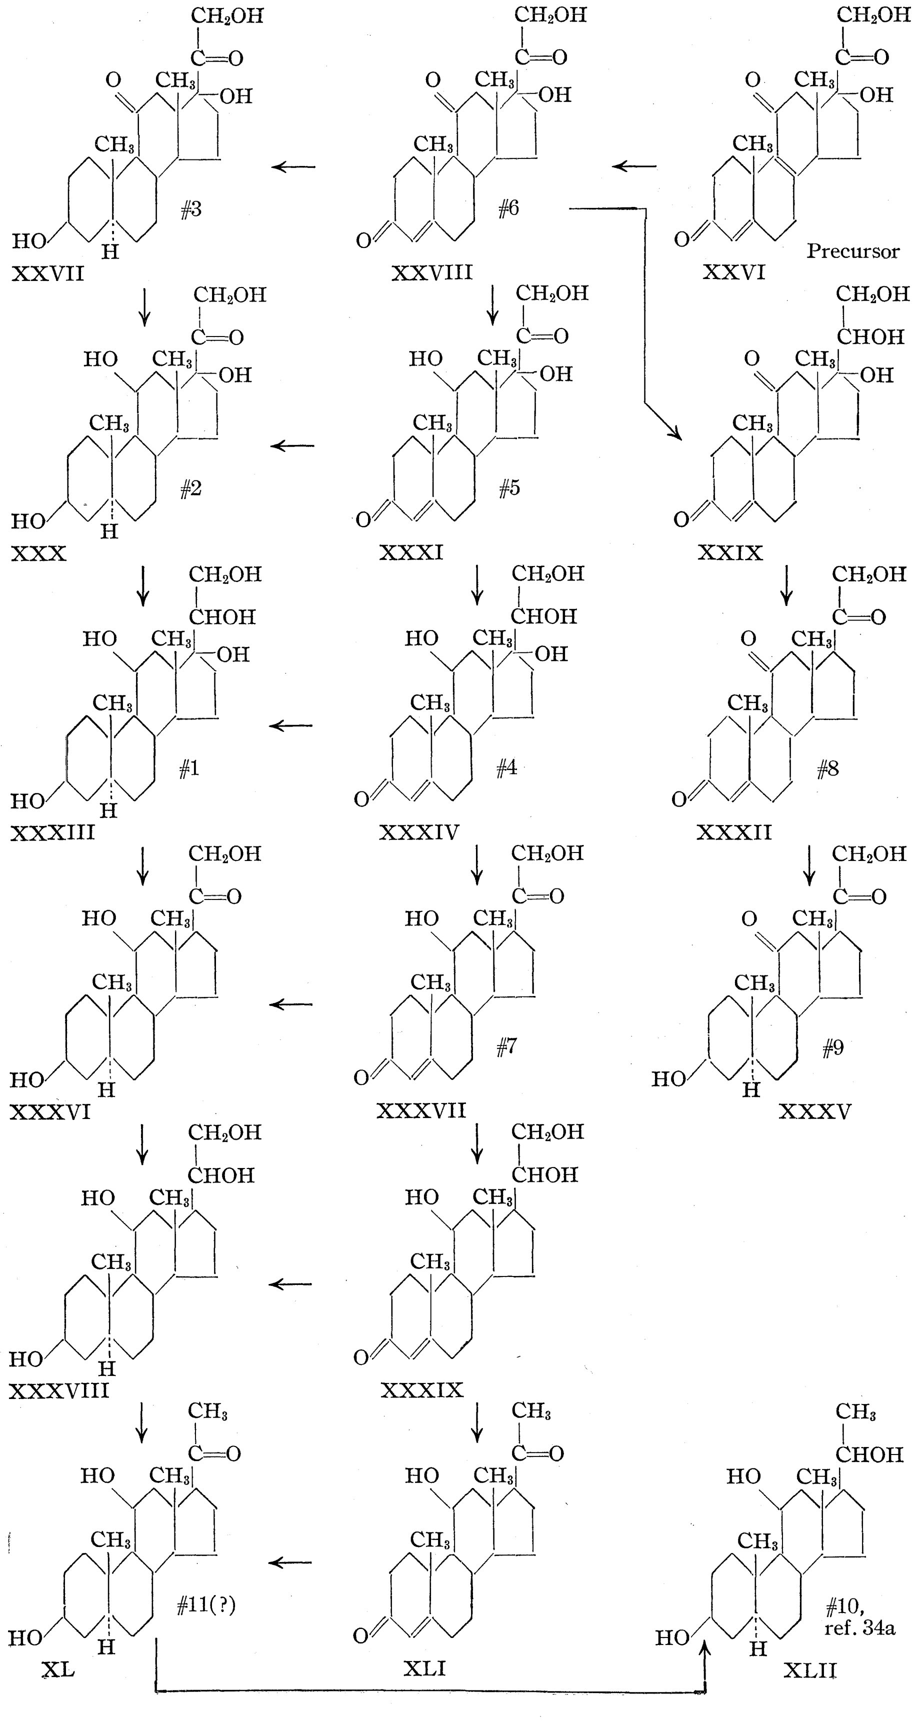

FIG. 4.—POSSIBLE COURSE OF REDUCTION (TYPES II AND III) OF PRECURSOR XXVI TO YIELD STEROIDS ISOLATED FROM CORTICAL EXTRACTS
The Arabic numbers given for the products isolated are those assigned by Reichstein in his Review Paper, Reference 27.

hydrogenation of compounds like corticosterone. While steroids having the cholestenone structure in Ring A usually give coprostane derivatives on catalytic hydrogenation,[31] the hydrogenation of the Δ^4-3-keto-cortical steroids yields only 3-β-hydroxy-*allo*-steroids. The presence of a 9β-configuration in Ring B may well account for the reduction of the Δ^4-double bond to give compounds of the *allo*-series rather than of the coprostane series, which are formed when cholestenone derivatives having a 9α-configuration are reduced.

While the suggestion that the cortical steroids may have a 9β-configuration cannot be proved definitely until diffraction and film measurements are made on cortical and urane derivatives, in this paper it will be assumed for consistency that the cortical steroids are *allo*-uranes. It is to be understood that the arguments for the theory of biogenesis of sex hormones presented in this paper are unaffected and remain valid regardless of the C-9 configuration of the cortical steroids.

In order to account for the inverted configuration at C-9 in urane and possibly in cortin derivatives, we assume that both types of substances are derived from the same hypothetical precursor, pregnadiene-4, 8-diol-17, 21-trione-3, 11, 20, (XXVI), or its hydrate at C-9, *which may be the as yet unisolated cortical hormone.* This substance would be expected to show the characteristic instability that cortin possesses, and upon reduction it could give rise to both C-9α and C-9β-compounds. This suggested precursor of the cortical and sex hormones can yield the compounds isolated from cortical extracts by an orderly scheme involving the application of definite rules in regard to the modes of reduction. Most of the compounds isolated from cortical extracts may be classified by the following statements: the structure of Ring A corresponds either to cholestenone or β-cholestanol; the asymmetric center C_9 probably has the β-configuration; the compounds possess carbonyl or β-OH groups at C-11, and have various oxygen-containing substituents at C-17 (as shown in Fig. 4). Figure 4 shows how these substances from cortical extracts may be formed in the course of the reduction of the hypothetical substance XXVI.

The first reduction product of the hypothetical parent hormone (XXVI) is assumed to be XXVIII a substance isolated by Wintersteiner and Pfiffner,[32] Kendall,[33] and Reichstein,[34] and designated respectively by them as compound F, E, and Fa. As has been mentioned previously, it is assumed that the asymmetric centers generated at C-8 and C-9 are of the normal (α) and *uro* (β) type, respectively.

The isolation of XXVII,[33,35] XXXI,[33,34] and XXXII[33] shows that further reduction of XXVIII to yield the other substances found in cortical extracts may follow at least three independent courses. According to the first mode of reduction a substance of the cholestenone type is reduced, in conformity with the rule of glandular reduction, to give the substances of the β-cholestanol type, while according to the second mode of reduction a C-11 carbonyl group is reduced to a 11-βOH-group. While this latter reaction proceeds with some difficulty in the laboratory, the large number of cortical derivatives with 11-OH groups indicate that *in vivo* the reaction proceeds readily. Alternatively, it is possible that the formation of 11-OH compounds occurs by a direct reduction of the hypothetical precursor XXVI, a reaction which might be expected to occur readily. According to the third mode of reduction the carbonyl group at C-20 is first reduced to a hydroxyl group. Although it is not possible yet to specify the configuration of the C-20-OH groups in cortical substances, it seems likely by analogy with the case of the reduction of progesterone that they will prove to be of the α-type. The substances of the glycerol type, XXXIII,[32,33,35] XXXIV,[34,35] and XXIX, are then assumed to be susceptible to ready biochemical dehydration, a reaction which may also be accomplished in the laboratory under not too vigorous conditions. The α-ketols XXXVI, XXXVII,[34,33] XXXII,[33] and XXXV[33] thus formed may be reduced further to the as yet unisolated α-glycols XXXVIII and XXXIX, which may suffer dehydration[34a] to yield the as yet unisolated ketone XLI, or the ketone XL which may be identical with Wintersteiner and Pfiffner's G.[32] Further reduction of the carbonyl group at C-20 will give rise to a 20-OH probably of the α-type.

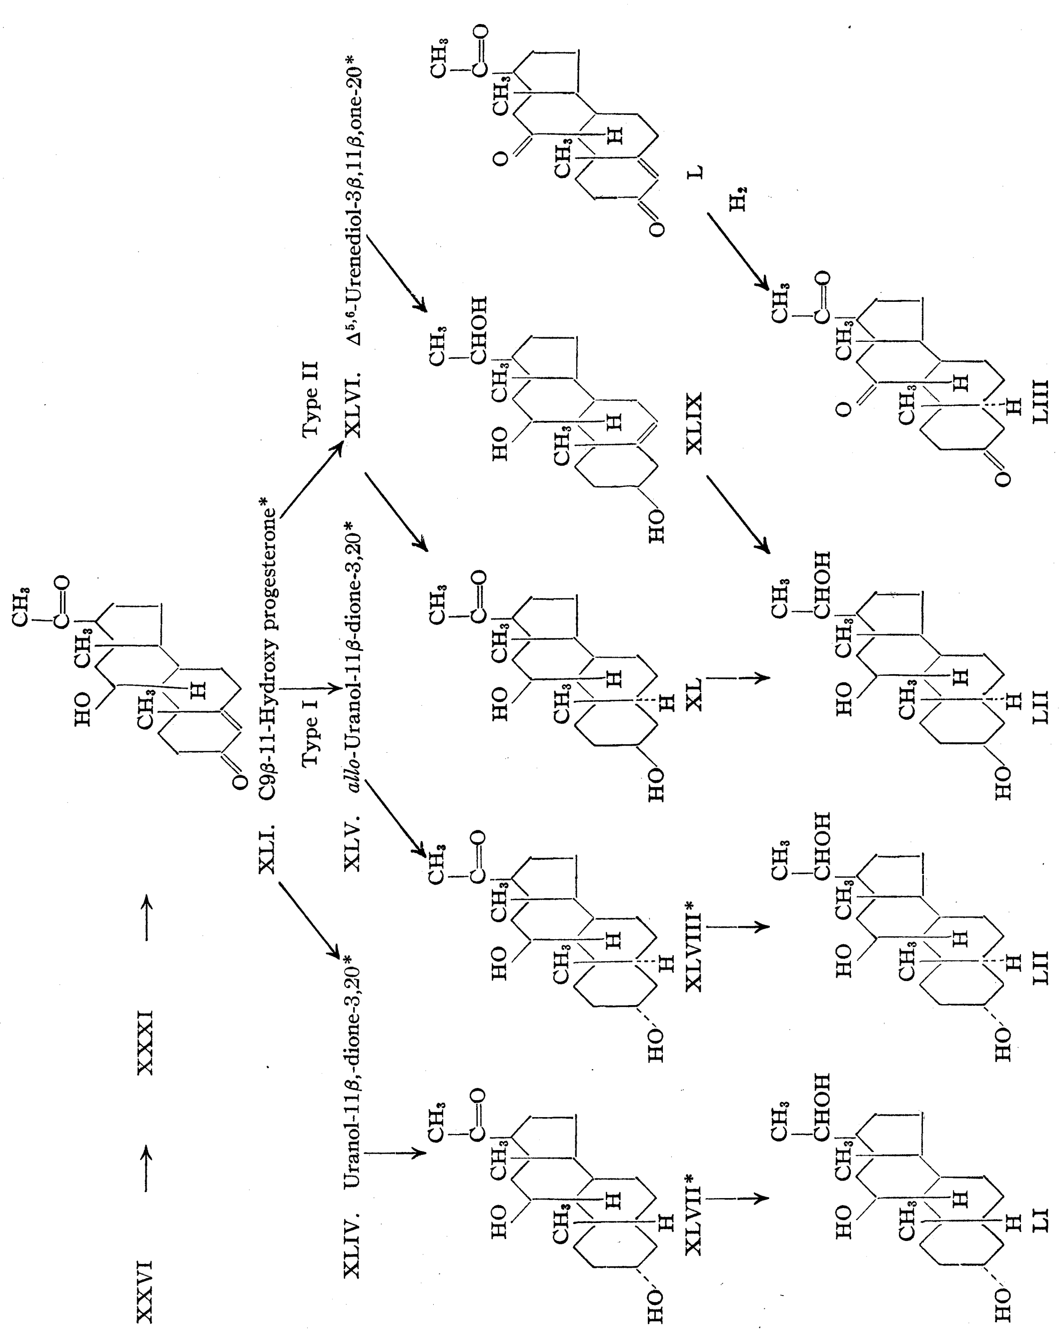

Fig. 5.—Possible Course of Reduction of Percursor XXVI to Yield Urane and *allo*-Urane Derivatives Compounds marked (*) have not been isolated as yet (L and LIII have been prepared synthetically).

The reduction of XXVI apparently proceeds further, for from urines there have been isolated a number of carbinols which appear to be derived from the cortical hormone, and evidence has been submitted of the occurrence of all other such compounds. Thus, from mares' pregnancy urine uranetriol-3α,11β,20α,[28] uranediol,[36] and uranolone[10] have been isolated and indications have been obtained of the occurrence of uranediol-3α,-11,[30] $\Delta^{5,6}$-urenetriol-3β,11,20 and of *allo*-uranetriol-3β,11,20.[37] Furthermore, it has been found that the carbinol fraction from mares' pregnancy urine yields ketones and acids on oxidation with periodic acid,[38] indicating the presence of the same characteristic glycol or glycerol residues that occur in the steroids from cortical extracts. Evidence has been obtained for the occurrence in stallions' urine of uranetriol-3α,11,20,[20] and *allo*-triol,[20] and an *allo*-tetrol.[20] These findings all

---

[37] Marker and Rohrmann, in press.

[38] Unpublished work of This Laboratory.

agree with the scheme given in Fig. 4. This seems to indicate that the cortical hormone, which may be identical with the hypothetical precursor XXVI, suffers the same type of biochemical reduction as progesterone and androstenedione. The formation of these urane and *allo*-urane derivatives from the hypothetical precursor XXVI may occur in the animal by several alternative or simultaneous processes. Thus the reduction of the conjugated system at 8, 9, 11 may yield either 11-keto-urane derivatives or 11-hydroxyurane derivatives, while at the same time the dihydroxyacetone residue may pass through the several stages of reduction and dehydration indicated in Fig. 4. The conjugated system at 3, 4, 5 at the same time may suffer reductions of Type I or Type II (Figs. 1 and 2).

In Fig. 5 a scheme is presented showing how all of the urane derivatives isolated to date may be formed by the reduction of the as yet unknown 11-hydroxy-9-β-progesterone XLI. It is to be understood, however, that several other intermediates, such as 11-keto-9β-progesterone, may, in accordance with the theory developed in this paper, also give rise to the urane derivatives found in urines. The reduction of 11β-hydroxy-9β-progesterone (XLI), if it proceeds according to Type I, will give rise, through the as yet unisolated compounds XLIV, XLV, XLVII and XLVIII, to uranetriol-3α,11β,20α (LI) and *allo*-uranetriol-3α,11β,20α (LII). The first of these compounds (LI) has been isolated from mares' pregnancy urine,[28] and its reactions and structure investigated.[30] Its presence in stallions' urine[20] has been demonstrated by the isolation of uranetrione-3,11,20 from the oxidation of an *epi*-carbinol fraction. *allo*-Uranetriol-3α,11β,20α (LII) may be identical with a triol whose presence has been demonstrated in stallions' urine.[20] If the reduction of 11β-hydroxy-9β-progesterone (XLI) proceeds according to Type II, it may give rise to either XL or XLIX. The first of these has not been isolated or demonstrated to exist in urines, but it may be identical with Wintersteiner and Pfiffner's compound G. Urenetriol-3β,11β,20α has not been isolated as such but its presence in mares' pregnancy urine has been demonstrated.[37] The digitonin precipitable carbinols from mares' pregnancy urine yielded an unsaturated fraction which on addition of bromine, oxidation, and debromination, yielded $\Delta^{4,5}$-urenetrione-3,11,20 (L), a substance which had been prepared previously from uranetrione.[30] The further biochemical reduction of either XL or XLIX would give *allo*-uranetriol-3β,11β,20α (XLII). The latter, which may be identical with the 3β-OH-*allo*-triol which was prepared as described above from stallions' urine, has been demonstrated to occur in mares' pregnancy urine.

From cortical extracts there is obtained,[35] besides the C_{21} compounds, a substance, adrenosterone (LIX) which has been shown to be androstenetrione-3,11,17. This compound shows androgenic activity, and may therefore be considered to be a connecting link between the cortical substances and the C_{19} and C_{18} sex hormones. It should be mentioned, however, that adrenosterone may have a *uro*-(β-type) configuration at C-9. The idea, suggested here, that cortical and sex hormones may be interrelated, is supported by numerous facts. The structures of the C_{21} cortical steroids and progesterone, on the one hand, and of adrenosterone and androstenedione on the other hand, indicate their close relationship. The influence of cortical disturbances on sexual characteristics is well known, and several instances can be cited where abnormal products related to sex hormones have been isolated from the urines of patients suffering from some disorder of the suprarenal gland. For example, Marrian and Butler[39] isolated pregnanetriol-3,17,20 from the urine of female patients with adrenal tumors, while Burrows, Cook and Warren[40] isolated $\Delta^{3,5}$-androstadienone-17, originating presumably from *epi*-dehydroandrosterone, from the urine of a man with an adrenal tumor.

This connection between cortical and sex hormones may be accounted for by the assumption that both types of hormones have a common precursor. We propose to show now how the hypothetical precursor (XXVI) of the adrenal steroids may be also the precursor of the sex hormones of the androgenic (C_{19}), progestational (C_{21}), and oestrogenic (C_{18}) types. In order to make the course of the conversions clear, it is necessary first to recount some recent work on the reduction of uranetrione in this Laboratory.[41]

When uranetrione (LIV) is reduced catalytically, there is formed (Fig. 6) in addition to uranetriol-3,11,20 (LV), uranediol-3,11 (LVI) and a

FIG. 6.—PRODUCTS FROM THE CATALYTIC REDUCTION OF URANETRIONE

mixture of pregnanediols (LVII). This implies that the carbonyl groups at C-11 and C-20, which are adjacent to tertiary hydrogens, are to some extent completely reduced to methylene groups, and, furthermore, that when the C-11-carbonyl is completely reduced, the molecular skeleton suffers inversion from the *uro*- (β) to the normal (α) form, although, as would be expected in view of the much greater stability of the normal (α), as compared to the *iso*- (β) type at C-17,[42] no inversion occurs when the C-20 carbonyl group is completely reduced. While at first sight this reduction may appear anomalous, it is by no means without parallel. Thus, when 7-keto-cholesteryl chloride is hydrogenated catalytically, α-cholestyl chloride is the major product.[43] It is evident, in view of the isolation from mares' pregnancy urine of uranediol, uranolone, and uranediol-3α,11β (the latter as uranedione from an *epi*-carbinol fraction), that this reduction of a C-20 carbonyl group to a methylene group occurs in the animal. Therefore, it is also likely that the reduction of a 9β-11-CO-system to a 9α-11-CH_2-system may occur in the animal as well as in the laboratory.

We are now able to understand how sex hormones may be formed from the hypothetical substance XXVI. This substance and a number of its possible reduction products contain dihydroxyacetone residues which are readily susceptible to oxidation to yield carbonyl groups at C-17. In the laboratory this oxidation may be accomplished by the use of lead tetraacetate, periodic acid, or almost any of the common oxidizing agents such as chromic acid or potassium permanganate; the fact that adrenosterone accompanies the C-21 steroids from cortical extracts shows that a similar type of oxidation occurs in the animal. Figure 7 illustrates how adrenosterone (LIX) or a precursor such as (LVIII) may give rise by biochemical reductions, to androstenedione (XIV) and therefore to the other male hormones. It will be evident, in view of the previous discussion, that the application of this theory will predict the possible existence in urines or glandular extracts of other related steroids, such as Δ^4-androstenol-11β-dione-3,17, which might arise by the various modes of reduction which

have been proposed, and, conversely, it should be noted that this theory predicts the *absence* in urines or glandular extracts of such a steroid as aetiocholanediol-3β,11β,-one-17. It should be emphasized that the reduction of the 11-carbonyl group to give an inversion from the 9β to the 9α-type is supposed to occur in the animal as well as during the catalytic hydrogenation *in vitro*.

The same type of simultaneous reduction and inversion of a 11-CO-9β system to a 11-CH$_2$-9α system in conjunction with the degradation of a dihydroxyacetone residue will account for the formation of progesterone and related steroids from XXVI. In Fig. 8, which shows how this may be accomplished, a number of the steps already shown in Fig. 7 are omitted, and it is to be understood that several alternate reduction schemes, which already have been discussed in similar instances, are omitted here for the sake of brevity.

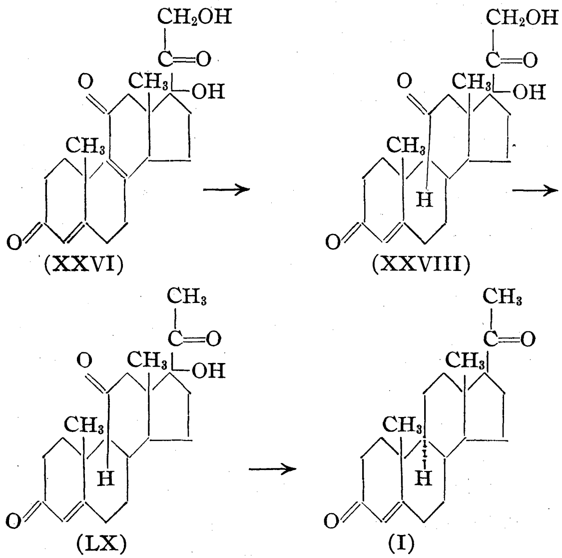

FIG. 8.—POSSIBLE FORMATION OF PROGESTERONE FROM (XXVI)

Not only is it possible to show how cortical steroids, male hormones, and progesterone derivatives may arise by orderly processes from XXVI, but it is also possible to show that the female hormones can be derived from the same parent compound. It is necessary to show first how the most characteristic feature of the female hormones, the occurrence of ring A, and sometimes B, in a benzenoid form, may arise. A number of examples are available to show that under drastic conditions, or because of the occurrence of an extended conjugated system, the methyl group at C-10 in many steroids may be lost as methane with the formation of benzenoid rings. One may cite the following examples: when apocholic acid is heated, methane is lost;[44] when ergopinacol is heated, neoergosterol is formed with the loss of methane;[45] when dianhydrostrophanthidin is treated with concentrated hydrochloric acid trianhydrostrophanthidin is formed;[46] when heptaacetyldesoxydihydroouabain is treated with hydrochloric acid and acetic acid the acetoxy lactone C$_{24}$H$_{30}$O$_4$, which contains a benzene ring, is obtained;[47] and finally when the debromination products of dibromoandrostanedione are heated, methane is evolved and phenolic compounds are formed.[48] These examples indicate that the elimination of methane with the formation of benzenoid rings is a type of reaction which may be expected to occur in the organism also if the parent molecule presents a sufficiently extended conjugated system, or some other structural feature which may be expected to facilitate the reaction. The hypothetical parent hormone (XXVI) has this type of molecular structure. In Fig. 9 a scheme is presented showing how the phenolic female hormones may be formed. It is not possible, of course, in view of the meager amount of data available, to state which of the several probably independent processes of dihydroxyacetone oxidation, loss of methane, and reduction of the 11-carbonyl group

may be expected to occur first. It should be noted that the mechanism indicates how equilin, as well as oestrone, may be formed. The formation of equilin by a migration of the double bond from the 8,9- to the 7,8-positions may occur in the animal, or it may occur in the course of the prolonged alkaline treatment of the urine. This drift of a double bond near a benzene ring is a familiar process in the chemistry of allyl- and propenyl-benzene derivatives, although usually the tendency is toward the establishment of an equilibrium mixture containing predominantly the propenylbenzene derivative. The formation of equilenin by the loss of hydrogen is also readily understandable as a tendency of the second ring to become aromatic. In fact, so great is the tendency for equilin to yield equilenin that when attempts are made to hydrogenate the former catalytically, the latter is always formed instead.[49] It is possible, furthermore, that a compound like LXII might suffer further loss of methane to yield, ultimately, *ar*-dihydroxycyclopentanophenanthrene derivatives, none of which have so far been found. In support of the hypothesis that oestrone and related female hormones are derived from a common precursor which is primarily not a sex hormone itself, we may note that oestrone is found in stallions' urine[50] as well as in mare and human female urines.

A discussion of the mode of biogenesis of the precursor XXVI is beyond the scope of this paper. It seems likely that the precursor may be formed from sugar units[51] in the pituitary or some other master gland, and supplied to the suprarenals, ovaries, corpus luteum, or testes for the production of the specific hormones elaborated by these glands. The reactions by which these syntheses are effected may be enzymatic, or they may be a part of some intramolecular oxidation and reduction in the glands, but it is not the purpose of this paper to discuss their nature. Since ascorbic acid occurs in the suprarenal glands, it may be that its function is the reduction of a precursor like XXVI to give steroidal hormones.

The author wishes to thank Dr. Elmer J. Lawson for his suggestions and assistance in the preparation of this manuscript, and all the members of his sterol group, Drs. Eugene L. Wittle, Elmer J. Lawson, Thomas S. Oakwood, Ewald Rohrmann, Harry M. Crooks, Stephen B. Binkley and David M. Jones for the use of their unpublished work.

Summary

1. Arguments are advanced to indicate that the steroidal hormones and bile acids do not originate from cholesterol.

2. It is suggested instead that the steroidal hormones, including the C-18, C-19, and C-21 sex hormones and the cortical steroids, may come from another common precursor, pregnadiene-4,8-diol-17,21-trione-3,11,20 (XXVI) or its hydrate at C-9.

3. Considerations of the interrelationships among the many steroids from urines and from gland extracts make it possible to propose a definite structure (XXVI) for the precursor of the steroidal hormones.

4. It is shown how the various steroids isolated may arise from this precursor by orderly processes following definite rules and having with few exceptions, their counterpart in the laboratory.

The Polycondensation of α-Methylacrolein

BY EVERETT E. GILBERT[1] AND JOHN J. DONLEAVY

It was shown by von Pechmann and Röhm[2] that in the presence of sodium methylate, methyl acrylate polycondenses to give a 10% yield of α-methyleneglutaric ester together with an uninvestigated higher fraction. A similar dimerization also was observed[3] in the case of methyl crotonate when an ether solution of this compound was exposed to the action of sodium methylate. Michael[4] obtained the same dimer by the action of sodium upon an ether solution of the ester.

In a discussion of the probable mechanism of the reaction, von Pechmann suggests that a molecule of sodium methylate first adds to the heteroconjugate system of a molecule of acrylic ester, thus producing the sodium enolate of a saturated molecule containing an active methylene group. In the presence of the strongly alkaline catalyst, a Michael reaction was thought to occur between this saturated molecule and an acrylic ester molecule. Loss of sodium methylate led to the formation of α-methyleneglutaric ester as the final product.

The purpose of this article is to record a similar type of polycondensation for α-methylacrolein. This investigation was conducted in connection with a study of the Michael polycondensation of various alpha, beta-unsaturated compounds being undertaken in this Laboratory. In this case the reaction occurred easily in the presence of dilute aqueous alkali. This extreme ease of reaction may be explained in part by the greater activation of the aldehyde group as compared to the ester grouping of ethyl acrylate. In addition, the final molecules produced from the methylacrolein contained no olefinic bonds, the addendum (water) being incapable of removal except by ring formation when stage II has been reached. A parallel is found in the dimerization of methyl vinyl ketone in the presence of dilute aqueous alkalies to produce octanol-8-dione-2,6.[5] A similar reaction, to be reported subsequently, has been observed in the case of acrolein.

Three polymers were isolated and identified—a trimer, a tetramer, and a pentamer. All three contained a molecule of water introduced during the polycondensation. They gave an immediate precipitate with Tollens' reagent, a delayed but positive test with Schiff's reagent, and an immediate precipitate of manganese dioxide when treated at room temperature with neutral aqueous permanganate. All three fractions yielded yellow 2,4-dinitrophenylhydrazones. As may be seen from Table I, the increases in refractive index and density from the trimer through the pentamer are approximately linear. A similar gradation was observed in the colors—the lowest fraction being colorless, the middle slightly yellow, and the top fraction a deeper shade of yellow. The three fractions were viscous oils, the viscosity increasing through the pentamer. All fractions possessed a mild and slightly spicy odor.

TABLE I

Fraction		Low	Middle	High
B. p.	°C.	113–118	159–164	175–180
	Mm.	12	12	9
	Bath., °C.	135–140	195–210	200–210

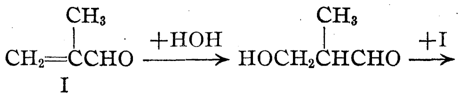
Hydrogen, %	Calcd.	8.77	8.73	8.70
	Found	8.94	8.86	9.00

The mechanism of the polycondensation is probably as follows. A molecule of water is first added to a molecule of α-methylacrolein, thus forming a β-hydroxyaldehyde containing the necessary active hydrogen. A series of Michael reactions then occurs, leading to the formation of the products isolated. Both of these processes are of a type known to occur with remarkable ease in the presence of alkalies. These reactions may be expressed as follows



$$\underset{\text{I}}{CH_2{=}\overset{CH_3}{\overset{|}{C}}CHO} \xrightarrow{+HOH} HOCH_2\overset{CH_3}{\overset{|}{C}}HCHO \xrightarrow{+I}$$

II

Experimental

The α-methylacrolein was purchased from the Shell Development Co. It was of about 98% purity and contained 0.05% hydroquinone as an antioxidant. Since it was desired to avoid polymerization produced by peroxides, and since the hydroquinone did not appear to inhibit the polycondensation, it was used as received without further purification.

Thirty-three grams of methylacrolein was mixed with 200 cc. of distilled water. About 50 cc. of ethyl alcohol was added to promote solution and ten cc. of 4% aqueous sodium hydroxide. A brown flash of color appeared which disappeared upon shaking. In about ten minutes turbidity appeared and a yellow oil began to settle. Heat was evolved; the flask was cooled by bathing in cold running water. After allowing the flask to stand for one hour (during which time it was shaken frequently), the solution was extracted three times with ether, and the extract was dried over sodium sulfate. The ether was removed and the oil was fractionated under reduced pressure. In the preliminary distillation three fractions were collected as follows:

(1)	Bath 165–170° (15 mm.)	141.1 g.
(2)	Bath 195–210° (10 mm.)	3.6 g.
(3)	Bath 225–250° (10 mm.)	7.6 g.

The total yield of crude oils was 71.3% of the theoretical Other experiments gave similar results.

Upon redistillation the above fractions were found to consist almost entirely of the pure polymers. The properties were determined from these purified fractions. The molecular weights were determined in freezing benzene. These and other data are listed in Table I.

Preparation of the Tri-2,4-dinitrophenylhydrazones of the Polymers.—The method employed was essentially that suggested by Shriner and Fuson.[6] An equivalent of dinitrophenylhydrazine for each aldehyde group was employed. Yellow tridinitrophenylhydrazones were obtained in each case. The derivative of the trimer separated from the reaction mixture even when boiling. Cooling was resorted to in the other cases to obtain crystallization of the derivatives. They were then recrystallized from benzene. The tridinitrophenylhydrazone of the trimer decomposed to a red liquid at 173–174° (uncorr.), but the other two derivatives decomposed indefinitely as the temperature was raised above 100°.

Anal. Trimer. Calcd. for $C_{30}H_{32}N_{12}O_{13}$: N, 21.8. Found: N (Dumas), 21.4. Tetramer. Calcd. for $C_{34}H_{38}N_{12}O_{14}$: C, 48.65; H, 4.53; N, 20.0. Found: C, 48.60; H, 4.82; N, 20.4. Pentamer. Calcd. for $C_{38}H_{44}N_{12}O_{15}$: N, 18.5. Found: N, 18.5.

Summary

α-Methylacrolein polycondenses by the Michael reaction in the presence of dilute aqueous alkali. A trimer, a tetramer, and a pentamer were isolated and characterized.

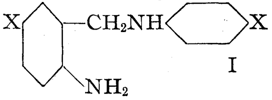
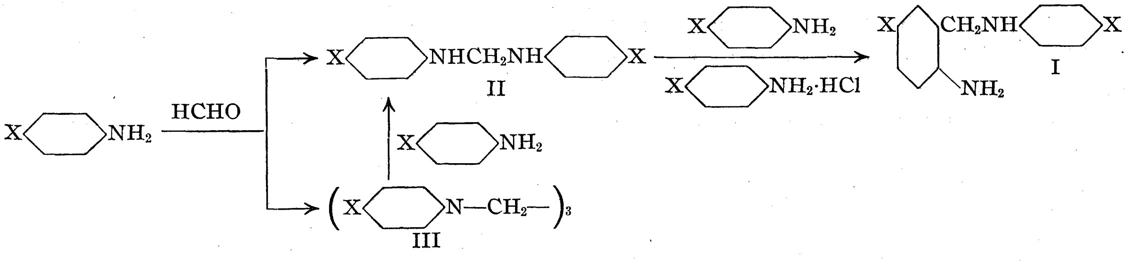
A Study of the Conversion of Para-substituted Methylene-bis-arylamines and Trimeric Methylene-arylamines to Substituted 2-Aminobenzylarylamines

By T. R. Miller and E. C. Wagner



I

Aminobenzylarylamines of type I may be prepared from para-substituted amines through the reactions



The only published procedure[1] is cumbersome, as it requires mechanical stirring of a mixture of methylene-*p*-toluidine, *p*-toluidine and *p*-toluidine hydrochloride for forty-eight hours at 20°, in the presence of enough nitrobenzene to yield a mass which is finally liquid. The mild conditions specified (which greatly prolong the reaction period) are clearly intended to exclude or minimize

---

(1) German Patent 105,797; *Friedl.*, **5**, 84; v. Walther and Bamberg, *J. prakt. Chem.*, [2] **71**, 153 (1905).

the further reaction by which I is converted to the diphenylmethane base. With diimines (II) and trimeric Schiff bases (III) obtained from amines with open para-position this reaction occurs readily on warming in the presence of amine salt (or free acid),[2] and can be excluded only by operating at or below 20°, at which temperatures aminobenzylarylamines of the type  are obtainable.[3] It is now known[4] that aminobenzylarylamines of type I (from para-substituted amines) are less readily converted to diphenylmethane bases: at 100° the conversion of *o*-amino-*m*-xylyl-*p*-toluidine (I) to 2,2′-diamino-5,5′-dimethyldiphenylmethane is slight,[5] and at 125° the conversion is only 50% complete.[6] These facts suggested the possibility of converting II or III more rapidly to I by use of temperatures well above 20°. As is shown in the experimental part the reaction goes well at 80–100°, and normal yields are obtained in a few hours, the nitrobenzene and (in small runs) mechanical stirring being dispensable.

The proportions of diimine (II) or Schiff base (III), free amine and amine salt hitherto used in these reactions appear to be based upon no published experimental work. As a result of Simons' study[7] of the reactions of diimines (II) with amines and amine salts it is established that II with amine salt yields as the normal end-product the corresponding dihydroquinazoline (*e. g.*, 6-methyl-3-*p*-tolyl-3,4-dihydroquinazoline), with I formed as an intermediate, but that presence of free amine tends to exclude the later steps of the complete transformation and thus favors survival of I. With 25 molar equivalents of amine to one equivalent each of II and amine hydrochloride an 82.5% yield of I was obtained. This amount of free amine is inconveniently large, for the excess, together with amine taken as hydrochloride, must be removed subsequently by steam distillation or otherwise, in the isolation of I. Experimental trials, reported below, showed that satisfactory practical molar ratios for preparation of I are diimine:amine:amine hydrochloride = 1:10–12:0.5. When the trimeric Schiff base is used, three equivalents of amine are consumed in the initial reaction[2b] requiring for the

$$(\mathrm{ArNCH_2}\!-\!)_3 + 3\mathrm{ArNH_2} \longrightarrow 3\mathrm{ArNHCH_2NHAr}$$

Schiff base the molar proportions trimer (III): amine : amine hydrochloride = 1 : 33–39 : 1.5. The proportions previously specified[1] for the cold reaction are III: amine: amine hydrochloride = 1 : 16.7 : 5.8, *i. e.*, more than the necessary amine salt (shown by Simons[7] to be 0.5–1.0 equivalent referred to the diimine), and an amount of amine less than adequate for the hot reaction. The most satisfactory combination of conditions includes the ratio of reactants stated, a temperature of 80–90°, and, for 0.01–0.1 molar quantities, a reaction period of two hours. With larger quantities the time should be extended to three to five hours and the mixture should be stirred mechanically.

The applicability of the procedure for preparative purposes appears to be limited. Satisfactory results were obtained in the preparation of the aminobenzylarylamines from *p*-toluidine, *p*-chloroaniline and *p*-bromoaniline. Attempts to prepare those from *p*-anisidine and *p*-phenetidine were unsuccessful, owing apparently to isolation difficulties, which it is safe to say would be greater with para-substituted amines not volatile with steam.

The conversion of II to I by substitutive ortho-coupling (rather than by rearrangement) suggests the possibility of making 2-aminobenzylarylamines of mixed type by warming diimines or Schiff bases with different amines and their hydrochlorides. The analogous process has been used for preparation of diphenylmethane bases of mixed type from simple aminobenzylarylamines.[8] Preliminary trials[9] yielded unpromising viscous liquids from which no well-defined product could be isolated.

Experimental

Chemicals.—Methylene-*bis*-*p*-toluidine (m. p. 95°), methylene-*bis*-*p*-chloroaniline (m. p. 59–60°) and methylene-*bis*-*p*-bromoaniline[10] (m. p. 92°) were made by the method of Eberhardt and Welter[2b] and Bischoff and Reinfeld.[11] The trimeric Schiff bases (melting respectively at 127, 151 and 166°[12]) were prepared by the procedure of J. G. Miller.[13]

Procedure.—The mixture of diimine or Schiff base (0.01 mole), amine and amine hydrochloride in a flask was heated in an oil-bath at the desired temperature (thermometer in the bath), and was then treated with enough sodium hydroxide solution to neutralize the acid taken as amine salt and was submitted to rapid steam distillation. When all steam-volatile material was removed the residual mixture was cooled to solidify the crude product, which was separated by filtration, washed once with water and then without drying was crystallized as follows. The moist product, in a 200-cc. flask, was heated on a water-bath, and ligroin (70–90°) was added gradually until a solution nearly saturated at the boiling point was obtained. Anhydrous potassium carbonate sufficient to "fix" the separated water was added, and the mixture was digested with about 0.5 g. of charcoal and then filtered rapidly using a heated filter. The liquid was chilled in ice, and the separated crystals were removed by filtration, washed with cold ligroin and dried in a vacuum desiccator. The yields stated represent nearly pure product but do not indicate quite the maximum yields obtainable, as the ligroin mother liquors were not worked up to recover the small amount of product still present though not readily isolable owing to presence of resinous impurities. In several experiments the mother liquors were found to contain small amounts of the dihydroquinazolines, isolated and identified as their picrates.

In the first series of experiments reported below the product was isolated and weighed as the benzal derivative.[7] This procedure indicated higher but less reproducible yields than the procedure described above.

Series 1: Effect of Temperature.—Conditions: methylene-*bis*-*p*-toluidine (II), 0.01 mole (2.26 g.), *p*-toluidine, 0.05 mole (5.5 g.), *p*-toluidine hydrochloride, 0.005 mole (0.70 g.); time one hour. Product isolated as benzal derivative.

Temperature, °C.	50	60	70	80	90	100
Yield of I, %	63.7	65.3	64.7	66.0	66.9	66.6

Series 2: Effect of Variation in Proportions of Reactants (and Time).—In experiments using the diimine (II) the above ratio of II to *p*-toluidine hydrochloride was held constant (being within the optimum limits reported by Simons[7]), and the ratio of *p*-toluidine to II was varied. In the experiments using the Schiff base trimer (III) the ratio of III to *p*-toluidine hydrochloride was 1:1.5, and the proportions of *p*-toluidine were varied. In the table the values for the ratio of *p*-toluidine to Schiff base refer to moles of *p*-toluidine available as "regulator," calculated in terms of equivalent moles of diimine, *viz.*, $(x - 3y)/3y$, in which x = moles of *p*-toluidine and y = moles of Schiff base; temperature, 80°.

Starting comp.	Ratio *p*-toluidine: II or III[a]	Yield of I, %	
	A, Time 0.5 hour		
III	10	50.1	51.6
III	15	57.4	
II	25	59.3	
	B, Time 1 hour		
II	5	48.7	
III	5	48.7	
III	8	50.2	
II	10	51.2	
III	10	50.0	
II	12	51.5	51.0[b]
III	12	52.0	
III	15	56.0	59.1
II	20	58.5	
III	20	60.4	
II	25	61.2	
III	25	62.0	

[a] Calculated in terms of equivalent II, as explained above. [b] Temperature 100°.

Series 3: Effect of Time.—In experiments with diimine the proportions of reactants were as in Series 1, *i. e.*, 1:10:0.5. In experiments using the Schiff base trimer the proportions were 1:33:1.5 (or 1:10:0.5 calculated to equivalent diimine); temperature 80°.

Starting compound	III	II	II	II
Time, hrs.	0.5	1	2	3
Yield, %	51.6	54.7	63.3	62.7
	50.1	54.0	60.0	

Preparative Trials

Cold Procedure.[1]—The starting compound was in all cases III, the amounts ranging from 53 to 73.5 g. The molar proportions, in terms of equivalent diimine, were 1:4.6:1.9, with nitrobenzene 1.7 cc. per gram of III. The reaction mixtures were stirred mechanically during forty-eight to fifty-three hours, at temperatures which ranged from 15 to 24° and which were for the most part not above 20°. The best yields obtained were 61.4 and 56.3%.

Hot Procedure.—The starting compound was II, the time two hours, and the temperature 80–90°. For ratio 1:12:0.5 the yield was 61.5%; for ratio 1:21:1.6 the yield was 64.5%.

The foregoing results, and those of series 1, 2 and 3 show the conversion of II or III to I to be fairly rapid at 80–90°, the yields increasing as the molar ratio of available free amine is increased. For preparative purposes a molar ratio of about 10:1 when the starting compound is II, or of 33:1 when the starting compound is III, is recommended. The yields are then satisfactory and the amount of amine to be removed during the isolation is not excessive. The diimine or the Schiff base may be used equally well as starting material.

Conversion of Diimines and Schiff Bases from *p*-Chloroaniline and *p*-Bromoaniline to Corresponding 2-Aminobenzylarylamines. Conditions.—Molar ratio for diimine 1:12:0.5, and equivalent ratio for Schiff base; temperature 80°; time two hours.

Starting compound	II	III
Yield of I, %		
Cl compound	45.3	46.3[14]
Br compound	50.2	47.3[14]

Grateful acknowledgment is made to the Faculty Research Committee of the University of Pennsylvania for a grant to assist this study.

---

(14) Some results by a closely similar procedure were mentioned in an earlier paper (Ref. 12, p. 879).

Summary

1. A study of the effects of variations in temperature, time and molar ratios of reactants upon the conversion of methylene-*bis-p*-toluidine or trimeric methylene-*p*-toluidine to N-(5-methyl-2-aminobenzyl)-*p*-toluidine, in the presence of *p*-toluidine and *p*-toluidine hydrochloride, showed: (a) at 80–100° the reaction is rapid and does not proceed beyond the aminobenzylarylamine stage. The conditions previously specified, *viz.*, a temperature of 20° and a reaction time of forty-eight hours, were based on a misconception. (b) The extent of the conversion increases with increase in the molar ratio of free amine to diimine or Schiff base. Highest yields require an inconveniently large excess of free amine. Satisfactory practical ratios, which give good yields and do not too greatly prolong the isolation procedure, are diimine : amine : amine hydrochloride = 1:10:0.5, or trimeric Schiff base : amine : amine hydrochloride = 1:33:1.5.

2. The procedure based upon the above conditions has been used for the preparation of the aminobenzylarylamines obtainable from *p*-toluidine, *p*-chloroaniline and *p*-bromoaniline. It failed in the cases of *p*-anisidine and *p*-phenetidine and its usefulness apparently is impaired by the limitations of the isolation method now available.

The Structure of Beta and Gamma Tocopherols

BY OLIVER H. EMERSON

To date there have been described in the literature three tocopherols, which we designated provisionally as alpha, beta and gamma.[1,2] Alpha was obtained from wheat germ oil, cottonseed oil, palm oil, and lettuce leaves. Beta was first obtained by us from wheat germ oil, and later by Todd, Bergel, Waldmann and Work, who obtained it in addition from rice bran oil.[3,4] It was obtained subsequently from wheat germ oil by Drummond and Hoover,[5] John,[6] who suggested the name cumo-tocopherol for it, and Karrer, Salomon and Fritsche,[7] who proposed the name neo-tocopherol. Dr. John[8] kindly compared a sample of our β-tocopherol allophanate with his cumo-tocopherol allophanate and found them identical. It is interesting that the European workers found that in their preparations of wheat germ oil, β-tocopherol predominated to such an extent that the suggestion was put forward that alpha might be an artifact,[9] whereas from the Californian wheat germ oil we have regularly obtained at least twice as much alpha as beta. γ-Tocopherol has been obtained from cottonseed oil and palm oil. In our experience at the University of California and in the Research Laboratories of Merck & Co., Inc., where several hundred pounds of cottonseed oil have been worked up, the ratio of alpha to gamma varies within wide limits. Sometimes there is as much gamma as alpha but usually much less. Other oils beside wheat germ and cotton seed, notably grape seed oil, are known to vary greatly in their chemical constituents, depending not only on the locality, but also on the year of the crop.

On pyrolysis Fernholz[10] showed that α-tocopherol yields durohydroquinone. Under similar conditions, from β-tocopherol John[6] obtained trimethylhydroquinone, and Bergel, Todd and Work[9] reported a mixture of trimethylhydroquinone and durohydroquinone.

Fernholz's original view that α-tocopherol is a simple mono-ether of durohydroquinone was modified by the results of the chromic acid oxidation,[11] whereby he obtained dimethylmaleic anhydride; a lactone $C_{21}H_{40}O_2$, the hydroxy acid of which forms a characteristic benzylthiuronium salt; and an acid $C_{16}H_{32}O_2$ which on vigorous oxidation yielded two moles of acetic acid. From this evidence Fernholz proposed formula I for α-tocopherol

I

We have oxidized β- and γ-tocopherol under the conditions described by Fernholz and have obtained from both the same lactone that had been obtained from α-tocopherol. We failed to obtain dimethylmaleic anhydride, but the amount of material used by us was much smaller than that employed by Fernholz so that dimethylmaleic anhydride, if formed, might have escaped our attention.

We have also pyrolyzed γ-tocopherol at 360°, and obtained trimethylhydroquinone. From these facts, it is evident that β- and γ-tocopherol differ from alpha only in the absence of one of the three methyl groups attached to the benzene ring. This had been suspected by John[6] and Karrer, Salomon and Fritzsche.[12]

Oxidation of β-Tocopherol.—Eight hundred and nine milligrams of β-tocopherol was oxidized as described by Fernholz.[11] A lactone was obtained which was purified by distillation in high vacuum (yield 351 mg.). This yielded a benzylthiuronium salt which, after several recrystallizations from acetone, melted at 116–117°. A sample of the corresponding benzylthiuronium salt, prepared by Fernholz from α-tocopherol, melted at 116–117.5°; mixed m. p. 116–117°. *Anal.* Calcd. for $C_{29}H_{52}O_3N_2S$: C, 68.45; H, 10.30; N, 5.50. Found: C, 68.22, 68.51, 68.15; H, 10.23, 10.44, 10.23; N, 5.42, 5.54.

Oxidation of γ-Tocopherol.—Three hundred and seventy four milligrams of γ-tocopherol, oxidized as above, yielded 90 mg. of lactone after purification by high vacuum distillation. This gave a benzylthiuronium salt melting at 116–117° which showed no depression on admixture with a sample of the corresponding benzylthiuronium salt of the same melting point from α-tocopherol. *Anal.* Calcd. for $C_{29}H_{52}O_3N_2S$: C, 68.45; H, 10.30; N, 5.50. Found: C, 68.59, 68.65; H, 10.35, 10.26; N, 5.48.

Pyrolysis of γ-Tocopherol.—Five hundred milligrams of γ-tocopherol was heated at 360° in an atmosphere of carbon dioxide. This gave 30 mg. of a crystalline sublimate, which appeared to be a mixture of trimethylhydroquinone with a little durohydroquinone. By careful recrystallization from benzene there was obtained a fraction melting at 167–170° which gave no depression with authentic trimethylhydroquinone. A benzoate was also obtained melting at 175–178° which gave no depression when mixed with an authentic sample of trimethylhydroquinone dibenzoate melting at 178–180°.

The trimethylhydroquinone and its dibenzoate were supplied by Professor Lee Irvin Smith to whom we wish to express our thanks.

Summary

Oxidation of β- and γ-tocopherols yielded the same $C_{21}H_{40}O_2$ lactone that had been obtained by Fernholz from α-tocopherol.

Carbamic Esters from Urea

BY RALPH A. JACOBSON

Esters of carbamic acid are usually prepared either by treating an alcohol with phosgene and adding ammonia to the chloroformic ester thus formed, or by treating the alcohol with cyanic acid. The reaction of urea with an alcohol has also been utilized[1] but the method has not been applied widely, probably because the lower alcohols, *e. g.*, methyl and ethyl, require pressure. Butanol, however, reacts with urea at atmospheric pressure[2] to give butyl carbamate in 75% yield. This suggests wider application of the method for the preparation of carbamic esters of alcohols having boiling points higher than that of butanol. In the present paper, we have adapted this method to the synthesis of octyl carbamate, *n*-dodecyl carbamate, and several other esters of carbamic acid.

The optimum temperature range for carbamate formation appears to be 175–190°. At this temperature, aliphatic monohydric alcohols react smoothly with urea with the evolution of ammonia and the formation of carbamates. While the reaction is usually over within a few hours at this temperature, a reaction period of twelve to twenty-four hours or longer is required for al-

[2] Davis and Lane, *Org. Syntheses*, **9**, 24 (1929).

cohols having boiling points considerably lower than the optimum temperature. In such cases the reaction is usually very slow initially, but as the concentration of carbamate in the mixture increases and the boiling point of the mixture approaches the optimum temperature, the reaction rate increases markedly. The products are isolated by filtering the mixture to remove the small amount of cyanuric acid usually formed, and distilling the filtrate. After removal of the alcohol, the less volatile carbamates are purified by distillation or by crystallization.

The formation of butyl carbamate from urea and *n*-butanol is expressed by Davis and Lane as follows

$$NH_2CONH_2 \longrightarrow NH_3 + HNCO \quad (1)$$
$$HNCO + C_4H_9OH \longrightarrow NH_2COOC_4H_9 \quad (2)$$

If these reactions correctly express the mechanism, the formation of carbonates by the reaction of urea with two molecules of the alcohol as shown in equation (3) is unlikely.

$$NH_2CONH_2 + 2ROH \longrightarrow R_2CO_3 + 2NH_3 \quad (3)$$

Since phosgene, however, reacts with two molecules of an alcohol to yield the carbonate, it seems at least theoretically possible that urea—the diamide from phosgene—could react similarly. In other words, the reaction expressed by equation (3) might take place in either direction depending upon the conditions. Indeed the reaction from right to left does go readily in the case of diphenyl carbonate which can be converted into urea and phenol in 70% yields by treatment with aqueous ammonia[3]

$$2C_6H_5CO_3 + 2NH_3 \longrightarrow NH_2CONH_2 + 2C_6H_5OH \quad (4)$$

Our attempts to force the reaction (3) from left to right, however, were unsuccessful since none of the experiments yielded carbonates. In one instance, sulfuric acid was added to a mixture of urea and *n*-dodecyl alcohol to remove the ammonia immediately upon formation, but quantitative dehydration of the *n*-dodecyl alcohol to *n*-dodecyl ether resulted.

The reaction of urea with polyhydric alcohols also was examined briefly. Ethylene glycol, sorbitol, and triethylene glycol reacted readily with urea to give viscous water-soluble sirups. Upon standing, the sirup from triethylene glycol deposited crystals of the diurethan (m. p. 108°). In general, however, the reaction of urea with polyhydric alcohols appears unpromising for the preparation of pure carbamates of polyhydric alcohols.

Experimental Part

***n*-Dodecyl Carbamate.**—A mixture of 120 g. of urea, 372 g. of *n*-dodecyl alcohol, and 12 g. of glycerol was heated at 170° for two hours and finally at 190° for three hours. The reaction mixture was distilled in a vacuum and 150 g. of *n*-dodecyl alcohol boiling at 135° under 12 mm. was recovered. The liquid in the distilling flask solidified on cooling. The crystalline product was washed with petroleum ether and melted at 81–82°[4]; yield 138 g. (60%). The product was soluble upon heating in toluene, alcohol, ethyl acetate, ether, carbon tetrachloride, and acetic acid.

Anal. Calcd. for $C_{13}H_{27}O_2N$: C, 68.12; H, 11.79. Found: C, 67.68; H, 11.14.

***n*-Octyl Carbamate.**—This compound was prepared as above except that purification was effected by distillation, followed by crystallization from benzene. The compound boiled at 136° under 4 mm. pressure and melted at 67°.[5] The yield was 55% of the theoretical.

Isobutyl Carbamate.—A mixture of 270 g. of urea, and 1813 g. of isobutanol was refluxed for seventy-two hours. The excess isobutanol was distilled and the residue extracted three times with ligroin, b. p. 90–100°. Urea amounting to 101 g. was recovered. After removal of the ligroin the isobutyl carbamate was collected at 117° under 25 mm. pressure, the product m. p. 65–66° weighing 225 g. (42.8% conversion or 65% based on the urea consumed).

An attempt was made to reduce the time of reaction by utilizing isobutyl phthalate to increase the initial boiling point of the mixture. Under these conditions isobutyl allophanate was obtained as a by-product.

A mixture of 120 g. of urea, 148 g. of isobutanol, 250 g. of isobutyl phthalate, and 12 g. of glycerol was heated on the hot-plate for nineteen hours. During the first twelve hours, the boiling point of the mixture increased from 123 to 137° and during the next seven hours from 137 to 170°. The solution upon cooling deposited crystals (15 g.) of isobutyl allophanate which on purification from acetone melted at 174°. The liquid portion was distilled and the fraction boiling at 95–110° under 12 mm. was collected. Upon cooling, the liquid solidified to a white crystalline solid which, after being washed with petroleum ether, melted at 65–66°.[6]

Anal. of isobutyl allophanate m. p. 174°. Calcd. for $C_6H_{12}O_3N_2$: C, 45.00; H, 7.50; N, 17.50. Found: C, 44.92; H, 7.10; N, 17.32.

Anal. of isobutyl carbamate m. p. 65–66°. Calcd. for $C_5H_{11}O_2N$: C, 51.28; H, 9.40. Found: C, 51.77; H, 8.96.

Mixed Carbamates from the Higher Alcohol Mixture Obtained in the Synthetic Methanol Process.—A mixture of 90 g. of urea, 9 g. of glycerol, and 308 g. of the fraction

---

[3] Kirkhgof and Astrova, *Khim. Farm. Prom.*, 281 (1933); *C. A.*, **28**, 3718 (1934).

[4] Béhal, *Bull. soc. chim.*, **25**, 480 (1919), prepared dodecyl carbamate by passing cyanic acid into the alcohol but gave 77° as the melting point.

[5] Béhal[4] reported 67° as the melting point.

[6] Béhal[4] gives 180.5° for the allophanate and 59.5° for the carbamate.

of higher alcohols boiling at 135–150° obtained from the synthetic methanol process,[7] was refluxed for twelve hours. The liquid was decanted from a small amount of solid material (4.5 g.) and distilled. After removal of the excess alcohols, the carbamate was obtained at 110–125° under 4 mm. pressure. The product was slightly yellow and remained liquid at room temperature. The yield was 137 g. or about 60% of the theoretical.

Ethylene Glycol and Urea.—A mixture of 240 g. of urea, 124 g. of ethylene glycol, and 12 g. of glycerol yielded a transparent water-soluble sirup after a heating period of six hours at 160–165° and four hours at 170–175°.

Triethylene Glycol and Urea.—A mixture of 60 g. of urea, 6 g. of glycerol, and 150 g. of triethylene glycol was heated at 140–150° for one and one-half hours and slowly increased during eight hours to 175°. The excess triethylene glycol was removed by distillation and 115 g. (57.8%) of a non-volatile water soluble sirup obtained. Upon standing for two weeks, a small amount of crystalline material separated which, upon crystallization from acetone, melted at 108° and proved to be the diurethan.

Anal. Calcd. for $C_8H_{16}O_6N_2$: C, 40.67; H, 6.77; N, 11.86. Found: C, 40.87; H, 6.65; N, 11.32.

Sorbitol and Urea.—Resins of varying viscosity were obtained depending upon the ratio of urea to sorbitol. Pure compounds could not be isolated.

Summary

n-Dodecyl carbamate, octyl carbamate, isobutyl carbamate, and the mixed carbamates from one fraction (b. p. 135–150°) of the higher alcohols obtained in the methanol synthesis have been prepared by the reaction of urea with the corresponding alcohols at atmospheric pressure. Attempts to obtain alkyl carbonates by the same procedure were unsuccessful.

Polyhydric alcohols reacted with urea under the same conditions to yield sirups from which pure compounds could not be isolated except in the case of triethylene glycol. The latter yielded a sirup from which a small amount of the diurethan of m. p. 108° was obtained.

A Critical Examination of the Reaction of Iodine Monobromide with Cholestenone and β-Cholestanone

BY J. O. RALLS

In a previous study,[1] it was shown that cholestenone was one of the products of the reaction of iodine monobromide with cholesterol. It was also shown that cholestenone behaved toward halogen in a manner that was then considered "abnormal." In addition, Copping[2] had stated that cholestenone did not yield analytically correct iodine numbers when Dam's[3] suggested application of the Rosenmund and Kuhnhenn[4] method was used. We were interested, therefore, in attempting to ascertain the causes of this peculiarity.

Inasmuch as $\Delta^{4,5}$-cholestenone, commonly called cholestenone (suggested name, coprostenone),[5] contains a double bond and a ketone group (in a conjugated system), the problem was one of attempting to evaluate the role of each in the reaction of cholestenone with iodine monobromide. Cholestanone, which contains no double bond, and cholestanoxime, which contains neither the double bond nor the ketone group, served to evaluate the effect of the carbonyl group; while cholestenoxime, which does not contain the ketone group but still possesses the double bond, was used in attempting to evaluate the role of the latter group.

In the course of the experimentation, hydrogen bromide catalysis of halogenation was investigated, as was, also, the effect of the oximino hydroxyl upon the halogenation of the ethylene group in cholestenoxime. In the latter work, the factors of solvent nature, of air (oxygen) inhibition, and of the configuration of the oxime were considered. In these studies, *syn*-styrylphenylketoxime, 3,5-diphenylisoxazol, and 3,5-diphenylisoxazoline were also used.

Discussion and Results

The peculiarities of the reaction of cholestenone with iodine monobromide (Curves 1, Fig. 1) are especially evident in the graph of the organic

---

halogen. There appears to be some autocatalysis, but it is not simple. Inasmuch as cholestenone contains both a double bond and a ketone group, the complexity might well have been due to the influence of these two groups. Because it contained the ketone group only, β-cholestanone was allowed to react with iodine monobromide. It was surprising to find that it consumed halogen more rapidly (Curves 2, Fig. 1) than did cholestenone. (Of course, it has long been known that it did react with halogen.[6,7]) Examination of the curves showed that, while the reaction of cholestanone lacked the aforementioned complexity, it did possess an autocatalytic nature. Doreé[6] has remarked on the initial lag followed by a rapid consumption of halogen accompanied by a marked evolution of halogen acid when cholestanone reacted with bromine. The above author suggested that substitution had occurred. In the work reported here, the ratios between the total halogen consumed and the halogen organically bound were two to one, which fact is indicative of substitution. But β-cholestanol, from which β-cholestanone is derived, did not undergo substitution under similar conditions.[1] Furthermore, substitution, in the common sense, would not be expected to display signs of autocatalysis. But a substitution preceded by an enolization or activation of a ketone group could do so. It is generally conceded that enolization or activation of a saturated ketone precedes its bromination.

The specific evidence that β-cholestanone also undergoes enolization or activation in its reaction with iodine monobromide is the following. First: when cholestanoxime was allowed to react with iodine monobromide, no appreciable reaction occurred (broken Curve 2, Fig. 1). Of course, this is not absolute evidence that the bromination of cholestanone is via enolization, because the presence of the oximino group in cholestanoxime might have changed the activity of nearby hydrogen. Second: determinations of the order of the reaction of cholestanone with iodine monobromide disclosed that it was monomolecular. (Table I is presented as an example of the results—other initial concentrations were also used.) This finding paralleled those of Meyer,[8] who studied the order of the bromination of malonic acid, and of Cohen,[9] who studied the bromination of acetone in organic solvents. Third: the initial speed of the reaction of cholestanone with iodine monobromide was increased when hydrogen bromide was added to the halogenating agent. These results were similar to those obtained in a like study of cholestenone (Figs. 2 and 3). On the basis of the work of Lapworth,[10] Meyer,[8] Dawson,[11] Cohen,[9] Hanson and Williams,[12] and of Kröhnke,[13] it is generally conceded that mineral acids catalyze the enolization or activation which precedes the bromination of ketones. Further, it is evident that such workers as Butenandt and Wolff[7] and Ruzicka, *et al.*,[14] tacitly assume that cholestanone enolizes during its bromination. Fourth: photographic records of the ultraviolet absorption spectra of cholestanone in chloroform, in chloroform–glacial acetic acid, and in chloroform–glacial acetic acid–hydrogen bromide (Plate 1) and of the enol ethyl ether of cholestanone (Plate 2) in chloroform were made. That of the cholestanone in the presence of hydrogen

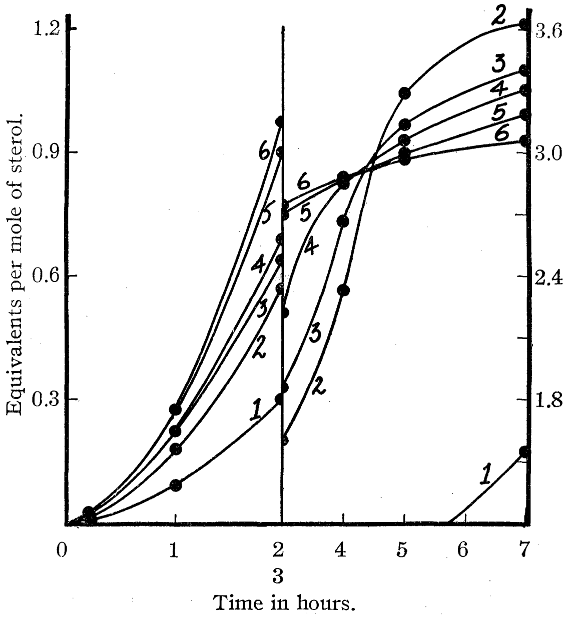

Fig. 2.—The influence of aqueous hydrogen bromide upon the consumption of halogen by cholestenone. Initial hydrogen bromide concentrations mμ 6 cc.: 1, 0.000; 2, 0.020; 3, 0.042; 4, 0.059; 5, 0.079; 6, 0.099.

bromide was similar to that of the enol ethyl ether in chloroform.

Table I

The Order of Reaction of Cholestanone with IBr

Cholestanone in CCl_4, IBr in CH_3COOH

	C = 0.082 mM			C = 0.041 mM		
Reaction time, min.	Milliequivalents Residual	Consumed	Equiv. per mole	Milliequivalents Residual	Consumed	Equiv. per mole
Blank	0.1648	0.0000	0.000	0.0824	0.0000	0.000
2	.1408	.0240	.300	.0704	.0120	.300
4	.1243	.0405	.493	.0624	.0200	.488

Order is apparently monomolecular, since $t_2/t_1 = 1 = 2^\circ = 2^{n-1}$.

Cholestanone in CCl_4, IBr in CCl_4

	C = 0.0764 mM			C = 0.0382 mM		
Reaction time, min.	Milliequivalents Residual	Consumed	Equiv. per mole	Milliequivalents Residual	Consumed	Equiv. per mole
Blank	0.1528	0.0000	0.000	0.0764	0.0000	0.000
2	.1457	.0071	.093	...	...	..
4	.1075	.0453	.594	.0536	.0228	.597
8	.0960	.0568	.743	.0480	.0284	.743
16	...	...	...	.0440	.0324	.849

Order is apparently monomolecular.

An error of 0.010 cc. in titration produces a minimum error of 0.010 in equivalents per mole when C = 0.080 mM, and one of 0.020 when C = 0.040 mM.

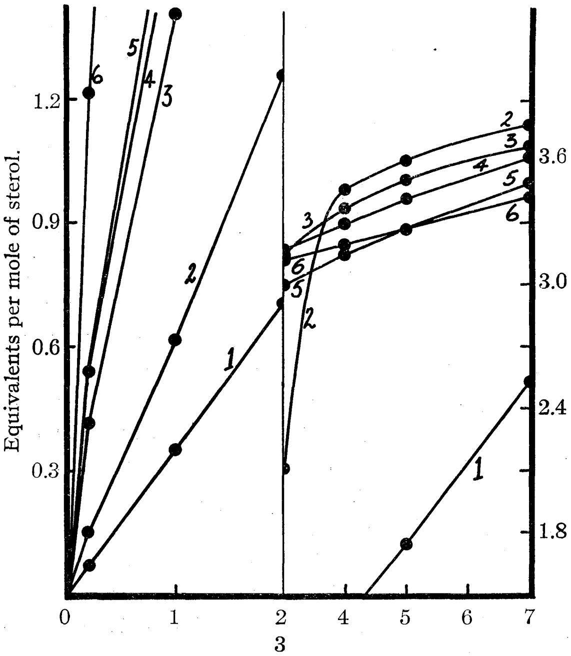

Fig. 3.—The influence of anhydrous hydrogen bromide upon the consumption of halogen by cholestenone. Initial hydrogen bromide concentrations, mμ in 6 cc.: 1, 0.000; 2, 0.020; 3, 0.042; 4, 0.059; 5, 0.079; 6, 0.099.

While our experiments were being carried on, Inhoffen[15] reported that cholestenone enolizes during its bromination and that hydrogen bromide stimulates the enolization. We, also, had noted that hydrogen bromide catalyzed the reaction of cholestenone with iodine monobromide (Figs. 2 and 3). Further, the reaction of cholestenone with iodine monobromide in carbon tetrachloride–glacial acetic acid, and in carbon tetrachloride alone, was found to be monomolecular. These results are similar to those obtained using cholestanone. Cholestenone reacted similarly to cholestanone in one other respect. Cholestenoxime, like cholestanoxime, resisted halogenation in the presence of glacial acetic acid (Fig. 1 and Table II). (Added hydrogen bromide did not

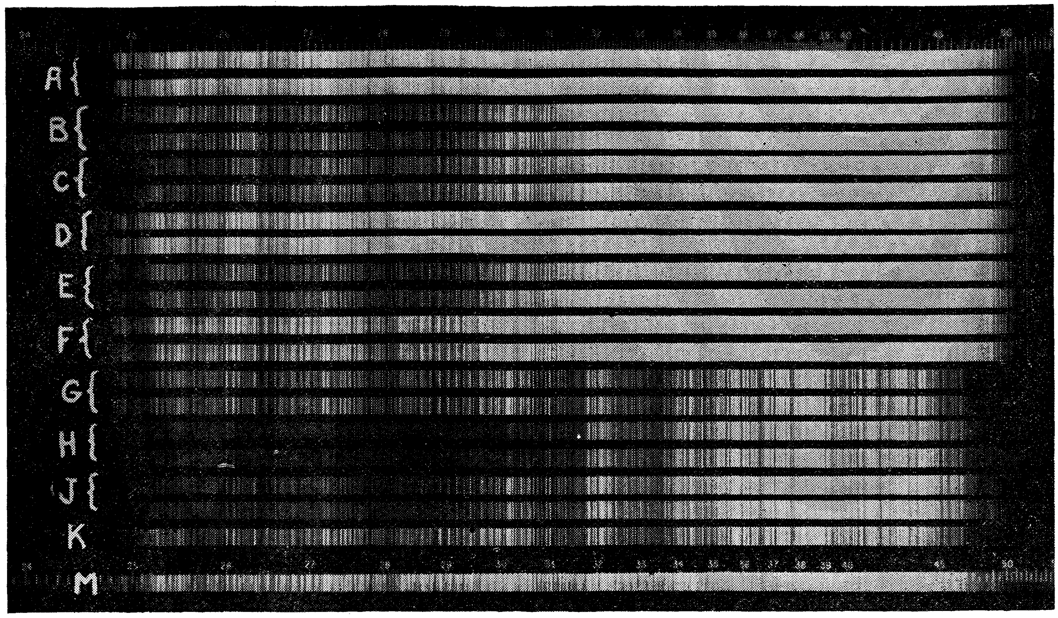

Plate 1.—Ultraviolet absorption spectra of cholestanone in various solvents: A, chloroform control; B, 0.02 *M* cholestanone in chloroform; C, 0.01 *M* cholestanone in chloroform; D, chloroform in 0.04 *M* glacial acetic acid; E, 0.02 *M* cholestanone in chloroform—0.04 *M* glacial acetic acid; F, 0.01 *M* cholestanone in chloroform—0.04 *M* glacial acetic acid; G, chloroform—0.04 *M* glacial acetic acid—0.01 *M* anhydrous hydrogen bromide; H, 0.02 *M* cholestanone in same solvent; J, 0.01 *M* cholestanone in same solvent; K, like J but with 2 × exposure; M, chloroform control.

induce any greater reaction.) This fact was further circumstantial, but not absolute, evidence that cholestenone enolizes during halogenation.

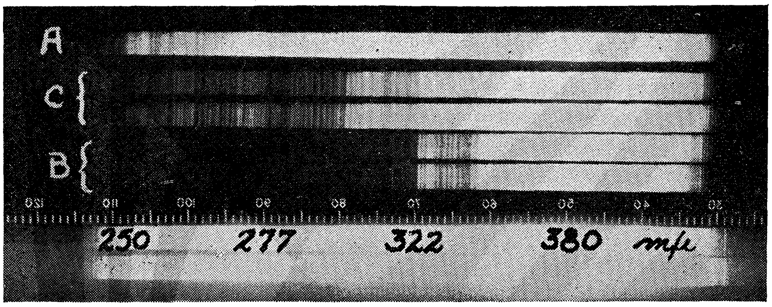

Plate 2.—Ultraviolet absorption spectra of enol ethyl ether of cholestanone: A, chloroform control; B, 0.02 *M* enol ethyl ether of cholestanone (based on the molecular weight of cholestanone) in chloroform; C, 0.01 *M* enol ethyl ether of cholestanone in chloroform.

The lack of appreciable reaction between cholestenoxime and iodine monobromide in glacial acetic acid–carbon tetrachloride indicated that, at least in that medium, the double bond of cholestenoxime was not "active." Inhoffen[15] has shown that the ethylene linkage of cholestenone resists bromination and exerts only a directive influence. It seemed to us that the simple statement, *the double bond is not active*, was not sufficient in the case of cholestenoxime. Accordingly, other factors were investigated. Our cholestenoxime was real, or normal, and was not the by-product described by Diels and Abderhalden,[16] for it melted at 151° and did not reduce Fehling's reagent. Air (oxygen) inhibition[17] was not involved (Table II). The nature of the reaction medium was found to affect the extent of reaction (at the end of the arbitrarily selected ninety minutes) of cholestanone, of cholestanoxime, of cholestenone, and of cholestenoxime. The effect was most marked in the case of the last substance and was paralleled by the effect upon the reactions of styryl phenyl ketone and *syn*-styryl phenyl ketoxime with iodine monobromide (Table II). There were five (at least) possible explanations for this marked difference: first, only the rates of reaction in the two media dif-

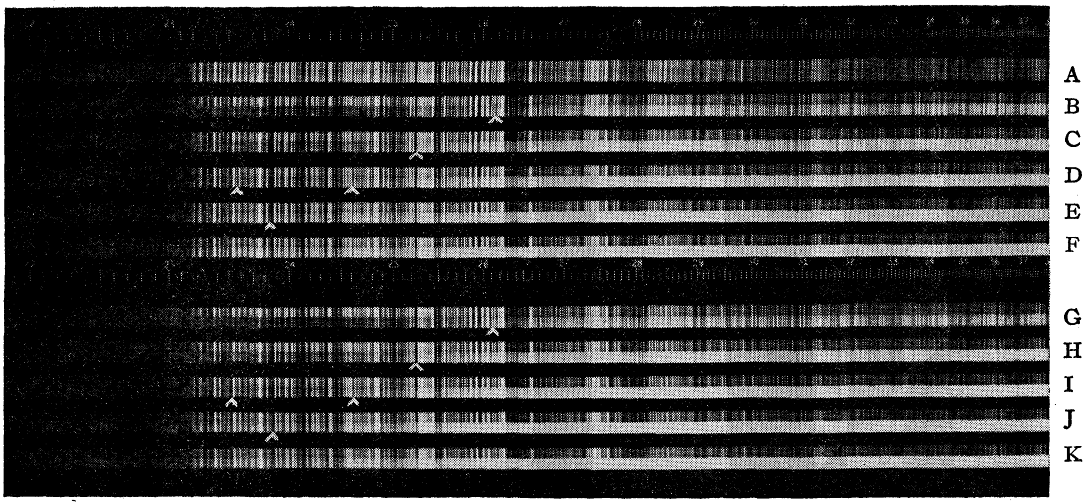

Plate 3.—Ultraviolet absorption spectra of "cholestenoxime" (after crystallization from glacial acetic acid) and of cholestenoxime: solvent, absolute alcohol; tube length 1 cm.; concn., 0.002% or 5 × 10^{-5} molar. Upper half of each spectrograph is that of the controlled or measured light; lower half is that of experimental substance. "Cholestenoxime:" A, control at $d = 0$; B, $d = 0.6$; C, $d = 1.0$; D, $d = 1.2$; E, $d = 1.40$; F, $d = 1.5$. Cholestenoxime: G, $d = 0.6$; H, $d = 1.0$; I, $d = 1.2$; J, $d = 1.4$; K, $d = 1.5$.

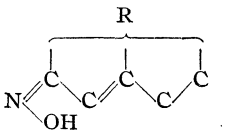
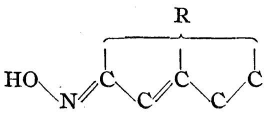
fered;[18] second, in the presence of glacial acetic acid, cholestenoxime might have rearranged to Diels and Abderhalden's by-product,[16] but this was not likely; third, glacial acetic acid might have added to the double bond—not at all probable; fourth, in glacial acetic–carbon tetrachloride, cholestenoxime might have undergone cyclization to produce an isoxazoline,[19,20] which cyclization would not occur in carbon tetrachloride alone; fifth, in glacial acetic–carbon tetrachloride, the stereoisomeric cholestenoxime A might have existed, whereas in carbon tetrachloride, B might have existed.



A



B

In A, due to the proximity of the two groups, coördination between the oximino hydroxyl and the ethylene linkage might have retarded halogenation. In B, the relations would not favor such action.

When cholestenoxime was dissolved in glacial acetic–carbon tetrachloride and recrystallized from that medium, crystals were obtained which differed in form from those of the original oxime and melted at 60°, resolidified around 90°, and remelted at 151.8° (m. p. of cholestenoxime). The new compound lost weight when it was heated to 90° or more, but this loss was too small for it to have been due to loss of solvent of crystallization. Since the nitrogen content of the compound was the same as that of cholestenoxime, the substance was not an addition product of acetic acid and cholestenoxime. It did not reduce Fehling's reagent, and so was not Diels and Abderhalden's[16] by-product. Its ultraviolet absorption spectrum appeared to be the same as that of the original cholestenoxime (Plate 3). Therefore, it was probably not an isoxazoline (the absorption spectrum of an isoxazoline should differ markedly from that of an α,β-unsaturated ketoxime). The apparent identity of the ultraviolet absorptions of the new compound and the cholestenoxime, together with the evident ease of converting the one into the other (after being heated to 120°, the new compound did not depress the melting point of cholestenoxime), indicated that the two were probably stereoisomeric ketoximes. When the new compound was allowed to react with iodine monobromide in carbon tetrachloride, it did so more slowly than did either the heat transformed substance or the original cholestenoxime (Table II). Unfortunately, in the only case on record where two stereoisomeric ketoximes have been halogenated, no statement concerning the relative speeds of the halogenations was made.[21] Moreover, the same product (*syn*-

dibromostyryl *p*-bromophenyl ketoxime) resulted from the action on both isomers.

Although increased initial concentrations of hydrogen bromide increased the initial rate of halogenation, these greater concentrations depressed the total amount of halogen consumed by cholestenone and by cholestanone (Fig. 2). Such phenomena, at least in other reactions,[22] are usually due to not less than two opposing forces. In these studies, the increased rates were due to the usual catalyzation of enolization. The repression of the halogenation observed at the longer reaction times (four or more hours) was due to the action of the hydrogen bromide but not to that of water, although water did repress the halogenation over its entire course[9] (Figs. 2 and 3). There appeared to be no differences between the general nature of the reactions at low and that at high hydrogen bromide concentrations: monomolecular at 2.5 and at 12.5 millimol. of hydrogen bromide per liter of reaction mixture. A clue as to the probable nature of the repressing action was seen in the fact that, at the lower hydrogen bromide concentration, only 45% of the reacted halogen was organically bound, whereas, at the higher concentration, 55% was so bound. According to Inhoffen,[15] the mechanism of the bromination of cholestenone is: 1, enolization; 2, bromine addition; 3, cleavage of halogen acid; 4, allylation; 5, enolization; 6, bromine addition; 7, halogen acid cleavage; 8, etc. Up to step 3, the product is an unstable dibromide. A stable dibromide results from the whole process. If the hydrogen bromide had partially inhibited step 3, the result would have been a diminished consumption of halogen but a larger proportion of that consumed would have been organically bound. On the other hand, direct addition of hydrogen bromide to the cholestenone in stage 1 could have produced the same observed relations. However, no halogenated steroid was obtained when, in the absence of iodine monobromide, cholestenone was treated with an extremely high concentration of hydrogen bromide.

It is well known that hydrogen bromide, iodine, and bromine interact to form complexes such as I_2Br^-, IBr_2^-, IBr_3, Br_3^-, and others. Of these I_2Br^- forms the least readily.[23,24] Transmission measurements (Fig. 4) showed that, in the medium we employed in our studies, a relatively low concentration of hydrogen bromide produced evidence of complex formation with iodine monobromide and with bromine, but that there was little evidence of iodine–Br^- complexes unless the hydrogen bromide concentration was relatively large. Furthermore, by other means, it was found that bromine was the active agent in iodine monobromide, a fact recently reported by Militzer also[25] (Fig. 5). Thus it was evident that an increase in the initial concentration of hydrogen bromide, while stimulating enolization, was also decreasing the concentration of the active halogenating agent. This latter action could have caused the diminished consumption of halogen.

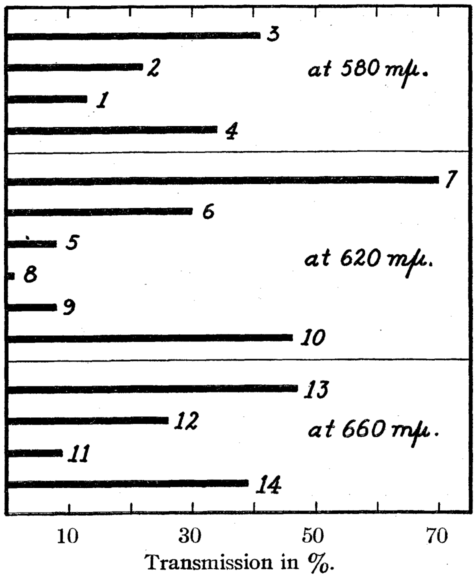

Fig. 4.—Light transmission through bromine, iodine, and iodine monobromide solutions with and without hydrogen bromide: solvent, glacial acetic acid; 1, 0.04 *N* bromine; 2, 0.03 *N* bromine; 3, 0.02 *N* bromine; 4, 0.04 *N* bromine–0.0232 *M* HBr; 5, 0.005 *N* iodine; 6, 0.0025 *N* iodine; 7, 0.0013 *N* iodine; 8, 0.01 *N* iodine–0.0058 *M* HBr; 9, 0.005 *N* iodine–0.0029 *M* HBr; 10, 0.005 *N* iodine–0.0261 *M* HBr; 11, 0.04 *M* iodine monobromide; 12, 0.02 *M* iodine monobromide; 13, 0.01 *M* iodine monobromide; 14, 0.04 *M* iodine monobromide–0.0232 *M* HBr.

Reaction Products

We did not isolate any of the products of the reaction of iodine monobromide with cholestenone, but, inasmuch as bromination resulted from the treatment with iodine monobromide, they, undoubtedly, would have been the same as those

described by Inhoffen[15] and by Butenandt, *et al.*[26,27]

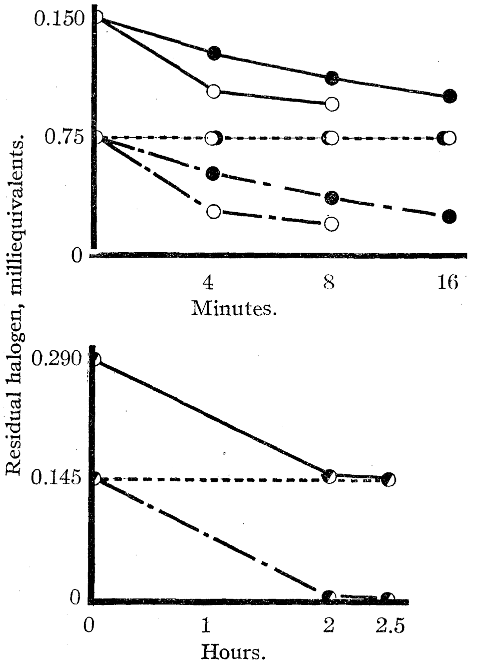

Fig. 5.—Residual total halogen, iodine, and bromine at certain periods in the reaction of iodine monobromide with cholestanone, with 2-bromocholestanone, and with cholestenone (solvent, carbon tetrachloride): ○, cholestanone; ●,2-monobromocholestanone; ◐,cholestenone; - - - - - - -, iodine; — - —, bromine; ———, total halogen.

From β-cholestanone–iodine monobromide reaction mixtures, three compounds were isolated: a monobromide, m. p. 171.5°; and two dibromides, m. p. 147 and 194°, respectively. The monobromide proved to be 2-monobromocholestanone.[7] Although the one dibromide (m. p. 147°) has not, as yet, been identified, it must contain at least one bromine atom at position 2 of the steroid structure, for it was a product of the reaction of iodine monobromide with 2-monobromocholestanone also.

The other dibromo compound (m. p. 194°) has been the subject of much debate. Ruzicka, *et al.*,[14] maintained that it was 2,2-dibromocholestanone, while Butenandt, *et al.*,[26] identified it as 2,4-dibromocholestanone. Lately, the latters' findings have been confirmed.[28] Although we firmly believe that the compound is 2,4-dibromocholestanone, we must admit that we were unable to get a diosphenol by treating it with potassium acetate.[26] On the other hand, the compound did yield a derivative with *o*-phenylenediamine, but this derivative was not the quinoxaline described by Ruzicka,[14] although it did have the same melting point (184°). It still contained halogen. Inasmuch as one bromine in the dibromo compound is known to be at position 2, and in view of the fact that the nitrogen and the halogen content of the *o*-phenylenediamine derivative were such as to indicate the presence of two atoms of each, it is believed that this *o*-phenylenediamine derivative was 3-*o*-aminoanilido-2,4-dibromocholestane, m. p. 184°, $C_{33}H_{50}N_2Br_2$, or

unreacted halogen, halogen acid, and organic halogen were determined as previously described.[1] The total halogen consumed and the organically bound halogen are plotted in Fig. 1, as equivalents of halogen per mole of sterol, against reaction time in hours.

The Order of the Reaction of Cholestenone, of Cholestanone, and of 2-Monobromocholestanone with Iodine Monobromide.—In determining the order of reaction, we employed the method described by Lewis[35] in which the time required for any fraction of the initial concentration (the initial concentrations of all reacting components are made equal) of a substance to react is compared with the time required for the same fraction to react when the initial concentration is different from the first. By this method, $n = 1 + \frac{\log t_2/t_1}{\log a_1/a_2}$, where n is the order of the reaction, t_1 and t_2 are the respective reaction times, and a_1 and a_2 are the respective initial concentrations. If a_1 is made equal to $2a_2$, then $n = 1 + \frac{\log t_2/t_1}{\log 2}$, or $2^{n-1} = t_2/t_1$.

In actually making the determinations, the steroid solution was measured into a 200 × 25 mm. test-tube and the iodine monobromide was measured from a microburet into a thin-walled glass bulb. The bulb was carefully slid into the tube and then quickly broken by means of a glass rod passed through the stopper used to close the tube. At the expiration of one or two or four or eight, etc., minutes, 3 cc. of 0.05 *M* potassium iodide was added and the unreacted halogen was titrated with standard sodium thiosulfate. As an example of the results, a sample of those for cholestanone are given in Table I. (The notation $C = 0.082$ *mM* means that there were that many milliequivalents of each reactant in the mixture.) The reaction was first order for each of the substances tested.

The Effect of Hydrogen Bromide upon the Reaction of Iodine Monobromide with Cholestenone, with Cholestanone, and with 2-Monobromocholestanone.—These reactions were run and the results obtained in a manner similar to that used for the study of the reaction of iodine monobromide with cholestenone and cholestanone, except that varying initial concentrations of hydrogen bromide were secured by adding definite quantities of aqueous 48% hydrogen bromide, or anhydrous hydrogen bromide in glacial acetic acid, to the iodine monobromide solutions. The results of the studies on cholestenone are plotted as equivalents of halogen consumed per mole of steroid (Figs. 2 and 3). The effect upon the reactions with cholestanone and 2-monobromocholestanone was the same except for slight differences in degree.

The Ultraviolet Absorption Spectrum of Cholestanone as Affected by Hydrogen Bromide.—Two hundredths molar (0.02 *M*) solutions of cholestanone in chloroform, in 0.04 *M* glacial acetic acid in chloroform, and in 0.04 *M* glacial acetic acid and 0.01 *M* anhydrous hydrogen bromide in chloroform were prepared. Diluting solutions like those above, but not containing the steroid, were also prepared. Using a 25-mm. absorption cell, photographs were made of the spectra of each solvent and of 0.02 and of 0.01 *M* cholestanone (Plate 1). Photographs were made of the spectra of chloroform and of 0.02 and 0.01 *M* enol ethyl ether of cholestanone in chloroform[36] (Plate 2). Unfortunately, the instrument used in the first part was not available for this second work.

The Reaction of Iodine Monobromide with Certain Substances as Affected by: (a) Nature of Solvent, (b) Air (Oxygen) and Hydrogen.—Cholestenone, cholestenoxime, cholestanone, cholestanoxime, benzalacetophenone, *syn*-styryl phenyl ketoxime, 3,5-diphenylisoxazol, 3,5-diphenylisoxazoline, and a product derived from cholestenoxime, by treatment with glacial acetic acid, were the materials used in these experiments. In each case, 0.033 mmol. of the substance was weighed accurately and transferred to a 200 × 32 mm. test-tube. Two cc. of carbon tetrachloride was added. The tube was closed with a two-holed rubber stopper carrying a glass stopcock and a glass tube closed by means of pinch-clamp on a rubber tube. The test-tube was evacuated and filled with hydrogen three times. Then 4 cc. of 0.04 *M* iodine monobromide in glacial acetic acid or in carbon tetrachloride was admitted. After ninety minutes, the unreacted halogen was titrated with standard thiosulfate. These experiments, but with the omission of the evacuation and filling with hydrogen, were repeated (see Table II).

The Effect of Glacial Acetic Acid upon Cholestenoxime.—Two hundred milligrams of cholestenoxime was dissolved in 12 cc. of carbon tetrachloride and 24 cc. of glacial acetic acid. After one hour, the solution was concentrated *in vacuo* at a low temperature. Upon chilling the concentrate, crystals separated which were filtered, washed with cold alcohol and cold water, and dried by suction. These crystals melted at 60°, resolidified at 90°, and then remelted at 151.8° (the latter is the melting point of cholestenoxime). When weighed samples were heated to 120° and then reweighed, they were found to have lost 1.85% of their weight. The calculated loss of weight for solvent of crystallization would have been: for 1 CH_3COOH, 13.0%; for 1 C_2H_5OH, 10.3%; for 1 H_2O, 4.2%; and for ½ H_2O, 2.2%.

Anal. Calcd. for $C_{27}H_{45}ON$ (oxime or isoxazoline): N, 3.5. Found: N, 3.5, 3.52.

The absorption spectrographs of 0.002% solutions of cholestenoxime and of the above product from glacial acetic acid displayed the same maximum at 238 mμ ($\log \epsilon = 4.4$) (Plate 3).

Two samples of crystals, described above (the one sample was heated to 120° and cooled, while the other was not so treated), were allowed to react with iodine monobromide. The untreated material consumed less halogen than did the other (Table II).

The Effect of Small and of Large Initial Hydrogen Bromide Concentrations upon the Order of the Reaction of Iodine Monobromide with Cholestenone.—These experiments were carried out in the same way as the others preceding these, except two different iodine monobromide solutions were used. The one was made 0.005 *M* and the other 0.025 *M*, with respect to hydrogen bromide. The reaction was first order in both solutions.

The Relation between the Halogen Combined with and the Total Consumed by Cholestenone Reacting with Iodine

---

[35] Lewis, "A System of Physical Chemistry," Vol. I, Longmans, Green and Company, New York, N. Y., 1918, pp. 397–8, B.

[36] The author wishes to thank Dr. G. H. Cartledge, of the University of Buffalo, Chemistry Department, for his aid and suggestions in the spectrophotometric work.

Monobromide Solutions Containing Small and Large Initial Amounts of Hydrogen Bromide.—The solutions of cholestenone and iodine monobromide were 0.035 *M*. The iodine monobromide solutions were made 0.005 and 0.025 *M*, with respect to hydrogen bromide. At the end of seven hours, total halogen consumed and organically bound halogen were determined as in the first "experimental" section. At seven hours, in the lower concentration of hydrogen bromide, cholestenone had reacted with 0.9 equivalent of halogen per mole of steroid. Of this 0.4 equivalent, or 45%, was organically bound. At the higher concentration of hydrogen bromide, the results were: 0.8 reacted and 0.46, or 55%, bound.

Attempt to Find Products of the Addition of Hydrogen Bromide to Cholestenone and to Cholestanone.—Solutions of 0.2 g. of cholestenone and of 0.2 g. of cholestanone in 20 cc. of carbon tetrachloride were prepared. Each solution was "loaded" with 2.5 cc. of 4.27 *N* anhydrous hydrogen bromide in glacial acetic acid. After four hours, the solutions were brought to dryness *in vacuo*. The residues from each were recrystallized from alcohol. No halogen containing products were found.

The Effect of Added Hydrogen Bromide upon Bromine, upon Iodine, and upon Iodine Monobromide in Glacial Acetic Acid.—Solutions of bromine, of iodine, and of iodine monobromide in glacial acetic acid were prepared. To portions of each, definite quantities of 4.27 *N* hydrogen bromide in glacial acetic acid were added. (For concentrations, please see the key to Fig. 4.) The transmission of light of various wave lengths was measured through 1 dm. of each solution. The results are shown as a barogram in Fig. 4. Only a few wave lengths are shown in order to avoid complexity.

Evidence that the Bromine of Iodine Monobromide, and Not the Iodine, nor Iodine Monobromide, Reacts with the Steroid in the Reactions under Investigation.—Into each of several large test-tubes were pipetted 2 cc. of 0.0167 molar solutions of steroid (cholestanone and 2-monobromocholestanone) in carbon tetrachloride and 2 cc. of 0.0373 *M* iodine monobromide in carbon tetrachloride. In the case of cholestenone, double the indicated volumes were used. At the end of definite intervals of time, total residual halogen was determined in the usual way, while the residual iodine was determined by means of a modification of a procedure for the determination of iodine and bromine in the presence of one another as described by Spitzer.[37] Our procedure was: to the reaction mixture, at the expiration of the reaction period selected, 3 cc. of 3% potassium bromide in water and 0.75 cc. of 5% sodium formate (made from redistilled formic acid) were added and the mixture was shaken moderately for three minutes. This treatment reduced the residual bromine but left the iodine untouched (glacial acetic acid must be absent). Then 3–5 cc. of 0.05 *M* potassium iodide was added and the iodine was titrated in the usual manner. Residual bromine was taken as the difference between the total residual halogen and the residual iodine. The results are plotted as milliequivalents of residual halogen against the time of reaction (Fig. 5). Iodine did not react.

The Isolation of the Products of the Reaction of Iodine Monobromide with Cholestanone.—A solution of 4.95 g. of cholestanone in 660 cc. of carbon tetrachloride was mixed with 1320 cc. of 0.04 *M* iodine monobromide in glacial acetic acid. A 6-cc. aliquot of this mixture required 4.37 cc. of 0.0737 *N* thiosulfate for the complete reduction of the halogen. When the titer had fallen to and remained constant at 2.95 cc. (2.7 equivalents of consumed halogen per mole of steroid), water, potassium iodide, and thiosulfate were added to remove the excess halogen. The carbon tetrachloride layer was washed free of acid with plenty of water and sodium bicarbonate. It was then dried and distilled *in vacuo*. The residue was leached with warm alcohol, from which, upon being cooled, crystals separated. Fractionation of these, with methyl alcohol–acetone, yielded three products: A, 3.60 g., m. p. 171.5°; B, 0.08 g., m. p. 147°; and C, 0.15 g., m. p. 194°.

Determination of the halogen content of each of these products was effected by means of the Willard–Thompson method.[38]

Anal. Subst. A. Calcd. for $C_{27}H_{45}OBr$: Br, 17.2. Found: Br, 17.9. Subst. B. Calcd. for $C_{27}H_{44}OBr_2$: Br, 29.4. Found: Br, 30.1. Subst. C. Calcd. for $C_{27}H_{44}OBr_2$: Br, 29.4. Found: Br, 30.4.

A is, therefore, monobromo, and B and C are dibromo compounds. It is noteworthy that a small amount of B and a larger amount of C were obtained when A reacted with iodine monobromide under the same conditions that produced A, B, and C from cholestanone.

The Action of Potassium Acetate upon Compound A (m. p. 171.5°).—Two-tenths gram of A and 19 cc. of 21% fused potassium acetate were mixed and heated at 200° for five hours. The mixture was then diluted with water and extracted several times with small portions of ether. The combined extracts were washed free of acid, dried, and distilled *in vacuo*. The residue, recrystallized from dilute alcohol, yielded a small amount of fine plates which melted at 111°. This melting point corresponds to that given for $\Delta^{1,2}$-cholestenone which is obtainable by the action of potassium acetate upon 2-monobromocholestanone.[7]

The Action of Dry Pyridine upon Compound A (m. p. 171.5°).—Two-tenths gram of A was dissolved in 8 cc. of dry pyridine and refluxed for fifteen hours. When the solution had cooled, 30 cc. of ether was added. The pyridine was washed out with water. The ether was dried and then distilled *in vacuo*. The residue, when recrystallized, proved to be the original starting material. The bromine of A was, therefore, not in position 4 or 5, but rather in position 1 or 2. This is further evidence that A is 2-monobromocholestanone.

The Action of Fused Potassium Acetate upon Compound B (m. p. 147°).—One-tenth gram of compound B was dissolved in 3 cc. of benzene and 7 cc. of absolute alcohol. Powdered fused potassium acetate was added and the mixture was allowed to stand at room temperature for forty-eight hours. Ether and water were then added. The ether layer was washed, dried, and distilled *in vacuo*. The residue crystallized from acetone as fine needles (m. p. 119°). The crystals contained no halogen. For want of material, no further work was done on compound B.

The Action of Fused Potassium Acetate and of Dry Pyridine upon Compound C (m. p. 194°).—Although compound C was treated with fused potassium acetate and

[38] Willard and Thompson, THIS JOURNAL, **52**, 1893 (1930).

with dry pyridine exactly as was A, no definitely crystalline product was obtained. Nor was a definitely pure crystalline product obtained when 650 mg. of compound C was refluxed with 60 cc. of butyl alcohol containing 3 g. of potassium acetate. The impure products, in each case, did not give a typical positive diosphenol reaction with ferric chloride. It did give a dirty brownish-red color, which, possibly, could be called positive.[26]

The Action of *o*-Phenylenediamine upon Compound C (m. p. 194°).—A solution of 0.5 g. of C and 0.2 g. of *o*-phenylenediamine in 170 cc. absolute alcohol was refluxed for five hours. The alcohol was then carefully distilled at low temperature *in vacuo*. The residue was dissolved in ether and the excess phenylenediamine was extracted with dilute hydrochloric acid. The ether, after being washed thoroughly, was dried and distilled *in vacuo*. The residue, dissolved in alcohol, yielded crystals which melted at 184°. This was the same as the melting point given for the compound said to be the quinoxaline derived from the purported 2,2-dibromocholestanone.[14] But our derivative still contained halogen.

Anal. Calcd. for $C_{33}H_{50}N_2Br_2$: N, 4.41; Br, 25.2. Found: N, 4.34; Br, 25.6.

Summary

1. The reactions of cholestenone and of cholestanone with iodine monobromide possess autocatalytic characteristics.

2. The reaction of iodine monobromide with cholestenone, with cholestanone, and with 2-monobromocholestanone is first order.

3. The oximes of cholestenone and cholestanone do not react readily with iodine monobromide in glacial acetic acid.

4. As in the case of the action of bromine upon cholestenone, evidence indicates that enolization is the first step in the reaction of cholestenone with iodine monobromide.

5. Hydrogen bromide speeds the action of iodine monobromide upon cholestenone, cholestanone, and 2-monobromocholestanone, but it has no detectable influence on the reaction with the oxime of either cholestenone or cholestanone.

6. The double bond in cholestenoxime is resistant to halogenation in a glacial acetic acid containing medium.

7. There is some evidence that cholestenoxime undergoes a rearrangement in glacial acetic acid.

8. In concentrations of hydrogen bromide greater than a small amount, the total halogen consumed by cholestenone, by cholestanone, and by 2-monobromocholestanone is decreased, but the proportion of organically bound halogen is increased.

9. The inhibiting influence of the larger concentrations of hydrogen bromide may be due to its effect on intermediate steps in the reactions, or to its formation of complexes with bromine or with iodine monobromide.

10. Bromine is the active ingredient of iodine monobromide.

11. 2-Monobromocholestanone, m. p. 171.5°, is a product of the reaction of cholestanone with iodine momobromide.

12. An unidentified dibromo derivative of cholestanone was isolated (m. p. 147°).

13. Further evidence that the dibromocholestanone, melting at 194°, is 2,4-dibromocholestanone, and not 2,2-dibromocholestanone, is given.

An Electron Diffraction Examination of Some Linear High Polymers

BY K. H. STORKS

Because of the general structural similarities between synthetic linear polyesters and many natural fibers, fundamental studies of the simpler compounds are of obvious importance. Several members of a series of these esters have been made the subject of X-ray study by Fuller and Erickson.[1] It is possible to prepare many of these in the form of films suitable for examination by electron diffraction. The experiments to be described here have two purposes: to demonstrate the utility of the electron diffraction method for studies of the structure of highly polymerized materials, and to discover the behavior of macromolecules in extremely thin layers. The methods are shown to be equally applicable to the natural polymer gutta-percha.

The fact that these materials can be cold drawn to a considerable extension without breakage is well known,[2] a high degree of orientation

---

[2] W. H. Carothers and J. W. Hill, *ibid.*, **54**, 1579 (1932).

being produced in the samples by this "stretching." Electron diffraction data for stretched polymers are directly comparable with many of the available X-ray data, and such a comparison will serve to demonstrate the utility of the method. In order to make this comparison polyethylene succinate, polyethylene adipate, polyethylene sebacate and two specimens of unvulcanized gutta-percha[3] (containing a small amount of antioxidant) have been examined in the stretched condition.

The second aim of this paper is accomplished by examinations of the conditions existing in unstretched films. Unstretched films of polyethylene sebacate and the two grades of gutta-percha have been studied.

Experimental

The transmission method is used exclusively in the experiments to be described here, the materials to be examined being prepared in the form of films 10^{-5} cm. or less in thickness. A film to be examined is placed in the path of a well-defined beam of electrons of homogeneous velocity and the resulting diffraction pattern recorded on a photographic plate. The camera employed has been described by Germer.[4]

Preparation of Stretched Films.—Specimens for examination in the stretched condition are prepared from relatively thick preliminary films. Such a preliminary film, approximately 10^{-4} cm. thick, is deposited on a conditioned microscope slide[5] by evaporation of a solution (approximately 2%) of the polymer in chloroform. If the slide is held at an angle of approximately 30° to the horizontal a long narrow strip of film with one end relatively thick is deposited when a drop of this solution is allowed to flow freely along the length of the slide.

The preliminary film prepared in this way on a glass slide may be stretched by one or both of two different methods, the choice of method being determined by ability of the film to resist change on contact with water. Films of polyethylene adipate and polyethylene sebacate are transferred from the slide to a water surface[6] and thence to a pair of jaws that can be separated by a screw. When all trapped water has evaporated the film is stretched by turning the screw. The stretched film is refloated and transferred to a slit type foil holder.[7] The orientation of the stretching direction is carefully noted. After all water has evaporated the film is found to be mounted firmly but without tension.

Films of stretched polymers also can be prepared and mounted without contact with liquid water. After the preliminary film is deposited, the thick end is loosened from the glass with a razor blade and the free end wound up on a round jeweler's file. The film can now be separated from the glass and stretched in the same operation. Best results are accomplished if the film leaves the slide at an angle of approximately 30° and if the stretching is continuous and rather rapid. If the stretched film is held under tension and laid across the foil holder the natural tackiness of the material will hold it in place and maintain the tension. This technique is found to be necessary when preparing polyethylene succinate films, and to be the simplest method of preparing stretched specimens of gutta-percha.

A double purpose is accomplished by each method of stretching; the films are thinned sufficiently for examination, and a high degree of fibrous orientation is produced.

Preparation of Unstretched Films.—If the pattern of an unstretched specimen is to be obtained, the proper thickness for examination must be deposited upon the glass slide. The thinner film is deposited from a more dilute solution (approximately 0.4%). These chloroform solutions do not spread well on monolayers of grease and mechanical spreading is found to be necessary. An efficient mechanical spreader has been made by clamping a new and freshly cleaned razor blade, edge down, above and parallel to a smooth level surface. A microscope slide, beneath which lies a thin sheet of paper, is placed under the blade which is lowered to a position of uniform and light contact. After removal of the paper spacer and after conditioning the slide, the latter is replaced and a drop of solution, in position near one end, is uniformly distributed over the conditioned surface by a single translation of the slide under the blade. After evaporation of the solvent the film is transferred to a water surface and finally to a foil holder. No indications have been found that a film is stretched by this manipulation.

Film Thickness Measurements.—Since knowledge of film thickness is of importance in interpretation of some of the following results, the method of obtaining this value will be indicated. A film of the polymer is prepared and mounted, from water, on a clean polished chromium surface. A known number of layers of barium stearate are now added to the polymer film by the Blodgett technique.[8] The interference color of the composite film is compared with colors of known numbers of barium stearate layers on a reference slide, and the barium stearate equivalent thickness is easily and accurately determined.

Extra Precautions.—All films are prepared at room temperature and, in most cases, under normal illumination from tungsten filament lamps. The early experiments upon the "Br-4" grade of gutta-percha have been repeated with the "Pure White" product[9] under low intensity

---

(3) These specimens were the "Br-4" and the "Pure White" grades of gutta-percha from "The Netherlands East Indies Government Rubber and Gutta-Percha Plantations, Buitenzorg, Java."

(4) L. H. Germer, *Rev. Sci. Instruments*, **6**, 138 (1935).

(5) A conditioned microscope slide is a slide coated with a monomolecular layer of grease. This layer is of considerable importance if thin films are to be easily separated from glass. The monolayer can be deposited from clean dry cheesecloth if a freshly cleaned slide is vigorously rubbed with this material.

(6) The transfer, microscope slide to water surface, is easily accomplished if the slide is held, film side up, at an angle of approximately 15° to the horizontal and lowered slowly through a clean water surface. The film is separated from the glass by this procedure and is left floating. The floating film is transferred to a holder by raising the holder under the film. The film is mounted more smoothly if the holder is uniformly wet by water.

(9) This material had been removed from the sealed shipping container and stored in a refrigerator away from light for about six months. The stock solution was made up from material from the inside of a massive block.

illumination from a 10-watt Mazda red lamp. Rate of oxidation should be decreased considerably by this precaution. In addition, the stretching properties of a preliminary film have always been tested immediately prior to preparation of a film for examination in the unstretched condition; satisfactory stretching characteristics are taken as sufficient evidence that oxidation in solution has not been serious.

Experimental Results

Data from Stretched Polymers.—Figures 1–5[10] are electron diffraction patterns from stretched samples of polyethylene succinate, polyethylene adipate, polyethylene sebacate, gutta-percha "Br-4" and gutta-percha "Pure White." The vertical axis of each of these patterns is parallel to the direction along which the material was stretched. In each case the primary beam was normal to the foil surface. No additional reflections are found when a foil is rotated around the stretching direction.

Table I contains representative data from patterns of this sort. Columns headed (D) contain the diametral separation of symmetrical spots in mm.; estimated intensities of these reflections are given in the columns headed (Int.), the higher numbers being assigned to the stronger reflections; the small letter (d) indicates interplanar spacings, in one column X-ray values, and in the other, values calculated in these experiments from measured separations (D) by means of the formula

$$d = 2L\lambda/D \qquad (1)$$

(In Eq. (1) λ is the electron wave length and L the plate specimen separation; the constant $L\lambda$ is determined by calibration against a foil of metallic silver.) The X-ray values of (d) are those given by Fuller and Erickson[1] and the customary designation of reflections, which they use, are given in the first columns.

[a] The plates for the two grades of gutta-percha are identical and only data from the "Pure White" grade are listed.

Values of the fiber periods obtained from the data of Table I are written down in the second column of Table II, together with the X-ray values of Fuller and Erickson in the third column.

TABLE II

	Fiber periods, Å. (Storks)	(Fuller and Erickson)
Polyethylene succinate	8.42	8.32
Polyethylene adipate	11.91	11.71
Polyethylene sebacate	16.92	16.67
Gutta-percha (β modification)	9.46	9.54

Data from Unstretched Polyethylene Sebacate.—Electron diffraction patterns from an unstretched specimen of polyethylene sebacate are reproduced in Figs. 6 and 7. The former was obtained with the electron beam incident normally upon the film, and the latter at 45° incidence, the film having been rotated about a horizontal axis as the pattern is reproduced here. The film which produced these patterns had a thickness of 200 ± 25 Å.

In order to describe data obtained from Fig. 7, Cartesian coördinates have been chosen on the photographic plate, with their origin at the primary beam position and the x-axis parallel to the axis about which the film was rotated when Fig. 7 was produced. These coördinates, and other useful quantities, are designated on Fig. 10. In this figure P represents the photographic plate and S the specimen film. O′O is the primary beam direction, O′X′ the axis of rotation in the specimen (parallel to OX), and O′N the normal to the film surface. The angle α defines the rotation of the specimen from the position normal to the beam, and the angles ϕ_1 and ϕ_2 the angular limits measured from the x-axis of a particular diffraction arc AB recorded on the photographic plate.

Numerical data obtained from the patterns of Figs. 6 and 7 are given in Table III. Except for the angles ϕ_1 and ϕ_2 which refer to arcs in Fig. 7, the quantities described in this table are the same as those of Table I. (X-Ray values of d have not been tabulated again.) For those arcs in Fig. 7 which are continuous across the x-axis no values of ϕ_1 can be recorded, and for arcs across the y-axis no values of ϕ_2.

Data from Unstretched Gutta-percha.—Patterns from unstretched gutta-percha, at normal and at 45° incidence, are reproduced in Figs. 8 and 9; data obtained from these patterns are given in Table IV. The angles ϕ referring to the pattern of Fig. 9 are values of $(\phi_1 + \phi_2)/2$.

[a] These reflections arise from an impurity that is occasionally found associated with organic films. Reflections which are designated without subscripts are assigned to layer lines only. Two designations are given to the same reflection if the spacing is too close for resolution.

These diffraction patterns were obtained from a film of "Pure White" gutta-percha about 200° Å. thick. Patterns also have been obtained from the "Br-4" grade of gutta-percha. These are found to be similar to those of Figs. 8 and 9 except for greater "spottiness" of diffraction features, indicating that the crystallites are considerably larger in films made from the "Br-4" grade than in films made from the "Pure White" grade.

[a] Reflection from the alpha modification.

Discussion of Results

Stretched Polymers.—In the introduction it was stated that the experiments to be described in this paper have two purposes, to demonstrate the utility of the electron diffraction method in the field of polymeric compounds, and to obtain new information regarding the structure of macromolecules in extremely thin layers—which cannot be studied by X-rays. The first of these purposes has been accomplished by the direct comparisons of X-ray and electron diffraction results upon stretched polymers. These comparisons are given in Table I and Table II. A few additional remarks regarding these data seem to be necessary, before passing on to the second part of the paper, which is concerned with the data of Table III and Table IV.

It has been pointed out that no additional reflections are found when a stretched foil is rotated around the stretching direction. This fact proves that individual crystallites are oriented with all degrees of rotation around this direction. Crystallites of small cross sectional areas in the planes normal to their fiber directions seem to be required to account for random rotation in foils as thin as those of these experiments, (400–1000 Å.).

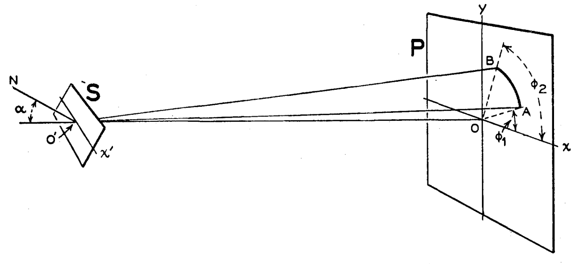

Fig. 10.

Fiber period reflections have not been observed in X-ray experiments upon polyethylene adipate or polyethylene sebacate, values of the fiber period spacings having been determined indirectly.[1] Such reflections are, however, shown clearly in Figs. 2 and 3[11] and are tabulated in Table I. The orders which appear are the 9th, 10th and 11th for the former and the 13th, 14th, 15th and 16th for the latter polymer. The occurrence of these particular high orders only seems rather curious. An approximate calculation of relative intensities has been carried out in order to understand why only these high orders are found. Assuming a macromolecular type of lattice[12,13] and macromolecules that are straight for distances greater than the length of a single chemical repeating unit, it is not difficult to show that, on account of the comparable sizes of the C–C and the C–O spacings, the geometrical structure factor for fiber period reflections has appreciable magnitude at a few orders only. These orders are multiples of the nth, and one or two successive orders above and below, where n represents the number of chain atoms in a chemical repeating unit. To obtain this result one assumes that any lengthwise displacement of neighboring chains is an integral multiple of the fundamental atomic spacing along the axis of the chain. Since there are 10 chain atoms in the repeating unit of polyethylene adipate and 14 in that of polyethylene sebacate, the observation of only the 9th, 10th and 11th orders of the fiber period reflection from the former and only the 13th, 14th, 15th and 16th orders from the latter seems to be adequately accounted for.

Unstretched Gutta-percha.—From the continuous but spotty rings of Fig. 8 one concludes that the individual crystals in a thin unstretched film of gutta-percha are relatively large and randomly oriented about the normal to the film surface. Inspection of Figs. 8 and 9 reveals at once, however, that these crystals are highly oriented. The nature of the orientation is immediately clear from the fact that the first four columns of Table IV (obtained from Fig. 8) contain only equatorial reflections ($hk0$); with the exception of five described by Fuller[13a] as very weak (VW), all equatorial reflections observed by him are obtained in the present studies and written down in the first four columns of Table IV. Thus in the unstretched film of gutta-percha the crystallites are oriented with their fiber axes approximately normal to the film surface. Furthermore, it seems possible to conclude that no appreciable number of crystallites have fiber axis directions that deviate by more than 15° from parallelism with this normal. Greater deviation would allow the occurrence of the layer line reflection for which $d = 1.25$ Å.

Figure 9 and the data of the last five columns of Table IV confirm these conclusions and enable one to calculate the precision of orientation of the fiber axis directions of the crystallites. From the orientation just described it is evident that for $\alpha \neq 0$ the equatorial reflections must occur as arcs across the x-axis of the plate, and some layer line reflections will in general appear as arcs on displaced layer lines. The first twelve reflections indicated on the right-hand side of Table IV, which are equatorial reflections occurring along the horizontal center line in Fig. 9, are in excellent agreement with the reflections observed at normal incidence.

The extreme half angle width of equatorial reflections in Fig. 9 is measured to be about $\Phi_A = 8°$. This is related to the largest angle (δ') between the normal to the specimen surface and an appreciable number of fiber axis directions by the equation

$$\sin \delta' = \sin \alpha \sin \Phi_A \qquad (2)$$

For $\alpha = 45°$ (Fig. 9) this yields $\delta' = 6°$ as a quantitative measure of the precision of orientation in the unstretched "Pure White" gutta-percha foil. Corresponding diffraction patterns and measurements upon an unstretched film of "Br-4"

grade gutta-percha have yielded $\delta' = 4°$ for this particular foil. It is clear that in general the orientation in thin unstretched films of gutta-percha is nearly perfect.

As a further check it is interesting to compare calculated with observed angular positions of the layer line reflections which appear in Fig. 9; this comparison is given in the last two columns of Table IV. The quantity ϕ represents here the mean value of ϕ_1 and ϕ_2 (see Fig. 10). Measured values of ϕ are taken directly from Fig. 9, and calculated values are obtained from the relation

$$\sin \phi \approx \cos \Theta/\sin \alpha, \quad (3)$$

in which Θ is the inclination of the crystallographic plane giving rise to the particular layer line reflection to the plane normal to the fiber axis. Values of Θ, necessary to calculate ϕ, have been obtained by direct angular measurement upon a diffraction pattern from a stretched film, Fig. 5. It is obvious that only those fiber period reflections can occur for which $(\Theta + \delta') > \alpha$, and that reflections for which α lies between $(\Theta + \delta')$ and $(\Theta - \delta')$ will lie across the vertical axis in Fig. 9.

In Table IV is listed a single reflection attributed to the alpha crystallographic modification, suggesting that the foil is a mixture of two polymorphic forms of gutta-percha. One concludes that the film is a mixture of the beta modification and a very small quantity of the alpha modification. No reflections attributable to the alpha modification have been observed in experiments on stretched specimens.

It is surprising that most of the crystallites are oriented with their fiber axis directions normal to the plane of a film the thickness of which is much less than the total length of a macromolecule. There is considerable evidence that the material has not oxidized sufficiently to cause serious depolymerization for some time after all but possible traces of "absorbed" solvent have evaporated. The possibility of crystallite rearrangement in the solid film after subsequent oxidation has shortened the chains appears to be doubtful. It therefore seems necessary that the macromolecular configuration of gutta-percha is not generally linear in these thin films. The gutta-percha macromolecule may possibly fold by a mechanism of rotation around single bonds. The chemical repeating unit of this polymer is short and relatively few folds per macromolecule are required in a film 200° Å. thick. It is conceivable that such infrequent folding would not affect the crystal structure.

Unstretched Polyethylene Sebacate.—From the continuous rings of Fig. 6 one concludes that the individual crystals in a thin unstretched film of polyethylene sebacate are relatively small and, as in the case of unstretched gutta-percha films, are randomly oriented about the normal to the film surface. The marked difference between Figs. 7 and 9 suggests at once that the type of orientation in the unstretched polyethylene sebacate film is, however, entirely different from that in gutta-percha. The nature of the orientation in thin unstretched films of polyethylene sebacate is not established so readily as is that in gutta-percha films. The difficulty arises from the low intensity of many of the reflections, and from the fact that in many instances layer line and equatorial reflections are found to correspond to nearly equal interplanar spacings.

The absence of the A_6 reflection in the data of Table III rules out the possibility of an orientation like that in gutta-percha. An indication of a possible orientation is found in the weak reflections corresponding to the spacings 1.29 and 1.19 Å. From the polyethylene sebacate data of Table I we find that the first of these could be a weak equatorial reflection, a weak seventh layer line reflection or the strong fiber period reflection ($XIII_0$); the second must be one or both of the strong reflections (XIV_0) or (XIV). The stronger reflection for which $d = 1.10$ could possibly be a weak seventh layer line reflection or the medium reflections (XV_0) and/or (XV). The occurrence of these reflections can be explained if the fiber axis directions lie approximately in the plane of the foil. If this is the case, the evidence of missing and abnormally weak reflections does not allow the crystallites of the foil to have all degrees of rotation around the fiber axis directions.

It is possible that confirmation of these ideas can be found in the pattern from the same foil with the primary beam incident at 45° from the surface normal. (A pattern at near grazing incidence could be interpreted more easily, but it is not possible to obtain such patterns from foils mounted for study by the transmission method.) The 45° incidence pattern is shown in Fig. 7, and numerical data obtained from it are recorded in the last six columns of Table III. Several facts are immediately apparent. All reflections which are observed with normal intensity in the normal incidence pattern occur as continuous arcs across the x-axis of the plate while those of abnormally low intensity have strengthened, on the average, to normal with extremely low intensity across x. Many reflections not observed in Fig. 6 are found as arcs lying in a single quadrant of the pattern. These observations confirm the existence of crystallite orientation and give assurance that the foil is actually scattering as a three dimensional grating. It is still impossible to identify positively all reflections and hence to establish the orientation unequivocally; but, with the designations assigned in column five of Table III, the results are in good agreement if the fiber axes of the crystallites lie approximately in the plane of the foil with a small degree of rotational freedom around the directions of these axes. Such orientation is probably due in part to the presence of carbonyl groups along the chain. The minimum value for the angle between chain axis directions and foil surface normal is estimated, from the angular positions of the arcs listed in Table III, to be of the order of 79°. The freedom of crystallite rotation around the fiber axis directions is estimated to be ±10°.

The angular limits of the arc positions are given by the equations

$$\sin \phi_1 = \frac{\sin \Theta \cos \delta \cos A - \cos \Theta \sin \delta}{\sin \alpha} \qquad (4)$$

$$\sin \phi_2 = \frac{\sin \Theta \cos \delta \cos B + \cos \Theta \sin \delta}{\sin \alpha} \qquad (5)$$

In these, $(90 - \delta)$ = the minimum angle between fiber axis directions and the specimen surface normal, $A = (\psi + \gamma_1)$, $B = (\psi - \gamma_1)$ or *vice versa*, while Θ and α have their former significance. The angle δ can be determined from the half angle width (Φ_F) of fiber period reflections and the equation

$$\sin \delta = \sin \alpha \sin \Phi_F \qquad (6)$$

The angle ψ is most clearly visualized by consideration of an average crystallite having the average rotation around the fiber axis and lying with this axis in the plane determined by the specimen surface normal and the rotation axis. ψ is the angle between this plane and the plane containing the fiber axis direction and the reciprocal lattice point corresponding to any reflection. γ_1 is the limit of crystallite rotation around the fiber axis directions, and is measured from the mean position.

A value of $\sin \phi_2 > 1$ indicates that the rotation of the foil around the surface normal cannot bring all planes of the particular set under consideration into diffracting positions. This condition produces an arc across the y-axis of the plate. Such an arc shows a relative intensity somewhat below normal.

A weakness of this interpretation lies in the low relative intensity of the several high order reflections previously mentioned as well as in the uncertainty of identification of a number of general reflections. Dr. Fuller has suggested that the perfection of chain arrangement may be greatly increased by the stretching process; if this is the case, a difference in intensity of fiber period reflections in patterns of stretched and unstretched material is understandable.

The electron diffraction method should supply an easy means of studying conditions in films of this and similar materials from the oriented unstretched state through a series of controlled degrees of stretching. Diffraction patterns obtained from the same film after varying amounts of stretching should not only definitely establish the orientation in the unstretched condition, but should supply considerable information concerning the mechanism of stretching. It is proposed to conduct such experiments in the near future.

It seems of further interest to consider briefly an estimate of the angle δ made by assuming thin rod-like crystallites of a length comparable to the average length of the polyester chain. The sample of polyethylene sebacate used in these experiments has an average chain length of approximately 1400 Å. If rod-like crystallites of this length are arranged at random between two surfaces 200 Å. apart, $(90 - \delta)$ is found to be of the order of 82°. The agreement of this value with the value of 79° previously estimated from the experiments suggests that the polyethylene sebacate chain configuration is generally linear.

Additional experiments with films of various thicknesses indicate that both δ and γ_1 increase as the film thickness increases. Combining this observation with the observation of Fuller and Erickson[1] that thick unstretched polyethylene sebacate specimens give complete Debye–Scherrer ring patterns, it seems likely that films of such esters will show a preferred orientation until the film thickness exceeds the average chain length. It is proposed that a systematic study of orientation, film thickness, and molecular weight distribution may provide interesting and useful information concerning the molecular structure and film behavior of various polymeric type compounds.

Acknowledgments.—The author wishes to make the following acknowledgments: to Dr. C. S. Fuller for the samples of synthetic polyesters and for many helpful suggestions and criticisms, to Dr. L. H. Germer for many suggestions concerning the preparation of this paper, to Mr. F. S. Malm for the samples of gutta-percha, and to Mr. A. J. Parsons for valuable assistance with the experimental work.

Summary

1. Electron diffraction experiments have been carried out upon very thin films of several synthetic polyesters and natural gutta-percha.

2. *Stretched films* show diffraction patterns characteristic of sharply oriented crystals. Measurements upon these patterns are in excellent agreement with existing X-ray data upon the same materials. The utility of the electron diffraction method for structural studies of polymerized substances is thus demonstrated.

3. *Unstretched films of gutta-percha* are found to be composed of relatively large crystallites which are precisely oriented with their fiber axis directions normal to the film surface. It is presumed that the macromolecules are folded back and forth upon themselves in such a way that adjacent sections remain parallel.

4. *Unstretched films of polyethylene sebacate* consist of relatively small crystals which are believed to be oriented with their fiber axis directions approximately in the plane of the film, but with limited rotation around the fiber axis directions.

NEW YORK, N. Y. RECEIVED MAY 4, 1938

Note on a Corresponding-States Equation of Practical Interest for General Physicochemical Computations

BY FREDERICK G. KEYES

During the last few years the desire to compute equilibrium physicochemical quantities under conditions removed from the range of validity of the ideal gas laws has led to a renewed interest in the search for an empirical relation of the corresponding-states character.

One form of this effort has been to test the relation of the fugacity–pressure ratio, γ, to the pressure–critical pressure ratio, π, using the existing p–v–T data for gases, to form a graph of constant temperature–critical temperature, θ, lines. The iso-reduced temperature lines of necessity start from $\gamma = 1$ on the vertical axis[1] and are approximately linear in π for θ large, but become increasingly convex relative to the horizontal, or π, axis for θ small. A chart of this sort for hydrocarbons was prepared and its uses discussed by J. D. Cope, W. K. Lewis and H. C. Weber; W. K. Lewis and C. D. Luke and others.[2] Recently[3] R. H. Newton brought together the data for twenty-four substances and found that within a range of 4%, with some exceptions, the data for the substances in the form $(\gamma)_\theta$ *versus* π fell together. A ficticious critical temperature and pressure, however, had to be selected for H_2 and He to bring the data for these substances into line with other substances.

The existence of an exact, universal correspondence in terms of a relation between θ, π, and φ has, however, good reason to be doubted. The cases of H_2 and He at higher temperatures are well-known examples of how badly the concept works out at ordinary temperatures when the form of the equation of state is based on the van der Waals concept of the molecular field.[4] There does exist, however, a range of temperature for all substances, perhaps, where the van der Waals concept leads to a fair approximation in representing the behavior of individual gases.

The van der Waals concept is equivalent to the assumption that molecules may be represented in their physical interaction by the existence of a positive potential which becomes infinite on contact of the supposedly rigid spherical molecules of invariable diameter σ, but zero for all distances of separation of molecular centers greater than σ when a spherically symmetrical negative potential appears. The latter may be represented in the simplest cases by the expression cr^{-m} where m is an integer not smaller than 4. If w represents the potential we may write for the van der Waals field the following relation

$$w = \begin{pmatrix} +\ \infty;\ r = \sigma \\ 0;\ r > \sigma \end{pmatrix} - cr^{-m}$$

The equation of state for low pressures may then be shown to be, for pure gases

$$p = \frac{RT}{v - B_0}$$

where

$$B_0 = \beta - A/RT \sum_{\nu=0}^{\nu=\infty} \frac{(m-3)^{\nu+1}}{(1+\nu)!\cdot 3^{\nu}\,[(1+\nu)\,m - 3]} \left(\frac{A}{RT\beta}\right)^{\nu} \tag{1}$$

For mixtures of gases we may write quite generally (p small)

$$p = \frac{RT\Sigma n_1}{V - [B_0]} \tag{1A}$$

$$[B_0] = \frac{1}{\Sigma n_1}\,[\Sigma B_{0\ 11}\, n_1^2 + 2\Sigma B_{0\ 12}\, n_1\, n_2] \tag{1B}$$

In the van der Waals form for B_0, β is four times the volume of the spheres contained in the volume v and A is proportional to the constant of the negative potential and an inverse power of σ depending on the exponent m. For $m = 6$ we find the following expression

$$B_0 = \beta - \frac{A}{RT}\left[\left(1 + {}^1\!/_6\,\frac{A}{RT\beta} + {}^1\!/_{30}\left(\frac{A}{RT\beta}\right)^2 \ldots\right]\right. \tag{2}$$

The chart produced by Roger H. Newton was based on the computation of γ by the equation

$$\gamma = f/p = \exp.\left[(RT)^{-1}\int_0^p (RT/p - v)\,\mathrm{d}p\right] \tag{3}$$

where p, v and T represent the experimental data for the substances. The integrand has been shown repeatedly not to vanish for $p \longrightarrow 0$ but on the contrary to reduce to a pure temperature function and this well-established fact accords with the prediction of the statistical theory of gases using for example the specialized concept of the intramolecular potential of van der Waals. Thus we find using equation (1)

$$\gamma = \exp.\ [(RT)^{-1}\,(-B_0)p] \tag{4}$$

Now taking the γ, π chart quite literally we would be justified in assuming that whatever the functional relation between γ and π for constant θ, provided only that it is finite and continuous, γ will be linear for π small. We may proceed to write as follows

$$\gamma = 1 + \mathrm{f}(\theta)\pi \text{ : for } \pi \text{ small} \tag{5}$$

Expanding γ we obtain further

$$1 - \frac{B_0 p}{RT} = 1 + \mathrm{f}(\theta)\pi \tag{5A}$$

or

$$\frac{B_0 p_c}{T_c} = -R\theta\mathrm{f}(\theta) \tag{6}$$

where the right-hand member is a universal function, the same for every substance in the gaseous state.

In the present state of our knowledge of the molecular field and the available data, no decisive opinion can be formed regarding the degree of exactness of relation (6). We observe, however, that it bears a close relation to Daniel Berthelot's expression for the effect of intramolecular potential in the equation of state.

Some years ago Beattie and Bridgeman[5] formulated the greater part of the existing data for gases using a correlative equation which employs for B_0 the expression

$$B_0 = \beta - \frac{A}{RT} - \frac{c}{T^3} \tag{7}$$

This is equivalent to a van der Waals expression in which the contribution of the series part or coefficient of A/RT of B_0 in equation (1) is represented by $1 + (CR/AT^2)$. I propose to designate this for reasons of convenience by the expression $1 + (\alpha_2)\ [A^2/(RT)^2\beta^2]$ where (α_2) is a quantity which may vary from substance to substance. What is here proposed for later use is the same thing as setting C equal to $(\alpha_2)\ (A^3/R^3\beta^2)$ and we write for B_0 the following equation

$$B_0 = \beta - A/RT - (\alpha_2)\,\frac{A^3}{(RT)^3\beta^2} \tag{7A}$$

We now obtain however using equations (6) and (7) the relation

$$B_{0\theta} = \beta(p/T)_c - \frac{A}{R\theta T_c}\,(p/T)_c - \frac{C}{\theta^3 T_0^3}\left(\frac{p}{T}\right)_c = -R\theta\mathrm{f}(\theta) \tag{6A}$$

or

$$B_{0\theta} = \beta_\theta - A_\theta/\theta - C_\theta/\theta^3$$

where the expectation derived from the γ, π chart is that β_θ, A_θ and C_θ will each turn out to be the same number regardless of the substance. Using

Non-polar gases $B_0\theta = 13.29 - \dfrac{34.9}{\theta} - \dfrac{5.47}{\theta^3}$

Substance	β	$A_0/R = A'\cdot 10^{-3}$	$C \times 10^{-6}$	β_θ	A'_θ	C_θ
NH_3	40.86	39.43	3053.0	11.24	26.74	12.59
H_2O	34.05	47.59	8842.0	11.48	24.80	10.99

Polar gases $B_0\theta = 11.36 - \dfrac{25.77}{\theta} - \dfrac{11.8}{\theta^3}$

Non-polar gas $C_\theta = 0.0227 \dfrac{(A_\theta)^3}{(\beta_\theta)^2}$

Polar gas $C_\theta = 0.089 \dfrac{(A'_\theta)^3}{(\beta_\theta)^2}$

The units are cc. per mole, atm. °K.

A somewhat astonishing accord of the numbers β_θ, A_θ, and C_θ for the different substances is evident. The case of helium is not significant since helium is the worst known example of a van der Waals molecule even at 100°K. Ether is really a polar gas and moreover the data are neither very exact nor sufficiently extensive in temperature range. The "universal equation" selected to represent the non-polar class of molecules is given at the foot of the table along with a similar one for the polar case. The latter equation is of course based on only two examples, but I have no knowledge of sufficiently precise data for other examples of polar gases. The reason for calling attention to the relation (6A) is solely because it has been found that certain important types of calculations may be facilitated using the "universal" functions B_0 with a combination rule for the constants of mixtures.

The combination rule whereby the constants for a mixture may be computed from the constants (β and A for example) for the pure substances is in a primitive stage. Data for the favorable case of nitrogen–methane mixtures[7] were obtained some years ago for the purpose of investigating the combination rule where the van der Waals form is a reasonable approximation in representing the behavior of the components. It was found that the rule

$$\beta_{12} = {}^1/_2(\beta_1 + \beta_2)\ ;\ A_{12} = (A_1A_2)^{1/2}$$

was suitable for this binary mixture of non-polar molecules. The result accords with quantum theory indications in the case of N_2 and CH_4 molecules as far as the A_{12} rule is concerned but if the van der Waals concept for the positive potential were exact the rule $\sigma_{12} = {}^1/_2(\sigma_1 + \sigma_2)$ would be justified. In the case of polar substances there are definite indications from current quantum theory that the A_{12} rule just given is over simplified. However, even in this case at high temperatures the rule should be a fair approximation.

Accepting the combination rule as stated and extending it to serve for the general case we have the following relationship which may be deduced from (1B)

$$[B_0] = \Sigma\beta_1n_1 - \frac{(\Sigma A_1{}^{1/2}n_1)^2}{RT\Sigma n_1} - \frac{1}{(RT)^3}\left[\Sigma(\alpha_2)_1 \frac{A_1{}^3}{\beta_1{}^2}\frac{n_1{}^2}{\Sigma n_1} + 2\Sigma(\alpha_2)_{12}\frac{A_{12}^3}{\beta_{12}^2}\frac{n_1n_2}{\Sigma n_1}\right] \quad (7B)$$

As examples of the practical applications of the "universal" functions, $B_{0\theta}$, and the equation (7), the Haber equilibrium constants ratio K_p/K^* will be computed and also the ratio px_1/p_1 for Gillespie's experiment[8] where ($BaCl_2 \cdot 8NH_3$) was used effectively as a semi-permeable membrane. Here K_p is the equilibrium constant for any pressure p and K^* is the same quantity for pressures approaching zero. For Gillespie's experiment px_1 is the Dalton's law pressure for NH_3 in a mixture of NH_3 and N_2 at total pressure p, while p_1 is the equilibrium pressure of the $BaCl_2 \cdot 8NH_3$ in contact with the gaseous $NH_3 : N_2$ mixture. Of course, every sort of calculation for gases may be made subject to the limitations of the $B_{0\theta}$ equations.

The general equation for the equilibrium constant ratio is

$$\ln K_p/K^* = -(RT)^{-1}\,\Sigma\nu \int_0^p \left[\frac{\partial V}{\partial n_1} - \frac{RT}{p}\right] \mathrm{d}p \quad (8)$$

For Gillespie's experiment we find the following equation from the relation $(\mu_{NH_3})_{p1} = [\mu_{NH_3}]_p$ where

---

[6] The constants for NH_3 and H_2O are taken from the author's formulations for these substances. The complete expressions are

$$(B_0)_{NH_3} = 2.4 - 2316\tau \times \text{exp. } 7.744 \times 10^4\tau^2$$

and

$$(B_0)_{H_2O} = 1.89 - 2641.6\tau \times \text{exp. } 1.858 \times 10^5\tau^2$$

where the units are in cc./g. The first two terms of the expanded exponential were assumed the equivalent of $(1 + CR/AT^2)$. This procedure is satisfactory provided the temperature is high enough.

[7] F. G. Keyes and H. G. Burks, THIS JOURNAL, **50**, 1100 (1928). The case is favorable from the point of view of interpretation because chemical action is excluded and the molecules are non-polar.

[8] E. Lurie and L. J. Gillespie, *ibid.*, **49**, 1146 (1927).

$(\mu_{NH_3})_{p1}$ is the chemical potential of the pure gas in equilibrium with the same gas in the mixture the chemical potential of which is $(\mu_{NH_3})_p$.

$$\ln \frac{px_1}{p_1} = (RT)^{-1} \left[\int_0^p \left(\frac{\partial V_1}{\partial n_1} - \frac{RT}{p} \right) dp_1 - \int_0^p \left(\frac{\partial V}{\partial n_1} - \frac{RT}{p} \right) dp \right] \quad (9)$$

where p_1 is the $BaCl_2 \cdot 8NH_3$ equilibrium pressure of pure ammonia and p the total pressure.

Using the relations (7) there results

$$\ln K_p/K^* = -(RT)^{-1} \left(\Sigma\nu_1 \frac{\partial [B_0]}{\partial n_1} \right) p \quad (8A)$$

$$\ln px_1/p_1 = (RT)^{-1} \, [B_{01}p_1 - \partial/\partial n_1 [B_{01}]p] \quad (9A)$$

where in (9A) B_{01} refers to pure ammonia in equilibrium through a semi-permeable membrane with the ammonia in the gaseous mixture $[B_{01}]$. In detail we find using (7) the following equations

$$\ln K_p/K^* = (RT)^{-1} \, [-\Sigma\beta_1\nu_1 + (RT)^{-1} (A) + (RT)^{-3} (B + C)] \quad (8B)$$

$$(A) = 2(\Sigma A_1{}^{1/2}x_1)(\Sigma A_1{}^{1/2}\nu_1) - (\Sigma A_1{}^{1/2}x_1)\Sigma\nu_1$$

$$(B) = \Sigma \mathbf{A}_1 x_1 \, (2 - x_1)\nu_1$$

$$(C)^9 = 2 \left\{ \begin{array}{l} [\mathbf{A}_{12}x_2(1 - x_1) + \mathbf{A}_{13}x_3(1 - x_1) - \mathbf{A}_{23}x_2x_3]\nu_1 \\ [\mathbf{A}_{12}x_1(1 - x_2) + \mathbf{A}_{23}x_3(1 - x_2) - \mathbf{A}_{13}x_1x_3]\nu_2 \\ [\mathbf{A}_{13}x_1(1 - x_3) + \mathbf{A}_{23}x_2(1 - x_3) - \mathbf{A}_{12}x_1x_2]\nu_3 \end{array} \right\} \text{for 3 components}$$

$$\ln \frac{px_1}{p} = (RT)^{-1}[-\beta_1(p - p_1) + (RT)^{-1} (Q) + (RT)^{-3} (S)] \quad (9B)$$

$$(Q) = [2(\Sigma A_1{}^{1/2}x_1)A_1{}^{1/2} - (\Sigma A_1{}^{1/2}x_1)^2]p - A_1p_1$$

$$(S) = \{\mathbf{A}_1(2 - x_1)x_1 - [\mathbf{A}_2x_2 - 2\mathbf{A}_{12}(1 - x_1)]x_2\}p - \mathbf{A}_1p_1$$

where $\mathbf{A} = (\alpha_2) \dfrac{A^3}{\beta^2}$; $(\alpha_2)_{12} = [(\alpha_2)_1(\alpha_2)_2]^{1/2}$; $\mathbf{A}_{12} = (\alpha_2)_{12} \dfrac{A_{12}^3}{B_{12}^2}$

Summary

It is shown that the recent fugacity–pressure ratio charts for constant reduced temperatures *versus* reduced pressure, taken literally, lead at low pressures to a simple reduced equation of state. The constants of this equation are deduced from the values of the van der Waals constants deduced for thirteen substances by Beattie and Bridgeman. It appears that there is a distinguishable difference in the reduced-constants values for non-polar compared with polar gases. A test of the usefulness of the reduced equation is made by computing the equilibrium constants for the Haber equilibrium for high pressures and for Gillespie's experiment. In applying the equation to mixtures of gases use was made of a "constants" combination rule previously found valid for nitrogen–methane mixtures. The results indicate that the reduced equation is useful for making approximate physico-chemical calculations involving gases under pressure. The present reduced equations suffer from the assumption that a van der Waals type of molecular field is assumed valid, and more precise data for gases and gas mixtures at low pressures are needed before the implications deducible from the existing fugacity–pressure ratio charts can be explored satisfactorily.

Thioesters of Choline and β-Methylcholine and their Physiological Activity. Onium Compounds. XIX

BY R. R. RENSHAW, P. F. DREISBACH,[1] M. ZIFF AND D. GREEN

The work described in the present paper is a continuation of an investigation of compounds in which sulfur was introduced into the structure of choline derivatives and into analogous compounds. Previous papers have described substances in which the onium element, nitrogen, has been replaced by sulfur to form sulfonium derivatives as well as to replace the oxygen of the hydroxyl group to form thiol derivatives, thioethers and sulfones. Certain acyl derivatives of "thiol-choline" are described here. In papers to be presented later, work on derivatives of sulfinic and sulfonic acids will be described.

Thiol-choline bromide, β-thiolethyltrimethylammonium bromide, was prepared in this Laboratory a number of years ago by the use of thiomethyluracil for replacing the halogen in bromocholine bromide by the thiol group.[2] Recently,[3] the introduction of the sulfur atom into the choline structure has been accomplished more readily by replacing the halogen in chloroethyldimethylammonium chloride by hydrolyzing the thiourea addition product of this compound. The same procedure was used in the present work and extended to the preparation of the β-thiolpropyldimethylamine.

The thiourea addition complexes of these halogen amines can be obtained in practically theoretical yield by heating the reactants in various alcoholic solutions. The thiolamines are obtained readily in good yield from the thiourea complex by hydrolyzing the latter with dilute bases. When the quantity of base used is sufficient to give marked alkalinity to the final reaction mixture, notable quantities of the disulfide are formed due to the ready oxidation of the thiol. For the preparation of certain derivatives, it is more convenient to oxidize the thiol at this stage and isolate the product as the disulfide.

The tertiary aminothiols acylate readily with acyl chlorides. The resulting thiol esters undergo hydrolysis and alcoholysis surprisingly easily considering the relative stability of compounds of similar structure (thiocaine) described by Hansen and Fosdick.[4] These tertiary amino thiol esters are readily converted into the quaternary compounds with alkyl halides. The resulting esters are more stable to alcoholysis and hydrolysis in acid solutions than the esters of the tertiary amines.

The addition of alkyl halides to the tertiary aminothiols to form the quaternary compounds does not take place in a clear-cut manner due to a simultaneous alkylation of the thiol group with the formation of tertiary amino thioethers. The latter may then be alkylated either on the nitrogen or sulfur atom or both.

By the action of the methyl iodide on β-thiolpropyldimethylamine a mixture of products was obtained from which two substances were isolated. The analysis of one product indicated a composition corresponding to the β-methyl thioether of propyltrimethylammonium iodide. This product melted nearly 40° higher than a product obtained by Mylius[5] by the action of methyl iodide on the methyl thioether of the corresponding primary amine. It has not been determined which of these products is the ammonium and which the sulfonium derivative. The second product isolated in small quantity showed, upon analysis, the composition of the expected β-methylthiolcholine. While it contained one active hydrogen, it did not show a thiol test and was probably the hydroiodide of the methyl thioether of the tertiary amine.

The quaternary thiols are best prepared by reduction of the *bis*-quaternary disulfide which may be obtained in nearly quantitative yields from the disulfides of the tertiary amines. They are also readily obtained by hydrolysis of the thioacyl derivative of the quaternary compounds.

Preliminary experiments carried out in this Laboratory in August, 1936, on the activities of acetylthiocholine and β-methyl-acetylthiocholine showed a remarkable variation in one of the ac-

tions of these compounds from what one would expect from the properties of other choline derivatives. It has been shown previously[6] that when the hydroxyl group of choline is replaced by the thiol group there is only a slight weakening of the typical depressor acetylcholine action. On the other hand, the stimulating nicotine action was diminished markedly and the paralyzing nicotine and curare actions augmented largely. In a more recent study of the acetyl derivatives of these thiols, the earlier results have been confirmed and extended.

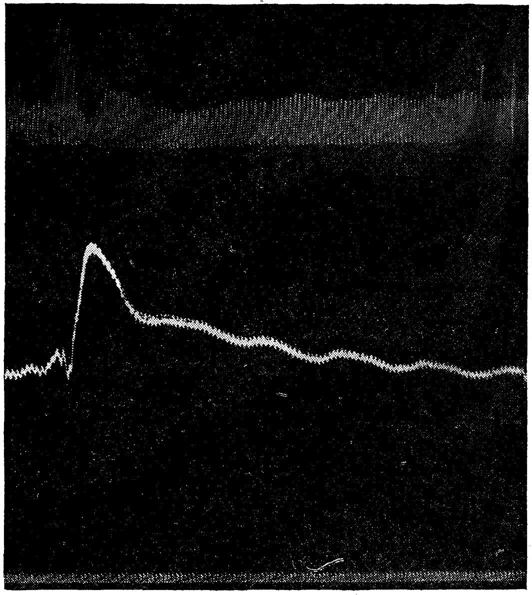

Fig. 1.—0.1 Mg. of thioacetyl-β-methylcholine iodide after atropine.

The acetylation of the thiocholine brings about a reversal of the effect of introducing the sulfur atom and produces a marked augmentation of the stimulating nicotine action. After atropine, 0.1 mg. of this product caused a rise of blood pressure from 128 to 166 mm. More remarkable is the fact that the acetyl derivative of the β-methyl-thiocholine produces a greater augmentation of the stimulating nicotine action. After atropine, 0.1 mg. of this substance caused the blood pressure to rise from 130 to 210 mm. The intensity of the activity of this compound was not greatly affected by the removal of the adrenals although the blood pressure returned to normal much more quickly after adrenalectomy. When one recalls that the introduction of the β-methyl group into acetylcholine nullifies the stimulating nicotine action of the latter, one is amazed at the extraordinary pressor activity of this sulfur β-methyl derivative. In large doses, both of these products have marked paralyzing nicotine and curare actions.

Chemical Experimental Part

With P. F. Dreisbach

β-(Chlorido-thiourea)-propyldimethylammonium Chloride.—A mixture of 50 g. of β-methyl-β-chloroethyldimethylammonium chloride and 25 g. of thiourea, dissolved in just enough *n*-propyl alcohol to effect solution when hot, was refluxed for nine hours and then allowed to stand at ice-box temperature for two days. The product formed was recrystallized from propyl alcohol, from which it separates in clusters of fine needles. These are slightly soluble in acetone and insoluble in ether; additional material obtained from the mother liquor gave a total yield of 92%, m. p. 201–202°.

Anal. Calcd. for $C_6H_{17}Cl_2N_3S$: Cl, 30.29. Found: Cl, 30.38, 30.37.

β-Thiol-propyldimethylamine.—A solution of 47 g. of β-chlorido-thiourea-propyldimethylammonium chloride and 22.5 g. of potassium hydroxide in 234 cc. of water was allowed to stand overnight at room temperature. The solution was then continuously extracted with ether for several days, a small amount of dicyandiamide separating out in the ether extract. From the dried ether extract, there was obtained by distillation 14.4 g. (61%) of a product boiling from 153 to 154° at 762 mm. and 46 to 51° at 14 to 18 mm. The amino thiol is soluble in water and the common organic solvents. With sodium nitroprusside it gives a positive test for the thiol group. It is relatively stable in air and in acid solution, but oxidation to the disulfide takes place rapidly in alkaline solution.

Anal. Calcd. for $C_5H_{13}NS$: H, 10.99; C, 50.34. Found: H, 11.39; C, 50.20.

The picrate crystallizes from glacial acetic acid in the form of needles melting with decomposition from 159 to 166° (sinters before melting).

Anal. Calcd. for $C_5H_{13}NS{\cdot}C_6H_3N_3O_7$: N, 16.09. Found: N, 15.99.

The cyano-mercury salt was obtained by treating the product with a saturated aqueous solution of mercuric cyanide. This salt crystallizes from water in the form of needle crystals which, when heated, gradually decompose from 125° upward.

Anal. Calcd. for $C_6H_{12}N_2SHg$: Hg, 58.18. Found: Hg, 57.93.

β,β′-Dithio-*bis*-(propyldimethylamine).—The hydrolysis of 48 g. of crude thiourea complex was carried out as above excepting that a small excess of potassium hydroxide was used so that the reaction solution acquired a decidedly alkaline reaction. Distillation of the ether extract gave 4 g. of pure thiol and, as the main product, 11 g. of the disulfide which boils at 151–154° at 14 mm. It is insoluble in water and alkali and soluble in dilute mineral acid, alcohol and ether. The disulfide was readily reduced to the thiol.

---

[6] Hunt and Renshaw, *J. Pharmacol.*, **44**, 151 (1932).

Anal. Calcd. for $C_{10}H_{24}N_2S_2$: H, 10.24; C, 50.77; mol. wt., 236.3. Found: H, 9.90; C, 50.55; mol. wt., 240.

β,β′-Dithio-*bis*-(propyltrimethylammonium Iodide).—Treatment of β,β′-dithio-*bis*-(propyldimethylamine) with excess methyl iodide in ethyl alcohol gave this product in almost theoretical yield. It crystallizes from ethyl alcohol as spheres of feather-like crystals which are soluble in water, slightly soluble in propyl alcohol and insoluble in acetone and ether; m. p. 207–208° (dec.).

Anal. Calcd. for $C_{12}H_{30}I_2N_2S_2$: H, 5.81; C, 27.69; N, 5.39; I, 48.79; active hydrogen, 0. Found: H, 5.91; C, 27.33; N, 5.53; I, 48.92; active hydrogen, 0.

Treatment of β-Thiol-propyldimethylamine with Methyl Iodide.—The addition of excess methyl iodide to an ether, benzene or toluene solution of β-thiol-propyldimethylamine gave, after three days of standing at room temperature, a precipitate consisting of a mixture of compounds from which there was isolated, by a series of fractional recrystallizations, a pure compound which turned brown at 189–195° and decomposed at 197–200°. The analysis of this is in agreement with the theoretical for β-(methyl-thio)-propyltrimethylammonium iodide, but the melting point does not agree with that of the product described by Mylius[5] as β-(methyl-thio)-propyltrimethylammonium iodide which he obtained by the action of methyl iodide on the thioether of isopropylamine. His product melted at 162–163°. Evidently, either his product or ours is the sulfonium iodide rather than the ammonium iodide. We did not attempt to prove the structure of this substance, but, due to the fact that our product is the higher melting, we suspect that it is the quaternary ammonium compound.

Anal. Calcd. for $C_7H_{18}INS$: C, 30.55; H, 6.59; I, 46.11. Found: C, 30.40; H, 6.87; I, 46.31, 46.17.

β-(Acet-thio)-propyldimethylammonium Chloride.—This product was obtained in almost theoretical yield by the slow addition of 4.4 g. of β-thiol-propyldimethylamine in 20 cc. of dry ether to 8 g. of acetyl chloride in 10 cc. of dry ether with vigorous agitation, while cooling the mixture in ice. When purified from an ether–amyl alcohol mixture, it forms hard, clear needles which are very hygroscopic and soluble in the common alcohols and esters; m. p. 91–92°. This ester is hydrolyzed rapidly in alkaline solution. Attempts to liberate the free base with sodium carbonate or sodium bicarbonate caused considerable hydrolysis. The free base also readily undergoes alcoholysis in alcohol solution.

Anal. Calcd. for $C_7H_{16}ClNOS$: Cl, 17.94. Found: Cl, 18.07, 18.28.

β-(Acet-thio)-propyltrimethylammonium Iodide.—A water solution of 7.5 g. of β-(acet-thio)-propyldimethylammonium chloride was shaken with excess silver oxide and the mixture then immediately extracted with ether. Addition of excess methyl iodide to the dried ether extract gave a product as a precipitate after standing at room temperature for five days. Recrystallized from butyl alcohol, it forms fine prisms which are very soluble in water and ethyl alcohol; yield 64%; m. p. 144–145°.

Anal. Calcd. for $C_8H_{18}NOSI$: I, 41.86. Found: I, 41.90, 41.78.

β-(Benz-thio)-propyldimethylammonium Chloride.—To 10 g. of benzoyl chloride in 10 cc. of dry ether there was added, slowly and with cooling, an ether solution of 5 g. of β-thiol-propyldimethylamine. The product began to precipitate immediately and the solution was then warmed on the steam-bath for one hour to complete the reaction. The product was obtained as clusters of fine, white needles by dropwise addition of ether to an ethyl alcohol solution. They are soluble in ethyl alcohol, slightly soluble in benzene and insoluble in ether and acetone; yield 90%; m. p. 122.5°.

The free base, which may be liberated from the hydrochloride by sodium bicarbonate, slowly undergoes alcoholysis on standing in ethyl alcohol.

Anal. Calcd. for $C_{12}H_{18}ClNOS$: Cl, 13.65. Found: Cl, 13.79, 13.74.

β-(Benz-thio)-propyltrimethylammonium Iodide.—An ether solution of β-(benz-thio)-propyldimethylamine was prepared by treating 5 g. of its hydrochloride in water with excess dilute sodium bicarbonate solution and immediately extracting with ether. The free base precipitated in the water solution as an emulsion. Excess methyl iodide was added to the dried ether extract and, after standing for several days at room temperature, the product had precipitated completely. It crystallizes from ethyl alcohol and from concentrated aqueous solution in the form of rosets of needles which are soluble in water and ethyl alcohol and slightly soluble in the higher alcohols; yield 85%; m. p. 185–186°. The substance is fairly stable in acid solution.

Anal. Calcd. for $C_{13}H_{20}INOS$: H, 5.52; C, 42.72; I, 34.75. Found: H, 5.55; C, 42.39; I, 34.53, 34.71.

β-(*p*-Nitrobenz-thio)-propyldimethylammonium Chloride.—A solution of 5.2 g. of β-thiol-propyldimethylamine in 25 cc. of benzene was added dropwise to 8 g. of *p*-nitrobenzoyl chloride in 20 cc. of benzene with cooling and shaking. The mixture was then refluxed for half an hour, after which precipitation of the product was complete. The product was purified by several recrystallizations from an absolute alcohol solution, m. p. 199–200°.

Anal. Calcd. for $C\ _2H_{17}ClN_2O_3S$: H, 5.62; C, 47.26; Cl, 11.64. Found: H, 5.77; C, 46.93; Cl, 11.77, 11.85.

The free base of this compound, prepared from its hydrochloride by dilute sodium bicarbonate solution, crystallizes from ligroin as orange-yellow plates, m. p. 85°. It is soluble in ether and insoluble in water. This product undergoes some hydrolysis even on standing in moist air. In alcohol solution, it alcoholizes almost immediately as is shown by the precipitation of ethyl *p*-nitrobenzoate from a freshly prepared alcoholic solution upon the addition of water.

Anal. Calcd. for $C_{12}H_{16}N_2O_3S$: N, 10.44. Found: N, 10.20, 10.35.

β-(*p*-Nitrobenz-thio)-propyltrimethylammonium Iodide.—An ether solution of the free base from 1 g. of β-(*p*-nitrobenz-thio)-propyldimethylamine hydrochloride was treated with excess methyl iodide and allowed to stand for two days at room temperature when precipitation of the product was complete. Recrystallized from a relatively small amount of water, it forms clear, orange-yellow needles; yield, 59%. It is moderately soluble in water and alcohol and insoluble in ether. In boiling alcohol, decomposition takes place; m. p. 190–191°.

Anal. Calcd. for $C_{13}H_{19}IN_2O_3S$: I, 30.94. Found: I, 30.91, 30.74.

β-(Chlorido-thiourea)-ethyldimethylammonium Chloride (With J. H. Williams[3]).—This product was obtained in practically theoretical yield when 55 g. of β-chloroethyldimethylammonium chloride and 30 g. of thiourea were refluxed for four and one-half hours in 60 cc. of absolute ethanol. Recrystallization from an acetone–ethanol mixture gave fine, colorless needles; m. p. 181–182°.

Anal. Calcd. for $C_5H_{15}N_3SCl_2$: Cl, 32.22. Found: Cl, 32.24, 32.19.

β,β'-Dithio-*bis*-(ethyltrimethylammonium Iodide).—Air was aspirated slowly for twenty minutes through a solution of 1 g. of β-thiol-ethyldimethylamine in 10 cc. of dilute potassium hydroxide solution kept at 80°. A layer of water insoluble liquid formed on the top surface and the whole was extracted with ether. Excess methyl iodide was added to the dried ether solution and, after six hours of standing, 1.1 g. of material had precipitated. This crystallizes from methyl alcohol solution as needles which turn brown at 220° and decompose at 230° when heated at the rate of 6° per minute, or at 235° heated at the rate of 12° per minute.

From the melting points and mixed melting point, this product was shown to be identical with a product isolated by Williams[3] in this Laboratory from the action of methyl iodide on β-thiol-ethyldimethylamine.

Anal. Calcd. for $C_{10}H_{26}N_2S_2I_2$: I, 51.56. Found: I, 51.35, 51.28.

β-(Acet-thio)-ethyldimethylammonium Chloride.—This product was prepared from β-thio-ethyldimethylamine and acetyl chloride according to the method outlined above for the corresponding β-methyl substituted compound in a yield of 78%. It recrystallized in needles from an ether–amyl alcohol mixture. The product is very hygroscopic; m. p. 95°.

Anal. Calcd. for $C_6H_{14}ClNOS$: Cl, 19.31. Found: Cl, 19.21, 19.24.

β-(Acet-thio)-ethyltrimethylammonium Iodide.—This was obtained from β-(acet-thio)-ethyldimethylammonium chloride, using silver oxide to liberate the free base, and methyl iodide by a method similar to that outlined for the preparation of the corresponding β-methyl substituted compounds; yield 77%. Recrystallized from propyl alcohol, it forms glistening plates which are soluble in water and the alcohols and insoluble in acetone and ether; m. p. 203–204°.

Anal. Calcd. for $C_7H_{16}INOS$: I, 43.90. Found: I, 43.70, 43.69.

β-(Benz-thio)-ethyldimethylammonium Chloride.—This compound was obtained from the tertiary amino thiol and benzoyl chloride; yield, almost the theoretical. Recrystallized from amyl alcohol, it forms colorless plates soluble in water and alcohols; m. p. 164.5–165°.

Anal. Calcd. for $C_{11}H_{16}ClNOS$: Cl, 14.44. Found: Cl, 14.61, 14.74.

β-(Benz-thio)-ethyltrimethylammonium Iodide.—This product was obtained from the corresponding amino-thiol hydrochloride, using dilute sodium bicarbonate solution to liberate the free base, and methyl iodide. Recrystallized from water, it forms glistening plates decomposing at 257° dependent on rate of heating; yield 84%. The product is soluble in water, slightly soluble in ethyl alcohol and insoluble in ether.

Anal. Calcd. for $C_{12}H_{18}INOS$: I, 36.15. Found: I, 36.12, 35.98.

β-(*p*-Nitrobenz-thio)-ethyldimethylammonium Chloride.—This *p*-nitrobenzoyl derivative was obtained in practically theoretical yield by a procedure analogous to the preceding. Recrystallized from isoamyl alcohol, it forms fine plates. It is soluble in water, ethyl alcohol and hot propyl and amyl alcohols; insoluble in ether and benzene; m. p. 187° (dec.).

Anal. Calcd. for $C_{11}H_{15}ClN_2O_3S$: Cl, 12.20. Found: Cl, 12.29, 12.31.

β-(*p*-Nitrobenz-thio)-ethyltrimethylammonium Iodide.—This quaternary ammonium compound was obtained from β-(*p*-nitrobenz-thio)-ethyldimethylammonium chloride, using dilute sodium bicarbonate solution to liberate the free base, and methyl iodide according to the method described above for the preparation of the corresponding β-methyl compound; yield 81%. The compound is moderately soluble in water, slightly soluble in the alcohols and insoluble in ether. Recrystallized from water, it forms yellow-orange plates which darken at 195° and melt at 212–216° to a red melt.

Anal. Calcd. for $C_{12}H_{17}IN_2O_3S$: I, 32.05. Found: I, 32.08, 32.05.

Pharmacological Experimental Part

With D. Green and M. Ziff

The experiments were performed upon cats anesthetized by means of nembutal. The following effects were noted:

1. Acetylcholine or "muscarine" action: a fall in blood pressure of vascular origin and prevented by atropine.
2. "Stimulating nicotine" action: a rise in pressure due to stimulation of sympathetic ganglia cells.
3. "Paralyzing nicotine" action: abolition of effects on the eye upon electrical stimulation of the cervical sympathetic; abolition of the rise in pressure caused by small doses of nicotine.
4. "Curare" action: abolition of response to electrical stimulation of motor nerves (femoral).

β-Acet-thio-ethyltrimethylammonium iodide had a moderate acetylcholine effect, being in the order of one hundredth as active as acetylcholine. In one experiment, 0.1 mg. of the drug caused a fall of 48 mm. as compared with a fall of 64 mm. produced by 0.001 mg. of acetylcholine. This effect was most marked in doses of the order of 0.1 mg. In larger doses, the "stimulating nicotine" effect was so great—even without previous administration of atropine—as to partially neutralize the fall in pressure by the production of a secondary rise. After atropine, the pressure rose abruptly and then fell rather slowly to normal. A curious feature of this return, after atropine, was the occcurrence of marked Traube–Hering waves.

After adrenalectomy, the "stimulating nicotine" effect was somewhat diminished, but still pronounced. The return of pressure to normal was much more rapid, however. The relationship of the acetylcholine to the "stimulating nicotine" effect, under various conditions, is shown in Table I.

TABLE I

Dose (mg./kg.)	Initial pressure	Fall to	2° Rise to
Acet-thiocholine iodide			
0.0277	158	110	164
.057	150	134	178
.33	136	98	194
.57	136	112	190
.75	122	76	120
2.2	144	40	74
After atropine			
0.0277	128	...	162
After atropine and adrenalectomy			
0.0277	144	...	164
.055	148	...	184
β-Methyl-acet-thiocholine iodide			
0.0277	158	136	190
.057	120	...	214
.50	114	96	148
.75	106	76	104
After atropine			
0.0277	130	...	208
After atropine and adrenalectomy			
0.0277	142	...	208
.055	154	...	236
Methyl-thiocholine iodide			
0.0455	138	104	150
.091	110	66	126
.435	128	84	132

The "paralytic nicotine" and "curare" effects of this compound became evident rather abruptly as one increased the dosage. Thus, evidences of these effects were lacking in doses of 0.285 and 0.33 mg. per kilogram; whereas, in doses of 0.75, 0.90 and 2.2 mg. per kilogram, both effects were not only strong but the curariform paralysis of respiration was ultimately sufficient to produce death.

β-(Acet-thio)-propyltrimethylammonium iodide had an acetylcholine action somewhat weaker than the acet-thiocholine. In one experiment 0.1 mg. caused a fall of 32 mm. as compared with a fall of 48 mm. produced by the same amount of the latter. The acetylcholine action of the compound was obscured to a far greater extent, however, by the "stimulating nicotine" effect, which was very pronounced, in some cases so great that the only observable blood pressure effect was a rise. The effect of the β-methyl group of this substance, which caused more than a two-fold increase in the pressor activity over that of the parent substance, seems remarkable. After atropine, the pressor effect was enhanced, and Traube–Hering waves observed. Adrenalectomy again diminished, somewhat, the "stimulating nicotine" action and markedly shortened its duration. "Curare" and "paralytic nicotine" effects were observed in doses of 0.5 to 0.75 mg. per kilogram, but unlike the effects with corresponding doses of acet-thiocholine they were transient and did not cause death of the animal.

β-Methylthio-ethyltrimethylammonium iodide was investigated briefly. It exhibited a moderately strong and consistent acetylcholine action, being in that respect about equal to that of the acetyl-thio derivative. There was in this compound (as in the others of the series) a definite rise in pressure observable even without the administration of atropine, as seen in Table I. "Curare" and "paralytic nicotine" effects were observed in doses of 0.435 mg. per kilogram. Respiratory paralysis was transient, however, and did not cause death.

PROTOCOL

Cat No. 11; 3.6 kg.; Nembutal 2.8 grains; blood pressure from the carotid artery; injections into femoral vein. AcC = acetylcholine bromide; PD-1 = acet-thiocholine iodide; PD-2 = β-methyl-acet-thiocholine iodide.

9:32 AcC, 0.001 mg. Blood pressure fell 64 mm. (160 to 96).

9:51 PD-1, 0.1 mg. Blood pressure fell from 158 to 110 mm. and then rose to 164. Respiratory stimulation.

9:54 PD-2, 0.01 mg. Practically no effect.

9:57 PD-2, 0.1 mg. Blood pressure fell from 158 to 136 mm. and then rose to 190 mm. Respiratory stimulation.

10:10 Atropine sulfate, 4 mg.

10:18 AcC, 0.001 mg. Blood pressure rose from 108 to 118 mm.

10:26 PD-1, 0.1 mg. Blood pressure rose from 128 to 162 mm. Traube–Hering waves noted.

10:30 PD-2, 0.1 mg. Blood pressure rose from 130 to 208 mm. and slowly returned to 136 mm.

10:40 Adrenalectomy bilaterally.

11:29 AcC, 0.001 mg. Little effect.
11:32 PD-2, 0.1 mg. Blood pressure rose from 142 to 208 mm. Rapid return to normal.
11:35 PD-1, 0.1 mg. Blood pressure rose from 144 to 164 mm. Traube–Hering waves. Transitory respiratory stimulation.
11:38 PD-2, 0.2 mg. Blood pressure rose from 154 to 236 mm. Traube–Hering waves. Transitory respiratory stimulation.
11:43 PD-1, 0.2 mg. Blood pressure rose from 148 to 184 mm. Traube–Hering waves. Transitory respiratory stimulation.

The authors wish to express their appreciation and thanks to Professor George B. Wallace, in whose laboratory most of the experiments were performed.

Summary

1. Methods of preparation of tertiary amino alkyl thiols are described.

2. Thioethyldimethylamine and its β-methyl derivative have been acylated and the resulting thioesters converted into quaternary ammonium derivatives yielding thioesters of choline and β-methylcholine.

3. The acetyl derivatives of thiocholine and the acetyl derivative and methyl thioether of β-methylthiocholine have been tested pharmacologically for their acetylcholine, "stimulating" and "paralytic nicotine" and "curare" actions.

[A COMMUNICATION FROM THE LABORATORY OF CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

Effects of Solvents on Polarographic Wave Heights

BY EDMOND S. PERACCHIO[1] AND VILLIERS W. MELOCHE

Since the discovery of the polarograph by Heyrovsky, many contributions have been made to the literature involving the use of the instrument. Aside from describing the process at the dropping mercury capillary electrode and developing equations for the polarographic curve, most papers were concerned with proof of reduction or qualitative detection of a great variety of substances. Actual applications of the method to quantitative analysis were few in number and often the procedures were poorly defined. Heyrovsky, Ilkovic and others have mentioned variables which affect wave height and its relationship to concentration of a given ion. In this connection they have included the mobility of the reducible ion as an important consideration. When one examines several papers which have appeared in the literature,[2] it may seem that a given amount of one reducible substance will give a wave height equal to that of an equivalent amount of another reducible substance or that differences between the wave for equivalent amounts of two different ions are not significant in quantitative analysis. From our studies it became evident that this was not necessarily true. At the same time it is true that the order of magnitude of these differences could be changed by the addition of various reagents to the solution of the sample.

Since in a preliminary investigation we found that the wave for lithium chloride was defined better in a solution containing ethyl alcohol than it was in water, it was decided to extend the study of the polarographic wave heights to systems containing high concentrations of non-aqueous solvents.

The purpose of this investigation is to illustrate the differences in wave heights which exist for equivalent weights of the alkali metals in certain aqueous solutions and to show how these differences are affected by the introduction of certain organic solvents.

Apparatus.—The usual Heyrovsky[3] polarographic system was used. A few changes were made in the manipulation and construction of the dropping mercury cathode. In the usual construction of the cathode, a mercury reservoir is suspended about 15 inches (38 cm.) above the capillary tip and is connected to the tip by means of gum rubber tube. This arrangement was not satisfactory even when the tube received special treatment. For our experiments, a 100-ml. dropping funnel was used as the reservoir, Fig. 1. The glass tube below the stopcock was long enough so that the distance from the surface of the mercury in the reservoir to the capillary tip afforded a mercury pressure of about 15 to 20 inches (38–51 cm.). The capillary was attached to the glass tube from the reservoir by a short piece of rubber tube which had been conditioned by

boiling in dilute sodium hydroxide, washing with hydrochloric acid and finally with water. Thermometer tube, 5.0 mm. o. d. and 0.5 mm. i. d., was used for the capillary tips, the tubes being drawn in such a manner that they had a long gradual taper. To prepare a tip for use, it was attached to the reservoir as described and immersed in water. Successive small portions were broken off until the mercury droplet barely formed. Using a solution 0.1 *N* in tetramethylammonium hydroxide and 0.001 *N* potassium chloride, the necessary connections were made preparatory to electrolysis and the trolley was set for a voltage nearly equal to the reduction potential for the potassium. Successive small portions were again broken from the tip until the oscillations of the galvanometer were at a minimum for a given voltage. Such a tip produces a smooth curve when used in the analysis of the alkali metals. The drop rate is usually about 1 drop every two seconds.

A straight-walled vessel was used instead of the usual Erlenmeyer type used by Heyrovsky and others (Fig. 2). The rubber stopper in the vessel had two holes. In one there was a glass tube which was slightly larger than the capillary tip and through which the tip could move freely as through a sleeve. The other hole provided for a tube through which hydrogen could be passed over the surface of the solution. The whole cathode, Fig. 1, was supported on a ring stand in such a manner that it could be raised or lowered by adjustment of a screw. In ordinary cases the hydrogen used for removing the dissolved oxygen from the solution of the sample was purified by passing it through alkaline pyrogallol and then through sulfuric acid. When the solution to be examined contained a highly volatile substance, the hydrogen was saturated by passing it through a portion of the solution before it passed through the sample in the vessel. This minimized the change of concentration caused by loss of the volatile substance.

Materials.—Tetramethylammonium hydroxide was used as the supporting electrolyte for all of the work with the alkali salts. It was prepared as follows: 17 g. of silver nitrate was dissolved in about 150 ml. of water. Four grams of sodium hydroxide was dissolved in about 150 ml. of water and poured with vigorous stirring into the silver nitrate solution. The precipitated silver oxide was washed 12 to 15 times by decantation using about 300 ml. of distilled water, mixing thoroughly each time and draining as completely as possible. Fifteen and six-tenths grams of tetramethylammonium bromide was dissolved in about 100 ml. of water and the solution poured with vigorous stirring into the washed silver oxide. After mixing, the solution was decanted and allowed to stand for several days. During this time most of the very fine particles of silver bromide settled. The solution was filtered through hard paper, diluted to 200 ml. and was ready for standardization.

Sodium chloride was prepared from a sample of fused sodium chloride by saturating a solution of the fused salt with hydrogen chloride, forcing the sodium chloride out of solution. The sodium chloride thus obtained was recrystallized from water.

Potassium chloride was prepared by treatment of analytical reagent potassium carbonate with hydrochloric acid and subsequent recrystallization of the potassium chloride.

Rubidium and cesium chlorides were prepared from analytical reagent quality materials. The chlorides were further purified according to the method of Wells and Stevens[4] for the separation of the alkali metals.

Lithium chloride was prepared from lithium metal and freshly prepared hydrochloric acid. The lithium chloride was extracted with pyridine to separate it from any of the other alkalies. Finally it was recrystallized from water.

Rochelle salt used as the supporting electrolyte in the cadmium and lead systems was reagent quality.

The alcohols used, methyl, ethyl, and propyl, were dried over calcium oxide and then fractionated. The fraction collected boiled over a 1° range. Ethylene glycol, trimethylene glycol, and glycerol were treated in a similar manner.

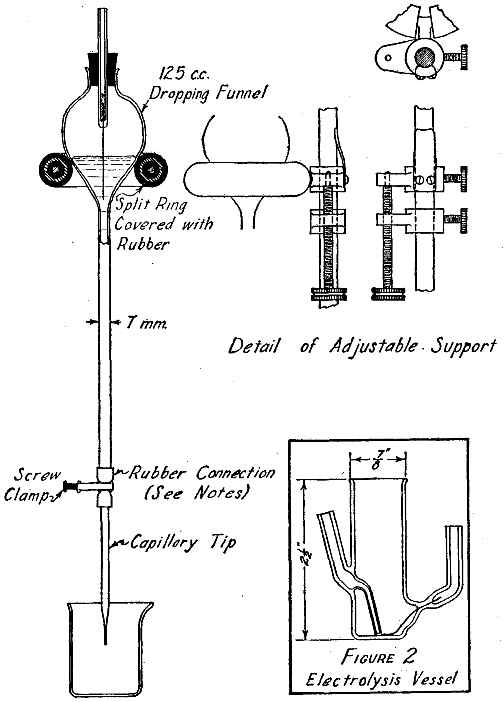

Fig. 1. Fig. 2.

1,4-Dioxane was dried over sodium metal and fractionated. Only freshly distilled product could be used. Apparently, on standing, the dioxane tends to form peroxides and these react with the mercury in the polarographic vessel. Freshly distilled dioxane did not do this.

Water was redistilled in a copper still and only the middle third collected for use.

The mercury used for the cathode and anode was aerated under a solution of sodium hydroxide, washed in a tower with 3% nitric acid, and finally with water. The dry mercury was distilled under reduced pressure.

Method.—Fairly concentrated stock solutions were prepared so that by taking a definite aliquot of each reagent and mixing them together the resulting solution contained each constituent in the desired concentration. The solutions used for electrolysis were made 0.001 *N* to the reducible ion, *i. e.*, sodium, potassium, etc., and 0.1 *N* to

---

[4] Wells and Stevens, *Ind. Eng. Chem., Anal. Ed.*, **6**, 439 (1934).

the supporting electrolyte, tetramethylammonium hydroxide.

The concentration of the organic solvent was generally 80% except in a few cases where the concentration is specified. A sufficient quantity of the solution was prepared so that a portion of it could be placed in the saturation vessel and a portion in the cell used for electrolysis. Oxygen-free hydrogen was passed through the two solutions until the oxygen was removed from the solutions. This operation required three to five minutes. The solution was then ready for electrolysis. Wave heights were measured according to the method described as A_4B_4 by Borcherdt, Meloche and Adkins.[5] There was a slight exception in that the slope of the base of the curves was more nearly horizontal than illustrated. Therefore an application of the method A_1B_1 would not alter the results very much.

Wave Heights in Aqueous Systems.—In the course of our polarographic investigations, it was observed that the wave heights for equivalent weights of sodium and potassium were not equal. An illustration of this difference appears in Fig. 3. The first four curves represent 0.001 *N* sodium chloride, the second four 0.001 *N* potassium chloride, and the last two represent a 1–1 mixture of sodium chloride and potassium chloride, the total concentration of the mixture being 0.001 *N*. The average wave height for sodium is 0.755″ (19.1 mm.) and the average for potassium is 0.858″ (21.8 mm.). An average value for the 1–1 mixture of sodium and potassium as represented in the last two curves of Fig. 3 is 0.823″ (20.9 mm.) and this is 0.068″ (1.7 mm.) more than the equivalent wave height for sodium. Since the reduction potentials for the alkali metals are close to each other, the polarograph does not register them separately. One might expect that the wave height for a 1–1 mixture of 0.0005 *N* sodium and potassium would give a wave height half-way between the equivalent height for 0.001 *N* sodium and 0.001 *N* potassium. The curves which illustrate this point actually show a difference of 0.103″ (2.6 mm.) between sodium and potassium, and the wave height for the mixture is 0.068″ (1.7 mm.) greater than the sodium, showing that the wave height for the mixture did not fall half-way between the height for the sodium and the potassium but nearly so. It did not seem that these differences were small enough to be ignored; hence this study was extended to include rubidium and cesium.

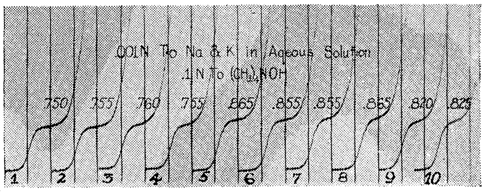

Fig. 3.—Curves 1, 2, 3, 4 for 0.001 *N* NaCl; curves 5, 6, 7, 8 for 0.001 *N* KCl; curves 9 and 10 for 0.0005 *N* NaCl and 0.0005 *N* KCl.

Solutions of equivalent weights of sodium, potassium, rubidium, and cesium chlorides were prepared and electrolyzed under conditions identical to those illustrated by the polarograms in Fig. 3. A representative set of curves for such a series is shown in Fig. 4. Direct comparison of the magnitude of the wave heights in Figs. 3 and 4 cannot be made because the sensitivity was different for each series and the tip also was different. By comparing the average wave heights in Fig. 4 one observes that the difference between sodium and potassium is 0.127″ (3.2 mm.), between potassium and rubidium 0.042″ (1.1 mm.), and between rubidium and cesium 0.067″ (1.7 mm.). The order of magnitude of the wave heights increases in the order sodium, potassium, rubidium, and cesium.

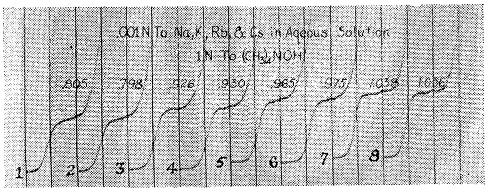

Fig. 4.—Curves 1 and 2 for 0.001 *N* NaCl; curves 3 and 4 for 0.001 *N* KCl; curves 5 and 6 for 0.001 *N* RbCl; curves 7 and 8 for 0.001 *N* CsCl.

Curves for lithium are not included in Fig. 4. This is due to the fact that the saturation wave for lithium is imperfectly, if at all, defined in aqueous systems.

In comparing the differences in wave heights for equivalent weights of elements of the alkali group, there is a variation in atomic weight from sodium to cesium. It is desirable to examine other elements not only to provide an element having a higher atomic weight but to provide two elements which are reduced at different potentials. Cadmium and lead were chosen for the purpose. For an electrolysis, it was found that 0.06 *N* Rochelle salt was satisfactory. The reducible ions, cadmium and lead, were 0.001 *N*. Representative results from this study are shown in Fig. 5. It can be seen that a difference does exist between the wave heights for equivalent weights of cadmium and lead. For a 1–1 mixture of the salts, the total equivalent weight being equal to that of the previous curves, the two waves did not appear in a ratio of 1–1 but appeared in heights nearly proportional to the differences shown in the two previous curves.

In the introduction we mention articles[2] that seem to indicate that equivalent amounts of cadmium, lead, and bismuth gave wave heights which were practically identical. While we will show that it is possible to change the environment in such a manner that the wave heights for equivalent amounts of different elements are the same, it did not seem that equal normal solutions necessarily should give equal wave heights for cadmium, lead, and bismuth when lithium nitrate and nitric acid were used as the supporting electrolyte in an aqueous system. Heyrovsky and Suchy[2] used lithium nitrate and nitric acid as supporting electrolytes when they studied the polarographic behavior of cadmium, lead, and bismuth. Since we had not used this particular supporting electrolyte, we repeated our experiments on cadmium, lead, and bismuth, duplicating as nearly as possible the conditions described by the above authors in their papers. Our results are shown in Fig. 6. It is observed that the differences in wave heights for cad-

---

(5) Borcherdt, Meloche and Adkins, THIS JOURNAL, **59**, 2171 (1937).

mium and lead in this system are even greater than they appeared in Fig. 5 when Rochelle salt was used as the electrolyte. The second curve in Fig. 6 illustrates the addition of bismuth to the mixture. So far as the sensitivity of this system is concerned, the addition of bismuth did not seem to alter the differences which were previously observed between cadmium and lead.

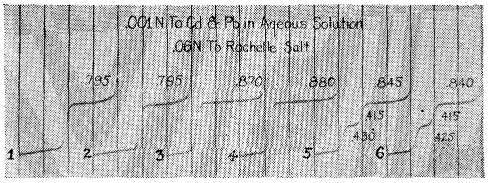

Fig. 5.—Curves 1 and 2 for 0.001 *N* $Cd(NO_3)_2$; curves 3 and 4 for 0.001 *N* $Pb(NO_3)_2$; curves 5 and 6 for 0.0005 *N* $Cd(NO_3)_2$ with 0.0005 *N* $Pb(NO_3)_2$.

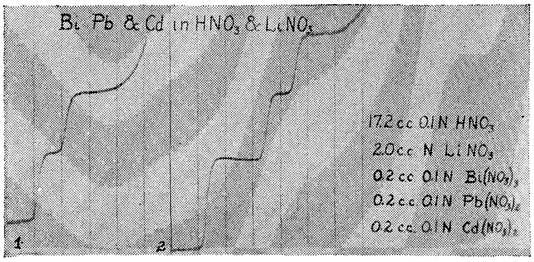

Fig. 6.—Curve 1 for 0.001 *M* $Cd(NO_3)_2$ with 0.001 *M* $Pb(NO_3)_2$; curve 2 for 0.001 *M* $Cd(NO_3)_2$; curve 2 for 0.001 *M* $Cd(NO_3)_2$, 0.001 *M* $Pb(NO_3)_2$ and 0.001 *M* $Bi(NO_3)_3$.

This information further substantiates the differences found for the elements of the alkali group, and indicates that when dealing with more than one element in solution, one cannot assume that equal wave heights of different elements mean equivalent concentration.

Wave Heights in Water–Alcohol Systems.—We know that aside from such factors as the capillary tip and temperature, we can alter the wave height for a given substance by changing the chemical environment. In the following experiments the effect of organic solvents on polarographic wave heights is described. A concentration of alcohol was selected which would easily change the character of the solution and yet not cause too great a difficulty in dissolving the salts of the alkali metals. Figure 7 represents the electrolysis of solutions containing the alkali chlorides 0.001 *N*, ethyl alcohol 80%, and tetramethylammonium hydroxide 0.1 *N* Several important differences can be noticed. In the water–alcohol system lithium now shows a reproducible saturation wave. The order of the differences in wave height is lithium, sodium, potassium, rubidium, and cesium. Differences in wave height for equivalent amounts of these elements are less in alcohol–water than in pure water.

Table I gives the order of magnitude of decrease in wave height for sodium or potassium in various concentrations of alcohol as well as the relative wave heights for equivalent weights of sodium or potassium in different alcohols. A graph of percentage alcohol against wave height reveals that, in general, wave height decreases as the concentration of the alcohol increases. An equivalent weight of sodium or potassium in 70% ethyl or methyl alcohol gives wave heights of about the same magnitude. For a solution of propyl alcohol, the wave heights are decidedly lower.

TABLE I

Conversion factor inches to mm. = 25.4

Curve	% alcohol	Wave height, inches		
		Methyl alc.	Ethyl alc.	Propyl alc.
		Sodium Chloride		
1	0	1.38	1.40	1.37
2	10	1.27	1.33	1.14
3	20	1.18	1.21	0.99
4	30	1.17	1.16	.89
5	40	1.10	1.09	.81
6	50	1.13	1.00	.78
7	60	1.01	0.99	.68
8	70	1.08	1.00	.56
		Potassium Chloride		
1	0	1.165	1.175	1.185
2	10	1.08	1.110	1.075
3	20	1.045	1.065	1.00
4	30	0.995	1.03	0.92
5	40	.915	1.03	.90
6	50	.945	1.02	.765
7	60	.92	0.975	.70
8	70	.935	.99	.68

Since we know that the differences in wave heights for sodium and potassium are greater in the water system than in the water–alcohol system, it seemed desirable to extend this study to certain other organic solvents. We therefore included ethylene glycol, trimethylene glycol, and glycerol.

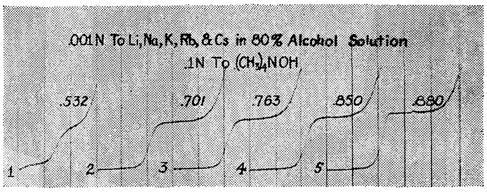

Fig. 7.—Curve 1 for 0.001 *N* LiCl; curve 2 for 0.001 *N* NaCl; curve 3 for 0.001 *N* KCl; curve 4 for 0.001 *N* RbCl; curve 5 for 0.001 *N* CsCl.

Polarograms for equivalent weights of sodium and potassium chlorides in ethylene glycol, trimethylene glycol, and glycerol are shown in Fig. 8. In curve 1 of Fig. 8, we have shown an equivalent weight of sodium chloride in water as a reference. Curve 2 shows sodium chloride in 80% ethyl alcohol; curve 3, sodium chloride in 80% ethylene glycol; curve 4, sodium chloride in 80% trimethylene glycol; curve 5, sodium chloride in 80% glycerol. Figure 9 represents a similar series for potassium. It will be noted that the wave heights for both sodium and potassium in these solvents decrease in the order mentioned, namely, water, ethyl alcohol, ethylene glycol, trimethylene glycol, and glycerol. As previously mentioned, in the water system, a given concentration of potassium gives a higher wave than an equivalent concentration of sodium. Equivalent concentrations of sodium and potassium give lower wave heights in 80% alcohol than in the water system, and the differences in height for sodium and potassium are less in the alcohol–water system than they are in pure water. While the wave height in 80% ethylene glycol is less than that in 80% ethyl alcohol, there is still a perceptible difference shown for equivalent weights of sodium and potassium. Wave heights in trimethylene glycol are only slightly smaller than those in ethylene glycol, and the differences shown for equivalent weights of sodium and potassium are almost imperceptible.

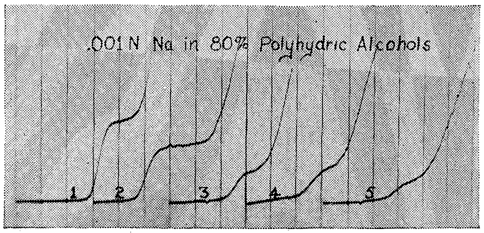

Fig. 8.—Curve 1 for 0.001 *N* NaCl in water; curve 2, same in ethyl alcohol; 3, in ethylene glycol; 4, in trimethylene glycol; 5, in glycerol.

The wave heights for equivalent weights of sodium and potassium in a solution containing glycerol are lowest of all, and there is no perceptible difference in the two wave heights. However, it will be noticed that while the shape of the curves for samples containing alcohol was almost ideal for quantitative measurements, the waves for the last three curves in Fig. 8 and Fig. 9 are successively less well defined. In this connection it may be observed that the viscosities of the last three media are relatively high.

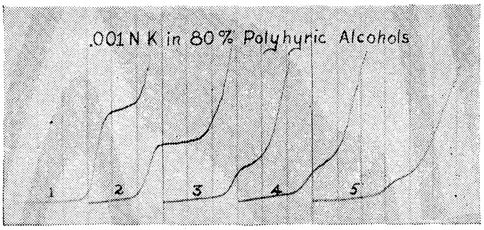

Fig. 9.—Curve 1 for 0.001 *N* KCl in water; 2, same in ethyl alcohol; 3, in ethylene glycol; 4, in trimethylene glycol; 5, in glycerol.

Wave Heights in Dioxane–Water System.—Figure 10 shows four curves, the first two of which represent equivalent weights of sodium and potassium in water and the second two represent the same weights of sodium and potassium in 70% dioxane. While the waves are less well defined in the dioxane system, it is important to note that the waves for sodium and potassium are practically identical. Figure 11 shows curves for equivalent weights of sodium, potassium, rubidium, and cesium in 80% dioxane. In this system the curves, so far as measurement is concerned, are identical. Since the curves in Fig. 10 are made with a different tip, they cannot be compared with curves in Figs. 8, 9, and 11. However, it may be mentioned that an equivalent weight of sodium or potassium in 80% dioxane gives a smaller wave height than it does in either water or alcohol systems.

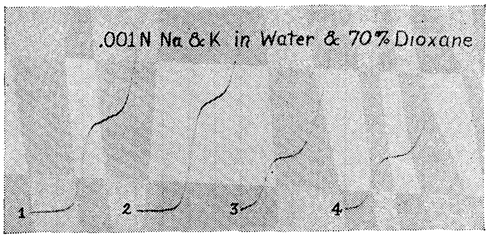

Fig. 10.—Curve 1 for 0.001 *N* NaCl in water; 2, 0.001 *N* KCl in water; 3, 0.001 *N* NaCl in dioxane; 4, 0.001 *N* KCl in dioxane.

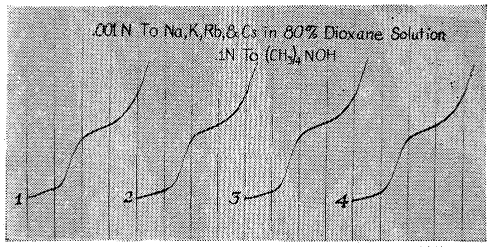

Fig. 11.—Curve 1 for 0.001 *N* NaCl in dioxane; 2, for 0.001 *N* KCl; 3, for 0.001 *N* RbCl; 4, 0.001 *N* CsCl.

Conclusion

In a preliminary paper before the Wisconsin Academy of Science[6] we reported that when solutions of sodium chloride and potassium chloride which are 0.001 *N* to chloride and 0.1 *N* to tetramethylammonium hydroxide are examined by means of the polarograph, the wave heights are not the same. In the present paper we have shown that the wave heights are different not only for equivalent concentrations of sodium and potassium chloride but also for all of the alkali chlorides. The wave heights increase in magnitude from sodium to cesium. These differences are not small enough to be ignored and therefore interfere with the application of the polarograph to quantitative analysis. In the usual procedure for the estimation of one element in an unknown an internal standard is used. The unknown is prepared in a suitable solution with a supporting electrolyte and a polarogram is recorded. Then a known amount of the element to be determined is added and another curve is recorded. The increase in wave height caused by the added standard is measured and from this the relationship

[6] Peracchio and Meloche, *Wisconsin Acad. Sci.*, April 17, 1936.

between wave height and concentration of the element is calculated. By this procedure a reasonably precise value is obtained.

When there is more than one reducible ion in solution, one cannot presume that if the relationship between wave height and concentration is established for one, it will also hold for the others. In the precise application of the polarograph to chemical analysis, one is faced therefore, with the necessity of correcting for the discrepancies which exist or eliminating them.

In reporting the effect of the addition of certain non-aqueous solvents to solutions used in polarographic analysis we have shown that the wave heights for equivalent concentrations of alkali chlorides were lowered and that the differences between the wave heights for the alkalies were lessened. We also indicated that in solutions which contained 80% dioxane the wave heights for equivalent weights of alkali chlorides were the same. From these data one might assume that in cases where more than one element is to be determined one should use dioxane in the solution. This is by no means the case. Certainly, at present there is no one set of conditions which satisfy all samples. Information must be collected for the case at hand.

Ilkovic, Heyrovsky, Kemula, and Maas[7] have reported studies on the limiting current and have suggested the dependence on the diffusion constant, on the rate of dropping and the size of the drops at the dropping mercury cathode. Little emphasis has been placed on the importance of mobility in the application of the polarographic method to quantitative analysis. The few papers in this field have ignored the existence of differences in mobility and consequent differences in wave heights. This would be permissible if the highest degree of precision is not attempted. However, wave height differences cannot be ignored if the application of the technique is to be precise.

Summary

Polarograms are shown for sodium, potassium, rubidium, and cesium chloride in aqueous solutions and differences in wave height are shown to exist for equivalent concentrations of the chlorides.

Contrary to indications in the literature, it is shown that equivalent concentrations of cadmium, bismuth and lead chlorides do not give equal wave heights.

It is shown that the presence of various alcohols lowers the wave heights exhibited in aqueous solutions. Differences between the wave heights for equivalent concentrations of alkali chlorides are lessened.

Addition of certain polyhydric alcohols to the aqueous solutions of the alkali chlorides also lowered the wave heights but in cases of the more viscous solutions the curves were poorly defined.

When dioxane was added to aqueous solutions of the alkali chlorides, the wave heights for equivalent concentrations of the salts were the same. Although the shape of the curves was not ideal, the wave heights could be measured and the curves were suitable for quantitative analysis.

While the universal use of organic solvents in solutions prepared for the polarograph is not recommended, there are many cases where the use of such systems is desirable and in some cases even mandatory.

The Hydroxyanthraquinones as Analytical Reagents. The Colorimetric Determination of Zirconium or Hafnium

BY HERMAN A. LIEBHAFSKY AND EARL H. WINSLOW

The use of the hydroxyanthraquinones in analytical chemistry has grown steadily since Atack[1] discovered that aluminum could be detected with alizarin red S,[2] the sodium salt of alizarin sulfonic acid. Their value as colorimetric reagents for precise quantitative work, however, has not been appreciated widely partly because the compounds (lakes) which these dyes form with all or nearly all metallic cations[3] are sparingly soluble, and partly because the dyes themselves are so intensely colored that the quantitative estimation by simple visual comparison of a small amount of lake in the presence of excess dye is practically impossible. In working with zirconium and hafnium, we have minimized the first difficulty by maintaining the lakes at great dilution in 95% ethyl alcohol. Color interference, the second difficulty, does not exist when a spectrophotometer[4] is used. This investigation is an attempt to establish the hydroxyanthraquinones as colorimetric reagents upon a systematic quantitative basis through accurate measurements of the light absorbed by these dyes and their lakes.

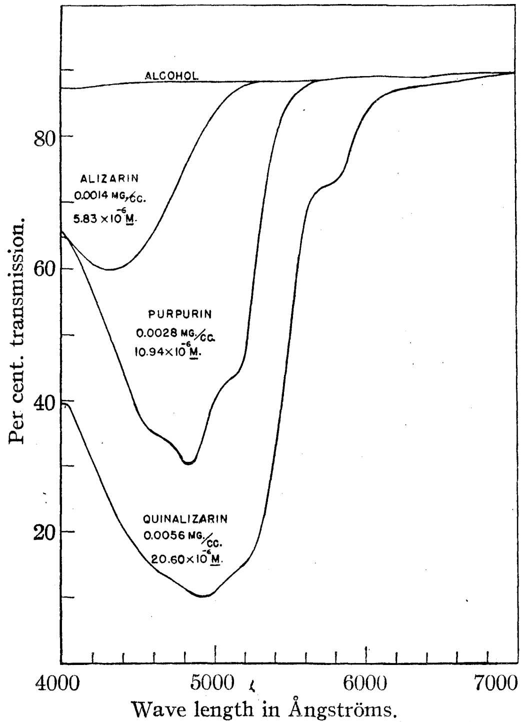

Fig. 1.—Transmission curves for each of the three hydroxyanthraquinones in dilute alcoholic solution.

The lakes formed by alizarin with most metallic cations, including aluminum, do not persist when an excess of a strong acid is added. The extraordinary stability of the alizarin–zirconium lake under these conditions was discovered by deBoer[5] as he attempted to use Atack's reaction to detect aluminum in the presence of zirconium. His work afforded us a welcome point of departure in the development of the colorimetric methods given below, with which it is possible to determine even a few micrograms of zirconium or hafnium with reasonable accuracy.

The absorption of visible light by acid alcoholic solutions of alizarin (1,2-dihydroxyanthraquinone), purpurin (1,2,4-trihydroxyanthraquinone) and quinalizarin (1,2,5,8-tetrahydroxyanthraquinone) is shown in Fig. 1. Each of these curves belongs to a family that was obtained to establish the molar extinction coefficients of the dyes, to be subsequently reported. Occasionally small decreases in transmission were observed near 6000 Å. with concentrated dye solutions; these were probably due to slight impurities not present in the stock solutions and introduced haphazardly in preparing the specimens for the transmission measurements; because of their infrequent, random occurrence, they were not investigated further.

The work was extended to include the detection of hafnium and fluorine with alizarin and other hydroxyanthraquinones by (b) deBoer, *Rec. trav. chim.*, **44**, 1071 (1925); (c) deBoer and Basart, *Z. anorg. Chem.*, **152**, 203 (1926), who give a method for the titration of fluoride in which the zirconium-alizarin lake serves as indicator. The zirconium–purpurin lake is utilized similarly by (d) Kolthoff and Stansby, *Ind. Eng. Chem.*, *Anal. Ed.*, **6**, 118 (1934).

General Experimental Details.—All transmission measurements were made with the General Electric Company recording photoelectric spectrophotometer.[4] The alcoholic solutions (or suspensions) were usually contained in a cylindrical quartz cell (inside length, 5.15 cm., inside diameter, 2.40 cm.) with nearly plane ends, which was always inserted into the instrument in the same way.

The standard zirconium solution, containing 1 mg. of zirconium per cc., was prepared by dissolving C. P. $ZrOCl_2 \cdot 8H_2O$ in strong hydrochloric acid at room temperature and diluting until the acid concentration was about 2 *N;* the strength of this solution, determined by igniting and weighing the precipitate obtained from a known volume with ammonium hydroxide, showed this salt to be over 99% pure. The standard hafnium solution was prepared by dissolving a known weight of hafnium dioxide (Deutsche Auer Gesellschaft, Berlin) in mixed concentrated hydrofluoric and nitric acids, fuming three times with sulfuric acid, diluting, repeatedly precipitating the hydroxide with ammonium hydroxide until the washings from the precipitate gave no test for sulfate, and finally dissolving this hafnium hydroxide in strong hydrochloric acid and diluting the resulting solution until the acid concentration was about 3 *N*. The hafnium content of this solution was determined by igniting the precipitated hydroxide. A large excess of acid is necessary to make certain that no hydrolysis beyond MO^{++} occurs; such hydrolysis interferes with the colorimetric methods given below.

The dyes, of good quality, were not purified further. They were dissolved by warming them in contact with 95% ethyl alcohol; the resulting solutions were cooled, filtered, and diluted with additional solvent. Solutions thus prepared precipitated the solute even after weeks or months of standing in the laboratory; this annoying behavior, which is in accord with Hüttig's[6] observations on aqueous solutions of alizarin, is probably due to the formation of unstable colloidal suspensions during the heating. (That the tendency to form suspensions of this sort is even more pronounced with the lakes formed by these dyes will appear subsequently.) The stable solutions finally employed contained: alizarin, 1.250 mg./cc.; purpurin, 0.754 mg./cc., quinalizarin, 0.328 mg./cc. Presumably solutions of these concentrations would have been stable initially.

The Colorimetric Method.—The following detailed instructions gradually evolved as zirconium determinations were carried out over a period of several months. Reasona[illegible] adherence to them is advisable if precise results are [illegible].

The [illegible]e formed in clean glass-stoppered graduated cylinders [illegible]ve been rinsed with alcohol. The proper volume (sat[illegible]ory volumes of our solutions: alizarin, 0.5 cc.; purp[illegible] 1 cc.; quinalizarin, 1.5 cc.) of the stable dye solution is added to a small amount (up to, say, 120 micrograms—the maximum amount permissible varies with the dye employed) of the zirconyl ion contained in 1 cc. or less of about 2 *N* hydrochloric acid solution. Strong ammonium hydroxide is now added drop by drop until the color change of the dye reveals that the solution is slightly alkaline. The mixture is then allowed to stand for two minutes, neutralized with 1 *N* hydrochloric acid, and 0.1 cc. of 7 *N* hydrochloric acid finally added. When this mixture has been diluted with alcohol to the proper volume (in our case 27 cc.), its absorption from 4000 to 8000 Å. is measured on the spectrophotometer.

The rate at which the lake forms when no ammonium hydroxide is used decreases as the acidity increases; the addition of ammonium hydroxide eliminates this difficulty. When, in subsequent work, the lakes were formed differently, the differences are described.

Analytical Results.—The transmission curves obtained for a series of zirconium–alizarin determinations are given in Fig. 2, those for a zirconium–purpurin series in Fig. 3. The curves for the zirconium–quinalizarin families resemble those of Fig. 3 closely enough so that it is unnecessary to reproduce them. The absorption due to the dye alone occurs mainly at the shorter wave lengths as the curve for the first colored solution in each series shows; at wave lengths beyond 5600 Å. (alizarin) or 5800 Å. (purpurin) this absorption is so small that the transmission of the dye solution can be taken as I_0 in evaluating the results according to Beer's law

$$\log_{10} \frac{I_0}{I} = \epsilon_2 \, l \, (L) = k\epsilon_2 \, l \, (\mathrm{ZrO}^{++}) \qquad (1)$$

I is the light transmitted at a longer wave length by the sample containing dye and lake; ϵ_2 is the molar absorption coefficient of the lake; *l* is the length of the cell in cm.; (ZrO^{++}) is the "concentration" (moles/liter) of this ion calculated from the micrograms of zirconium added to 27 cc.; *k* is a proportionality constant introduced because the combining ratio of zirconium to dye is unknown; (*L*) is the "concentration" (moles/liter) of the lake in the final solution. The data of Figs. 2 and 3 evaluated in this way for several wave lengths are shown in Figs. 4 and 5; a quinalizarin series is evaluated in Fig. 6; the product $k\epsilon_2$ is given in parentheses for each line beside the corresponding wave length. Examination of these figures reveals that: (1) alizarin gives precise results over the entire range of abscissa explored; (2) quinalizarin is the most sensitive reagent (largest value of $k\epsilon_2$), purpurin being intermediate; (3) as increasing amounts of the zirconium–purpurin lake are formed, *I* becomes too small, leading to positive deviations from Beer's law, which *increase* with the wave length; (4) under the same conditions, *I* for the quinalizarin lakes becomes too large, leading to negative deviations that tend to *decrease* with the wave length. The positive deviations will be discussed below; the negative in a subsequent article. We have found it convenient to use the following

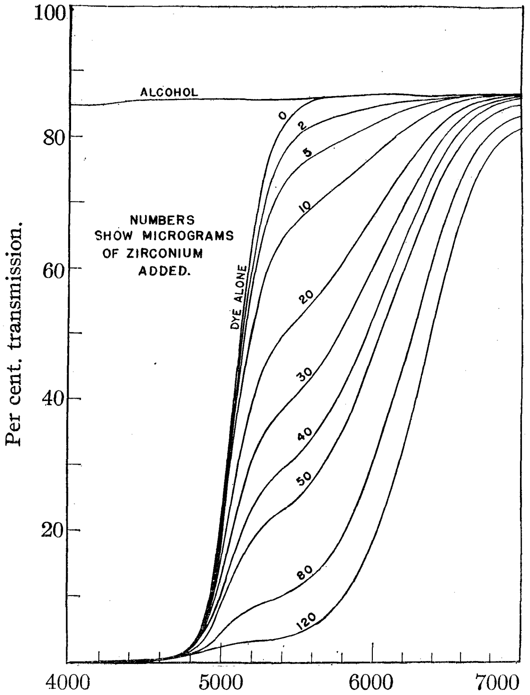

Fig. 2.—Standard transmission curves for the estimation of zirconium with alizarin.

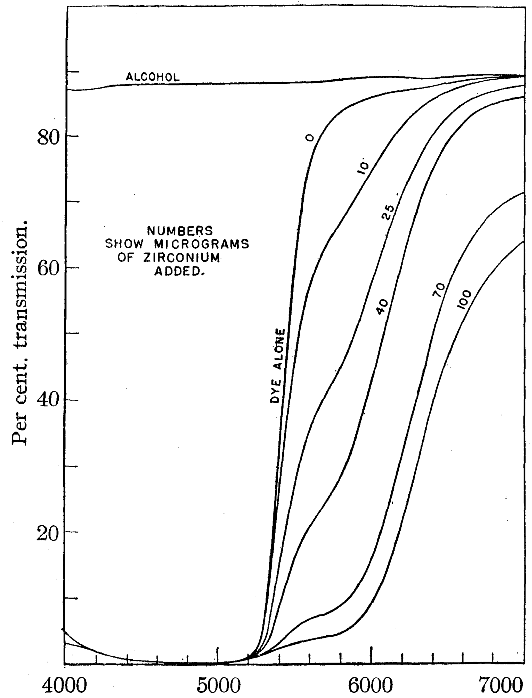

Fig. 3.—Standard transmission curves for the estimation of zirconium with purpurin.

wave lengths (at which absorption by the dye is negligible) in analytical work: alizarin, 5600 Å.; purpurin, 5800 Å.; quinalizarin, 6200 Å.

Effect of Added Substances.—Since the problem of removing interference by most other metallic cations often can be solved by increasing the acid concentration until interfering lakes will not form, the effect of added acid on lake formation was investigated. As 12 *N* hydrochloric or perchloric acid was added before dilution with alcohol to the lake formed from 50 micrograms of zirconium, a minimum in the transmission for 5600 Å. was observed with 0.05 cc. of excess acid. The other transmissions corresponded to the following decreases in micrograms of zirconium: 4.2 (no excess acid); 4.2 (0.5 cc. excess); 11.6 (1 cc. excess). The large transmission at 7000 Å. increased continuously with added excess of acid and the change expressed in micrograms of zirconium was much more pronounced at this wave length.

Sulfate and fluoride ions unite with zirconyl ion to form complex ions so stable that lake formation in the presence of sulfuric or hydrofluoric acid is decreased or prevented.[7] Preliminary experiments indicate that our colorimetric method is adapted to estimating small amounts of either of these interfering anions. Sulfate ion has been studied more thoroughly, and with the following results. When the alizarin lake is formed in the usual manner, and sulfuric acid is added before dilution, the color due to the lake disappears at a measurable rate which increases with greater amounts of added acid. When the acid is added after dilution, the change is similar but less rapid; the transmissions in such experiments increased markedly at first, more slowly afterward: whe[illegible] 0.05 cc. of 12 *N* acid was added to the final [illegible] cc.) volume, the transmissions at 56[illegible]r different times were 55.1% (one-h[illegible]our); 68.6% (fifteen hours); 70.4% ([illegible]y-three hours); 71.2% (forty-seven hours[illegible] The transmission without added sulfuric a[illegible] was 13.6% at 5600 Å. and increased only a few per cent. in forty-eight hours.) When the sulfuric acid is present initially, much less lake is formed; if ammonium hydroxide is used, lake formation is less than when the sulfuric acid is not neutralized;

---

(7) Feigl (ref. 3, p. 254) mentions that fluorides, sulfates, phosphates, organic hydroxy acids, molybdates and tungstates interfere with or modify the formation of the zirconium-alizarin lake. The literature on complex zirconium ions containing fluoride and sulfate is extensive; *cf.* (a) Venable, "Zirconium and its Compounds," Chemical Catalog Co., New York, 1922; (b) Ruer and Levin, *Z. anorg. Chem.*, **46**, 449 (1905); (c) Chauvenet, *Ann. chim.*, [9] **13**, 59 (1920).

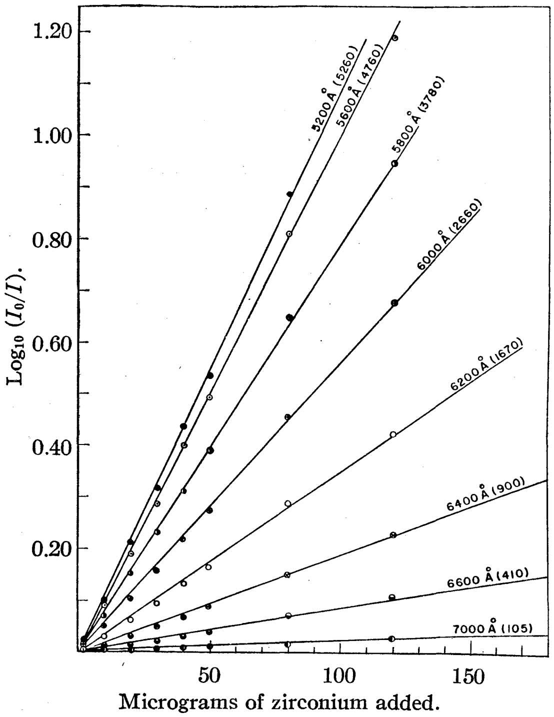

Fig. 4.—Beer's law curves for Fig. 2.

in the 0.05 cc. sulfuric acid experiment soon after mixing, the transmissions at 5600 Å. were 64.8% in the former case and 61.0% in the latter. (It is strange that these transmissions should be smaller than the limiting value, near 70% observed above.) Since the presence of 30 mg. of sulfuric acid increases the transmission due to the zirconium lake from 14 to 65%, it is obvious (since the transmission values are accurate to 0.1 or 0.2%) that this colorimetric method could be used for a rapid estimation of sulfate as well as for studying the formation of zirconyl–sulfate complex ions. A parallel investigation for fluoride ion ought to present no serious difficulty.

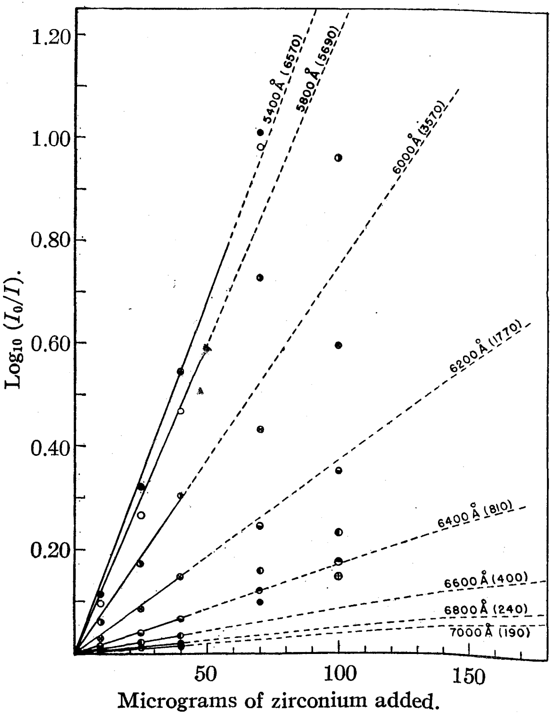

Fig. 5.—Beer's law curves for Fig. 3.

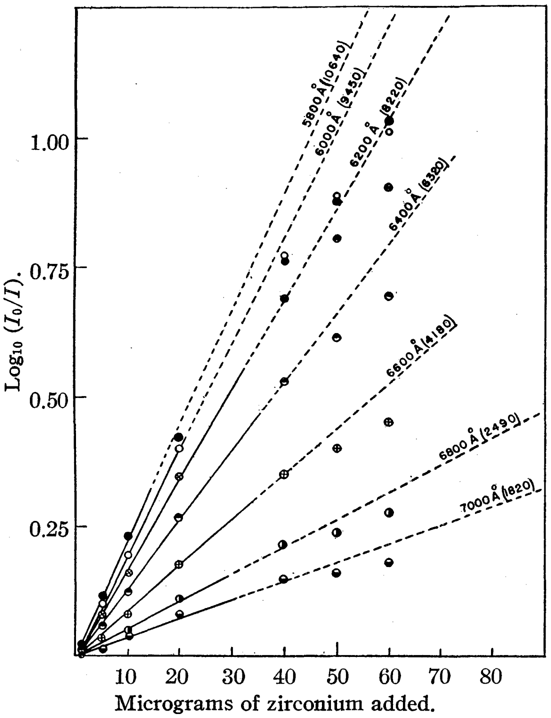

Fig. 6.—Beer's law curves for zirconium-quinalizarin experiments like the alizarin experiments of Fig. 2.

The interference of representative metallic cations not in the same periodic table group with zirconium was studied by adding 1 mg. of these ions to 10 micrograms of zirconium and then forming the lakes in the usual manner, that is, using 0.1 cc. of 7 N hydrochloric acid in excess. Under these conditions, the amount of zirconium cannot be determined accurately from data like those in Fig. 4; but the discrepancy in most cases will not exceed 50%, and may be positive or negative. Fe^{III}, Cr^{III} and Co^{II} decrease the transmission most markedly, without changing greatly the shape of the curve; W^{VI} and Mo^{VI} give curves much steeper than those for zirconium in the 5600 Å. region; many cations (Cd^{++}, Cu^{++}, Pb^{++}, Al^{+++}), when added in the presence of hydrochloric acid, increase the transmission, indicating that here, as with sulfate and fluoride, lake formation is decreased. In order to discover whether this decrease persists when chloride ion (which readily forms complexes) is absent, the experiments described in Fig. 7 were performed.

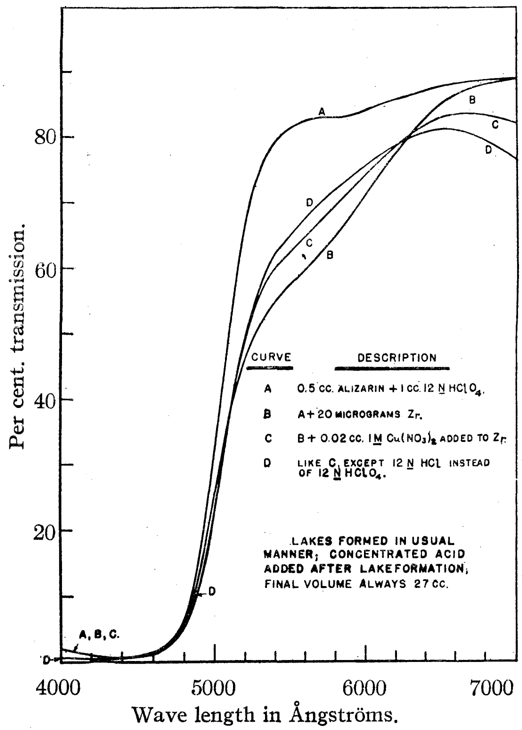

Fig. 7.—Interference of cupric ion with the determination of zirconium.

The curves show that lake formation is decreased even with perchloric acid, although to a smaller extent than with hydrochloric. (It was proved in experiments not given that the absorption near 7000 Å. persists when no dye is used; *i. e.*, it is the absorption due to the blue, solvated cupric ion.) The simplest explanation for the decreasing lake formation encountered when cations like Cu^{++} are added assumes that complex ions (*e. g.*, $CuCl_4^{=}$) derived from them unite with the zirconyl ion. If this explanation is correct, it is surprising to discover that a similar union can occur when perchlorate is the principal anion present: if ZrO^{++} can involve perchlorate in complex ion formation, it probably can react similarly with any other anion.

Experiments have shown that positive errors encountered with ions like Fe^{+++} can be reduced by increasing the amount of excess hydrochloric acid added; under these conditions, of course, the absorption due to the zirconium lake is also decreased.

To summarize: When present in hundred-fold excess, many cations interfere with the colorimetric estimation of zirconium because they either form lakes themselves or because they involve the zirconyl ion in complex formation. The former interference can be mitigated at the expense of sensitivity by increasing the excess of added acid; the latter, by working with perchlorates; either type of error can be compensated obtaining data like those in Fig. 4 with the interfering ion present; the shape of the spectrophotometric curves often reveals whether interference is occurring. There is no reason to believe that these cations will influence appreciably the colorimetric determination of a comparable amount of zirconium.

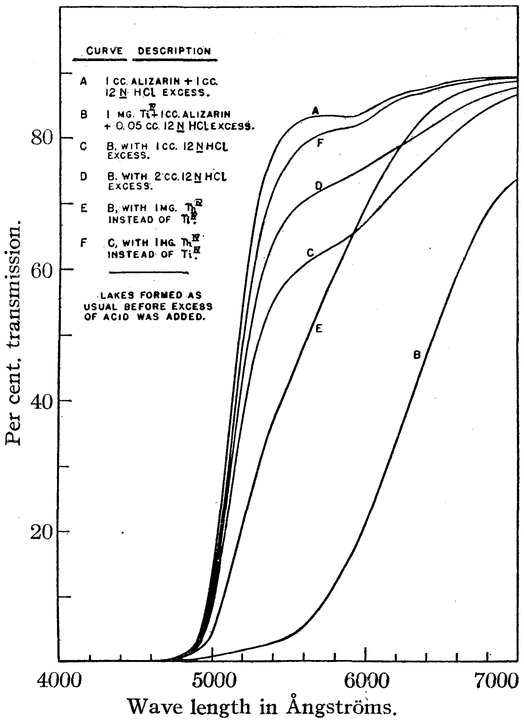

Fig. 8.—Interference of $Ti^{(IV)}$ and $Th^{(IV)}$ with the determination of zirconium.

Other Elements of Group IV.—Figure 8 shows the transmission curves obtained when varying excesses of concentrated hydrochloric acid were added to alizarin lakes formed in the usual manner with hydrochloric acid solutions containing Ti^{IV} and Th^{IV}. The curve from the thorium experiment with 1 cc. of excess acid is not greatly different from the curve for the dye alone; in other words, under our conditions interference by thorium is less serious than interference by titanium. Also, the absorption spectrum of the thorium lake differs markedly from those of the titanium and zirconium lakes, which resemble each other. This difference probably can be traced to the much smaller tendency of thorium to hydrolyze.

Although the close chemical similarity of hafnium to zirconium militates against the existence of any marked difference in their reactions with the hydroxyanthraquinones, there was some hope of finding a difference detectable by the spectrophotometer. Curves analogous to those of Fig. 2 were obtained for each of the three lakes, but they are not reproduced because each is qualitatively identical with the curve for the corresponding zirconium lake. The Beer's law data for the hafnium–alizarin family are given in Fig. 9. Comparison of these $k\epsilon_2$ values with those of Fig. 4 shows the latter to be, on the average, 1.30 times larger; in other words, a gram atom of zirconium combined as the alizarin lake behaves toward the spectrophotometer like 1.3 gram atoms of hafnium similarly combined. It follows that 1 g. of zirconium is spectrophotometrically equivalent to 2.55 g. of hafnium, and that the two elements can be determined in a known weight of sample provided other metallic cations can be removed if they are present. Experiments on hafnium lake formation with varying excesses of perchloric or sulfuric acid gave results similar to those obtained with zirconium.

The Lakes as Suspensions.—The general behavior of the lakes formed in this colorimetric work proves that they form suspensions, not true solutions. No matter what dye is used, the lakes eventually will settle out provided excess dye is present; the settling occurs more rapidly with purpurin and quinalizarin; the purpurin lakes are the most turbid initially, while those of alizarin seem at first to be in solution; the quinalizarin lakes form the most voluminous precipitate. The alizarin and purpurin lakes are red, with the latter darker; the quinalizarin lakes are purple. Having once settled out, the lakes can be re-dispersed easily by shaking; the transmission curve of the re-dispersed lake is very little different from that of the lake freshly prepared.

Crude sedimentation experiments[8] gave 1 micron as the order of magnitude of the average particle diameter in these lakes. Microscopic examination revealed that the diameters ranged, say, from 0.5 to 5 microns; the larger particles appeared to be clusters of smaller ones. It appears, therefore, that we are dealing with particles, near 1 micron in diameter, suspended in an alcoholic dye solution, from which they precipitate as coagulation occurs.

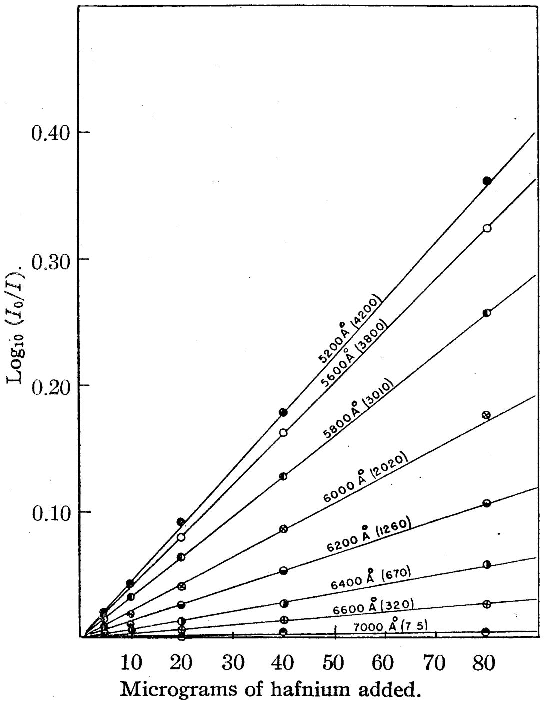

Fig. 9.—Beer's law curves for hafnium–alizarin experiments like the zirconium experiments of Fig. 2.

The rates at which these particles form and dissociate are of interest. Variation, by addition of alcohol, of the volume in which the zirconium–alizarin lake was formed gave the following transmissions for 5600 Å.: 10.0% (usual volume, *ca.* 0.5 cc.); 16.7% (10 cc.); 19.6% (25 cc.). Eight hours later these transmissions were: 10.0, 14.9 and 17.4%; obviously, lake formation, complete in the first experiment, was proceeding very slowly in the other two. To test the reverse reaction, 0.2 mg. of zirconium was converted to the lake with 1 cc. of dye solution and diluted to 50 cc. with alcohol. Aliquot parts of the resulting suspension were diluted 5 and 25 times; the following transmissions were measured at 5600 Å. (the transmission of alcohol was taken as I_0):

Relative dilution	1	5	25
Log (I_0/I) after 1 hr.	1.01	0.179	0.028
Log (I_0/I) after 24 hrs.	0.94	.181	.013

With no change whatever occurring, the values of log (I_0/I) should be inversely proportional to the relative dilution; this is nearly true, not only im-

---

[8] *Cf.* Freundlich, "Kapillarchemie," Vol. I, Akademische Verlagsgesellschaft, Leipzig, 1930, p. 491.

mediately after preparation but also after one day's standing. (An increase in transmission from 83.6 to only 84.3 caused the large change in log (I_0/I) for the most dilute experiment.) Since no appreciable dissociation of the lake was observed in these experiments, more extreme conditions were sought. A zirconium–quinalizarin lake was centrifuged out of the dye solution and redispersed in alcohol: no quinalizarin absorption was detected in this suspension even after several days of standing, after violent shaking (the lake precipitated from alcohol also), or after boiling for five minutes on the steam-bath; the transmission curve of the lake was virtually unaltered by this treatment. The conclusion from these experiments is either that an infinitesimal concentration of the dye or zirconium prevents the dissociation of the lake, or (what is much more probable) that this reaction is very slow. The latter explanation is more easily reconciled with the observation, already mentioned, that sulfuric acid will react with a small amount of lake even when the total volume is 27 cc.

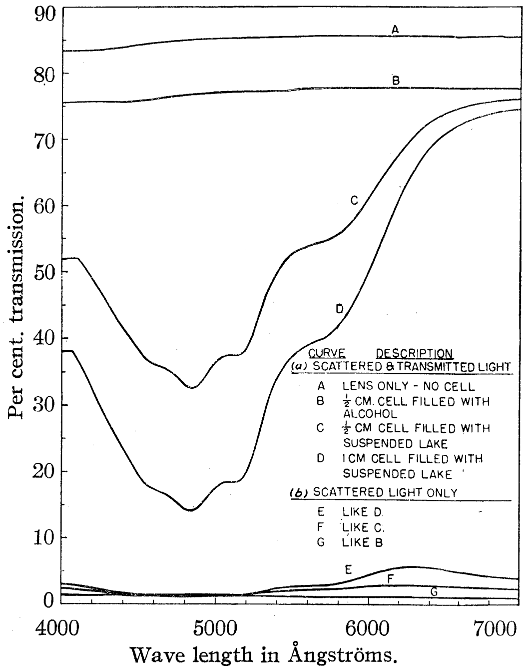

Fig. 10.—Direct measurement of light scattered by a suspended zirconium–purpurin lake.

Scattering of Light.—Particles approximately 1 micron in average diameter will scatter visible light of all wave lengths. Since this diameter does not greatly exceed the average wave length of visible light, the scattering is intermediate between scattering according to Rayleigh's law (amount of scattered light proportional to $1/\lambda^4$) and scattering by white fog (amount of scattered light independent of wave length).[9] It would not be surprising, therefore, to find that the amount of light scattered by the suspended lakes decreased slightly with the wave length.

Two methods of utilizing the spectrophotometer for measuring scattered light were employed. (1) A lens was inserted in the path of the transmission beam so that this beam, normally almost an ellipse (1″ × $^{13}/_{16}$″ or 2.54 × 2.06 cm.) at the entrance to the integrating sphere, converged to an approximate rectangle ($^1/_{16}$″ × $^3/_{16}$″ or 1.58 × 4.75 mm.) at that point. A removable piece of black tape just large enough to block out the beam could be placed on the cell to permit separate measurement of the scattered, and of the scattered plus transmitted light (Fig. 10). (2) Transmission measurements were made with a 1-cm. cell in two positions: against the integrating sphere ("near" position) and 5.5 cm. removed ("far" position). The proportion of scattered light entering the sphere obviously would be much less in the second position (Fig. 11). Glass cells were used for this work; reference to a description of the instrument[4] will aid in showing how the measurements were carried out.

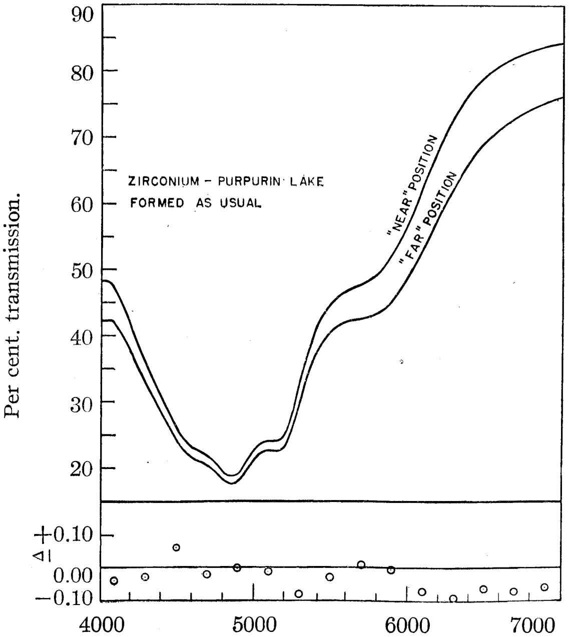

Fig. 11.—Indirect measurement of light scattered by a suspended zirconium–purpurin lake.

---

[9] Langmuir and Westendorp, *Physics*, **1**, 273 (1931).

In connection with Fig. 11, assume (1) that a narrow transmitted beam I^t decreases in intensity from I_0^t to I_l^t as it passes through a 1-cm. cell; (2) that the scattering and the spatial distribution of scattered light are independent of wave length; (3) that the scattered light I_l^s entering the sphere results from a narrow beam I_m^s, whose intensity is proportional to that of the transmitted beam, from which it deviates at a point[10] m, where the intensity, the "mean" intensity, of the latter is I_m^t. I_m^s will travel through the cell along a path a, which is greater than l-m, and will have decreased in intensity to I_l^s when it reaches l. In the "near" position, the light entering the sphere will be $I_l^t + I_l^s$; in the "far" position, the entering light will be assumed equal to I_l^t, although it will be slightly greater since this position is not at infinite distance from the sphere. Under these simplified conditions, if second-order effects are neglected, it can be shown that

$$-\mathrm{d}\log\left(\frac{I_l^s}{I_l^t}\right)\bigg/\mathrm{d}\lambda = [(m + a) - l]\mathrm{d}\epsilon/\mathrm{d}\lambda \quad (2)$$

This treatment is so approximate that $[(m + a) - l]$ will be taken as unity, thus anticipating the results to some extent. Then

$$\Delta = \mathrm{d}\log\left(\frac{I_l^s}{I_l^t}\right)\bigg/\mathrm{d}\lambda + \mathrm{d}\epsilon/\mathrm{d}\lambda = 0 \quad (2a)$$

For Fig. 11, I_l^s/I_l^t at every wave length was calculated as the difference of the two transmission curves divided by the transmission, I_l^t, for the "far" position; ϵ was deduced according to Beer's law from I_0^t, the transmission of alcohol, and I_l^t; the results obtained by applying Eq. 2 to the curves in Fig. 11 are given in the lower part of the figure. (An increase of 0.1% in I_l^t at 4800 Å. produces, other things equal, a decrease of 0.15% in the absolute value of I_l^s, and a decrease at 4700 Å. in Δ from -0.02 to -0.06. This extreme example illustrated the precision required of the spectrophotometer for these measurements.) At the longer wave lengths, Δ is consistently negative, which means, since ϵ is decreasing continuously in this region, that I^s is not increasing rapidly enough. Beyond 5800 Å., log I_l^s/I_l^t actually decreases; only in this region do both quotients in Eq. 2 have the same sign. The simplest explanation of this behavior is that here the second assumption made above is no longer valid—probably because the wave length is large enough relative to the diameter of the particles to decrease their scattering power. Similar calculations have not been carried out for Fig. 10 because the scattering background (near 1% at all wave lengths as shown by the Curve G) is so large that I_l^s cannot be estimated for all wave lengths. Qualitatively Figs. 10 and 11 are in agreement; the decrease in I_l^s is particularly noticeable in the former.

This simplified analysis of scattering by the suspended lakes shows such scattering to be the cause of the positive deviations in Fig. 5; these deviations are greater at longer wave lengths because the ratio of scattered to absorbed light increases with the wave length. Scattering by the lakes (and hence their average particle size) decreases in the order purpurin, quinalizarin, alizarin; scattering by the dilute dye solutions is too small to be measured on the spectrophotometer. The increase in transmission at 7000 Å. observed when excess acid was used (see above) probably results from decrease in the amount of scattered light, indicating that the particle size is smaller with excess acid.

Applicability of the Methods.—Because lake formation by the hydroxyanthraquinones appears to occur with all metallic cations if the hydrogen ion concentration is properly adjusted, there is reason to believe that these dyes can be used for the accurate colorimetric estimation of, say, 10 micrograms of any isolated metallic cation. In other words, their value as *general* reagents for the estimation of any cation may well offset their failure to act as *specific* reagents in all cases. Perhaps the simplest way to carry out the estimation of any isolated metallic cation is by precipitating the lake in ammoniacal solution, washing it free of excess dye, and re-dispersing it in basic or acid alcohol for the transmission measurements. (Preliminary work on the estimation of small amounts of barium has shown the feasibility of this method.) When more than one metallic cation is present, specificity, to a limited degree at least, may be sought by adjusting the hydrogen ion concentration, or by adding ammonium salts to form complexes with the interfering cations.

The scope of the hydroxyanthraquinones as colorimetric reagents thus corresponds roughly with that of dithizone (diphenylthiocarbazone),

---

(10) The point m should lie in the half of the cell nearest the integrating sphere for two reasons. (1) Scattered light originating in the other half of the cell must travel a longer path before reaching the sphere and hence will be more strongly absorbed. (2) Because of geometrical considerations, light from this half of the cell has a smaller chance of finding the opening in the sphere.

which Fischer[11] has so thoroughly investigated. Our experience indicates that dithizone is a good deal more sensitive than the hydroxyanthraquinones (thus ϵ_2 for copper dithizonate is about 35,000[11a]; ϵ_2 for the zirconium–quinalizarin lake is only 10,000); that the former reagent is much more difficult to prepare and to keep unchanged; that procedures involving it are likely to be more tedious, and that precise results are more difficult to obtain when it is used.

Summary

With the aid of a photoelectric recording spectrophotometer, precise colorimetric methods for the determination of zirconium or hafnium in small amounts have been developed. The methods involve lake formation with the hydroxyanthraquinone dyes.

Hafnium and zirconium, while qualitatively indistinguishable, can be estimated in a known weight of sample provided other cations can be removed if they are present.

The effect on lake formation of varying the acid concentration has been studied.

Interference by other cations is negligible unless these are present in larger excess.

The decrease in lake formation caused by complex formation between zirconyl and sulfate ions has been investigated. This decrease is pronounced enough to warrant the belief that the colorimetric methods could be used for the estimation of the various anions, particularly fluoride, that form complexes of this kind.

The scattering of light by the lakes, which are present as suspensions in the alcoholic dye solutions, has been briefly investigated and discussed.

A comparison of the hydroxyanthraquinones with dithizone, another colorimetric reagent that reacts with many cations, shows the latter to be several times more sensitive while the former are simpler to prepare and keep, and are capable of giving accurate results with the expenditure of less time and effort.

Artificial Radioactivity as a Test for Minute Traces of Elements

By G. T. Seaborg and J. J. Livingood

The high voltage and large current of the Berkeley cyclotron[1] have made it possible to obtain radioactive isotopes with activities of extremely high intensities, especially when deuterons are used as the bombarding particles. It is the purpose of this note to show how this circumstance has made it possible to identify extremely small amounts of impurities by means of their characteristic half-lives, after the substance containing the impurities has been bombarded with deuterons in the cyclotron. A quantitative estimation of the amount of the impurity can be made in those cases where the yield of the reaction involving the impurity has been previously determined. In the cases where this yield is not known an estimate can be made by means of a comparison with the known yield of some reaction of the same type. As an example the detection of extremely small amounts of gallium in iron is described. Other examples are given more briefly.

When a sample of iron was bombarded with deuterons it was found that two of the radioactivities produced could be ascribed to an extremely small amount of gallium impurity in the iron (~ six parts in one million, as will be shown later). This was established by the fact that the half-lives of the two activities, 22 min. and 14 hr. (electron emitters), were identical with the known half-lives of electron emitting Ga^{70} and Ga^{72}, respectively.[2,3] A chemical separation according to the methods of Noyes and Bray was performed upon a sample of bombarded iron to which a small amount of "carrier" gallium had been added after the bombardment. The 22 min. and 14 hr. periods appeared only in the gallium fraction.

---

[2] Amaldi, D'Agostini, Fermi, Pontecorvo, Rasetti and Segre, *Proc. Roy. Soc.* (London), **A149**, 522 (1935).

[3] Sagane, *Phys. Rev.*, **53**, 212 (1937).

The radioactive isotopes are formed according to the reactions

$$Ga^{69} + H^2 \longrightarrow Ga^{70} + H^1 \quad (1)$$
$$Ga^{71} + H^2 \longrightarrow Ga^{72} + H^1 \quad (2)$$

and decay as follows

$$Ga^{70} \longrightarrow Ge^{70} + e^- \; (T_{1/2} = 22 \text{ min.}) \quad (3)$$
$$Ga^{72} \longrightarrow Ge^{72} + e^- \; (T_{1/2} = 14 \text{ hr.}) \quad (4)$$

It would be possible to make an accurate estimate of the amount of gallium impurity in the iron if the cross section of reaction (1) or (2) were known, but the yield of these reactions has not been determined. However, an approximate estimate of the amount can be made by comparing the initial intensity of Ga^{70} or Ga^{72} with the initial intensity of another radioactive isotope formed by the same type of reaction under the same conditions from an isotope of known concentration. It has been established[4] by chemical separations that one radio-iron isotope is produced when iron is bombarded with deuterons (in addition to several radio-cobalt and radio-manganese isotopes), and that this radio-iron activity is due to Fe^{59} produced according to the reaction

$$Fe^{58} + H^2 \longrightarrow Fe^{59} + H^1 \quad (5)$$

The Fe^{59} emits electrons and decays with a half-life of 47 days

$$Fe^{59} \longrightarrow Co^{59} + e^- \quad (6)$$

Iron and gallium were separated together by an ether extraction from a sample of iron which had been bombarded in the cyclotron for forty-five minutes with 50 microamperes of deuterons with 6.4 million electron volts of energy. The initial measured activities of the 22 min. Ga^{70}, 14 hr. Ga^{72} and 47 day Fe^{59}, as measured with a Lauritsen type quartz fiber electroscope, were 0.12, 0.0033 and 0.10 divisions/sec., respectively. After correction to infinite bombardment time (through the relation $N_0 = N_\infty\,(1-e^{-0.693\,t/T_{1/2}})$), these initial activities become 0.16, 0.091 and 217 divisions/sec., and these corrected initial activities should be proportional to the concentrations of Ga^{69}, Ga^{71} and Fe^{58} in the bombarded iron. (This assumes that the cross sections of reactions (1), (2) and (5) are equal; they should be nearly equal for elements of nearly the same atomic weight.) It is known that the concentration of Fe^{58} in iron[5] is 0.5% and that gallium[5] is composed of 61.2% Ga^{69} and 38.8% Ga^{71}. Therefore the corrected initial intensities of Fe^{59} and either Ga^{70} or Ga^{72}, together with these abundance ratios, lead to a concentration of six parts per million of gallium in the bombarded iron. One-tenth this much could readily have been detected.

The half-life of an activity can be established quite well (unless it is very short) if it has an initial measured intensity of several times the background (natural leak) of the electroscope. Radioactive isotopes with initial measured activities of ten million times the electroscope background can be formed in many elements (*e. g.*, manganese, nickel, copper) by deuteron bombardments of the order of 100 microampere-hours at 6 to 8 million electron volts. Thus when these elements are present as impurities to as small an extent as one part in a million they can be detected after a deuteron bombardment has been made. The radioactive atoms formed from such minute impurities often must be chemically separated (after the addition of inactive material to act as "carrier") in order that their weak activities may not be buried in the much stronger radiation of the main activity.

On the other hand, larger amounts of impurities (0.01–0.1%) often can be detected by measuring the composite decay curve of a bombarded sample which has not been subjected to a chemical separation. Upon the analysis of the decay curve extraneous periods appear which can be attributed to known radioactive isotopes and hence can be used to identify some of the impurities in the bombarded sample. This method has the advantage that the material is not used up or disturbed in any way. In this manner the presence of a small amount of copper in nickel was established as the result of a neutron bombardment of the nickel. (The neutrons were produced by the reaction of deuterons with beryllium.) The well-known 6 min. electron emitting activity[2] of Cu^{66} and the 12.5 hr. positron and electron emitting activity[6] of Cu^{64} appeared. These were formed according to the reactions

$$Cu^{63} + n \longrightarrow Cu^{64} + \gamma \quad (7)$$
$$Cu^{65} + n \longrightarrow Cu^{66} + \gamma \quad (8)$$

The presence of a small amount of iron in a sample of cobalt oxide was established by a deuteron bombardment of the oxide. The analysis of the composite decay curve revealed an 18-hr. positron emitting activity. It has been shown that this activity is due to a radio-cobalt which can be formed only by the bombardment of iron.[4]

(5) Livingston and Bethe, *Rev. Modern Phys.*, **9**, 380 (1937).

(6) Van Voorhis, *Phys. Rev.*, **49**, 876 (1936).

In other experiments it has been possible to establish the presence of extremely small amounts of phosphorus and sulfur as a result of the appearance of the 14-day electron emitting activity of P^{32}. The P^{32} was formed according to the reactions

$$P^{31} + H^2 \longrightarrow P^{32} + H^1 \qquad (9)$$
$$P^{31} + n \longrightarrow P^{32} + \gamma \qquad (10)$$
$$S^{32} + n \longrightarrow P^{32} + H^1 \qquad (11)$$

For example, a neutron bombardment of a sheet of paper revealed the presence of the sulfur as the result of reaction (11).

This research has been made possible through the generous coöperation of the Research Corporation, the Chemical Foundation and the Josiah Macy, Jr., Foundation.

Summary

It is shown how it is possible to detect and identify very small amounts of impurities by means of their characteristic half-lives, after the substance containing the impurities has been rendered radioactive by bombardment with charged particles of high energy or with neutrons. With the help of a chemical separation after the bombardment, impurities present to the order of one part in a million can sometimes be detected. For example, a gallium impurity of six parts per million was found in a sample of iron. Impurities to the extent of one part in one thousand to ten thousand can often be detected without subjecting the sample to chemical analysis.

The Magnetic Properties and Structure of Manganous and Cobaltous Dipyridine Chlorides

BY DAVID P. MELLOR AND CHARLES D. CORYELL

It has been reported by Cox, Shorter, Wardlaw, and Way[1] on the basis of a determination of unit cell dimensions that manganous dipyridine chloride and the α-form of cobaltous dipyridine chloride have square *trans*-coördination of pyridine and chlorine about the metal atoms. Complexes of atoms with square bonds have been the object of much interest since this type of structure was first proposed by Werner to explain the existence of certain isomeric platinum compounds.[2] With the extension of our knowledge about the nature of chemical bonds there has been formulated[3] a reliable magnetic criterion by which the existence of square covalent structures for manganous, ferric, ferrous, cobaltic, cobaltous, and nickelous atoms may be determined. It is concluded in this paper that the results of magnetic measurements on the manganous and α-cobaltous dipyridine chlorides are not compatible with the square coördinated structure proposed by Cox and coworkers, but that they are compatible with an octahedral ionic type of structure.

Magnetic measurements were carried out on the manganese compound by the Gouy method. The forces in mg. (Δw corrected for blank) for a cylindrical tube with water in the upper compartment and air in the lower compartment were for two different field strengths -2.03 and -3.39. The forces with manganous dipyridine chloride, twice crystallized from ethanol and packed to a density of 0.99_5 g./ml., were $+135$ and $+234$, respectively, at 22° against air. With use of an estimated value of -160×10^{-6} for the molecular diamagnetism of the compound and with the assumption of the validity of Curie's law, the calculated values of the magnetic moment are 5.94 and 6.00 Bohr magnetons, the average being 5.97. The expected value of the moment for the manganous atom forming four dsp^2 bonds, essentially covalent and directed toward the corners of a square, is 3.88 plus a small orbital contribution; the expected value for the atom with tetrahedral sp^3 bonds or for the ion is 5.92 magnetons with no orbital contribution (normal state $^6S_{5/2}$). The measurements are in good agreement with the second of these values.

Barkworth and Sugden[4] have shown that the α-form (violet modification) of cobaltous dipyridine chloride has a moment of 5.34 Bohr magnetons, and that the β-form (blue modification) has

[3] L. Pauling, THIS JOURNAL, **53**, 1367 (1931).

[4] E. D. P. Barkworth and S. Sugden, *Nature*, **139**, 374 (1937).

a moment of 4.60 magnetons. The expected moment for the cobaltous atom forming dsp^2 bonds is 1.73 plus orbital contribution, and that for the atom forming sp^3 bonds or for the ion is 3.88 plus orbital contribution. We accordingly conclude that the bonds to the cobalt atom are essentially ionic, with an unexpectedly large orbital contribution in the case of the α-form.

A tetrahedral configuration is not compatible with the small dimensions of the c-axes (3.73 and 3.65 Å., respectively) of the manganous and cobaltous compounds, as pointed out by Cox and his co-workers. This configuration is not, however, the only alternative to a square configuration. A reasonable structure for the complexes, one not considered by these workers, can be formulated with each metal ion sharing four coplanar chloride ions in pairs and holding two pyridine molecules at right angles to the plane of the chloride ions. The proposed structure thus contains an ionic octahedral complex with two shared edges. The metal-metal distances in the metal-dichloride chains are calculated[5] to be 3.7 and 3.6 Å., respectively. The pyridine rings lie in planes the same distance apart. The calculated distances agree with the observed c values to within the accuracy of the ionic radii.

Both the α- and β-forms of the cobalt compound give in organic solvents[6] identical blue solutions, which have been shown[1,6] to contain monomeric solute molecules in bromoform, chloroform, and phenol. It is probable that the configuration about the cobalt ion is tetrahedral in these solutions. The fact that the colors of the solutions are nearly the same as that of the solid β-modification suggests that there is tetrahedral coördination around the metal ions in this solid.

Compounds with a coplanar configuration containing ionic bonds are to be expected only if the electronegative groups are part of a rigid plane structure, as for example in ferriheme chloride (hemin) and ferroheme, in both of which the iron atoms were shown[7] to be held as ions. It seems very likely that the bonds to beryllium in beryllium phthalocyanin and the bonds to magnesium in chlorophyll are predominantly ionic. The existence of these compounds accordingly is not proof that the metals form square covalent bonds; whereas square coördination with groups which are free to rearrange is an indication of the predominant covalent character of the bonds.[3,8] Square bonds have not as yet been found in any manganous compound; it has been reported that impure cobalt phthalocyanin[9] and an impure cobaltous phenanthroline cyanide[10] show magnetic evidence for square bonds, but these observations have not been verified with pure substances.

Summary

The magnetic criterion for bond type indicates that manganese and cobalt atoms in the dipyridine dichloride compounds form ionic bonds rather than covalent dsp^2 bonds. It is suggested that an octahedral ionic type of structure occurs in the manganese and α-cobalt compound and a tetrahedral ionic type occurs in the β-cobalt compound.

The Preparation of Fully Acetylated Amides of Aldonic Acids

BY GORDON B. ROBBINS AND FRED W. UPSON

Acetylgluconic acid was prepared by Upson and Bartz[1] by direct acetylation of δ-gluconic lactone. Tetraacetylgluconic acid monohydrate which results on acetylation of δ-gluconic lactone was reported in the journal article but the 2,3,4,5,6-pentaacetylgluconic acid was also prepared by further acetylation of the 2,3,4,6-product and is reported in the thesis of Bartz. More recently Major and Cook[2] report the pentaacetyl derivative prepared by the same method. This method, however, has not proved to be a general one for the preparation of fully acetylated acids since all other lactones with which we have worked have yielded acetylated lactones. It is necessary to start with a derivative such as the amide or ester which is not lactone in character.[2,3]

Major and Cook have made, from completely acetylated aldonic acids, the corresponding acid chlorides which offer a number of possibilities for the synthesis in the sugar series.

A method for the preparation of fully acetylated sugar acids has been reported by Hurd and Sowden[4] using the following sequence of reactions: aldose ⟶ aldose oxime ⟶ acetylated nitrile ⟶ acetylated amide ⟶ acetylated acid.

Acetylated amides of the aldonic acids have been prepared in this Laboratory by a method which is general in its application and is less complicated than that of Hurd and Sowden. The aldonic acid lactone is converted to the amide by solution in liquid ammonia followed by spontaneous evaporation of the excess ammonia.[5]

The amide results in pure condition and the yield is excellent. The amide is then subjected to direct acetylation using either sulfuric acid or zinc chloride as the catalyst. We have been able to explain a discrepancy between the work of Miksic[6] and that of Zemplén and Kiss.[7] Miksic reported the preparation of acetyl derivatives in which both the amide group and the hydroxyl groups are acetylated whereas the latter authors have obtained an acetyl derivative of an unacetylated amide group. Zemplén and Kiss used zinc chloride as the catalyst whereas Miksic used sulfuric acid. The work here reported indicates that the use of zinc chloride causes acetylation of the hydroxyl groups only whereas acetylation occurs in the amide group as well when sulfuric acid is the catalyst. This is illustrated in the acetylation of gluconamide and galactonamide using the two substances as catalysts.

The acetyl amides are readily converted to the corresponding acids by the method of Hurd and Sowden[4] through the action of nitrous acid in glacial acetic acid solution. We have shown that it is not necessary to isolate the acetyl amide. The acetylating mixture containing the amide may be treated directly with nitrous oxide giving excellent yields of the acetyl aldonic acid. Experiments with these acetyl aldonic acids will be reported in a later paper.

Experimental

Below is described the acetylation of the amides of several aldonic acids together with the properties of the resulting products. In all cases the rotatory power of the compounds was determined by means of a Bates saccharimeter using white light and a dichromate solution as a filter.

Pentaacetyl-*d*-gluconamide.—Fused zinc chloride (5 g.) was dissolved in acetic anhydride (50 cc.) and the mixture was cooled to 0°. Gluconamide (7.5 g.) was added with shaking, and the mixture was kept in an ice-bath for an hour. The reaction mixture stood at room temperature for twenty-four hours (or until all amide was dissolved).

The mixture was poured out into 200 cc. of ice and water, and stirred vigorously for forty-five minutes, giving a crystalline powder. The solid was filtered and washed with water. It was recrystallized from 95% alcohol: m. p. 184–185°; $[\alpha]^{25}\text{D}$ +23.6° (*c*, 0.9 in $CHCl_3$)[1,4,7].

Pentaacetyl-*d*-galactonamide.—Galactonamide was acetylated as described above. No solid separated upon stirring. Extraction with chloroform was followed by evaporation of solvent. Addition of ether gave a solid product which was filtered. Recrystallization from benzene yielded pure pentaacetyl-*d*-galactonamide: m. p. 165–166°; $[\alpha]^{25}\text{D}$ +26.7° (*c*, 1.8 in $CHCl_3$).[4]

Anal. Calcd. for $C_{16}H_{23}O_{11}N$: C, 47.38; H, 5.73. Found: C, 47.36; H, 5.74.

Pentaacetyl-*d*-mannonamide.—Mannonamide was acetylated as described above and the chloroform extract was evaporated to a gum which crystallized on standing. Recrystallization was accomplished from butyl ethyl ether

Pentaacetyl-*d*-gulonamide.—This compound was prepared from a sample of *d*-gulonic lactone ($[\alpha]^{20}D$ −54.4°), using the method described in the preparation of the galactonic derivative. Recrystallization several times from absolute alcohol gave crystals melting at 162–164°; $[\alpha]^{25}D$ +22.7° (*c*, 1.6 in $CHCl_3$).

Anal. Calcd. for $C_{16}H_{23}O_{11}N$: C, 47.38; H, 5.73. Found: C, 47.19; H, 5.68.

Hexaacetyl-*d*-gluconamide.—Acetic anhydride (50 cc.) and concentrated sulfuric acid (3 cc.) were mixed and cooled to 0°. Gluconamide (6 g.) was added and the reaction was completed as in the case of the pentaacetyl derivatives. The solution was poured into ice water and sodium bicarbonate (10 g.) was added. Chloroform extraction yielded a sirup which crystallized upon standing. Ether was added and it was filtered. Recrystallization from alcohol gave the hexaacetyl-*d*-gluconamide: m. p. 110°; $[\alpha]^{25}D$ +25.8° (*c*, 1.8 in $CHCl_3$).

Anal. Calcd. for $C_{18}H_{25}O_{12}N$: C, 48.31; H, 5.64. Found: C, 48.14; H, 5.70.

Hexaacetyl-*d*-galactonamide.—Galactonamide was acetylated in the same manner as for preparation of the hexaacetyl-*d*-gluconamide. A solid separated upon stirring with ice water and sodium bicarbonate. The material was filtered and recrystallized from benzene: m. p. 149.5–150°; $[\alpha]^{25}D$ +19.0° (*c*, 1.8 in $CHCl_3$).

Anal. Calcd. for $C_{18}H_{25}O_{12}N$: C, 48.31; H, 5.64. Found: C, 48.08; H, 5.71.

Summary

1. A general preparation of acetylated sugar acid amides has been indicated. This offers an easier route to obtain the fully acetylated sugar acids.

2. The product of acetylation of amides of sugar acids is governed by the catalyst used. Concentrated sulfuric acid gives a product in which both hydroxyl groups and amide nitrogen are acetylated. Zinc chloride gives a product in which only hydroxyls are acetylated.

3. The above methods have been applied to the preparation of several acetylated amides, of which four are new compounds.

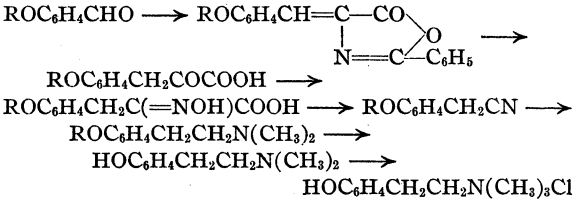
β-Phenylethylamine Derivatives.[1] Tertiary and Quaternary Salts

BY JOHANNES S. BUCK, RICHARD BALTZLY AND WALTER S. IDE

The present paper describes the preparation and properties of tertiary amine salts and quaternary salts containing the phenylethyl group. One series consists of alkoxy- and hydroxy-β-phenylethyldimethylamine hydrochlorides, of the type of hordenine, the other of the quaternary derivatives of these compounds.

Hordenine has received considerable attention in the literature, and a few related compounds also have been dealt with. For the most part the syntheses are unsatisfactory and not capable of being applied generally. The authors therefore worked out a series of reactions, a composite of various literature methods, which is generally applicable and which gives good yields at each stage. Starting with a substituted benzaldehyde, this is converted successively into the azlactone, the phenylpyruvic acid, the pyruvic acid oxime, and the phenylacetonitrile. This latter is then reduced, in one step, to the alkoxy-β-phenylethyldimethylamine, by catalytic reduction in the presence of excess dimethylamine. The tertiary amine may be converted readily into the quaternary salt, or O-dealkylated to give the hydroxy compound, which, in turn, easily forms the quaternary compound.

The series of reactions used is as follows



$$ROC_6H_4CHO \longrightarrow ROC_6H_4CH{=}\underset{\displaystyle N{=}C{<}C_6H_5}{C{-}CO{>}O} \longrightarrow ROC_6H_4CH_2COCOOH \longrightarrow ROC_6H_4CH_2C({=}NOH)COOH \longrightarrow ROC_6H_4CH_2CN \longrightarrow ROC_6H_4CH_2CH_2N(CH_3)_2 \longrightarrow HOC_6H_4CH_2CH_2N(CH_3)_2 \longrightarrow HOC_6H_4CH_2CH_2N(CH_3)_3Cl$$

Experimental

The intermediates required were all prepared by the methods given below. A number of them have been described previously in the literature (many prepared by other methods). Only the ones not previously recorded are given (Table I).

Azlactones (2-Phenyl-4-(alkoxybenzal)-oxazolones).—These compounds were prepared in the conventional way from the appropriate benzaldehyde and hippuric acid,[2] and

were recrystallized from acetic acid, in which they are rather sparingly soluble, until pure. The unrecrystallized material is usually satisfactory for the subsequent hydrolysis. With most aldehydes the yield is from 60 to 70%.

Alkoxyphenylpyruvic Acids.—The azlactones were hydrolyzed by sodium hydroxide and the phenylpyruvic acid separated from benzoic acid by means of sulfur dioxide, followed by washing with ether where the solubility permitted.[3] For analysis they were recrystallized until pure, from aqueous acetic acid, aqueous alcohol, or ether–pentane. Ordinarily, the reaction product was used directly for the next step (oximation). Melting points are usually unsharp. The yields vary widely with different acids, from 55 to 90%.

Alkoxyphenylpyruvic Acid Oximes.—The method of Baker and Robinson[4] was found to be quite satisfactory for the preparation of these compounds. However, attempts at rigid purification were in general unsuccessful, dehydration and decarboxylation gradually taking place, the corresponding phenylacetonitrile being obtained ultimately. For this reason, the unpurified oxime, after drying, was used directly for the next step, a procedure for which there is ample precedent.[5] The yields of the oximes are high, usually well over 80%.

Alkoxyphenylacetonitriles.—Decarboxylation and dehydration of the oximes were carried out simultaneously by means of acetic anhydride, using not more than 20 g. of oxime for a preparation.[4] Acetic anhydride is retained persistently by the nitriles so that, after isolation, washing and distillation, they were again washed and redistilled or recrystallized from hexane. The liquid nitriles have only a faint nitrile-type odor. The yields vary according to the oxime used, but usually are considerably over 80%.

Alkoxyphenylethyldimethylamine Hydrochlorides.—The alkoxyphenylacetonitrile, in methanol solution, with excess (2.5 mol) of dimethylamine (33% in methanol) was reduced catalytically with a palladium catalyst. This reaction, first used by Kindler and Hesse,[6] gave excellent results. After reduction was complete the catalyst was removed, excess dimethylamine and methanol distilled off, and the residual oil dissolved in dilute hydrochloric acid. Non-basic material was extracted with ether, and the aqueous solution then cooled in ice and treated with sodium nitrite solution (40 g. nitrite per mole of base). After thorough extraction with ether, the acid solution was made strongly alkaline and the base extracted with ether. After drying the extract over solid potassium hydroxide, the hydrochloride was obtained by passing hydrogen chloride into the ether solution. The crude hydrochlorides were recrystallized twice or more from methyl or ethyl alcohol, with ethyl acetate and/or ether, and were so obtained as well crystallized white salts, readily soluble in alcohol, water and hydrochloric acid and practically insoluble in ether, ethyl acetate, etc. Some of them are hygroscopic.

The palladium catalyst was either the commercial "palladium mohr" or material prepared by the Willstätter–Waldschmidt-Leitz method. The optimum speed of reduction appears to be about 1 g. nitrile per hour (Burgess–Parr apparatus, at room temperature and 3 atm. pressure) and relatively large amounts of catalyst, one-quarter upward of the weight of nitrile, were used to obtain this speed. The nitrile must be very pure.

Hydroxyphenylethyldimethylamine Hydrochlorides.—These compounds were obtained by demethylating the corresponding methoxy hydrochlorides with hydrochloric acid (two hours at 160° in carbon dioxide atmosphere). The acid solution was then evaporated to dryness under reduced pressure and the residue recrystallized as with the

alkoxy hydrochlorides. The *p*-hydroxy compound was identical with authentic hordenine. The properties of the compounds (hydroxy and alkoxy) are given in Table II.

Alkoxy- and Hydroxyphenylethyltrimethylamine Chlorides.—The quaternary salts were prepared from the tertiary amines, this method being preferable to using the primary amine. The starting hydrochloride was dissolved in water and the base liberated by potassium carbonate solution, extracted with (or, if solid, dissolved in) benzene, and dried with solid potassium hydroxide (for the alkoxy bases) or sodium sulfate (for the hydroxy bases). A considerable excess of methyl iodide was added, when the quaternary iodide rapidly separated out. After some hours ether was added to the usually gelatinous mass, and the solid filtered off, washed with ether, dissolved in water, and converted into the chloride by silver chloride. The aqueous solution was evaporated to dryness under reduced pressure and the residue recrystallized from alcohol–ether.

The chlorides form well-crystallized compounds, soluble in water, alcohol and hydrochloric acid, and practically insoluble in ether, ethyl acetate, etc. They are unusually difficult to analyze. Their properties are described in Table III.

Summary

A series of hydroxy- and alkoxyphenylethyldimethylamine hydrochlorides (18 compounds) and a series of hydroxy- and alkoxyphenylethyltrimethylamine chlorides (18 compounds) have been prepared, all by the same sequence of reactions, which appears to be general. The preparation of the intermediates also is described.

TUCKAHOE, NEW YORK RECEIVED MAY 20, 1938

[CONTRIBUTION FROM THE BIOCHEMISTRY LABORATORY OF THE UNIVERSITY OF OKLAHOMA MEDICAL SCHOOL]

Relations of *cis-trans* Isomerism to Asymmetric Oxidation of Sugars[1]

BY M. R. EVERETT AND FAY SHEPPARD

Richtmyer and Hudson[2] recently reported the interesting phenomenon of unequal quantitative reduction of alkaline copper reagents by *d*- and *l*-forms of aldoses, when *d*- or *l*-tartaric acids were used in Shaffer–Hartman–Somogyi reagents. We have now completed similar experiments with *d*-, *l*- and *meso*-tartrate Folin–Wu reagents.[3] The *l*-tartaric acid employed was prepared by the method described by Richtmyer and Hudson, and had the correct $[\alpha]^{20}\text{D}$ $-14°$. The *d*- and *meso*-tartaric acids were Central Scientific Co. and Eastman Kodak Co. products with $[\alpha]^{20}\text{D}$ $+14$ and $+0.05°$, respectively. The sugar solutions and special reagents[4] were freshly prepared, immediately before analysis. Several concentrations of each sugar were investigated and compared with suitable *d*-glucose standards. Determinations were made under strictly comparable conditions.

The results reported in Table I are the reducing equivalents relative to *d*-glucose and *d*-tartrate reagent taken as 1.00 and are averages of four or more determinations. Corrections for moisture content of sugars and proportionality of the analytical method have been applied. The reagents employed by us appear to be somewhat more sensitive to spacial configuration than the copper reagents used by Richtmyer and Hudson, but both investigations show that *d*-forms of arabinose, fructose and mannose and *l*-forms of fucose and rhamnose select the *l*-tartrate reagent; *d*-forms of galactose, lactose and mannoketoheptose and *l*-arabinose select the *d*-tartrate reagent; and *d*-forms of glucose and xylose show little selectivity. For sugars not investigated by Richtmyer and Hudson, we find that *d*-forms of maltose, melibiose and ribose select the *l*-tartrate reagent; *d*-forms of galacturonic and glycuronic acids, mannoheptose and sorbose select the *d*-reagent; *d*-forms of cellobiose, gentiobiose, glucosamine and lyxose and *l*-forms of ascorbic acid, sorbose and xylose are not very selective. Our *meso*-tartrate reagent is reduced more than either of the *trans* reagents by *d*-forms of cellobiose, gentiobiose, glycuronic acid, lactose, maltose, α-mannoheptose, mannoketoheptose and mannose.

It is evident from these results that asymmetric oxidation of sugars bears no simple relation to ordinary optical or planar isomerism, and is influenced by extraplanar molecular relations (group substitution, *cis–trans* relations, etc.). The reducing values of Table I are definitely related to the *cis–trans* classification of sugars suggested by the authors.[6,7] This arrangement of sugars in eight *cis–trans* groups, corresponding to the eight aldopentoses, is reproduced in Table II.

Oxidation in alkaline solution is complicated by mutarotation and epimerization, and recently Isbell[8] has shown that mutarotation is correlated with *cis–trans* configuration. The behavior of

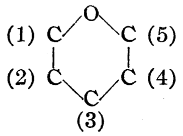
Type formula



Carbon 1 is the characteristic potential carbonyl.

pentoses with alkaline reagents (Table I) follows epimeric relations; thus, xylose and lyxose (epimeric *trans* types) react almost equally with *d*- and *l*-tartrate reagents, whereas ribose and arabinose (epimeric *cis* types) select opposite enantiomorphs of reagents. Six and seven carbon sugars behave qualitatively like related epimeric pentose types, but deviate quantitatively. Additional carbon at pyranoid positions 1 or 5 (Table II) limits mobility of the cyclic oxygen, allowing opposite planar arrangements of cyclic oxygen in aldohexoses of each *cis–trans* group and the resultant alteration of *cis–trans* influences at pyranoid position 5.

In our experiments *cis* sugars with opposite extraplanar relationships showed opposing selectivity for asymmetric oxidizing agents. *d*-Mannose and *l*-rhamnose, with 2,3-*cis* hydroxyls *trans* to cyclic oxygen, selected *l*-tartrate reagent, and *d*-galactose, an extraplanar opposite as far as positions 2, 3 and 4 are concerned, selected the *d*-reagent (Table I). The oxidation of sugars is thus influenced by spacial configuration in three dimensions.

In Table III we have listed molar reducing equivalents of sugars and their percentage deviations from the *d*-glucose standard. The molar equivalents have been calculated as percentages

[a] Concentrations as in Table I.

of the reduction of *d*-tartrate reagent by *d*-glucose. The deviations are defined as follows: X, representing planar influences for *trans* reagents, is the molar equivalent for the *d*-reagent minus that for the *l*-reagent. Y, representing extraplanar influences for *trans* reagents, is the equivalent for that *trans* reagent most reduced by any particular sugar minus the equivalent of the *trans* sugar, *d*-glucose, for the *d*-reagent. Z, representing the total influence upon the *meso* reagent, is the equivalent for this reagent minus that of *d*-glucose for the *d*-reagent.

The deviations of monosaccharides with *trans* tartrate reagents reveal that epimerized *d*-glucose, *d*-glucosamine, *d*-xylose, *d*-lyxose and *l*-sorbose are most symmetrical in a planar sense, since their X deviations approach zero. However, these *trans* sugars have average Y deviations of 0, −4.5, −16, −20 and −17.5, respectively. The presence of the CH_2OH group at position 5 in *d*-glucose therefore increases the *trans* characteristics of the pyranoid molecule. In the three-dimensional strainless model of *d*-glucopyranose, viewed from the plane of the ring, the additional hydroxyl group of carbon 6 balances the other oxygens in both a planar (right and left) and an extraplanar (polar) sense. In *l*-sorbose and *d*-xylose models the oxygens are well balanced in a planar sense but not in an extraplanar sense, since there is no CH_2OH group at pyranoid position 5.

Lengthening the carbon chain therefore results in appreciable alteration of extraplanar influences, which are interrelated with planar influences. The interrelation is demonstrated by the fact that *d*- and *l*-isomerism can be represented alternately as a polar phenomenon relative to the pyranoid cyclic oxygen. Inversion of strainless pyranoid models of *l*-sugars, whose ring systems are thus viewed as identical with those of *d*-sugars, reveals polar interchanges between carbons 1 and 5 and between carbons 2 and 4. Relating sugar antipodes in this fashion facilitates comparisons which are difficult with the usual right and left disymmetric formulas. Since planar and extraplanar influences have a common space coördinate, the substitution of CH_2OH or COOH groups at pyranoid positions 1 or 5 affects both *cis–trans* (Y) and planar (X) influences, the latter causing a "shift to the right" in reagent selection by ketoses and alduronic acids. (Compare these with related aldohexoses in Table III.)

Of the monosaccharides studied, *d*-glucose gives rise to the most symmetrical three-dimensional epimeric system. In a planar sense, epimerized *d*-glucosamine, *d*-xylose, *l*-sorbose and *d*-lyxose are just as symmetrical, while *d*-galacturonic acid, *d*-ribose, *d*-arabinose and *d*-galactose (3,4-*cis* types) are most unsymmetrical. In an extraplanar sense, *d*-glucose, *d*-glucosamine and *d*-fructose are most symmetrical, the latter evidently going to a balanced epimeric system by a Lobry de Bruyn rearrangement; methylpentoses are most unsymmetrical and reduce less copper than other sugars.

The *trans* arrangement of epimerized *d*-glucose and its relatives, *d*-fructose and *d*-glycuronic acid, is also the most favorable influence for reduction of *meso*-tartrate reagent (Table III). With aldopentoses, extraplanar deviations (Y) for *trans* reagents are uniformly less than the total deviations (Z) for the *meso* reagent, and the latter is not always reduced equally by planar antipodes. (See xylose and sorbose in Table III.) Analogous smaller deviations occur even with the non-asymmetric Sumner reagent.

The fact that *d*-glucose reduces *meso* reagent 23% more than does *d*-xylose, indicates again that mutarotation and epimerization of the *trans* pentose are insufficient to balance its molecule in all dimensions and that terminal CH_2OH groups are active. Certain sugars which are not optical antipodes reduce the *meso* reagent equally (*d*-xylose and *d*-sorbose, also *d*-mannose and *d*-galacturonic acid); others (*d*-glucose, *l*-ascorbic acid, the methylpentoses and ketohexoses) have approximately equal Y and Z deviations.

More detailed correlation is problematical because the concentration of certain sugars affects their oxidation. Notable instances are *d*-mannose and *d*-glycuronic acid with *trans* tartrate reagents (Table III), but the most remarkable example is α-glucosan with *d*-tartrate.[7]

The β-glucose-glucosides, cellobiose and gentiobiose, resemble the parent monosaccharide with *trans* reagents, but differ in their effects upon *meso* reagent. Cellobiose presents a space arrangement for *meso* oxidation markedly superior to that of any sugar studied (Table III). The marked reduction of Sumner's reagent by disaccharides is significant.

We have called attention previously to the usefulness of Sumner/Folin–Wu ratios of glucose equivalents for differentiating sugars in solution.[7,9]

(9) Everett, Edwards and Sheppard, *J. Biol. Chem.*, **104**, 11 (1934).

The present study provides a more scientific basis for these ratios and correlates them with sugar structure.

Summary

1. Quantitative studies have been made of the oxidation of twenty-five sugars by *d*-, *l*- and *meso*-tartrate modifications of the Folin–Wu alkaline copper reagent and by Sumner's dinitrosalicylate reagent.

2. The behavior of reducing sugars is determined by the entire sugar molecule, but intramolecular influences can be conveniently classified as planar and extraplanar, *cis–trans* relations being important extraplanar influences.

3. Epimeric sugars have related behaviors, the glucose epimeric system being most symmetrical in all dimensions. *cis*-Sugars are most unsymmetrical in a planar sense and methylpentoses in an extraplanar sense.

4. *meso*-Tartrate reagent is susceptible to both planar and extraplanar influences.

Hydantoins Derived from the Analogs of 1,3-Dichloroisopropoxyethyl Methyl Ketone[1]

BY BRUCE B. ALLEN WITH HENRY R. HENZE

As a continuation of attempts to prepare substances possessing soporific properties, attention has now been directed to the synthesis of 5,5-disubstituted hydantoins in which one of the substituents is of the halogenoalkoxyalkyl type. In this Laboratory, the application of Bucherer's[2] hydantoin synthesis has been extended to the preparation of disubstituted heterocyclic compounds from such bifunctional carbonyl substances as alkoxymethyl alkyl (or aryl) ketones[3] and phenoxymethyl alkyl (or aryl) ketones,[4] and has been shown to be advantageous over other accepted methods as regards yield, ease of execution, and degree of purity of product. In the present investigation, then, successful use of the Bucherer method in hydantoin formation from dichloroisopropoxyethyl alkyl or aryl ketones resulted in further extension of the application of the method. The ketones used were, with one exception, of the type $(CH_2Cl)_2CH\text{-}O\text{-}CH(CH_3)\text{-}COR$ where R represents alkyl and includes those groups which have been shown most active physiologically; the preparation and characterization of these ketones have been described by us previously.[5] Since the hydantoin derived from the phenyl analog of this series of ketones represents a halogenoalkoxyl derivative of Nirvanol (5-ethyl-5-phenylhydantoin), a substance shown to possess useful medicinal value,[6] it was deemed pertinent to effect its preparation and subsequent conversion into the corresponding hydantoin.

Experimental

Preparation of α-1,3-Dichloroisopropoxyethyl Alkyl Ketones.—The eight ketones of this series which were employed were prepared from α-1,3-dichloroisopropoxypropionitrile by means of the Grignard reaction, these preparations having been described previously.[5]

Preparation of α-1,3-Dichloroisopropoxyethyl Phenyl Ketone.—The general method as described for the preparation of the alkyl analogs was employed in the synthesis of this ketone. The Grignard reagent from 48.1 g. (0.31 mole) of phenyl bromide, 7.3 g. (0.3 atom) of magnesium in the form of turnings, and 250 cc. of anhydrous ether was treated with the solution of 45.5 g. (0.25 mole) of α-1,3-dichloroisopropoxypropionitrile in an equal volume of ether. Although vigorous reaction occurred throughout the nitrile addition, completion was ensured by refluxing for two hours over a steam-cone. The addition product, which separated as a gray-colored solid, was decomposed in the usual manner with chilled, dilute hydrochloric acid and crushed ice; the resulting ether layer was separated, washed with dilute sodium carbonate solution and then water, and finally dried over anhydrous calcium chloride. The crude material was freed of ether by evaporation and then purified by two fractionations under 4 mm. pressure; the pure ketone is a colorless, almost odorless, quite viscous liquid which develops a deep red coloration upon standing; yield, 45.4 g. (69.6%); b. p. 169° (4 mm.); d^{20}_4 1.2356; n^{20}_D 1.5398; *MR* calcd., 66.18;[7] *MR* found, 65.31; γ^{20} 35.53 dynes/cm.; *P* calcd. (Sugden's atomic constants), 538.4; *P* found, 516.0.

Anal. Calcd. for $C_{12}H_{14}Cl_2O_2$: Cl, 27.16. Found: Cl, 26.91.

Synthesis of 5-[1-(2-Chloro-1-chloromethylethyl)-oxy]-ethyl-5-alkyl or -5-phenylhydantoins.—Bucherer's method[2] was applied to the formation of this series of compounds: one mole of the appropriate dichloroisopropoxyethyl alkyl or aryl ketone was added to the suspension of 1.25 moles of potassium cyanide and 3 moles of freshly powdered ammonium carbonate in as much 50% alcohol as would approximate seven times the volume of the ketone, and then the resulting mixture heated from six to eight hours in a flask equipped with an air-condenser and maintained at 55–62°. In most cases, the solid hydantoin began to separate from the warm reaction mixture after heating had continued for three to five hours. After completion of reaction, the mixture was allowed to cool and the solid which had formed was removed by filtration; when the solution was concentrated and again cooled, a second portion of more finely crystalline solid material was obtained. Occasionally, however, the material separating after concentration was in the form of an oil but generally solidified and could then be recrystallized. Finally, acidification of the mother liquor caused separation of still another small amount of solid or oil. Two of the hydantoins, namely, the isopropyl and secondary butyl, failed to conform with this behavior in that there was no separation of material during the reaction period; after concentration of the reaction mixtures to relatively small volumes and acidification, the crude hydantoins separated as dark-colored oils. It was only after prolonged boiling with 20% hydrochloric acid, treatment with Norit, and dissolving in warm alcohol followed by pouring the resulting solutions on crushed ice that the substances were obtained in solid form. The hydantoins could then be recrystallized readily from the usual solvents.

The hydantoins, all white solids, were recrystallized easily from 50–60% alcohol; the butyl and amyl analogs lacked the definite crystalline structure of the lower alkyl and phenyl analogs, separating from the solvent as amorphous solids which were powders when dried, but which possessed sharp melting points. The hydantoins were readily soluble in the organic solvents such as acetone and 95% alcohol and in aqueous alkali, but were quite insoluble in water. The data for melting points, percentage yields, and the analytical results for the nine hydantoins prepared have been summarized in Table I.

It is of interest to note that although the conditions favoring nitrile formation were present during these hydantoin preparations, namely, an alkyl halide in the presence of aqueous-alcoholic potassium cyanide, no replacement of chlorine by cyanide was observed.

Summary

1. The preparation of eight new hydantoins from a series of dichloroisopropoxyethyl alkyl ketones extended the application of Bucherer's method for preparing 5,5-disubstituted hydantoins to include the alkyl halogenoalkoxyalkyl type.

2. From the Grignard reaction, involving interaction of phenylmagnesium bromide and α-1,3-dichloroisopropoxypropionitrile, was obtained the phenyl analog to the dichloroisopropoxyethyl alkyl series of ketones, this synthesis representing the initial preparation of an aryl chloroalkoxyalkyl ketone.

3. The successful conversion of the latter into the corresponding hydantoin further extended the use of Bucherer's method to preparation of a hydantoin of the 5-aryl-5-chloroalkoxyalkyl type and resulted in the formation of a new derivative of the medicinal Nirvanol.

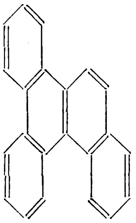
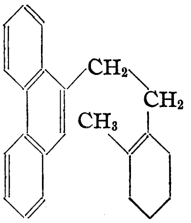
1,2,3,4-Dibenzophenanthrene. I

BY ERNST BERGMANN

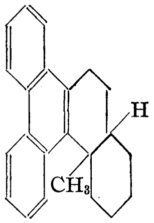
Of the possible aromatic systems consisting of five benzene rings, three are unknown so far: 1,2,3,4-dibenzophenanthrene (I), 1,2,5,6-dibenzophenanthrene and 1′,2′-naphtha-1,2-anthracene.[1] We have undertaken their synthesis and report here experiments for the preparation of (I), which followed the lines worked out for the isolation of the similar 1,2-cyclopentenotriphenylene[2] (I is 1,2-benzotriphenylene). The magnesium derivative of β-(9-phenanthryl)-ethyl chloride reacted upon 2-methylcyclohexanone to give α-(9-phenanthrylethyl)-β-methyl-Δ^{α}-cyclohexene (II), which was cyclized by means of anhydrous stannic chloride. As the product formed by subsequent selenium dehydrogenation gave only very small amounts of an aromatic hydrocarbon of the desired analytical composition, the cyclization product of (II) seems not to be 5,6,7,8,9,10,11,12-octahydro-11-methyl-1,2,3,4-dibenzophenanthrene (III), but a spirane, and the aromatic hydrocarbon, which forms a yellow picrate, a rearrangement product.[3]



I



II



III

In the experimental part some more unsuccessful experiments to synthesize (I) are recorded. The investigation is being continued.[3a]

Experimental

α - (9 - Phenanthryl - ethyl) - β - methyl - Δ^{α}-cyclohexene (II).—When *o*-methylcyclohexanone (10 g.) was added to the solution of β-(9-phenanthryl)-ethylmagnesium chloride (from 2.5 g. of magnesium turnings and 24 g. of the chloride),[2] a vivid reaction took place, which was completed by boiling for three hours. On decomposition with dilute acid, some 1,4-di-(9′-phenanthryl)-butane (1.4 g.) separated. The ether residue decomposed partly when heated on the water-bath, giving off water, and therefore it was heated with potassium hydrogen sulfate (20 g.) to 160° for one hour. Distillation in a good vacuum (0.01 mm.) gave after a small head fraction, which probably was 9-ethylphenanthrene, the desired product (10 g.) as a colorless, viscous oil, b. p. 220°, which could not be induced to crystallize (Calcd. for $C_{23}H_{24}$: C, 92.0; H, 8.0. Found: C, 92.1; H, 8.3). The **picrate**, prepared in concentrated benzene solution, precipitated on chilling as an orange-red powder. From propyl alcohol it formed silky needles, which melted at 124–125° to a dark-red liquid (Calcd. for $C_{29}H_{27}O_7N_3$: C, 65.8; H, 5.1. Found: C, 66.0, 66.0; H, 5.3, 5.5).

Bromine Titration.—0.6594 and 1.3185 g. of the hydrocarbon absorbed 0.3260 and 0.7056 g. of bromine, the theoretical amounts required for 1 double bond being 0.3517 and 0.7032 g., respectively.

Cyclization.—A solution of the foregoing hydrocarbon (II) (15 g.) in benzene (150 cc.) was saturated with dry hydrogen chloride, treated with stannic chloride (6 g.), and kept at room temperature for forty-eight hours. Decomposition with ice and concentrated hydrochloric acid gave the spiranic cyclization product; colorless oil, b. p. 220° (0.01 mm.); yield, 12 g. (Calcd. for $C_{23}H_{24}$: C, 92.0; H, 8.0. Found: C, 91.6; H, 7.9). On mixing its benzene solution with the equivalent amount of picric acid in benzene, a red solution was obtained, which deposited the **picrate** on evaporation. From propyl alcohol this formed orange-red, prismatic needles, m. p. 172° (Calcd. for $C_{29}H_{27}O_7N_3$: C, 65.8; H, 5.1. Found: C, 65.9; H, 5.2).

Cyclization of (II) by means of aluminum chloride did not always give satisfactory results.

Dehydrogenation of the Presumable Spirane.—The above hydrocarbon (3 g.) was heated with selenium (5 g.) at 300–320° for twenty hours in a sealed tube. The reaction product was extracted with chloroform and the residue purified by distillation in a high vacuum (0.01 mm.). After a small head fraction at 160–190° bath temperature, the desired product distilled at a bath temperature of 260–280°. It solidified spontaneously and was triturated with petroleum ether (b. p. 80–100°) and recrystallized from the same solvent, giving faintly yellow, star-like aggregates of prismatic needles, m. p. 184°; yield 1–3%. (Calcd. for $C_{22}H_{14}$: C, 95.0; H, 5.0. Found: C, 95.0; H, 5.1%). The picrate separated from its dark yellow benzene solution in silky, yellow needles, m. p. 220°.

The head fraction mentioned above crystallized from methyl alcohol in the form of leaflets of m. p. 99° and was identified as **phenanthrene.** Its formation is due to thermolytic fission. An analogous observation has been made recently in our laboratory[4] in the dehydrogenative preparation of 2′,1′-naphtha-1,2-fluorene.[5] Its 10-methyl-3,4,9,10-tetrahydro derivative, when heated with selenium, gives partly 3,4-dihydrophenanthrene.

Several other synthetic methods for the preparation of

(4) Unpublished results.

(5) Bachmann, Cook, Hewett and Iball, *J. Chem. Soc.*, **54** (1936).

(I) have been tried without success. Dicyclohexenyl (4.5 cc.)[6] and 1,2-naphthoquinone (10.4 g.) condensed at 180° to form an unworkable black resin, and 3-bromo-1,2-naphthoquinone (1.6 g.) did not react at all with this hydrocarbon (1.1 g.) when heated at 100° for four hours in the presence of *sym*-tetrachloroethane[7] (10 cc.). The potassium derivative of ethyl cyclohexanone-*o*-carboxylate could not be coupled with β-(9-phenanthryl)-ethyl chloride, even on prolonged heating,[8] and finally the fact may be recalled,[9] that 9-cyclohexenylphenanthrene does not react with maleic anhydride to form a derivative of 1,2,3,4-dibenzophenanthrene.

Summary

By interaction between 2-methylcyclohexanone and the Grignard derivative of β-(9-phenanthrylethyl) chloride and subsequent cyclization, a spirane is formed instead of the expected octahydro-methyl-1,2,3,4-dibenzophenanthrene. Its dehydrogenation gave small amounts of an aromatic hydrocarbon. Several other methods of synthesis also failed.

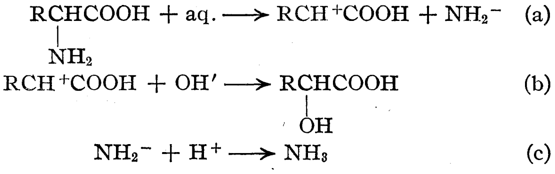
The Photochemical Deamination of Amino Acids in Water Solution. II

BY CH. WEIZMANN, Y. HIRSHBERG AND ERNST BERGMANN

In the first paper on the subject,[1] we were able to demonstrate that under the influence of ultraviolet light water solutions of amino acids undergo hydrolysis according to the scheme



$$\underset{\displaystyle NH_2}{RCHCOOH} + aq. \longrightarrow RCH^+COOH + NH_2^- \qquad (a)$$

$$RCH^+COOH + OH' \longrightarrow \underset{\displaystyle OH}{RCHCOOH} \qquad (b)$$

$$NH_2^- + H^+ \longrightarrow NH_3 \qquad (c)$$

In order to see how the nature of the group R influences the speed of the reaction, we compared alanine and phenylalanine under identical conditions. Phenylalanine decomposes about 2.7 times as quickly as alanine, in 0.1 *N* solution, and 2.2 times as quickly in 0.05 *N* solution. This influence of the phenyl group may be due to two effects, to its loosening the C–N bond and to the increase in light absorption,[2] both effects perhaps being connected in some way. The necessary measurements could be made only in the first stage of the reaction, as phenylalanine undergoes a side reaction, leading to an insoluble coating on the quartz walls and to the formation of an unpleasantly smelling volatile product. In the first minutes of irradiation, however, only ammonia is formed, according to the above scheme. The same complication as with phenylalanine occurs in the case of phenylglycine, $C_6H_5CH(NH_2)COOH$, the decomposition of which therefore could not be studied. Apparently, these side reactions are due to the presence of the aromatic nucleus, as similar observations have been made before with tyrosine solutions.[3]

The constitutional change brought about by coupling alanine with glycine to form alanylglycine also increases the speed of the photochemical deamination. Alanylglycine is hydrolyzed 4.2 times as quickly as alanine in 0.1 *N* solution, and 2.6 times as quickly in 0.05 solution. It is difficult to explain this difference, but it may be assigned to the greater distance between the amino and the free carboxyl group enhancing the ionization of the C–N bond, or to the increased light absorption[4] or to both effects. It may be added that we think it safe to ascribe the ammonia formed exclusively to the decomposition of the $-C-NH_2$ and not of the amide group, since the amide group, as far as we know, is much stabler toward photochemical hydrolysis.[5] It appears that peptides are attacked in the same way as amino

---

[2] Compare Allen, Steiger, Magill and Franklin, *Biochem. J.*, **31**, 195 (1937).

[3] Compare Part I. The ultraviolet absorption spectra of tyrosine and phenylalanine are practically identical: Feraud, Dunn and Kaplan, *J. Biol. Chem.*, **112**, 323 (1935).

[4] Magill, Steiger and Allen, *Biochem. J.*, **31**, 188 (1937).

[5] Compare, *e. g.*, the experiments of Paternò, *Gazz. chim. ital.*, **44**, I, 237 (1914). Allen, Steiger, Magill and Franklin[2] have stated recently that in acylated amino acids and peptides hydrolysis of the –CO–NH-group occurs on irradiation. While that may be true in the case of acylated amino acids, which do not contain the amino group necessary for photolysis, there apparently is no need for that assumption with regard to peptides.

acids, although Guillaume and Tanret[6] have failed previously to detect photolysis of peptides.

The quantum yield of the reactions has been studied with greater accuracy. The measurements were carried out with a vertical mercury arc lamp, which had four jackets.[7] The first and the fourth served for cooling with running water, in the second and third we had (a) water and monochloroacetic acid, or (b) the amino acid and monochloroacetic acid of equal normalities. The difference in the decomposition of monochloroacetic acid gave us the light absorbed in the amino acid layer, and its comparison with the degree of decomposition as determined by the amount of liberated ammonia gave the desired quantum yield. (In view of our preparative experiments,[1] it seemed safe to assume that the liberation of ammonia (or trimethylamine) is the only reaction occurring). Naturally, the jacket walls have to be kept extremely clean, as otherwise the translucence would not be identical in all experiments. Our experiments showed that in the case of alanine and glycine the quantum yield is equal to 0.09 and 0.1, respectively, while for betaine 0.06 has been observed. The ratio between the amino acids and betaine is about the same as found in Part I, and may be explained as suggested there,[8] although the absolute values according to our new more accurate measurements are definitely lower. The low absolute values are due, at least partly, to the increase in absorption, which sets in during irradiation according to Allen, Steiger, Magill and Franklin.[9]

The hydrolysis reaction we observe in the cases studied may be interesting from a biochemical point of view, as its occurrence in green plants may account for the relatively wide distribution in them of α-hydroxy acids. Other ways for the hydrolytic fission of amino acids, in any case, seem not to be available to the cell, as has been pointed out already in Part I. It has been suggested occasionally that bacteria are able to produce hydrolysis of the above type,[10] but observations like that of Otani and Ichihari,[11] that *Oospora lactis* produces (+)-lactic acid from both the forms of alanine, suggest that the amino acid is first oxidatively de-aminated and the keto acid formed subsequently hydrogenated. The same holds true for higher animals. Kotake, Kotake and Taniguchi,[12] *e. g.*, obtained after tyrosine feeding *p*-hydroxyphenyllactic acid along with *p*-hydroxyphenylpyruvic acid. For the classical photolytic conversion of amino acids into aldehydes in the presence of oxygen, on the other hand, it seems justified to assume hydroxy acids as intermediary products, although no definitive proof can be advanced.[13] The reducing properties of irradiated amino acid solutions,[14] *e. g.*, could be attributed to hydroxy acid formation.

Quantum Yield of the Glycine Photolysis.—The inner chamber of the quartz lamp contained 115 cc. of water or of the 1 N amino acid solution, respectively, the outer one 200 cc. of 1 N monochloroacetic acid solution. Owing to the fact that glycolic acid as formed from monochloroacetic acid is unstable by itself, the amino acid solution was irradiated for one hour, while during only half of this time the outer jacket was filled with the chloro acid solution. 200 cc. of the 1 N monochloroacetic acid, *e. g.*, gave within thirty minutes 150 cc. of 0.1 N Cl^-, when irradiated through water, and 110 cc. of 0.1 N Cl^-, when irradiated through glycine solution. During one hour of irradiation, this glycine solution liberated 8.8 cc. of 0.1 N ammonia; quantum yield $8.8/2(150-110) = 0.11$. The following figures have been obtained in a number of analogous experiments: 0.11, 0.10, 0.09, 0.10, 0.09, 0.10, 0.12, 0.12, 0.11; average, 0.10.

Quantum Yield of the Alanine Photolysis.—The following figures have been determined: 0.088, 0.086, 0.094, 0.085, 0.087, 0.084; hence average, 0.087.

Quantum Yield of the Betaine Photolysis.—The following data have been secured: 0.065, 0.066, 0.064, 0.064, 0.062; hence average, 0.064.

Summary

The photolysis of alanine in water solution has been compared with that of phenylalanine and alanylglycine; in both cases the speed of the reaction is increased with regard to the velocity of the alanine decomposition. In the case of phenylalanine (and of phenylglycine), secondary reactions also take place, obviously due to the presence of the phenyl group.

The biological importance and the unique position of this photolysis is stressed, no other biological ways of amino acid hydrolysis being known.

The quantum yield of the photolytic fission has been more accurately redetermined in the cases of glycine, alanine and betaine; again, a markedly lower value has been obtained for betaine.

Dipole Moments and Molecular Structure. XIX.[1] Dipole Moments of Anthracene Derivatives and the Stereochemical Mechanism of Addition and Splitting Reactions in the Anthracene Series

BY ERNST BERGMANN AND ANNA WEIZMANN

Recently,[2] one of the present authors, has given a classification of halogen additions to double bonds. Since all mechanisms concerned involve a two-step reaction, it is understood that usually the entering halogen atoms (or ions) arrange themselves as remotely as possible from each other ("*trans*-addition").[2a] Therefore, we think it worth while communicating that the addition of chlorine[3] to 1,5-dichloroanthracene (to form I) and 9,10-diphenylanthracene (to form II) is a pure *cis* reaction,[4] the dichlorides formed having dipole moments of 3.7 and 3.0, respectively. We are inclined to assume that this unexpected course is due to steric factors. The anthracene model shows that a chain of two atoms easily may form a bridge between the 9,10-positions of the anthracene nucleus, so that the *chlorine molecule* will be able to enter the anthracene molecule as such. From this point of view, the chlorination parallels the "Einlagerung" of oxygen molecules (III)[5] or of substances of the maleic anhydride type (IV).[6]

A similar explanation for the course of an ad-

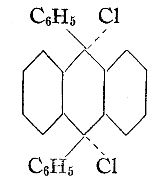
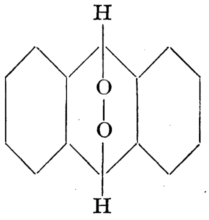
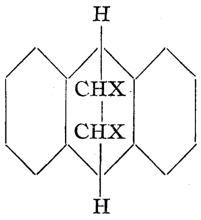
I



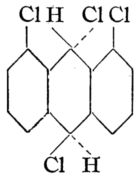
II



III



IV



V

dition reaction has been given recently by K. Ziegler and co-workers[7] in the case of the lithium addition to butadiene, *cis* reaction taking place because of the oriented adsorption of the hydrocarbon on the metal surface.

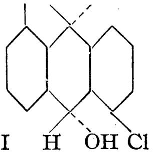
1,8-Dichloroanthracene apparently adds chlorine "normally" in *trans* reaction, the 1,8-dichloroanthracene-9,10-dichloride (V) having an even smaller dipole moment ($2.4D$) than the parent substance ($\mu = 3.2D$), while the *cis* isomeride of (V) should have a markedly higher moment (4.5–$5D$).[8] Perhaps the close proximity of the two halogen atoms in the positions 1 and 8 prevents the above mechanism from being valid in this case.[9]

With regard to the numerical values observed, two remarks may be made. It is not clear why I and II do not have identical moments, the moments of di- and triphenylchloromethane being nearly equal:[10] one would suggest an inductive influence of the nuclear halogen atoms in (I)[11] (see below). The unexpectedly high difference in moments between 1,8-dichloroanthracene and its 9,10-dichloride may be due to the presence in the former substance of an ortho-chlorinated styrene system, the effect of which has been studied before by the authors.[1]

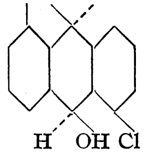
In studying the splitting reactions of dihalides of types (I) and (V), de Barry Barnett and his co-workers[12] have assumed that only *cis* reactions are likely to occur, divergent observations being explained by previous steric rearrangement of the dihalide or by its stereochemical inhomogeneity. These suggestions seem unsatisfactory. First of all, the substances used in our work were well-crystallized and certainly homogeneous. Second, it is difficult to understand that heating of 1,8-dichloroanthracene dichloride, *e. g.*, by itself or in presence of boiling xylene or cymene gives different results (removal of hydrogen chloride or chlorine, respectively), if these differences are due to previous rearrangement in one case. Third in terms of Barnett's hypothesis, it is unexplainable why under the above conditions 1,5,9-trichloroanthracene-9,10-dichloride loses hydrogen chloride while 1,8,10-trichloroanthracene-9,10-dichloride loses chlorine under the influence of potassium hydroxide. We prefer the view that there is *no visible rule governing the steric course of the splitting reaction.*

Obviously, in substitution reactions, configurational inversion may occur. One example is that 9,10-diphenyl-9,10-dihydroxy-9,10-dihydroanthracene, a homogeneous substance, reacts with dimethylaniline to yield two isomeric forms of 9,10-diphenyl-9,10-di-(*p*-dimethylamidophenyl)-9,10-dihydroanthracene.[13] 1,5-Dichloroanthracene 9,10-dibromide, on interaction with water in presence of acetone and calcium carbonate, affords according to E. de Barry Barnett[12] two isomeric 1,5-dichloro-9,10-dihydroxy-9,10-dihydroanthracenes (m. p. 210 and 244°, respectively)

VI



and



VII

We have measured the moment of the lower-melting form and found $2.95D$; for the isomeric form, due to its low solubility, we can only say that its moment is smaller. Therefore, the sub-

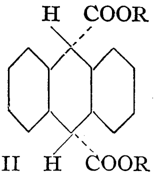
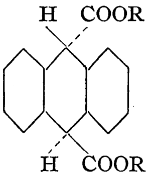
stance of m. p. 210° would be the *cis* diol, the other one the *trans* form, in accordance with Barnett's assumptions. The formation of the *cis* diol from the *trans* dibromide involves a single inversion, the formation of the *trans* form none, or a double one.

In connection with these experiments, the two isomeric dimethyl 9,10-dihydroanthracene-9,10-dicarboxylates described by Schlenk and Bergmann[14] have been investigated. Their dipole moments



VIII

and



IX

have been found to be 2.6D for the β-ester and 1.7D for the α-ester, respectively. As in the case of diethyl maleate and fumarate,[15] the lower moment should correspond to the *trans* isomeride.

---

[14] Schlenk and Bergmann, *Ann.*, **463**, 134 ff. (1928).

This is in accordance with the fact that alkali converts the β- into α-acid, probably *via* an enol form.

Finally, the dipole moment of 1-chloroanthraquinone (1.9*D*) may be recorded, the rather high value probably being due to induction or resonance effects.

Experimental

1. Materials

1,5-Dichloroanthracene.[16]—Commercial 1,5-dichloroanthraquinone (50 g.) is heated with 20% ammonia solution (1 liter) on a steam-bath, and zinc dust (250 g.) gradually added. The mass, first blood-red, becomes slightly reddish, it is filtered after standing for ten hours and extracted several times, while still wet, with acetone. The acetone residue on crystallization from butanol gives yellow 1,5-dichloroanthracene, m. p. 187°, while a colorless product remains in the mother liquors; from petroleum ether this gives needles, m. p. 102–103°. It is 1,5-dichloro-9-hydroxy-9,10-dihydroanthracene (Calcd. for $C_{14}H_{10}OCl_2$: C, 63.4; H, 3.8. Found: C, 63.0, 63.3; H, 4.0, 4.0). On dissolving this in hot propyl alcohol and adding a few drops of concd. hydrochloric acid, 1,5-dichloroanthracene precipitates in a pure state. The most convenient method, therefore, is to dissolve the crude acetone residue in the minimum amount of propyl or butyl alcohol and to add a few drops of hydrochloric acid; yield 30 g.

1,5-Dichloroanthracene-9,10-dichloride (I) was prepared according to Liebermann and Beudet[17] at 0° from 1,5-dichloroanthracene and an excess of chlorine solution in carbon tetrachloride. After three hours the product was collected, washed with ligroin and dried; m. p. 214–215° (Calcd. for $C_{14}H_8Cl_4$: C, 52.8; H, 2.5. Found: C, 52.3; H, 2.7). The bromide was prepared in the same way; m. p. 220° (after short sintering).

1,8-Dichloroanthracene from toluene, m. p. 185°, and its **dichloride** (V), m. p. 184° (dec.), were obtained in the same way as the 1,5-compounds, **9,10-diphenylanthracene-9,10-dichloride** (II) from 9,10-diphenylanthracene and chlorine or more conveniently according to Bergmann and Blum-Bergmann.[18] 1-Chloroanthraquinone (commercial sample) was recrystallized.

1,5-Dichloro-9,10-dihydroxy-9,10-dihydroanthracenes.[12] (a) *cis* **Isomeride.**—1,5-Dichloroanthracene-9,10-dibromide (16 g.) was heated with acetone (190 cc.) and water (120 cc.) for four hours. The filtered solution (residue mainly 1,5-dichloroanthracene) deposits a yellowish precipitate which is carefully recrystallized from toluene to a constant m. p. of 210–212°; colorless prisms; yield 1.65 g. (b) *trans* **Isomeride.**—1,5-Dichloroanthracene-9,10-dibromide (31 g.), acetone (300 cc.) and calcium carbonate (8.5 g.) were boiled for eight hours. The insoluble product (the solution contains mainly the *cis* diol) was collected and recrystallized several times from xylene; fractionation removed a small quantity of a yellow substance (apparently 1,5-dichloroanthracene); m. p. 241°; yield 0.5 g.

The *trans* compound was too slightly soluble for a series of measurements. At a molar fraction of 0.0272, the dioxane solutions of the two isomerides had the same refractive index, but with the *trans* compound the dielectric properties of the solution were not markedly different from those of the pure solvent.

2. Measurements

The significance of the figures is as in previous communications. The data for α-methylnaphthalene have been reported by Bergmann and Schuetz.[19]

Summary

Dipole moment measurements reveal that the addition of chlorine to 1,5-dichloroanthracene and 9,10-diphenylanthracene is a *cis* reaction; it is suggested that, in contradistinction to the usual behavior, the chlorine *molecule* is added. 1,8-Dichloroanthracene adds chlorine in *trans* reaction. The splitting reactions of anthracene-9,10-dihalides show no recognizable regularity.

Hydrolysis of 1,5-dichloroanthracene-9,10-dibromide is accompanied, at least partially, by Walden inversion; the dipole moment of the corresponding *cis* diol has been measured. On the basis of the dipole moments, the spatial arrangement of the isomeric dimethyl 9,10-dihydroanthracene-9,10-dicarboxylates has been determined.

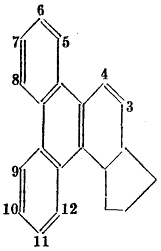
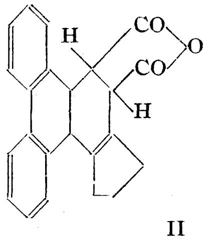
1,2-Cyclopentenotriphenylene. II

BY ERNST BERGMANN AND FELIX BERGMANN

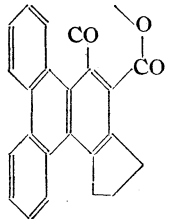
In a previous paper,[1] synthetic experiments had been reported expected to yield 1,2-cyclopentenotriphenylene (I). In the course of this synthesis, three hydrocarbons were isolated, to which, on the basis of mere analogies, the following formulas were assigned: "cyclopentenotriphenylene" m. p. 171–172.5°; picrate, m. p. 172–173°; "9-methyl-3,4-benzpyrene,"[2] m. p. 157.5–159.5°; picrate, m. p. 153–155°; "1,2,3,4-dibenzfluorene," m. p. 115–116°; picrate, m. p. 165–167°. In order to determine definitely the structure of the three products, we have tried both chemical and physical methods. A possible synthesis of 1,2-cyclopentenotriphenylene by an unambiguous method was suggested by our observation[3] that this hydrocarbon system can be obtained easily by the diene reaction of 9-cyclopentenylphenanthrene and maleic anhydride. When the condensation product (II) was treated with lead tetraacetate[4] four hydrogen atoms were removed, leaving 1,2-cyclopentenotriphenylene-3,4-dicarboxylic acid anhydride (III). Direct decarboxylation proved difficult, but eventually two different stepwise methods have been worked out. (a) With quinoline and basic cupric carbonate,[5] a monocarboxylic acid "A" was formed, m. p. 299–300° (methyl ester, m. p. 197–198°), the potassium salt of which was decarboxylated thermally with relative ease, giving the desired cyclopentenotriphenylene (I).[6] (b) The anhydride (III), on heating with soda-lime, gave an isomeric cyclopentenotriphenylene carboxylic acid (3 or 4) "B," m. p. 249° (methyl ester, m. p. 117°). This, when treated with basic cupric carbonate in quinoline, gave again the desired hydrocarbon (I). The substance was identified in each case by the characteristic orange-yellow picrate, m. p. 165–167°. Therefore, the hydrocarbon formerly supposed to be 1,2,3,4-dibenzfluorene, actually is 1,2-cyclopentenotriphenylene.



I

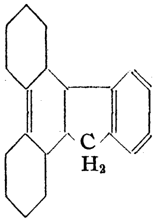


II



III

IV



V

The spectrum of the substance formerly supposed to be cyclopentenophenanthrene ($C_{21}H_{16}$) shows even on qualitative examination[7] so close a resemblance to 3,4-benzpyrene[8] that we definitely may assign to it the structure of 9(?)-methyl-3,4-benzpyrene,[9] ($C_{21}H_{14}$). The intense green-yellow fluorescence of our substance points in the same direction; even the melting point of our hydrocarbon is almost identical with that of 3,4-benzpyrene[10] and is not depressed by its admixture.[11,12]

The third of the above hydrocarbons (m. p. 157.5–159.5°) finally has been identified as 1,2,-3,4-dibenzfluorene. After some unsuccessful attempts, reported in the experimental part, it was synthesized by a method based on a recent observation by Alder and Rickert.[13] Dicyclohexenyl (IV)

[5] Fieser, Fieser and Hershberg, *ibid.*, **58**, 2324 (1936).

[6] The same result was obtained when the monocarboxylic acid A was distilled over zinc dust *in vacuo*.

[7] The detailed report on the spectrographic analysis will be published later.

[8] Mayneord and Roe, *Proc. Roy. Soc.* (London), **152B**, 299 (1935).

[9] The analytical figures for $C_{21}H_{14}$ and $C_{21}H_{16}$ and for the respective picrates are relatively similar, so that a definite decision on the basis of the combustion analyses was not to be expected.

[10] Compare Cook and Hewett, *J. Chem. Soc.*, 403 (1933). The two respective picrates, although almost identical in appearance, have different m. p's. (172–173° as against 197–198°).

[11] The possibility that the methyl group is situated at C_8 of the pyrene skeleton has to be borne in mind, in view of the observation by Vollmann [*Ann.*, **531**, 36 (1937)], that in the synthesis of 1,2-cyclopentenophenanthrene 3-methyl-pyrene is formed along with the 4-isomer.

[12] The same conclusion on the structure of our hydrocarbon has been expressed recently by Hewett, *J. Chem. Soc.*, 193 (1938).

[13] Alder and Rickert, *Ber.*, **71**, 379 (1938).

was condensed with indene by heating at 180°[14] to give the dodecahydro derivative (V) of 1,2,3,4-dibenzfluorene, which could be dehydrogenated easily. The hydrocarbon so obtained melted at 158–159°; picrate, m. p. 153–155°. The melting points were not depressed by admixture of the appropriate preparations described in our previous paper on the subject.

Experimental

1,2 - Cyclopentenotriphenylene - 3,4 - dicarboxylic Acid Anhydride (III).—(a) A solution of the tetrahydro compound (II)[3] (1 g.) in glacial acetic acid (25 cc.) and acetic anhydride (25 cc.) was cooled to 75° and added to a suspension of lead tetraacetate[15] (25 g.) in glacial acetic acid (10 cc.). The reaction mixture, immediately turning yellow, is kept on the water-bath for twenty minutes and then in the refrigerator for two hours. The melting point (296°) of the crystals is not raised by recrystallization from xylene, decalin or ethyl benzoate; yellow needles, yield 100 mg. (*Anal.* Calcd. for $C_{23}H_{14}O_3$: C, 81.7; H, 4.2. Found: C, 81.9, 81.8; H, 4.6, 4.4.) (b) A somewhat less pure product was obtained when the anhydride (15 g.) suspended in glacial acetic acid (100 cc.) was mixed with lead tetraacetate (30 g.) in glacial acetic acid (100 cc.) and the mass heated for two hours on the water-bath. The yield in this case was 8.5 g., but the product had to be recrystallized several times.

1,2 - Cyclopentenotriphenylene - 3(4?) - carboxylic Acid ("A").—The above anhydride (III, 4 g.) was boiled for two hours with quinoline (25 cc.) and basic cupric carbonate (0.8 g.). The reaction product was poured into dilute sulfuric acid, extracted with ether and isolated by vacuum distillation. The brown oil, b. p. 245–255° (0.7 mm.), solidified on trituration with acetone and was recrystallized from butyl acetate or ethyl benzoate: clusters of needles, m. p. 299–300°. (*Anal.* Calcd. for $C_{22}H_{16}O_2$: C, 84.6; H, 5.1. Found: C, 84.4; H, 5.5.) The **methyl ester** prepared by means of diazomethane can be recrystallized most conveniently from acetic anhydride, giving needles, m. p. 197–198°. (*Anal.* Calcd. for $C_{23}H_{18}O_2$: C, 84.7; H, 5.5. Found: C, 84.7; H, 5.6.)

1,2 - Cyclopentenotriphenylene - 4(3?) - carboxylic Acid ("B").—The anhydride (III, 6 g.) was heated with soda-lime (18 g.) to 180° for one hour and to 300° for two hours in a sealed tube. The product was poured into hydrochloric acid and extracted with chloroform. The residue of this solution crystallized spontaneously; it was triturated with methyl alcohol and recrystallized from a mixture of butyl acetate and ligroin: shiny needles, m. p. 249°. (*Anal.* Calcd. for $C_{22}H_{16}O_2$: C, 84.6; H, 5.1. Found: C, 83.7; H, 5.9.) The **methyl ester,** prepared as above, does not crystallize well. It was obtained as a sirupy mass, which was distilled in high vacuum and then treated with a mixture of isopropyl alcohol and acetone; m. p. 117°.

1,2-Cyclopentenotriphenylene (I).—(a) The methyl ester (0.6 g.) of the monocarboxylic acid ("A") was boiled for one hour with alcoholic potassium hydroxide (2 mols). The alcohol was distilled off and the residue heated to 320–250° for four hours in a sealed tube. Water and ether were added and the product isolated by high vacuum distillation; b. p. 250–330° (0.3 mm.). The distillate was dissolved in benzene and directly converted into a picrate by means of alcoholic picric acid solution: orange needles, m. p. and mixed m. p. with the product of E. Bergmann and O. Blum-Bergmann, 165–167°. (b) The monocarboxylic acid ("B") (0.6 g.) was boiled with quinoline (15 cc.) and basic cupric carbonate (1.2 g.) for twenty-four hours and the mass worked up as usual. The product boiled at 260–280° (2.5 mm.) and again was converted into the characteristic picrate; m. p. and mixed m. p. 165–167°, after recrystallization from a mixture of benzene and alcohol. (c) The monocarboxylic acid ("A") (0.2 g.) was mixed with zinc dust (20 g.) and distilled slowly at 30 mm. The distillate was taken up with acetone and the acetone residue distilled at 25 mm. and converted into the picrate; m. p. 165–167°.

Dodecahydro-1,2,3,4-dibenzfluorene (V).—Dicyclohexenyl (IV, 50 g.) and indene (25 g.), both freshly distilled, were mixed and heated at 180° for twenty hours in a sealed tube, and the product fractionated in vacuum (0.3 mm.). The condensation product was secured in two portions, the first one boiling at 180–185° (14 g.) and the second at 185–190° (12 g.). It may be that they represent different steric forms of the condensation product (V), although diene condensations generally take place in a sterically homogeneous manner (Fraction I: Calcd. for $C_{21}H_{26}$: C, 90.7; H, 9.3. Found: C, 90.5; H, 9.2. Fraction II: Found: C, 90.5; H, 9.0). Both gave the same results on dehydrogenation.

1,2,3,4-Dibenzfluorene.—The dodecahydro derivative (V) (6 g.) was heated with selenium (20 g.) at 300° for twenty hours. The reaction product was removed mechanically from the excess selenium and recrystallized several times from isopropyl alcohol and butyl alcohol; needles, m. p. 158–159°; the picrate, prepared according to E. Bergmann and O. Blum-Bergmann,[1] melted at 153–155°; yield 3.8 g.

Unsuccessful Experiments to Synthesize 1,2,3,4-Dibenzfluorene.—We applied to our problem the chrysene synthesis devised by Ruzicka, Ehmann, Goldberg and Hoesli,[16] which has been utilized in the analogous case of 1′,2′-naphtha-2,3-fluorene by Cook, Dansi, *et al.*[17] 9-Chloromethylphenanthrene, which was prepared easily from 9-phenanthrylcarbinol, reacted with the sodium derivative of ethyl cyclohexanone-2-carboxylate to yield ethyl 2-(9′-phenanthryl-methyl)-cyclohexanone-2-carboxylate (VI), but unfortunately cyclization according to the scheme

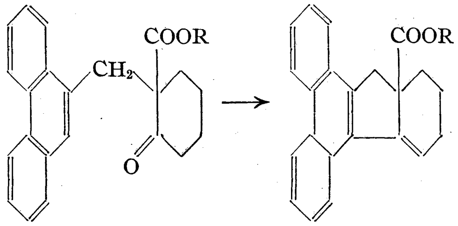
---

[14] For other diene reactions with dicyclohexenyl, see ref. 4c.

[15] For the preparation of lead tetraacetate, the following method has proved very convenient. To glacial acetic acid (250 cc.), minium (75 g.) is added in small portions at room temperature, while the mass is stirred thoroughly. The operation takes about thirty minutes; the product starts crystallizing during this time. The mass is kept in the icebox for two hours and filtered. The crystals, containing only traces of unchanged minium, are transferred, while still wet, to a desiccator. Working at room temperature permits a much quicker addition of minium, as no decomposition is to be feared.

[16] Ruzicka, Ehmann, Goldberg and Hoesli, *Helv. Chim. Acta*, **16**, 833 (1933).

[17] Cook, Dansi, *et al.*, *J. Chem. Soc.*, 1319 (1935).



(VI) (VII)

occurred to a negligible extent only.

9-Phenanthrylcarbinol[18] (14 g.) (from benzene as needles, m. p. 150°) is mixed with dimethylaniline (12 g.) and benzene (40 cc.) and treated at 0° with thionyl chloride (7 cc.). The crystalline cake formed is kept for ten hours at room temperature and then heated to 100°, until the evolution of sulfur dioxide ceases. On addition of water and ether, part of the 9-chloromethylphenanthrene separates spontaneously; the remainder was obtained by evaporation of the ethereal layer. From light petroleum the m. p. is 98°; it is useful to induce crystallization by scratching; yield 12 g.[19]

Ethyl 2-(9′-Phenanthrylmethyl)-cyclohexanone-2-carboxylate (VI).—9-Chloromethylphenanthrene (3.7 g.) was added to ethyl sodio-cyclohexanone-2-carboxylate (from 0.4 g. of sodium and 3.1 g. of the ester, b. p. 119° (26 mm.)) in toluene (25 cc.) and the whole boiled for six hours. After treatment with dilute sulfuric acid, the toluene was evaporated and the oily residue triturated with methanol and acetone. It gave 2.5 g. of the desired product, which was recrystallized from light petroleum as dimorphous white needles and yellow stout prisms; m. p. 118–119°. (*Anal.* Calcd. for $C_{24}H_{24}O_3$: C, 80.0; H, 6.7. Found: C, 79.3; H, 6.)

Cyclization VI ⟶ VII.—The foregoing ester (10 g.) was heated at 140° for twelve hours with water (100 cc.) and concentrated sulfuric acid (55 cc.). The organic material was extracted with ether and benzene and distilled *in vacuo*. At 230° (0.03 mm.) a viscous, nearly colorless oil distilled and on treatment with glacial acetic acid gave a crystalline mass (2.9 g.). It consisted almost completely of the starting material, which was recovered by recrystallization from propyl alcohol. A small amount of material proved insoluble in this solvent and was subsequently recrystallized from ethyl malonate. The analysis of the prisms, m. p. 250°, so obtained, was consistent with (VII). (*Anal.* Calcd. for $C_{24}H_{22}O_2$: C, 84.2; H, 6.4. Found: C, 83.8; H, 6.2.) From the glacial acetic acid mother liquor no homogeneous material could be isolated, even after dehydrogenation with platinum black at 320–340°.

Summary

The three hydrocarbons, previously obtained from 9-phenanthrylmagnesium bromide and cyclopentanone, are now identified as 1,2-cyclopentenotriphenylene, 9(?)-methyl-3,4-benzpyrene and 1,2,3,4-dibenzfluorene, respectively.

1,2-Cyclopentenotriphenylene was synthesized from the addition product of 9-cyclopentenylphenanthrene and maleic anhydride by dehydrogenation and subsequent stepwise decarboxylation.

For the synthesis of 1,2,3,4-dibenzfluorene, dicyclohexenyl was condensed with indene and the addition product dehydrogenated by means of selenium. The attempt to apply Ruzicka's chrysene synthesis to the case of 1,2,3,4-dibenzfluorene was unsuccessful.

Optical Properties of Cellulose Dispersed in Cuprammonium Hydroxide Solution[1]

BY JACK COMPTON

The current concept regarding the nature of the colloidal solutions resulting from the dispersion of cellulose by cuprammonium hydroxide solution, Schweizer's reagent, depends on the theories of cellulose fiber structure, namely, the continuous, or macromolecular, theory, and the discontinuous, or micellar, theory.

The continuous, or macromolecular, theory, developed by Staudinger on the basis of viscosity measurements, may be summed up in the following statement:[2] "Accordingly cellulose and its derivatives are molecular colloids and on the length and form of their macromolecules depends the colloidal behavior of their solutions." The macromolecules in cellulose fibers are considered regularly lined up under the influence of covalent forces in a direction parallel to the fiber axis.

The discontinuous, or micellar, theory, postulated by von Nägeli[3] and extended to cellulose by Karrer[4] in 1921, assumes that the micelle of cellu-

---

[2] H. Staudinger, *Ber.* **70**, 2514 (1937).

[3] C. von Nägeli, "Die Stärkekörner," Friedrich Schulthess, Zurich, 1858.

[4] P. Karrer and F. Widmer, *Helv. Chim. Acta*, **4**, 174 (1921).

lose is formed by the union, or bundling, of many molecules of the elementary substance. Hess and co-workers,[5] in applying the law of mass action to the optical behavior of cellulose dispersed in cuprammonium solution, obtained results that were best explained when the cellulose molecule was assumed to be $C_6H_{10}O_5$. To explain the high viscosity of cellulose in cuprammonium solution on the basis of so small a unit, he assumed that the $C_6H_{10}O_5$ groups are associated to form a larger molecular aggregate. Later Hess[6] concluded that the cellulose fiber should be regarded as a physical aggregation of small units and Meyer and Mark[7] postulated that the cellulose micellae were formed from primary valence chains held together by "micellar forces." Recently, Lieser,[8] in summing up his results, writes: "It may be stated as most important that cellulose in viscose and ammoniacal copper oxide forms micellar solutions, in organic bases and inorganic acids solutions with a not yet clearly definable character. It was further shown that all celluloses regenerated from solution are of micellar structure." The dimensions of the micelle in cellulose fibers have been estimated[9] to be approximately 50 Å. diameter and over 500 Å. long.

The observations of Farr and Eckerson[10] that cotton fibers are composed of microscopic, ellipsoidal, cellulose particles of uniform size (1.1 × 1.5 μ), arranged with their long axis parallel to the fiber axis and held together by an intercrystalline "cementing" material, are of fundamental importance. Cellulose particles obtained from cotton fibers possess all the properties recognized as characteristic of native cellulose other than high viscosity in cuprammonium solution. The low viscosity of the separated particles is attributed by Farr[11] to the removal, or destruction, of the viscosity producing "cementing" material. Qualitative examination of cuprammonium dispersions of cotton fibers with the slit ultramicroscope, or working carefully with the stage microscope, revealed the presence of the apparently unchanged cellulose particles. Upon regeneration, these dispersions yielded a product containing randomly distributed particles similar to the original aggregates. From a study of the X-ray diffraction patterns of cellulose particles, Sisson[12] has concluded that a microscopic unit of cellulose particle dimensions (1.1 × 1.5 μ) adequately satisfies the fundamental requirements of the micelle, with the exception of size.

Since it is commonly accepted that the micelles are composed of macromolecules of cellulose, the theories of cellulose fiber structure do not necessarily conflict. There are, however, many divergent views as regards the nature of the cellulose dispersions in reagents such as cuprammonium solution. The purpose of the present investigation is: first, to investigate the entire cuprammonium viscosity range of cotton fiber to determine if, at any time, a relation exists between the viscosity and optical rotation of the cuprammonium dispersions; second, to determine in general the contribution of each component of native cotton fiber, *i. e.*, crystalline cellulose particles and the intercrystalline phase, to the phenomena of viscosity and optical activity of cuprammonium dispersions; third, to study quantitatively the effect of varying the concentration of differently treated celluloses dispersed in cuprammonium solution on the microscopic particle count, using the slit ultramicroscope; fourth, to study the mechanism of the dispersion phenomenon of crystalline cellulose particles by cuprammonium solution.

Experimental

Apparatus.—The equipment of the Leitz slit ultramicroscope included a micro cell and an eyepiece micrometer ruled in 1.0-mm. squares. In all counts reported in Table II, a 6L objective and a 10X eyepiece were used.

The optical rotations were determined in a Schmidt and Haensch Polariscope with an 85-watt capillary mercury arc lamp as the light source. A combination of monochromatic glass filters (No. 7) recommended by the Corning Glass Works was used to transmit only the 0.4358 μ blue mercury line.

Viscometers of the type recommended by Clibbens and Geake,[13] slightly modified by the addition of ground glass stoppers in place of the rubber stoppers previously specified were used in determining the viscosities of the celluloses dispersed in cuprammonium solution.

Preparation of the Cuprammonium Solution.—The cuprammonium solution prepared by the method of Clibbens and Geake,[13] containing 15 g. of copper, 240 g. of ammonia and 1 g. of sucrose per liter was satisfactory for determining the viscosity, optical activity, and particle

counts of the various cellulose dispersions. It was possible to carry out all three determinations on one dispersion when necessary.

Preparation of Cellulose Samples Used in Studying the Effect of Various Treatments on the Viscosity, Optical Rotation, and Particle Count after Dispersion in Cuprammonium Solution.—Raw cotton (*Gossypium hirsutum* L.) was extracted with alcohol–benzene (1:1) in a Soxhlet extractor for twenty-four hours, thoroughly washed with water, and air-dried at room temperature. This material was used in the experiments listed below.

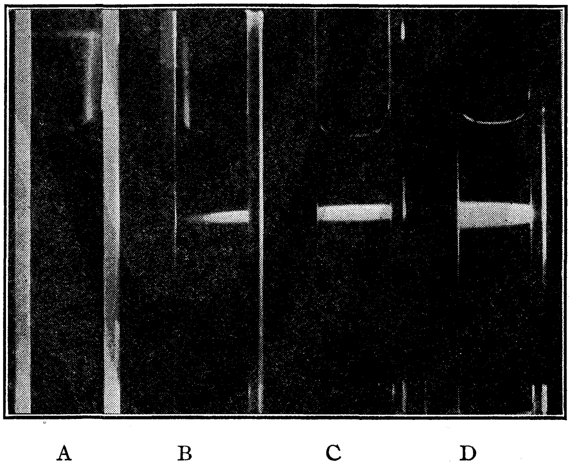

Fig. 1.—Effect of increase in concentration of cellulose dispersed in cuprammonium solution on the Tyndall phenomenon: (A) cuprammonium solution, control; (B) 0.5%, (C) 1.0%, and (D) 2.00% dispersions of cellulose particles in cuprammonium solution.

(1) **Treatment of Cotton Cellulose with 0.01 *N* Hydrochloric Acid Solution at 75°.**[14]—Ten grams of cotton cellulose was placed in 1 liter of 0.01 *N* hydrochloric acid solution previously heated to 75° and after vigorous stirring and shaking samples were removed at stated intervals of time, Table I. The sample was rendered neutral immediately after removal by plunging it into a large volume of ice-cold sodium bicarbonate solution. After agitating for ten minutes the sample was washed thoroughly with distilled water and air-dried at room temperature.

(2) **Treatment of Cotton Cellulose with Concentrated Hydrochloric[10] Acid (d. 1.18) at 25°.**—Cotton cellulose (10 g.) was placed in concentrated hydrochloric acid (250 cc.) at 25°. The removal and treatment of samples was effected in the manner described above (1). After twenty-two hours, slight pressure on the cover glass of a microscopic slide of this material destroyed the fiber structure completely. Many free cellulose particles could thus be disengaged from the fragments of fibers.

(3) **Treatment of Cotton Cellulose with 0.04 *N* Sodium Hypochlorite[15] Solution of *p*H 9 at 25°.**—Ten grams of cotton cellulose was treated with two liters of 0.04 *N* sodium hypochlorite solution containing 1.42 g. of available chlorine per liter, the solution being buffered at *p*H 9. Samples were removed at definite intervals of time, Table I, immediately washed with water, and given the standard acid wash. After again thoroughly washing in water the samples were air-dried at room temperature.

(4) **Treatment of Cotton Cellulose with Excess Hydrogen Peroxide in the Presence of 4% Sodium Hydroxide Solution.**[14]—Five grams of cotton cellulose was placed in 200 cc. of 4% sodium hydroxide solution and heated to boiling during the portion-wise addition of 3% hydrogen peroxide solution over a period of ten hours. The fiber structure could be disrupted completely by pressure at the end of this time, yielding microscopic cellulose particles. The fine white powder was washed with water, dilute acetic acid, and with water until neutral. After final washings with alcohol and ether, the material was allowed to air-dry at room temperature. The fluffy white material was then pulverized by light grinding in a mortar.

(5) **Preparation of Cellodextrin (Biosan).**—Cellodextrin was prepared according to the procedure of Hess and Friese.[16] Analysis of this material confirmed the observation[17] that it has a chain length of from eight to twelve glucose anhydride units.

Method Employed in the Dispersion of Cellulose in Cuprammonium Solution.—The method employed in the dispersion of the various cellulose samples listed in Tables I and II, and Fig. 2, was essentially the same as that described by Clibbens and Geake.[13]

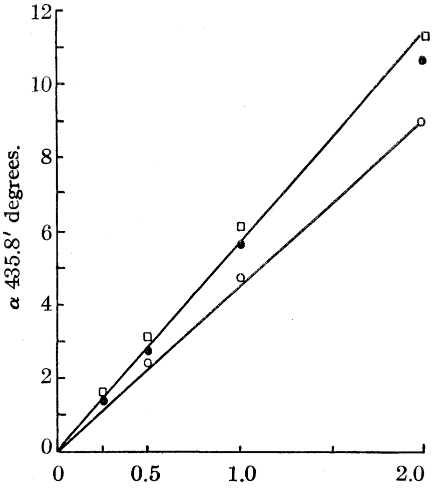

Fig. 2.—Effect of increase in concentration on the optical rotation of: ○, cellodextrin (biosan); ●, cellulose particles, expts. (2) and (4); □, kiered and bleached cotton, dispersed in cuprammonium solution.

Samples of celluloses were taken to yield dispersions of the per cent. actual cellulose concentration specified when dissolved in a volume equal to that of the calibrated viscometers. The material was finely divided, and, in the case of cotton fibers, the material was cut across with scissors into lengths not greatly exceeding a sixteenth of an inch (1.6 mm.). The samples were conveniently weighed

on a small watch-glass and quantitatively transferred to the viscometers. A moisture content of 4% was assumed, previous experiments having shown that this figure was a representative average value.

A small amount of the cuprammonium solution was drawn up into the capillary end of the viscometer and closed off by folding over the attached rubber tube. The tube was fixed in an upright position, 0.7 cc. of clean mercury run in from a 1-cc. pipet, and the cellulose transferred to the viscometer by means of small tweezers and tapping the conical-shaped paper which holds it. The tube was then half filled with cuprammonium solution and the cellulose stirred in the solvent for a few seconds to remove entangled air. The viscometer was filled with the solvent to within an inch (2.5 cm.) of the top, the rod being washed at the same time. Finally, the viscometer was filled completely with cuprammonium solution and the stopper inserted, so that the excess liquid, displacing all air, overflowed through the top capillary and rubber tube, which was then folded over and made tight with a rubber band; the ground-glass stopper was fastened in place by use of steel springs. The viscometer was fastened securely in a box and placed in an apparatus constructed so as to make four revolutions per minute. The end over end motion of the instrument and the resulting motion of the mercury produced an agitation in the liquid which was continued until a homogeneous dispersion was obtained. A uniform period of eighteen hours was sufficient for complete dispersion of the high viscosity celluloses prepared above. The mixture was maintained at a temperature of 4° during dispersion by placing the whole apparatus in a cold room thermostatically controlled.

To measure the viscosities of the resulting dispersions, the viscometers were removed from the box and immersed[13] in a thermostat at 25°. After standing for thirty minutes, the stopper was removed from the viscometer and the solution allowed to flow freely through the capillary. The time in seconds necessary for the liquid meniscus to fall from the top to the bottom ring was noted with a stop watch.

In determining the optical rotations and particle counts, Tables I and II and Fig. 2, after viscosity measurements, the dispersions were stoppered and centrifuged (1800 r. p. m.) to remove any entangled mercury droplets. The apparently clear homogeneous dispersions thus obtained were transferred to the polarimeter tube and the micro cell of the ultramicroscope and the optical rotations and particle counts determined.

Effect of Increasing the Concentration of Cellulose in Cuprammonium Solution on the Tyndall Phenomenon.—A typical example of this effect is shown in Fig. 1. Cellulose particles (Expt. 2 above) were dispersed in cuprammonium solution in the manner previously described, and a strong beam of light focused into the solutions.

Method Used in Making Particle Counts on Cuprammonium Dispersions of Cellulose Using the Slit Ultramicroscope.—Refinement of the Tyndall phenomenon by use of the slit ultramicroscope enables one to arrive at a quantitative estimate of the number of cellulose particles present in a definite volume of the dispersions. The cuprammonium dispersions of the various cellulose samples were introduced into the micro cell and sealed immediately with a cover glass to prevent evaporation and formation of hydrated copper oxide. The light was then properly focused into the cell and the number of particles in a unit area counted. The average of ten counts at various positions of the field were taken, and this value checked similarly by an independent observer. Controls were run on the cuprammonium solution alone and corrections applied to the particle counts. Cuprammonium solutions containing more than one-tenth of a particle in the unit volume were rejected. Knowing the focal depth, and the calibration of the eyepiece micrometer for the microscopic lens system used, the unit volume in which the particle counts are made can be calculated. The dimensions of the unit volume were: focal depth (2.4 μ) × unit area on eyepiece micrometer (29 × 29 μ) = 2018.4 $\bar{\mu}^3$, or 2.018×10^{-9} cc. The results obtained are recorded in Table II.

To calculate the theoretical number of particles that should be present in the unit volume at a definite concentration, it is necessary to know, first, the average volume of the cellulose particle and, second, the total volume of cellulose dispersed in the solution. The volume of the cellulose particle, V_1, may be calculated from the dimension $1.1 \times 1.5\ \mu$ by substituting in the equation for the volume of a prolate spheroid, $V_1 = 4/3\pi ab^2$, where a and b are the major and minor semi-axes, respectively. Thus, $V_1 = 4.189 \times 0.75\ \mu \times (0.55\ \mu)^2 = 0.95\ \bar{\mu}^3$, or 9.5×10^{-13} cc. For a 0.5% (0.5 g. cellulose in 100 cc.) dispersion of cellulose the actual cellulose volume, $V = 0.5$ g./1.5, density of cellulose = 0.33 cc. In the unit volume, 2.018×10^{-9} cc. there would be, accordingly, a cellulose volume, V_2, of 6.66×10^{-12} cc. The theoretical number of cellulose particles, N, in the unit volume is obtained from the formula $N = V_2/V_1$. Thus, $N^{18} = 6.66 \times 10^{-12}$ cc./9.5×10^{-13} cc. = 7.0, for a 0.5% soln. The corresponding values for other concentrations may be calculated in a similar manner.

Effect of Increasing the Concentration of Various Celluloses in Cuprammonium Solution on the Optical Rotation.—The experiments were carried out essentially in the manner described by Hess,[7] with the exception that a cuprammonium solution containing 15 g. of copper, 240 g. of ammonia and 1 g. of sucrose per liter was employed. Dispersion of the various celluloses was carried out as described above. The results obtained are plotted in Fig. 2.

Determination of the "Saturation Point" of Cellulose Particles in Cuprammonium Solution.—The possibility of the existence of a mass action equilibrium between the cellulose–copper complex and cellulose in cuprammonium dispersions has been considered previously.[5,19] In the present experiment cellulose particles (Expts. 2 and 4 above) have been used to determine the point at which the cuprammonium solution could no longer cause permanent dispersion. When the concentration was increased beyond 4.5%, the excess undispersed cellulose could be centrifuged unchanged (1800 r. p. m.) from the permanently dispersed phase. That this saturation point is not connected with the copper content of the cuprammonium solution was shown by the fact that the same "saturation point" occurred when A. C. S. cuprammonium solution (containing 30 g. copper, 165 g. ammonia, and 10 g. sucrose per liter) was used.

Discussion

The two general methods employed for the gradual disintegration of cellulose fibers are: first, the action of dilute acids, and, second, the action of mild oxidizing agents. The disintegrating action of these reagents, which is accompanied by a lowering of the cuprammonium viscosity, Table I, has been interpreted previously as indicating a decrease in the chain length of the cellulose molecules. Based on the dual structure of the cellulose fiber, however, a new interpretation is now placed on this behavior. Since the crystalline phase, or cellulose particles, remains largely intact by these treatments, it follows that the intercrystalline "cementing" material is the phase easily modified or destroyed. The conclusion may also be drawn that this unstable, reactive phase of native cellulose fibers is largely responsible for their high viscosity when dispersed in cuprammonium solution. This interpretation is somewhat similar to that of Joyner,[14] who postulated the existence of a cellulose A with high and a cellulose B with low viscosity in native cellulose fibers.

The high optical activity of cellulose colloidally dispersed in cuprammonium solution was considered by Hess[5] to be due to the uniform formation of an asymmetric complex cellulose–copper compound $[(C_6H_{10}O_5)_2Cu][Cu(NH_3)_4]$. It was further shown that with low viscosity celluloses there was no relation between optical activity and change in cuprammonium viscosity. The present work extends this conclusion to the entire viscosity range possible with cotton cellulose, Table I. Thus, the cellulose particle, or crystallite, seems to be responsible for the high optical activity, for as the viscosities of the cuprammonium dispersions are lowered, indicating removal of the intercrystalline "cementing" material, the rotations remain constant. The high optical activity of celluloses of high viscosity shows that either the rotation of the intercrystalline–copper complex is very similar to that of the cellulose particle–copper complex, or that the intercrystalline phase is present in quantities so minute as to escape detection.

It has long been recognized that cuprammonium is not a true solvent for cellulose[20] but in many researches this fact has been neglected. The Tyndall phenomenon characteristic of colloidal dispersions is exhibited clearly by cellulose dispersed in cuprammonium solution, Fig. 1. The slit ultramicroscope enables one to examine such dispersions in strong light under high magnification. Thus examination of cuprammonium dispersions of disintegrated cotton fibers whose viscosity had reached a constant low value, Table I, showed practically the theoretical possible number of cellulose particles to be present, Table II. The

(18) Due to the variable values reported for the true density of cellulose [*cf.* A. J. Stamm and L. A. Hansen, *J. Phys. Chem.*, **41**, 1007 (1937)] and allowing for possible slight error in the dimensions of the cellulose particle, the values of N cannot be considered absolute, but do not exceed a possible correction of more than ± 20%.

(19) D. MacGillavry, *Rec. trav. chim.*, **48**, 18 (1929); E. Valkó, *Kolloid. Z.*, **51**, 130 (1930).

(20) E. Heuser, "Textbook of Cellulose Chemistry," 2d ed. German translation by C. J. West and G. J. Esselen, Jr., McGraw-Hill Book Co., Inc., New York, N. Y., 1924, p. 138.

variable deviations of the observed number of particles from the theoretical with increasing concentration is due to the difficulty of obtaining an absolute estimate from relatively few counts. When the number of counts on the samples was increased, the average value more closely approached the theoretical. The significant fact, however, is the trend toward an increase in particle count with increase in cellulose concentration. Due to the Brownian movement of the dispersed particles and the convection currents set up in the micro cell by heat from the light beam, an accurate count is difficult to obtain on more than one per cent. concentrations of low viscosity cellulose. With high viscosity cellulose, however, such as kiered and bleached cotton, motion in the dispersion is greatly reduced. Wood pulp dispersed in cuprammonium solution showed the same particle count tendency as cotton celluloses, thus indicating that both are composed of the same elementary units.

Inasmuch as cuprammonium dispersions of cellulose contain microscopically visible particles and possess high optical activity, it would appear that the organized units must be able both to transmit and reflect light. In ordinary light without high magnification, these dispersions seem to be true solutions due to even lighting from all directions of the transparent cellulose particle–copper complex.

Cuprammonium dispersions of a cellodextrin such as "biosan" are slightly less optically active than cellulose (Fig. 2). Dilute dispersions are optically void when examined in the slit ultramicroscope, but upon increasing the concentration a few particles are observed, Table II. It thus appears that this cellulose-like substance is dispersed beyond the limits of microscopic visibility. The conclusion thus may be drawn that regardless of the state of aggregation of the cellulose–copper complex, the optical rotation is of the same order of magnitude.

The existence of a definite equilibrium between the permanently dispersed cellulose particle–copper complex phase and the excess undispersed solid cellulose at concentrations exceeding 4.5% is shown by the fact that saturation is reached at this point. The saturation point is independent of the copper concentration and has only been observed with cellulose particles (Expt. 2) as the viscosity of native cellulose is much too high to make the point distinguishable. The excess undispersed cellulose phase may be almost entirely recovered unchanged upon centrifuging cuprammonium dispersions containing more than 4.5% cellulose particles. X-Ray diffraction analysis[21] shows the excess undispersed phase, thus recovered from a more than saturated cuprammonium dispersion, to be native cellulose, whereas the permanently dispersed phase upon regeneration gives a mercerized or hydrated cellulose pattern. Since the undispersed cellulose phase is not combined with the copper or ammonia in any way, it appears that the intermediary formation of the cellulose–copper complex is necessary for the transformation of native cellulose into the mercerized form, or that copper complex compound formation and dispersion of cellulose occur simultaneously.

Summary

1. The successive lowering of the cuprammonium viscosity of native cotton fibers by the action of dilute acids or mild oxidizing agents is not accompanied by a change in the optical activity of the resulting dispersions, a conclusion in agreement with the work of Hess on celluloses of low viscosity.

2. From (1) it follows that the optical activity of cellulose dispersions in cuprammonium solutions is dependent upon the formation of a cellulose particle–copper complex.

3. Quantitative examination of various celluloses dispersed in cuprammonium solutions, using the slit ultramicroscope, reveals the presence of approximately the theoretical number of cellulose particles (1.1 × 1.5 μ).

4. Further evidence that cellulose–copper compound formation precedes dispersion of cellulose in cuprammonium solution is presented.

5. Visible cellulose particles (1.1 × 1.5 μ) observed in the living cytoplasm, cellulose fibers and dispersions of cellulose in cuprammonium solution possess the essential features, with the exception of size and shape, of the hypothetical micelles.

YONKERS, N. Y. RECEIVED FEBRUARY 3, 1938

---

[21] Prior to the author's independent observation, W. A. Sisson of this Laboratory noted this apparent equilibrium from a qualitative examination of cuprammonium dispersions of cellulose particles.

The Preparation of *d*-Galacturonic Acid from *d*-Galactose[1]

BY HAROLD M. SELL AND KARL PAUL LINK

The synthesis of *d*-galacturonic acid from the parent sugar *α-d*-galactose involves the following transformations: I, the acetonation of *d*-galactose to 1,2,3,4-diacetone-*d*-galactose; II, the oxidation of diacetone-*d*-galactose to diacetone-*d*-galacturonic acid with alkaline potassium permanganate; III, the conversion of the potassium salt of diacetone-*d*-galacturonic acid to diacetone-*d*-galacturonic acid; IV, the hydrolysis of diacetone-*d*-galacturonic acid to *d*-galacturonic acid and subsequent crystallization of the free acid.

Ohle and Berend,[2] the originators of this method of synthesizing *d*-galacturonic acid, did not obtain the acid in a crystalline condition and resorted to the use of derivatives (brucine and osazone phenylhydrazine salts). In 1934 Niemann and Link[3] were able to put the method on a more practical basis in that they were able to realize the acid in a crystalline condition, with a yield of 30% of the theoretical. Reichstein and coworkers[4] introduced an improvement in step IV by eliminating the use of a mineral acid in the hydrolysis of the acetone residues.

For most laboratories the logical starting product for the synthesis of *d*-galacturonic acid is the parent sugar *α-d*-galactose. Consequently, we have made a careful study of each stage of the synthesis and have worked out the conditions necessary for success under average conditions.

The major change made in step I is the elimination of the necessity for the purification of the diacetone-*d*-galactose by a high vacuum distillation. The yield of diacetone-*d*-galactose has been increased from 60 to 92%.[2,5] In step II the oxidation has been placed on a firmer basis by increasing the ratio of potassium permanganate from 3 to 5 moles per mole of diacetone-*d*-galactose to be oxidized. By employing anhydrous acetone as the means of inducing the crystallization of the potassium diacetone-*d*-galacturonate this intermediate can be obtained in an analytically pure condition free from the troublesome hygroscopic properties that are usually encountered when the procedure of Ohle and Berend is used.[2] Reichstein and co-workers[4] had placed step IV on such a basis that further improvement was not necessary.

If the procedure outlined below is followed carefully the preparation of pure *d*-galacturonic acid can be realized with ease.

Experimental

Acetonation of *α-d*-Galactose.[2,3]—In a 6-liter wide-necked bottle with ground-glass stopper are placed 90 g. (0.5 mole) of finely pulverized *α-d*-galactose (m. p. 170°; $[\alpha]^{20}{}_{\rm D}$ +80.3°; dried for ten hours at 90° over phosphorus pentoxide in a vacuum oven), 200 g. (1.25 moles) of powdered anhydrous copper sulfate,[6] 10 cc. of sulfuric acid (sp. gr. 1.84), and 2 liters (27.4 moles) of dry alcohol-free acetone (dried over anhydrous calcium chloride). After the mixture has been shaken on a mechanical shaker for twenty-four hours it is filtered and the filter cake washed with dry acetone. To the filtrate is added 25 g. of powdered calcium hydroxide and the mixture is shaken for about two hours. The addition of 25-g. portions and the shaking are continued until the solution gives a neutral reaction to Congo red paper. A total of approximately 100 g. (1.35 moles) of calcium hydroxide is required to neutralize the sulfuric acid. The acid must be removed completely to avoid the hydrolysis of the acetone residues during the concentration of the solution.

After the unreacted calcium hydroxide and the calcium sulfate have been removed by filtration, the filter cake is washed with dry acetone. The filtrate is concentrated, first to a thin sirup at atmospheric pressure, then at 50° and 15 mm. (water pump), and, finally, to remove the last traces of acetone, at 100° and 6 mm. (oil pump). The yield of crude diacetone-*d*-galactose, as a thick sirup, is 100–120 g. (76–92%). Pure diacetone-*d*-galactose distils at 130–140° under 0.01–0.001 mm. pressure; $[\alpha]^{20}{}_{\rm D}$ −54.7 (*c*, 3.565; $CHCl_3$); negative Fehling's test.

Oxidation of Diacetone-*d*-galactose.[2]—To a solution of 100 g. (0.38 mole) of crude diacetone-*d*-galactose in water (4.5 liters) and potassium hydroxide (104 cc., 7.5 *N*) contained in a six-liter jar is added 300 g. (1.9 moles) of powdered potassium permanganate in 60-g. portions over a period of five hours. The solution is stirred mechanically throughout the oxidation, which is usually complete in twenty-four hours. If an excess of potassium permanganate is present, it is destroyed by the addition of hydrogen peroxide. The manganese dioxide is removed by filtration on an asbestos mat on a Büchner funnel and washed thoroughly with water. The filtrate is treated with car-

[6] The anhydrous copper sulfate is best prepared by drying the pentahydrate in an oven at 110° for several days and then heating in a casserole over a free flame until the powder is white. It should be used immediately after dehydration.

bon dioxide gas until the solution gives no color with phenolphthalein.[7] Concentration of the aqueous solution at 6 mm. and not over 65° leaves a dry residue which is extracted twice with 300-cc. portions of boiling ethanol, the insoluble portions remaining on the filter. Removal of the alcohol (15 mm. and 50°) and addition of 300 cc. of dry acetone (in which monoacetone-*d*-galactose and the unreacted diacetone-*d*-galactose are soluble) yields the crystalline potassium salt of diacetone-*d*-galacturonic acid. Addition of dry acetone to the concentrated mother liquors gives a second crop of the potassium salt, which is recrystallized by dissolving in a small volume of ethanol and then adding acetone. The yield of the potassium diacetone-*d*-galacturonate is 60–80 g. (49–65%); m. p. 200–205° (dec.); $[\alpha]^{20}D$ −61.1 (*c*, 2.046; H_2O).

Conversion of Diacetone-*d*-galacturonic Acid Potassium Salt to Diacetone-*d*-galacturonic Acid.[2]—A solution of 60 g. (0.19 mole) of the *carbonate-free* potassium salt ($C_{12}H_{17}O_7K \cdot 0.5H_2O$) in sulfuric acid (376 cc. of 0.5 *N*) is extracted four times with 250-cc. portions of ether. The combined ethereal extractions, dried over anhydrous sodium sulfate, are concentrated to dryness at 15 mm. and 50°. The residue is dissolved in 50 cc. of warm benzene. Crystallization is induced by adding 200 cc. of petroleum ether. The yield of diacetone-*d*-galacturonic acid is 40–45 g. (78–88%); m. p. 157°; $[\alpha]^{20}D$ −84.0°.

Hydrolysis of Diacetone-*d*-galacturonic Acid to *d*-Galacturonic Acid.[4]—A solution of 40 g. (0.15 mole) of diacetone-*d*-galacturonic acid (m. p. 157°) in water (120 cc.) is heated on a water-bath at 95 to 100° for two hours. After decolorizing with 5 g. of activated carbon the clarified solution should be concentrated *immediately* as *rapidly* as possible to a mobile sirup (50°, 6 mm.). The sirup is transferred to an evaporating dish and upon vigorous scratching it will set to a solid crystalline cake.[8] The product is collected on a Büchner funnel, washed with ethanol, dry ether, and dried over phosphorus pentoxide at 25° and 12 mm. pressure. The yield of *d*-galacturonic acid is 20–25 g. (65–81%). The product, being a mixture of the α- and β-forms, will show an initial rotation of $+60° \longrightarrow +80°$ depending on the time involved in concentrating the final solution. Pure α-*d*-galacturonic acid sinters at 110–111° and decomposes at 159–160°. The $[\alpha]^{20}D$ is +98° initial, final value +50.9° (*c*, 2.1; H_2O).

Summary

An improved method for the synthesis of *d*(+)-galacturonic acid has been described. The yield is 50 g. of *d*(+)-galacturonic acid from 100 g. α-*d*-galactose.

The Molecular Structure of Arsenious Oxide, As_4O_6, Phosphorus Trioxide, P_4O_6, Phosphorus Pentoxide, P_4O_{10}, and Hexamethylenetetramine, $(CH_2)_6N_4$, by Electron Diffraction

BY G. C. HAMPSON AND A. J. STOSICK

In a recent paper,[1] which was published while this work was in progress, there were reported the results of an electron diffraction investigation of the structures of phosphorus trioxide, phosphorus pentoxide and arsenious oxide. The values which we have obtained for P_4O_6 and As_4O_6 are in good agreement with those of Maxwell, Hendricks and Deming. On the other hand, the latter authors were unable to deduce a structure for P_4O_{10} and came to the conclusion that the molecule probably has lower symmetry than that of the point group T_d. The reason for their failure probably lies in the fact that the molecule has an abnormally short P–O distance and we were led to our final structure, which gives an excellent fit with the photographs, only after very many models had been shown to be wrong.

The visual method of measurement was used, the results being compared in the usual way with the approximate scattering formula

$$I = \Sigma_{ij} Z_i Z_j \frac{\sin sr_{ij}}{sr_{ij}}$$

in which r_{ij} is the distance between the *i*th and *j*th atoms, Z_iZ_j their atomic numbers and $s = (4\pi \sin \theta/2)/\lambda$, where θ is the scattering angle and λ the wave length of the electrons. Radial distribution curves[2] were also calculated and interatomic distances deduced from them. When a molecule contains several approximately equal distances, the radial distribution method fails to resolve the closely spaced maxima and very little information can be obtained from the curve. A modification of the method, suggested by Dr. V. Schomaker of these Laboratories, in which the estimated intensities are multiplied by a factor

$s^3e^{-as^2}$, with a chosen such that the exponential factor is equal to one-tenth for the last measured ring, gave a satisfactory resolution of most of the distances, and was invaluable in fixing the model for P_4O_{10}.

As_4O_6, P_4O_6, P_4O_{10}, and $(CH_2)_6N_4$ were measured in Oxford using the apparatus described by de Laszlo;[3] for his assistance in operating the electron diffraction camera we are greatly indebted to Dr. A. H. Gregg. The measurements on As_4O_6, P_4O_6, and P_4O_{10} were then repeated in Pasadena using the apparatus described by Brockway,[4] and the two sets of results were found to agree to within 1%. With the latter apparatus two or three extra outer rings were obtained, but the longer jet-to-camera distance employed in the de Laszlo apparatus enabled some inner fine structure to be resolved which was of great help in the P_4O_{10} investigation.

Experimental

The As_4O_6 used was the C. P. arsenious oxide of commerce which was not further treated.

The P_4O_6 was prepared by the method of Wolf and Schmager,[5] a modification of the older method of Thorpe and Tutton.[6] The trioxide so prepared contains 1 to 2% of free yellow phosphorus even after repeated vacuum distillation. The greater share of this free phosphorus was removed by irradiating the impure oxide for two days with a mercury vapor lamp. This treatment largely converts the yellow form into the much less volatile red form permitting separation by a subsequent distillation *in vacuo*.

The P_4O_{10} used was commercial C. P. phosphorus pentoxide which was sublimed in a stream of oxygen to remove lower oxides. This treatment is necessary since the lower oxides are all more volatile.

The hexamethylenetetramine was a commercial sample purified by vacuum sublimation.

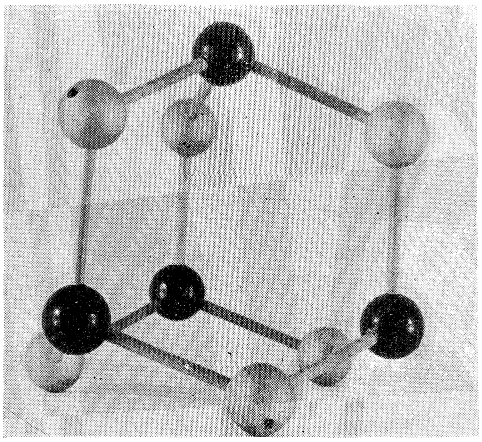

Fig. 1.—Photograph of model of As_4O_6, P_4O_6, or $(CH_2)_6N_4$. The black balls represent As, P, or N; the silver balls represent O or CH_2.

Arsenious Oxide.—The models tried for As_4O_6 consist of four As atoms at the positions (v,v,v), ($\bar{v}$,$\bar{v}$,v), ($\bar{v}$,v,$\bar{v}$) and (v,$\bar{v}$,$\bar{v}$) and six O atoms at the positions ($\pm$u,0,0), (0,$\pm$u,0) and (0,0,$\pm$u) (Fig. 1).

The photographs of As_4O_6 show thirteen maxima, eleven of which were measurable. The first, second and fourth maxima are strong. Preceding the fifth maximum and following the sixth maximum there are deep minima of about equal depth. The fifth and sixth maxima are of equal intensity. The values of s_0 for the maxima and minima and the estimated intensities of the maxima are given in Table I together with the weighted intensity values, c, used in the modified radial distribution method. The corresponding values of s for models VII and VIII are also given.

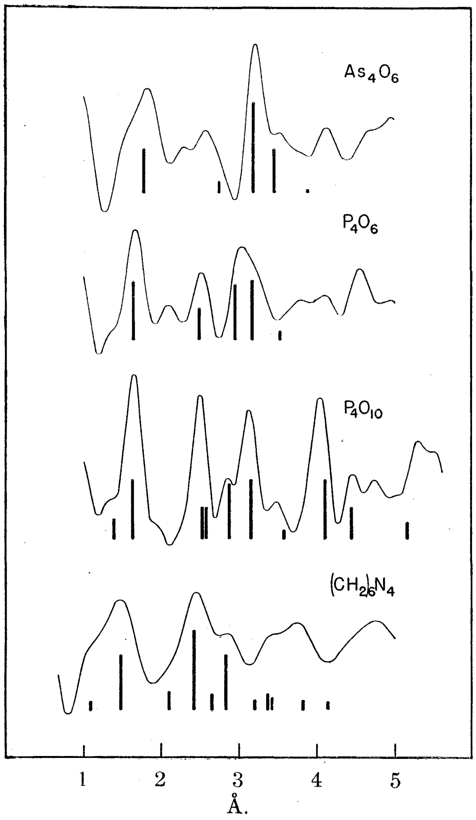

Fig. 2.—Radial distribution curves.

In Table II the parameters of all the models for which intensity curves were calculated are given.

Models VII and VIII are both satisfactory since both are in qualitative agreement with the photographs. Model V is not satisfactory because for it the eighth maximum becomes a shelf, and model VI is not satisfactory because the sixth maximum has become weaker than the fifth.

Table II

Model	u	v	As–As	As–O	O–As–O	As–O–As
I	2.310	1.155	3.26 Å.	2.00 Å.	109°28′	109°28′
II	2.057	1.308	3.70	2.00		
III	1.890	1.160	3.27	1.79		
V	1.890	1.142	3.23	1.78	97°20′	130°14′
VI	2.038	1.142	3.23	1.84	102°34′	121°58′
VII	1.981	1.142	3.23	1.82	100°39′	125°6′
VIII	1.959	1.142	3.23	1.81	99°54′	126°20′

Models VII and VIII lead to the following values of the interatomic distances and valence angles

Model VII	Model VIII
As–As = 3.20 Å.	As–As = 3.20 Å.
As–O = 1.80 Å.	As–O = 1.79 Å.
O–As–O = 100°39′	O–As–O = 99°54′
As–O–As = 125°6′	As–O–As = 126°20′

The radial distribution method applied to the As_4O_6 photographs gives a curve with maxima at 1.82 and 3.21 Å. corresponding to the values given above for the distances in the molecule. The curve for this calculation is given in Fig. 2. In Fig. 3 the theoretical intensity curves for As_4O_6 are

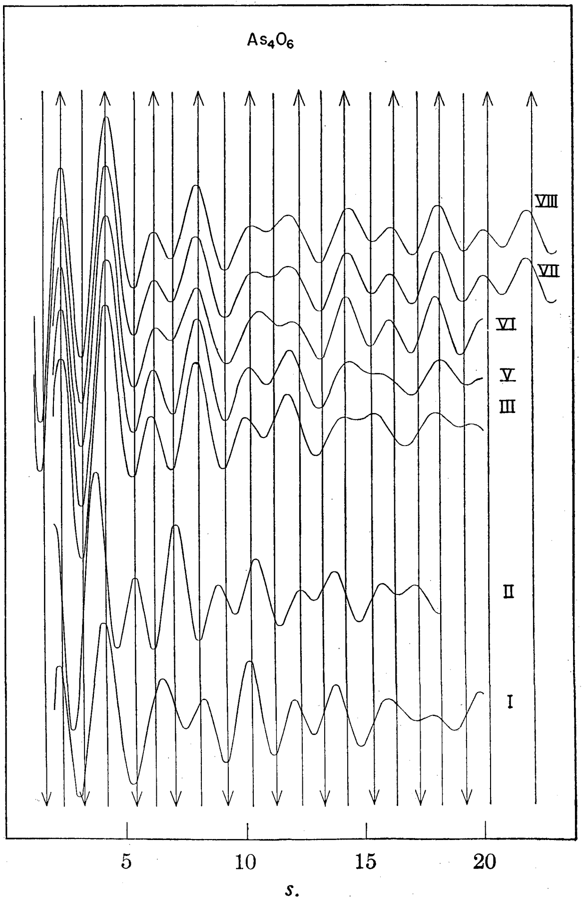

Fig. 3.—Calculated intensity curves for As_4O_6.

TABLE III

Max.	Min.	I	c	s_0	s(VI)	s(VIII)	s_{VI}/s_0	s_{VIII}/s_0

	7			14.319	14.09	14.05	.984	.981
7		2	18	15.548	15.69	15.62	1.009	1.005
	8				16.95	16.84		
8		1			17.70	17.58		
	9				18.52	18.44		
9		2	16	19.90	19.71	19.63	0.990	0.9866
							Mean .9802	Mean .9769

given. As final values of the distances the following are given:

As–As = 3.20 ± 0.03 Å. As–O–As = 126 ± 3°
As–O = 1.80 ± 0.02 Å. O–As–O = 100 ± 1.5°

Maxwell, Hendricks and Deming[1] give As–As = 3.20 ± 0.05 Å. They were unable to fix the oxygen parameter because of the much greater scattering power of the As atoms. Fair agreement was found with the oxygen valence angle As–O–As equal to 120°, 127.5° or 140°.

Phosphorus Trioxide.—The models used for P_4O_6 are of the same type as for As_4O_6. The four P atoms are at positions (v,v,v), $(\bar{v},\bar{v},v)$, $(\bar{v},v,\bar{v})$, and $(v,\bar{v},\bar{v})$, and the six O atoms at $(\pm u,0,0)$, $(0,\pm u,0)$, and $(0,0,\pm u)$.

The photographs of P_4O_6 show nine maxima, eight of which are measurable. The first, second and fourth maxima are strong; the second maximum is followed by a weak, almost shelf-like maximum; the sixth and seventh maxima are strong, of nearly equal intensity, separated by a broad and deep minimum; and the minimum following the weak eighth maximum is slightly deeper than that which precedes.

The values of s_0 for the maxima and minima and the estimated intensities of the maxima are given in Table III. Values of the parameters of models for which theoretical intensity curves were calculated are listed in Table IV.

Models VI and VIII were found to be in satisfactory qualitative agreement with the photographs. Model VII is unsatisfactory because the minimum following the eighth maximum has become weaker than that which precedes. Also any model with the value of the parameter u greater than that of model VIII would make this same minimum too deep in comparison with the preceding one.

TABLE IV

Model	u	v	P–P	P–O	O–P–O	P–O–P
IV	1.600	1.064	3.010	1.597	90°11′	140°48′
I	1.664	1.064	3.010	1.620	93°10′	136°31′
V	1.750	1.064	3.010	1.654	96°53′	130°59′
VII	1.780	1.064	3.010	1.666	98°6′	129°6′
VI	1.800	1.064	3.010	1.675	98°50′	127°52′
VIII	1.820	1.064	3.010	1.684	99°41′	126°39′
III	1.900	1.064	3.010	1.721	102°36′	121°53′
II	2.128	1.064	3.010	1.843	109°28′	109°28′

Models VI and VIII lead to the following values of the interatomic distances:

Model VI	Model VIII
P–P = 2.95 Å.	P–P = 2.94 Å.
P–O = 1.64 Å.	P–O = 1.65 Å.
O–P–O = 98°50′	O–P–O = 99°41′
P–O–P = 127°52′	P–O–P = 126°39′

A final choice of model must lie between models VI and VIII, possibly favoring model VI. This leads to the final values of the distances:

P–P = 2.95 ± 0.03 Å.
P–O = 1.65 ± 0.02 Å.
O–P–O = 99° ± 1°
P–O–P = 127.5 ± 1°

The results given by Maxwell, Hendricks and Deming[1] are:

P–P = 3.00 ± 0.05 Å.
P–O = 1.67 ± 0.03 Å.
P–O–P = 128.5 ± 1.5°

Radial distribution calculations result in a curve (Fig. 2) with maxima corresponding to interatomic distances of 1.66 and 3.03 Å. The theoretical intensity curves for P_4O_6 are given in Fig. 4.

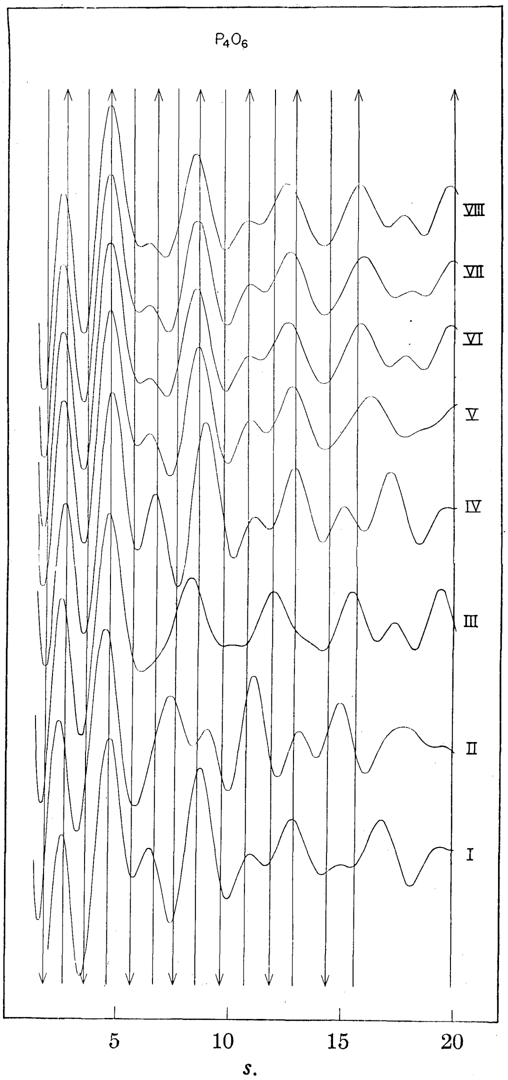

Fig. 4.—Calculated intensity curves for P_4O_6.

Phosphorus Pentoxide.—The photographs taken show eleven measurable maxima. The second maximum is the strongest and is followed by a shelf with no observable minimum interposed; and the third maximum is moderately strong and is followed by a broad shelf-like region. On photographs which were taken using a longer jet-to-camera distance (28.0 cm.) this shelf appears as two very weak maxima with poorly marked minima interposed. With the shorter camera distance (10.85 cm.) the doublet is not resolved. Following the eighth measured maximum there is another doublet of which only the outer ring is measurable. The second ring of this doublet is followed by a fairly pronounced minimum and a much stronger maximum. The last measured maximum is broad, and is preceded by a well marked minimum. The minima immediately preceding and following the weak seventh maximum are both weak, the outermost being possibly a little deeper. The measured values of s_0 of the maxima and minima and the estimated intensities of the maxima are listed in Table V. In Table VI the models for which theoretical intensity curves were calculated are listed.

VIII	0.992	1.720	2.008	2.81	1.58	1.76	100°36′	125°15
IX	.993	1.840	1.795	2.81	1.64	1.39	104° 0′	117°46′
X	1.045	1.750	1.830	2.96	1.64	1.36	98° 0′	129°14′
XI	1.022	1.795	1.829	2.89	1.64	1.40	101°30′	123°42′
XII	1.040	1.795	1.829	2.94	1.65	1.40	100°18′	125°39′
XIII	1.020	1.800	1.836	2.88	1.64	1.41	101°49′	123°12′
XIV	1.018	1.792	1.827	2.88	1.63	1.40	101°39′	123°28′

All of the models are for the four P atoms at positions (a,a,a), $(\bar{a},\bar{a},a)$, $(\bar{a},a,\bar{a})$, and $(a,\bar{a},\bar{a})$, six O atoms at positions (±b,0,0), (0,±b,0), and (0,0,±b), and the remaining four O atoms at the positions (c,c,c), $(\bar{c},\bar{c},c)$, $(\bar{c},c,\bar{c})$, and $(c,\bar{c},\bar{c})$. Models XI, XIII and XIV are all satisfactory in their qualitative agreement with the photographs. Model XIV is roughly the mean of models XI and XIII, and it has been used for the final calculations of the interatomic distances of the molecule. The following distances result from these calculations:

P–P = 2.84 ± 0.03 Å. OPO = 101.5 ± 1°
P–O = 1.62 ± 0.02 Å. POP = 123.5 ± 1°
P–O′ = 1.39 ± 0.02 Å. OPO′ = 116.5 ± 1°

The angle designated by OPO′ is the angle formed by the P atom at (a,a,a) and the O atoms at (b,0,0) and (c,c,c) (Fig. 5). It may be seen from an inspection of the models listed that the valence angles are very closely limited. Model XII differs from model XI only in the phosphorus coördinates, causing a change in the P valence angle of only about one degree, but it is not in qualitative agreement with the photographs in that for it the shelf-like region following the fourth maximum has become a real maximum with a preceding minimum. The short P–O′ distance is also fixed closely by the disagreement of model VII. This model differs from the satisfactory models only in that the coördinates of the outer four O atoms are changed by a very small amount.

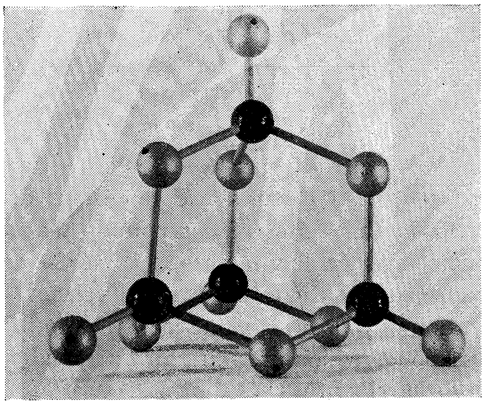

Fig. 5.—Photograph of model of P_4O_{10}. The black balls represent P; the silver balls represent O.

The modified radial distribution method suggested by Dr. Schomaker gave a remarkably good resolution of the various peaks, nearly all the interatomic distances in the molecule appearing as separate maxima. The curve is shown in Fig. 2. From the data which it provided, the three parameters could be determined within narrow limits, these parameters agreeing well with those chosen for the final model.

The theoretical intensity curves for the models of Table VI are shown in Fig. 6.

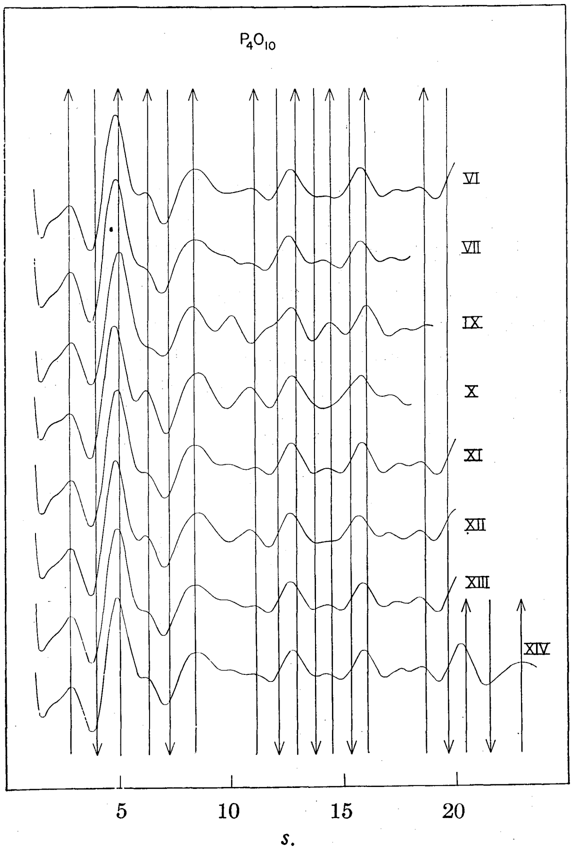

Fig. 6.—Calculated intensity curves for P_4O_{10}.

Hexamethylenetetramine.—The photographs of this substance were taken using a long jet-to-camera distance and show six maxima. The first two are strong, the third broad and diffuse, the fourth very weak, the fifth fairly strong and the sixth very weak.

The hexamethylenetetramine model is essentially the same as that for P_4O_6 and As_4O_6. Four N atoms are in positions (v,v,v), ($\bar{v}$,$\bar{v}$,v), ($\bar{v}$,v,$\bar{v}$) and (v,$\bar{v}$,$\bar{v}$), six C atoms in positions (±u,0,0), (0,±u,0) and (0,0,±u) and the twelve H atoms in positions (x,$\bar{x}$,z), ($\bar{x}$,x,z), etc. The hydrogen parameter could not be deduced from the photographs and an assumed value of 1.09 Å. for the C–H distance was used in computing the theoretical intensity curves. A model in which all the angles had the regular tetrahedral value of 109.5° and with a C–H distance of 1.48 Å. (N–N or C–C = 2.42 Å.) was found to agree well with the photographs. The curve for this model is shown in Fig. 7. Table VII gives the measured values of

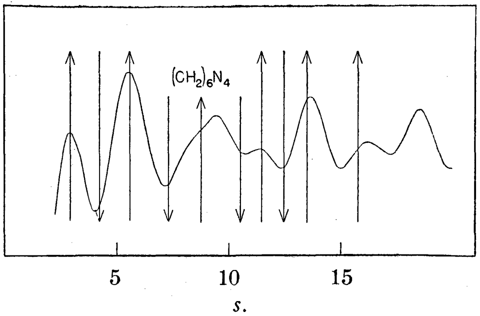

Fig. 7.—Calculated intensity curve for $(CH_2)_6N_4$.

s_0 for the maxima and minima together with the estimated intensities of the maxima; the s values for the above model are also listed, and the average value of s/s_0 is seen to be practically unity.

Table VII

Max.	Min.	I	c	s_0	s	s/s_0
1		10	2	2.966	2.93	0.988
	1			4.261	4.06	.953
2		8	15	5.606	5.56	.992
	2			7.303	7.15	.979
3		4	5	8.774	9.41	1.073
	3			10.54	10.75	1.020
4		2	2	11.47	11.40	0.995
	4			12.49	12.35	0.989

6		1	4	15.79	16.25	1.029
					Mean	1.003

The radial distribution curve shown in Fig. 2 gives C–N = 1.47 Å. and C–C or N–N = 2.43 Å. agreeing well with the above model.

Discussion of Results

Of the substances reported in this paper, two, hexamethylenetetramine and arsenious oxide, have been studied in the solid form. Hexamethylenetetramine crystallizes in a body-centered cubic lattice, Dickinson and Raymond[7] reporting a regular tetrahedral arrangement of valences with C–N = 1.44 Å. Gonell and Mark[8] gave C–N = 1.48 Å. and C–C = 2.58 Å., and this same type of structure has also been confirmed by Wyckoff and Corey,[9] who give C–N = 1.42 ± 0.08 Å. The sum of the covalent single-bond radii[10] of carbon and nitrogen is 1.47 Å. in good agreement with the value which we find here.

Arsenolite, cubic As_4O_6, was reported by Bozorth[11] to be a lattice of As_4O_6 molecules in a diamond-type arrangement. Both the As and the O valence angles are tetrahedral in this solid, the As–As distance 3.28 Å. and the As–O distance 2.01 Å. There are two strong bonds for each O atom to two As atoms in the same molecule, and two weak bonds to two As atoms of a neighboring molecule. This attraction between neighboring molecules apparently draws the O atom out, increasing the As–O distance and decreasing the oxygen valence angle from the values observed for the vapor molecule to those observed in the solid. To a smaller extent this applies to the As atoms too, since each forms three strong bonds to oxygens in the same molecule and three weak bonds to oxygens of adjacent molecules. A redetermination of the crystal parameters was made by Harker and Eskijian[12] in these Laboratories confirming the older values but fixing them more closely (to within about 0.03 Å.).

Arsenic apparently has a tendency to form bonds at angles smaller than the tetrahedral angle, as As_4O_6 is not unique in this respect. In this compound where the atoms form closed rings it might be thought that the As valences are strained into taking up this angle because of the tendency of the oxygen angle to expand beyond the tetrahedral value[13] but even in compounds where the groups attached to the As atom form no other bonds, the As bond angle is considerably less than 109°28′. Examples are $AsCl_3$ 103°,[14,15] 101 ± 4°,[16] $AsBr_3$ 100 ± 2°,[16] $As(CH_3)_3$ 96 ± 5°.[17]

The remarkable constancy of this angle of around 100° already has been remarked upon.[16] Steric effect and electrostatic repulsions are so different in this series of compounds that they cannot be the deciding factors in fixing the angle. According to the theory of directed valency[18] the utilization of p orbitals alone leads to the formation of bonds which are mutually perpendicular. Hybridization with the s orbital gives rise to stronger bonds which, if hybridization is complete, as with carbon compounds, are at an angle of 109°28′. If, however, there are unshared electrons, as in the case we are considering, hybridization may not be complete, for there are two opposing tendencies. On the one hand, hybridization tends to stabilize the bonds but at the same

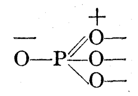
time this means that the unshared electrons also tend to become hybridized between the *s* and *p* orbitals, whereas the unshared pairs of electrons are always most stable when they occupy the *s* orbitals. As usual the actual configuration taken up is that which gives the lowest energy.

The sum of the covalent single-bond radii[10] of arsenic and oxygen is 1.87 Å. The decrease from the sum of the radii to the observed value of 1.80 Å. may be explained as the result of double bond character caused by unshared pairs from the oxygen atoms forming double bonds with the As atoms.[14–16] The value 126 ± 3° which is observed for the oxygen angle is close to 125°16′, the angle between a double and a single bond on the regular tetrahedral model.

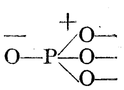
Phosphorus, like arsenic, shows a tendency to form bond angles less than the tetrahedral angle. In P_4O_6 it is found to be 99°. In other substances where the groups attached form no other bonds the same behavior is noted. Examples are PF_3 99 ± 4°,[14] PCl_3 100 ± 2°,[14] PBr_3 100 ± 2°,[16] PI_3 98 ± 4°,[16] $POCl_3$ 104°,[19] $P(CH_3)_3$ 100 ± 4°.[17]

The sum of the covalent radii[10] for phosphorus and oxygen is 1.76 Å. Again the observed value is lower presumably because of double-bond character, as with As_4O_6.

In P_4O_{10} the phosphorus angles are 101.5 and 116.5°. The latter angle is that between an outer oxygen atom and one within the P_4O_6 "kernel." Addition of this outer oxygen atom has had very little effect on the other bond angles and this might have been anticipated from the values given for PCl_3 and $POCl_3$. The most startling feature of the P_4O_{10} molecule is the unusually short distance of 1.39 Å. between each P atom and the "extra" O atom. The value found is about 79% of the sum of the single bond radii (1.76 Å.) and is approximately that expected for a triple bond between the two atoms. A similar anomaly has been observed in thiophosphoryl chloride, $PSCl_3$,[20] where the P–S distance is found to be 1.94 Å. instead of the normal single bond distance of 2.14 Å. It is clear that double bond character in a structure such as , I, is not sufficient to explain such a large shortening as is observed. The addition of four extra oxygen atoms to P_4O_6 has very little effect on the dimensions of this P_4O_6 "kernel," and since we have postulated single-double bond resonance in P_4O_6, it seems reasonable to conclude that it also occurs in P_4O_{10}. The important systems are probably II and III in resonance with I.



II



III

There is another piece of evidence which favors this conclusion. In P_4O_6 the contribution of a double-bonded structure IV  was postulated to explain the shortening of the P–O bond below the single bond value. In this structure the phosphorus and oxygen atoms carry opposite charges and so there is no "formal charge effect"[21] influencing the bond length. On the other hand, in structures II and III of P_4O_{10} the positive charge on the oxygen or phosphorus atom is not compensated by a negative charge within the P_4O_6 "kernel" and hence because of the increased effective nuclear charge we should expect the bond length to be diminished. The P–O distance in P_4O_6 is 1.65 Å. and the corresponding distance in P_4O_{10} is indeed shorter, being 1.62 Å. The difference may be due to experimental error, although in view of the above argument it may be of some significance. As regards the other P–O distance having the extremely low value of 1.39 Å., the "formal charge effect" in structure II (negative charge on the oxygen, no charge on the phosphorus) would lead one to expect an increase rather than a decrease. One is forced to conclude that the predominant factor here must be the polar character of the bond. In discussing $PSCl_3$, Beach and Stevenson[20] ruled out any effect of ionic character and formal charges on the length of the bond, but concluded that the shortening of the P–S distance must be due to a considerable (about one half) contribution of  without, however, giving any reasons. The short P–O distance in P_4O_{10} is in accord with the chemical properties of this molecule. Such short bonds are presumably extremely stable, and the thermal stability and resistance to reduction of P_4O_{10} are well known.

We wish to express our thanks to Professor Brockway, Professor Pauling and Professor Sidgwick for their help and interest in this work,

and the Commonwealth Fund for a Fellowship to one of us (G. C. H.).

Summary

Electron diffraction measurements on arsenious oxide, phosphorus trioxide and hexamethylenetetramine show that the molecules consist of four phosphorus or nitrogen atoms in positions (vvv) $(\bar{v}\bar{v}v)$ $(\bar{v}v\bar{v})$ and $(v\bar{v}\bar{v})$ and six oxygen atoms or methylene groups in the positions $(\pm u00)$ $(0 \pm u0)$ and $(00 \pm u)$. In phosphorus pentoxide there are four additional oxygen atoms in the positions (www) $(\bar{w}\bar{w}w)$ $(\bar{w}w\bar{w})$ and $(w\bar{w}\bar{w})$.

The interatomic distances and angles are: for As_4O_6, As–O = 1.80 ± 0.02 Å., O–As–O = 100 ± 1.5°, As–O–As = 126 ± 3°, for P_4O_6, P–O = 1.65 ± 0.02 Å., O–P–O = 99 ± 1°, P–O–P = 127.5 ± 1°, for $N_4(CH_2)_6$, C–N = 1.47 ± 0.02 Å., C–N–C = N–C–N = 109.5°, for P_4O_{10}, P–O = 1.62 ± 0.02 Å., P–O′ = 1.39 ± 0.02 Å., O–P–O = 101.5 ± 1°, P–O–P = 123.5 ± 1° and O–P–O′ = 116.5 ± 1°.

The shortening of the bond distances in As_4O_6, P_4O_6 and P_4O_{10} below the theoretical single-bond values is attributed to single-bond double-bond resonance. It is concluded that the abnormally low value of 1.39 Å. for the P–O′ bond in P_4O_{10} is due to the polar character of the bond.

The Properties of Osmium Tetroxide in Carbon Tetrachloride Solutions. The Thermodynamic Constants of Osmium Tetroxide[1]

By LeRoy H. Anderson and Don M. Yost

Introduction

Osmium tetroxide is known to be moderately soluble in water and very soluble in carbon tetrachloride. Von Wartenberg[2] determined the solubility to be 6.47 g. per 100 g. of water, and about 250 g. per 100 g. of carbon tetrachloride, at 20°. The distribution ratio of osmium tetroxide between carbon tetrachloride and water was determined by Yost and White[3] for dilute solutions to be 13 when the concentrations are expressed in moles per liter of both solvents. Distribution ratios were determined independently, and at about the same time, by Tschugajeff and Lukashuk[4] with essentially the same results. These authors also made solubility determinations in water but the result, 6.23 g. per 100 g. of water at 25°, does not seem to be consistent with that of Von Wartenberg.

The distribution ratio calculated from solubilities is much higher than that found in the experiments on dilute solutions. This fact indicated that either the concentrated solutions in carbon tetrachloride were exhibiting some abnormal behavior, or that in the distribution experiments water possibly was associated with the tetroxide in carbon tetrachloride layer, thus forming a different solute. In order to settle this point, distribution experiments were made with solutions whose concentrations varied from very dilute to saturation, the solubilities of osmium tetroxide in both water and carbon tetrachloride were redetermined, and the vapor pressures of carbon tetrachloride above solutions of osmium tetroxide in it were measured for the range of concentrations up to saturation.

Preparation of Materials and Experimental Methods

Osmium Tetroxide.—Osmium metal freed from ruthenium was heated to 300–400° in a glass tube in a stream of dried oxygen. The vapors of osmium tetroxide (b. p. 130°) were condensed in the distribution vessel or capsules by means of a solid carbon dioxide–alcohol bath.

All other chemicals used were of the best grade obtainable. The carbon tetrachloride was further purified by fractional distillation.

Analytical Methods.—Osmium tetroxide is frequently determined iodimetrically,[4,5] but the colored tetravalent osmium solutions hide the end-point in all but rather dilute solutions, and atmospheric oxygen affects the results. After some experimentation the following procedure was

adopted: the weighed sample of osmium tetroxide solution was placed in a glass-stoppered flask containing 25 cc. of an acidified (0.35 *N* in hydrochloric acid) potassium iodide solution that had been saturated previously with carbon dioxide. After about thirty minutes of gentle shaking in the dark, the resulting solution was diluted to 200 cc. with distilled water saturated with carbon dioxide, and was then titrated with standard thiosulfate with starch as an indicator. Although this method can be made to give reproducible results, it cannot be said to be highly satisfactory, and, except for the dilute solutions, was replaced by a gravimetric method in which metallic osmium was weighed.

In the gravimetric method 0.1 to 0.3 g. of hydrazine hydrochloride was dissolved in 10 cc. of 3 *N* hydrochloric acid contained in a glass-stoppered flask. After warming this solution to 55–65°, the weighed sample of osmium tetroxide solution was introduced, and the resulting mixture was digested over a water-bath for an hour. This mixture was transferred to a weighed, glazed Rose crucible, and evaporated to dryness on a hot-plate. A stream of hydrogen was started through the crucible and the latter heated over a Bunsen burner for twenty to thirty minutes. The stream of hydrogen was continued until the crucible had cooled to room temperature, and then the hydrogen remaining was displaced with carbon dioxide. This last precaution is necessary to avoid the rapid combustion of hydrogen in the presence of the finely divided metallic osmium when the crucible cover is removed.

The Distribution and Solubility Experiments.—The distribution experiments were carried out in a 20-cc. cylindrical all-glass vessel equipped with two 1-mm. diameter tubes which extended into the carbon tetrachloride and aqueous layers, respectively. A little air pressure served to force samples of either layer out through the 1-mm. tubes and into a weighing bottle or capsule. The distribution vessel itself was fastened to a mechanical shaker operating in a thermostat so that equilibrium was certainly attained in all experiments. At no time did the tetroxide solutions come in contact with oxidizable substances.

In some of the distribution experiments, and in all of the solubility determinations, small, weighed, evacuated capsules equipped with long narrow outlet tubes were used for sampling. The outlet tubes were bent at right angles near their tips, and the short tips could be broken easily under the solution. The fragment of glass broken off was recovered and weighed.

The solubility experiments were carried out in a 10-cc. glass-stoppered tube that was shaken in the thermostat at 25° for twenty-four hour periods. Solubility equilibrium was approached from both directions.

The Vapor Pressure Experiments.—The apparatus used for the vapor pressure measurements consisted of a 20-cc. cylindrical glass container equipped with an all glass "click" gage and with side-arms which held easily breakable Capsules of osmium tetroxide and carbon tetrachloride. The capsules were broken when desired by means of glass enclosed, magnetically operated iron plungers. To attain more conveniently the higher dilutions, a separate calibrated carbon tetrachloride container was connected through a stopcock and a long (20 cm.) 0.5-mm. glass capillary tube to the solution container. The carbon tetrachloride was distilled into the solution container by cooling the latter with liquid air. In order to make sure that the solution was homogeneous at all times a stirrer consisting of a glass enclosed piece of soft iron was placed in the solution container and caused to move up and down by means of an external solenoid. The osmium tetroxide could at no time come in contact with any substance other than glass. Its low partial vapor pressure and the slow diffusion through the long capillary tube prevented appreciable loss of osmium tetroxide by reaction with the stopcock grease. The whole apparatus was highly evacuated and then closed off from the pumps. From time to time the contents of the system were condensed with liquid air and pressure measurements made to assure that no air had leaked into the apparatus.

Results of the Experiments

In Table I are presented the results of the distribution experiments made at 25°. All concentrations are expressed in mole fractions.

TABLE I

RESULTS OF THE DISTRIBUTION EXPERIMENTS AT 25°

Formula mole fraction OsO_4 in water layer, N_w	Formula mole fraction OsO_4 in CCl_4 layer, N_c	Distribution ratio $R = N_c/N_w$
0.0001464	0.01204	82.2

Solubility OsO_4 in 100 g. water at 25° = 7.24 ± 0.01 g.
Solubility OsO_4 in 100 g. CCl_4 at 25° = 375 ± 17 g.

[a] Iodimetric determinations. All others were gravimetric. [s] From solubility measurements.

The experimental error of 17 g. or 4.5% in the solubility in carbon tetrachloride arises from the fact that the solutions are very concentrated, that they have a tendency to supersaturate, and that the solubility appears to have a large temperature coefficient. The result given here is the mean of four determinations which seemed free of criticism.

In the first and second columns of the table are given the formula mole fractions of tetroxide in the aqueous and carbon tetrachloride layers, respectively, that is, the mole fractions calculated from the results of analyses on the assumption that OsO_4 is present as such. Most of the ratios are the average of two or more values obtained for the same distribution experiment. At low concentrations the error in the gravimetric method of analysis is high due to the small amount of osmium weighed. At high concentrations the volumetric method of analysis is worthless due to the errors in taking small samples of the carbon tetrachloride phase or to the errors described above.

The distribution ratio, $R = N_c/N_w$, increases slowly at first and then more rapidly with concentration. It is also evident that the ratio at the high concentrations is approaching the last value in the table which was calculated from the solubility measurements. It would appear, therefore, that the carbon tetrachloride layer contains no water associated with the osmium tetroxide.

In order to establish still more definitely that the non-ideality of the carbon tetrachloride solution is independent of the presence of water, vapor pressure measurements were made on solutions of osmium tetroxide in dry carbon tetrachloride. The results are presented in Table II. The total vapor pressures observed were corrected for the small partial pressures of osmium tetroxide on the assumption that the laws of perfect solutions were valid. For such small corrections this assumption is justified. The last column of the table contains vapor pressures calculated on the basis of an assumption to be discussed below.

Table II

The Partial Vapor Pressure of Carbon Tetrachloride above its Solutions of Osmium Tetroxide at 25°

Formula mole fraction OsO_4, N_c	Partial vapor of CCl_4 in cm. P	Vapor pressure calcd. from Raoult's law concn. = N_c	Vapor pressure calcd. from Raoult's law but assuming $4OsO_4 = (OsO_4)_4$
0.000	11.46	11.46	11.46
.0402	11.02	11.00	11.00
.081	10.56	10.55	10.55
.1105	10.05	10.20	10.20
.395	7.86	6.92	7.72
.5982	6.19	4.61	5.97
.693	5.39	3.52	5.17

It is clear from column three of the table that the vapor pressures calculated from Raoult's equation and the formula mole fractions in column one are not equal to the observed pressures, that is, the solutions are not ideal. Now it is known from electron diffraction experiments[6] and the Raman spectrum[7] that the osmium tetroxide molecule is highly symmetrical, the four oxygen atoms being at the corners of a tetrahedron with the osmium atom at the center. Carbon tetrachloride has the same symmetrical structure. In spite of this high symmetry, mixtures of the two substances do not form ideal solutions.

The results of equilibrium experiments on non-ideal binary solutions may be treated quantitatively in either of two ways. (1) By the application of the thermodynamically exact Gibbs-Duhem equation and the definition of fugacity, the fugacities of the components may be calculated for any concentration. The results of such calculations are useful and necessary for the calculation of thermodynamic quantities. (2) The assumption may be made that Raoult's equation is the expression of a law and that deviations from it are to be interpreted as indicating the formation of ions, compounds or polymers. This orthodox way of treating experimental results, especially results obtained with concentrated solutions of the kind presented here, has been criticized[8] for several reasons, one of which is that it sometimes requires the assumption of polymers in the case of inert substances such as the noble gases.

If the results of the present distribution experiments are assumed to indicate the formation of an $(OsO_4)_n$ polymer in the carbon tetrachloride solutions, it is not difficult to show that they are in accord with the assumption that the following rapid reversible reaction takes place.

$$4OsO_4 = (OsO_4)_4$$
$$K = (OsO_4)_4/(OsO_4)_4 = 6.3$$

To evaluate the equilibrium constant the limiting value of $R = 78$ for infinitely dilute solutions was determined graphically.

The vapor pressure measurements are in quantitative agreement with the assumption of this polymerization as can be seen by comparing the second and last columns of Table II.

This analysis of the results is not, however, unique, it being possible to obtain equally satisfactory agreement with the distribution and vapor pressure experiments by assuming equilibria involving a series of polymers. This would still be true if a very high degree of accuracy were feasible. Such behavior is characteristic of this method of treatment.

If the osmium tetroxide is present in carbon

[8] Hildebrand, "Solubility," Reinhold Publishing Corp., New York, N. Y., Second Edition, 1936. See also this author and others for a general discussion on liquids and solutions, *Trans. Faraday Soc.*, **33**, 1–279 (1937).

tetrachloride solutions as an equilibrium mixture of polymers, the nature of the bonds or interaction becomes of interest. One type of bond could be assumed to consist of an oxygen atom shared by two osmium atoms. This would imply that the normal oxygen–osmium–oxygen bond angle is distorted to make way for the shared oxygen. A less conventional but perhaps more rational picture of the assumed association of tetroxide molecules is provided by London's dispersion effect.[9] This effect gives rise to an additive interaction energy of attraction between molecules, even though the molecules themselves possess no average dipole (or multipole) moment. The additive property makes the interaction energy between any two molecules of a cluster practically independent of the number of molecules in the cluster. Accordingly, when only this type of interaction obtains there is no effect of saturation, and clusters of two, three and more molecules are conceivable. If the clusters can be regarded as polymers in equilibrium with each other then it is proper to treat the deviations from Raoult's equation of the type shown by osmium tetroxide in carbon tetrachloride as indicating polymer formation, providing, of course, that the clusters are, on the average, sufficiently far apart so that their interaction with each other is small.

It is possible that the interactions between the assumed clusters are of the same order of magnitude as those between the molecules in the clusters. In that event the calculation of equilibrium constants for assumed polymer formation in concentrated solutions of the type reported here provides no more than a convenient empirical method for expressing the properties of the solutions.

The shape and size of the osmium tetroxide molecule were determined by Brockway[6] from electron diffraction experiments. Langseth and Quiller[7] photographed the Raman spectrum. From these results the standard entropy of osmium tetroxide gas may be calculated. The heat of formation and the vapor pressures of the tetroxide were measured by von Wartenberg.[2] The entropy of metallic osmium was calculated by Lewis and Gibson,[10] and that of oxygen has been determined by Giauque and Johnston.[11] This information taken together permits the calculation of the free energies of formation of both gaseous and solid osmium tetroxide. The necessary data and the results of the calculations are presented in Table III.

TABLE III

THE THERMODYNAMIC CONSTANTS OF OSMIUM TETROXIDE

Interatomic distance Os— O $= 1.66 \pm 0.05$
Symmetry number $\sigma = 12$

Raman frequencies in cm.$^{-1}$ and their degeneracies (in parentheses)

$\omega_1(1)$	$\omega_2(2)$	$\omega_3(3)$	$\omega_4(3)$
971	568	1187	688

Standard entropies at 25° and one atmosphere in cal./deg.

OsO_4(g), 65.65 Os(s), 7.8 ± 0.5 O_2(g), 49.03

Solubility in water = 0.0284 mole/kg. water at 25°

Free energies and heat contents.

$Os(s) + 2O_2(g) = OsO_4(s)$
$\Delta F^\circ_{298} = -70{,}900$ cal. $\Delta H = -93{,}600$ cal.
$OsO_4(s) = OsO_4(g)$
$\Delta F^\circ_{298} = 2{,}800$ cal. $\Delta H = 13{,}500$ cal.
$Os(s) + 2O_2(g) = OsO_4(g)$
$\Delta F^\circ_{298} = -28{,}000$ cal. $\Delta H = -80{,}100$ cal.
$Os(s) + 2O_2(g) = OsO_4(aq)$
$\Delta F^\circ_{298} = -68{,}788$ cal.

The stability of osmium tetroxide is shown by the large negative value of ΔF°_{298}. The observation made by von Wartenberg that the tetroxide does not decompose at 1500° may be shown by an easy calculation to be consistent with the above free energy and heat content values.

The free energy values might also be combined with the results of Kirschman and Crowell[12] to obtain the free energies of some of the reduced forms of osmium in aqueous solutions.

Summary

The distribution ratios of osmium tetroxide between carbon tetrachloride and water have been measured at 25° for the whole range of concentrations up to saturation and found to vary from $R = N(\text{in } CCl_4)/N(\text{in } H_2O) = 78$ to $R = 136$. The results of solubility measurements are in agreement with the ratio at high concentrations.

The vapor pressures of dry carbon tetrachloride above its solutions of osmium tetroxide were measured at 25° and over the range of concentrations up to saturation. The results do not accord with Raoult's equation.

Electron diffraction, spectroscopic and thermal data are used to evaluate the free energies of gaseous, solid and aqueous osmium tetroxide.

The Heat Capacity and Entropy of Barium Fluoride, Cesium Perchlorate and Lead Phosphate

BY KENNETH S. PITZER,[1] WENDELL V. SMITH AND WENDELL M. LATIMER

While the calculation of ionic entropies was the immediate purpose for which these heat capacity measurements were made, the data so obtained should, nevertheless, have considerable value from other points of view. The present paper contains the heat capacity results together with calculations of the entropies of the three salts. The ionic entropy calculations will be presented in another publication.

Materials.—The precipitation of barium fluoride from aqueous solution gives a very fine powder which would seem questionable as a thermodynamic reference state. The sample employed in the following measurements was prepared by melting "C. P." barium nitrate and potassium fluoride together in a platinum crucible, and then extracting the potassium nitrate and excess barium nitrate from the cooled melt with hot water. The extraction was continued until the wash water gave no test for either potassium ion or nitrate ion. The product appeared to be definitely crystalline on examination with a microscope. Analysis by precipitation of barium sulfate from dilute nitric acid solution gave 99.7 ± 0.5% of the theoretical barium content. The authors wish to extend their thanks to Dr. Oliver L. I. Brown for the greater part of the work in preparing this sample.

The tertiary lead phosphate was prepared from lead acetate and Na_2HPO_4, both of "C. P." grade. Hot, dilute solutions of the two salts were slowly mixed with vigorous stirring, and the resulting precipitate was washed thoroughly and then dried by heating for several days at 300°. Electrolytic analysis showed the theoretical amount of lead within 0.2%.

The cesium perchlorate was prepared from samples of "C. P." cesium nitrate and iodochloride by the addition of perchloric acid in dilute solution. Chemical tests indicated the absence of appreciable amounts of nitrate or iodochloride, while the absence of other alkali metals was established by spectroscopic examination. The product was dried by prolonged heating at 140°. The lack of any rise near the ice point in the heat capacity curves shows that none of the salts contained an appreciable amount of water.

Heat Capacity Measurements.—The general method of Latimer and Greensfelder[2] was followed, including, however, certain improvements which also have been reported.[3] The calibrated thermocouple in the calorimeter was rechecked against the vapor pressure and triple point of hydrogen between the measurements on barium fluoride and those on lead phosphate and cesium perchlorate, while the heat capacity of the empty calorimeter was remeasured after their conclusion. The results are expressed in terms of a defined calorie (=4.1833 int. joules). The barium

fluoride sample weighed 242.88 g. (1.3849 moles); the lead phosphate sample, 196.59 g. (0.24220 mole); while the cesium perchlorate weighed 139.12 g. (0.59896 mole). All weights are reduced to a vacuum basis. The results are presented in Tables I, II and III and shown as a function of the temperature in Fig. 1. Smooth values of the heat capacity for even temperatures are listed in Table IV.

TABLE V

MOLAL ENTROPIES OF BARIUM FLUORIDE, LEAD PHOSPHATE, AND CESIUM PERCHLORATE IN CAL. PER DEGREE

Substance	BaF_2	$Pb_3(PO_4)_2$	$CsClO_4$
Debye extrapolation, 0–15°K.	0.09	1.07	0.82
Graphical from data, 15–298.1°K.	22.94	83.38	41.07
Entropy at 298.1°K.	23.03 ± 0.1	84.45 ± 0.4	41.89 ± 0.2

Entropies.—The entropies were calculated by graphical integration, using large scale plots of C_p against log T, combined with extrapolations to the absolute zero, using the Debye specific heat equation. The calculations are summarized in Table V.

Summary

The heat capacities of barium fluoride, tertiary lead phosphate, and cesium perchlorate have been measured from 15 to 300°K. Their entropies have been calculated to be 23.03 ± 0.1, 84.45 ± 0.4, and 41.89 ± 0.2 cal. per degree, respectively, at 298.1°K.

The Heats of Solution of Cesium Perchlorate, Rubidium Perchlorate, Rubidium Chlorate, and Lead Phosphate

BY KENNETH S. PITZER

Using the calorimeter described in an earlier publication,[1] the integral heat of solution has been measured for the four salts listed in the title. These data were of particular interest in connection with the calculation of the entropies of the ions involved. The calculations will be presented in a later publication.

Material.—The cesium perchlorate and rubidium chlorate were taken from samples used in low temperature heat capacity investigations.[2] The rubidium perchlorate was prepared by precipitation from a dilute solution of the pure rubidium chlorate sample with perchloric acid. The lead nitrate and sodium phosphate solutions which were used in the precipitation of lead phosphate were prepared from "C. P." salts.

Heat of Solution Measurements.—The results of the heat of solution measurements are presented in Table I. The heat capacity of the calorimeter was determined frequently by electrical heating experiments. The volume of water was 885 ml. in each experiment.

1.7452	.01167	11,400	−20	11,380
				11,410 ± 60

Heat of Precipitation of Lead Phosphate.—It was found to be impractical to measure the heat of solution of tertiary lead phosphate, due to the slow rate of solution even in solvents which would eventually dissolve a very considerable amount. Consequently a heat of precipitation was measured. The reaction chosen was the following

$$3Pb^{++} + 4HPO_4^{--} = Pb_3(PO_4)_2 + 2H_2PO_4^-$$

Four measurements were made on the heat absorbed when 10 ml. of 0.5 molal lead nitrate solution was mixed with 875 ml. of 0.01 molal Na_2HPO_4 solution. The results obtained were

4.45, 5.25, 4.00 and 3.90 cal. with an average of 4.4 ± 0.4 cal. The heat absorbed in the dilution of 10 ml. of 0.5 molal lead nitrate solution with 875 ml. of water was also measured, with the results: 8.40, 8.30, 9.45, and 9.00 cal., average 8.8 ± 0.4 cal. Combining this value with the data of Plake,[3] the heat absorbed in the dilution to zero concentration of the lead nitrate solution was found to be 9.3 cal. With the aid of the Debye–Hückel theory, the increase in heat content with dilution was estimated to be 0.8 cal. greater for the final solution than for the initial phosphate solution. Combining these quantities, one finds $\Delta H^0 = -2460 \pm 360$ cal. for the above equation.

Making use of the heats of ionization of phosphoric acid recently published by the writer,[1] one obtains also the following results

$Pb_3(PO_4)_2 + 2H^+ = 3Pb^{++} + 2HPO_4^{--}$; $\Delta H^0 = 860 \pm 400$ cal.

$Pb_3(PO_4)_2 = 3Pb^{++} + 2PO_4^{---}$; $\Delta H^0 = 7860 \pm 1000$ cal.

All values given are for 25°.

Summary

Values have been obtained for the heats of solution at infinite dilution and 25° of the following substances: $CsClO_4$, $\Delta H^0 = 13{,}260 \pm 100$ cal.; $RbClO_4$, $\Delta H^0 = 13{,}570 \pm 60$ cal.; $RbClO_3$, $\Delta H^0 = 11{,}410 \pm 60$ cal.; $Pb_3(PO_4)_2$, $\Delta H^0 = 7860 \pm 1000$ cal.

The Entropies of Aqueous Ions

BY WENDELL M. LATIMER, KENNETH S. PITZER AND WENDELL V. SMITH

In the course of the research program for the evaluation of the entropies of aqueous ions, in progress for some time in this Laboratory, a considerable body of data has accumulated which makes possible the calculation of the entropies of eleven additional ions. Because in most cases the entropy values depend on those for other ions, an extensive revision would be necessary in order to make these new values the best possible. Consequently it seemed best to make a complete revision of all ionic entropies and to include the new ions at the same time.

In order to avoid unnecessary length, specific references have been given only where the data are not included in some summary publication. Most of the new calculations are based upon data taken from recent publications in this research series[1] and from the references cited in the earlier summary paper.[2] In general entropies have been taken from the excellent summaries of Kelley,[3] heats of reaction from Bichowsky and Rossini,[4] and activity coefficients and other free energy data from the Landolt–Börnstein Tabellen.[5]

The calculations are summarized in Table I and the best values of the ionic entropies collected in Table II. Different methods of obtaining a given entropy are included only if they are independent in the least accurate step. An attempt has been made to include all sources of error in estimating the uncertainty in the final values. For this reason the uncertainty given for a final value is often much larger than the difference between the various values for that quantity would indicate.

The standard state for ionic entropies has been defined in several earlier papers, wherein the theoretical significance and practical importance of ionic entropies also have been discussed. As the body of data becomes larger, however, its consistency becomes more notable, and offers more and more evidence of the validity of the third law of thermodynamics when applied to crystalline inorganic salts. The possibility of difficulties in the case of hydrated crystals has arisen recently and has been discussed elsewhere.[1b] It is felt that errors from this source cannot have any serious effect on the values obtained in this paper.

The Reactions between Silica and Calcium Oxide in Aqueous Solutions and their Relation to Pozzolanic Action

BY ALFRED E. BEITLICH[1]

Our modern conception of pozzolanas defines them as materials which, though not cementitious in themselves, contain constituents which will combine with calcium oxide at ordinary temperatures in the presence of water to form stable insoluble compounds possessing cementitious properties. Most natural or artificial pozzolanic materials are generally composed of silica, alumina, iron oxide, and calcium oxide. There may also be present magnesia, potassium, and sodium oxides, and possibly other elements in very small quantities. In contrast to portland cement, no definite chemical composition can be ascribed to pozzolanas; the type of oxides present and their percentages vary within wide limits. They are materials of very complex mineralogic aspects, and complete petrographic researches are still lacking. Only one thing is common to all pozzolanas, and that is their ability to harden under water or in air in the presence of moisture when mixed with calcium oxide or a material which liberates calcium oxide.

Many investigations have failed to produce fundamental data because of the complexities of the systems studied. From previous work it has been established that the presence of water, silica, and calcium oxide is important for the development of pozzolanic action. It was decided, therefore, to confine the present study to the reactions between silica and calcium oxide in aqueous solutions, thus eliminating many complicating factors.

Experimental Part

Apparatus and Procedure.—An electrical conductivity method was selected, since this gave promise of providing a ready means of following continuously the reactions taking place. All experiments were carried out at a constant temperature of 30 ± 0.01° in a thermostatically controlled water-bath. For measuring the electrical conductivity, a precision slide wire Wheatstone bridge hookup was employed with a conductivity cell of the dip type. The constant of the cell was determined at 30° with 0.01 N potassium chloride solution and was found to be 0.1191. Conductivity water, prepared in a specially designed Pyrex still which produced a satisfactory water with a specific conductivity of less than 1.2×10^{-6} mho, was used in all experiments.

It was necessary to determine the conductivities of calcium oxide solutions at various concentrations, which was done over the range of from very dilute solutions to the saturation point. The stock solution with an excess of the oxide to ensure constant saturation was stored in a paraffin-lined glass bottle. The concentration of the solution was determined gravimetrically and by titration with standardized hydrochloric acid.

For the conductivity measurements mentioned above, measured quantities of the stock solution were diluted with conductivity water so as to provide the desired range of concentration. The results were plotted on large-scale coördinate paper in terms of grams of calcium oxide per liter and the corresponding electrical conductivities of the solutions. With this graph it was possible to determine accurately and rapidly the concentration of any calcium oxide solution by determining its electrical conductivity.

The silica used in this study was C. P. silicic acid, containing 80.00% SiO_2, ground to pass a 300-mesh sieve. In the first series of experiments, which were necessary to obtain information on the general nature and rate of reaction and the best manner of proportioning the three reacting agents (silica, calcium oxide, and water), the reaction chamber consisted of a 3-necked Pyrex flask. One liter of calcium oxide solution of the desired concentration was transferred to the flask immersed in the water-bath. The center tubulature was provided with a mercury seal stirrer rotating at a speed of 1000 r. p. m. Extreme care was taken to protect all calcium oxide solutions from exposure to air. The conductivity of the solution was determined after the solution had reached the bath temperature. Then a weighed amount of silica was introduced and conductivity readings again taken immediately. While the solution was being agitated continuously, measurements were made at short intervals until equilibrium was reached.

The conductivity method for determining the rate of combination of calcium oxide with silica proved very convenient and successful. The procedure permitted following accurately the reactions from the very earliest stages to final equilibrium without disturbing the system by the withdrawal of portions of the solution. The time required for one measurement was only thirty seconds. The method is distinguished by perfect reproducibility, and the entire course of the reactions can be plotted in small intervals over the entire range.

The amount of silica per liter of calcium oxide solution was kept constant at 0.8954 g. in this series of tests, and the concentration of the solutions ranged from 0.025 to 1.191 g. of calcium oxide per liter. In all cases the measurements showed a decided drop in electrical conductivity during the first few minutes of contact of the reacting agents, indicating a lowering of the calcium oxide content of the solution. As the time of agitation progressed, the rate of drop in conductivity became less, and finally a state was approached asymptotically in which there was no more

---

[1] Associate Chemist.

change in conductivity. The more concentrated the initial calcium oxide solution was, the more slowly the final state of equilibrium was reached, requiring agitation periods of several months. Because of this slowness of reaction and to enable several tests to be run at the same time, a shaker was installed in which eight Erlenmeyer flasks of 500-cc. capacity were agitated simultaneously. To facilitate the interpretation of the results, silica and calcium oxide in the suspensions were proportioned on a molecular basis rather than on the gram basis used in earlier experiments.

The second series included thirty-four samples in which the molecular ratios of CaO to SiO_2 at the beginning of the experiment (initial ratios) were varied from 0.05 to 3.75. The amount of calcium oxide ranged from 1.0 to 75.0 milliequivalents (m. e.). The amount of silicon dioxide was 20.0 m. e. in most cases, although some samples contained 10.0 and 30.0 m. e. of silicon dioxide in order to broaden the field of investigation. In the range of high calcium oxide, above the point of saturation, solid calcium oxide was added, together with the silicon dioxide, to the saturated calcium oxide solution.

Equilibria in the System Calcium Oxide–Silica–Water.—The data on equilibria secured in this system are best explained by means of Table I and Fig. 1. In the first two columns of Table I are recorded the amounts of calcium oxide and silica which were allowed to react in water until equilibrium had been reached. The term equilibrium in this report refers to an apparently steady state in which there is practically no further change in conductivity with time. It is understood that such a state does not represent a true equilibrium, but the latter is attained exceedingly slowly at the temperature of the experiment, and the differences between apparent and true equilibria can be neglected without affecting the findings of this investigation. The initial ratios of CaO to SiO_2 are recorded in the third column. The conductivities of the solutions when equilibrium has been reached are given in the fourth column, and the amounts of uncombined calcium oxide remaining in solution at equilibrium (which were calculated from the conductivity data) are listed in the fifth column. The last column shows the ratio of combined CaO to SiO_2 at equilibrium.

Interpretation of Results.—An attempt was made to establish the nature of the combination of calcium oxide with silica, the question being whether it is a chemical reaction or an adsorption, or both. It was sought to determine whether the removal of calcium oxide from solution by the silica follows the Freundlich adsorption isotherm, which is generally taken as characteristic of a surface adsorption, or whether the observed data would suggest a different interpretation. Since the Freundlich adsorption isotherm is usually expressed by the equation

$$X = aC^{1/n} \text{ or } \log X = \log a + 1/n \log C \quad (1)$$

a straight line should result if the logarithms of the adsorbed quantities are plotted against the logarithms of the corresponding concentrations.

Figure 1 shows the results of the experiments entered on log–log paper. The concentrations of the calcium oxide solution at equilibrium in milliequivalents ($C \times 10^3$) are plotted as abscissas and the ratios of combined CaO/SiO_2 (X) as ordinates (Columns 5 and 6, Table I). A graph consisting of several straight lines is obtained by connecting the points. The numerals accompanying these points give the molecular ratios of CaO/SiO_2 at the start of the experiments (Column 3, Table I).

The portion A–B represents equilibria attained with suspensions having initial ratios of CaO/SiO_2 from 0.05 to 0.30. The fact that all points fall upon or very close to a straight line indicates that the Freundlich equation is applicable in that range and that the calcium oxide is adsorbed by the silica in suspension. Evaluating the constants $1/n$ and a yielded the equation

$$X = 159.6\ C^{0.98} \qquad (2)$$

which enables the calculation of the adsorption of calcium oxide in the range A–B, that is, from 0.05 to 0.30 initial CaO/SiO_2 ratios.

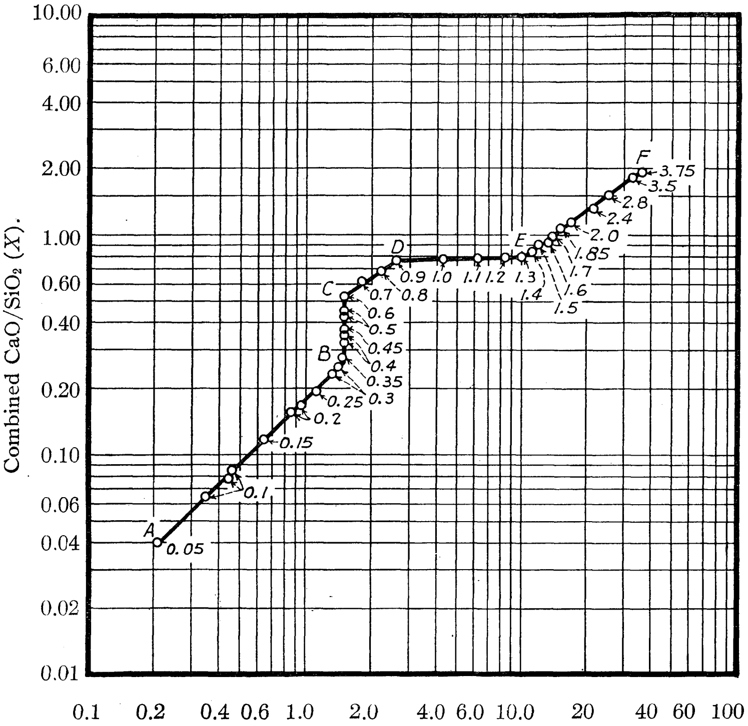

Fig. 1.—Relationship between molecular ratio of combined CaO/SiO_2 and concentration of CaO in the liquid phase.

As the concentration is increased above the ratio of 0.30, the line connecting the points in the graph makes a sharp turn upward and continues in a vertical straight line to point C. This indicates that comparatively more of the available calcium oxide is combined with silica than in the range A–B, and equilibria are being attained when the concentrations of the calcium oxide solutions have been reduced to one containing approximately 1.5 m. e. of calcium oxide per liter. C, which is at the end of this range, is located near a point where the ratio of combined CaO/SiO_2 is 1 to 2. Therefore, it seems justified to assume that, after the first phase of adsorption reactions has been completed and an equilibrium concentration of 1.5 m. e. of calcium oxide per liter has been reached, a further increase in calcium oxide concentration leads to chemical combination of calcium oxide and silica to form a hydrated $CaO \cdot 2SiO_2$. This combination is completed when the initial ratio of CaO/SiO_2 has been raised to 0.60.

From point C to point D the straight connecting line proceeds upward at an angle, and Freundlich's adsorption isotherm is again applicable for that range. It appears that further increases of the calcium oxide concentration lead to an adsorption of calcium oxide onto the newly formed $CaO \cdot 2SiO_2$ hydrate. The adsorption equation for this range is

$$X = 44.95\ C^{0.68} \qquad (3)$$

Point D on the graph is reached with a sample having an initial CaO/SiO_2 ratio of 0.9, and the ratio of combined CaO/SiO_2 becomes 4 to 5. On increasing the initial CaO/SiO_2 ratio from 0.9 to 1.3, no more adsorption is taking place. The line leads horizontally to point E. In this range, D–E, the combination of calcium oxide and silica proceeds to a state in which the ratio of 4CaO to $5SiO_2$ is maintained, and only after increasing the initial CaO/SiO_2 ratio above 1.3 is more calcium oxide being combined.

Beyond point E, the line proceeds upward again, indicating a third range of adsorption reactions. The calculation of the constants gives the adsorption equation

$$X = 23.38\ C^{0.74} \qquad (4)$$

for the range of initial CaO/SiO_2 ratios from 1.3 to 3.75. The ratio of combined CaO/SiO_2 in the adsorption product at point F is 1.946 to 1, and the solution in which it is stable at equilibrium is very close to the saturation point of calcium oxide at that temperature. This suggests that a hydrated $2CaO \cdot SiO_2$ exists in a saturated solution of calcium oxide. The exploration of the field with still higher concentrations of calcium oxide is not possible with the conductivity method used in this investigation, since its usefulness ends when the solution at equilibrium is saturated.

Discussion

The study of the reactions of calcium oxide and silica in the presence of water revealed that, under the conditions of the experiment, definitely identified adsorption reactions take place. It also showed that chemical compounds are formed in which the ratios of calcium oxide to silicon dioxide are very close to 1:2, 4:5, and 2:1, corresponding to $CaO \cdot 2SiO_2 \cdot xH_2O$, $4CaO \cdot 5SiO_2 \cdot xH_2O$, and $2CaO \cdot SiO_2 \cdot xH_2O$.

The adsorptive capacity of hydrated silica for calcium oxide has been studied by Shaw and MacIntire[2] in connection with a research on the components of soils. These investigators found that "the adsorption of $Ca(OH)_2$ by hydrated silica occurs in accordance with the Freundlich adsorption isotherm, when the final concentrations of $Ca(OH)_2$ are above 0.005 N. When the final concentrations are less than 0.005 N, several inflections appear in the adsorption curve and these point to a series of chemical combinations between the $Ca(OH)_2$ and the SiO_2." No information is given in their paper about the causes of these inflections and the nature of the chemical combinations. The adsorption isotherm calculated by Shaw and MacIntire does not agree with the equation established in this paper for the same range of concentrations. This discrepancy can be explained easily by the fact that the former equation expresses the adsorption phenomena for a contact period of only five days, while the latter was established after equilibrium had been attained. The chemical combinations in concentrations below 0.005 N strength, or less than 5 m. e. calcium oxide per liter, the existence of which was held possible by Shaw and MacIntire, have been established in the present paper, together with the two additional ranges of adsorption reactions in the lower field of concentrations.

The possibility that adsorption reactions can take place in the system $CaO–SiO_2–H_2O$ has been advanced also by Baylis,[3] who stated that there may be a definite chemical reaction between calcium hydroxide and hydrous oxides of silica forming a compound closely approaching $CaO \cdot SiO_2$. In addition to this, considerable calcium hydroxide appears to be adsorbed by this compound when the concentration of calcium hydroxide in the surrounding solution is increased over that necessary to form the definite compound. Although the present investigation proves the existence of adsorption phenomena, a definite hydrated calcium silicate in which the ratio of calcium oxide to silicon dioxide is unity, was not found.

Flint and Wells[4] carried out an extensive study of the reactions of calcium oxide and silica in the presence of water and state that the solid phase in equilibrium with solutions which contain only a few hundredths of a mole of calcium oxide per mole of silicon dioxide may consist of hydrated silica with a small amount of adsorbed calcium oxide. Determinations of the OH ion concentration showed that calcium oxide and silica in solution are combined in a ratio of less than 1CaO to $1SiO_2$ at low calcium oxide concentrations and at a ratio greater than 1 to 1 at high calcium oxide concentrations. It appeared that the molar ratio $2CaO:1SiO_2$ is approached when the solid phase is in equilibrium with a saturated calcium oxide solution.

The findings of the present study support the assumption of Flint and Wells that calcium oxide is adsorbed by silica at low concentrations and that a hydrated $2CaO \cdot SiO_2$ is stable in saturated calcium oxide solution. There are, however, some differences in the findings about the formation of chemical compounds in the intermediate range. While Flint and Wells obtained data which they assume to represent compositions of the ratio $1CaO:2SiO_2$ and $1CaO:1SiO_2$, the conductivity determinations revealed the formation of two hydrated silicates in which the ratios of calcium oxide to silicon dioxide are 1:2 and 4:5. No hydrated monocalcium silicate was found.

By agitating an excess of diatomaceous earth in calcium oxide solutions, Cummins and Miller[5] obtained in the solid phase a compound having a molecular ratio of CaO to SiO_2 of 5:6, corresponding to the formula $5CaO \cdot 6SiO_2$.

The question concerning the types of hydrated calcium silicates which may exist in aqueous solutions was attacked in the opposite direction by Kühl and Mann[6] by preparing anhydrous melts of calcium oxide and silica of various predetermined compositions and agitating them in calcium oxide solutions of varying concentrations. These investigators found that a hydrated calcium silicate which is less basic than $CaO \cdot SiO_2 \cdot xH_2O$ does not exist. A gel of the composition $CaO \cdot SiO_2 \cdot aq.$ is stable in a solution containing 0.131 g. calcium oxide per liter, and a series of hydrated calcium silicates exists having ratios of calcium

oxide to silicon dioxide ranging from 1:1 to 2:1. Since the materials used by Kühl and Mann were synthetic melts and the products at equilibrium not formed by the combination of the basic constituents calcium oxide and silica but by hydrolysis or hydration of the silicates, the results do not lend themselves to a direct comparison with the observations reported here.

Summary

On the basis of the results secured by means of the conductivity method and under the conditions of the experiment, the reactions between calcium oxide and silica proceed in the following manner:

With dilute solutions the silica adsorbs calcium oxide in accordance with the Freundlich adsorption isotherm. Above an initial ratio of CaO/SiO_2 of 0.30 and up to 0.60, chemical combination takes place, and a reaction product is formed in which the ratio of CaO/SiO_2 is 1 to 2. This product is stable in a solution containing 1.5 m. e. of calcium oxide per liter.

On increasing the calcium oxide concentration further above an initial ratio of 0.60, adsorption takes place again, which proceeds until the initial ratio of CaO/SiO_2 is 0.90 and the ratio of combined CaO/SiO_2 is 4 to 5.

The reaction product with the ratio of 4CaO to $5SiO_2$ is stable up to an equilibrium concentration of 10 m. e. of calcium oxide per liter. With higher concentrations of calcium oxide and initial ratios from 1.3 to 3.75, a third range of adsorption reactions takes place. As the point of saturation of the calcium oxide solution at equilibrium is reached, the ratio of CaO/SiO_2 in the reaction product approaches 2:1, indicating the probable existence of a hydrated $2CaO \cdot SiO_2$ in saturated calcium oxide solution.

The Electron Diffraction Investigation of the Molecular Structures of (1) Phosphorus Oxytrichloride, Oxydichlorofluoride, Oxychlorodifluoride, Oxytrifluoride, Fluorodichloride, Pentafluoride, and Trifluorodichloride, and of (2) Disilane, Trichlorosilane, and Hexachlorodisilane

BY L. O. BROCKWAY[1] AND J. Y. BEACH[2]

The molecular structures of the halogen derivatives of the non-metals are of special interest because of the systematic deviations from additivity of bond radii which are observed in many of these substances.[3,4] With the exception of those of the first row elements, the observed distances in the halogen derivatives are all smaller than the sum of the corresponding radii for single covalent bonds. This decrease is apparently greatest in the silicon compounds and is less marked in the elements toward the right and in the lower rows of the periodic table. The effect, moreover, is greatest in the fluorides and decreases in order with the other halogens. While the regular way in which the effect varies from one element to another suggests that the same causes are operating in all of them, the nature of the causes is not entirely certain. It seemed desirable to extend the investigation of phosphorus and silicon compounds, where the effect is greatest, and we have determined the structures of a number of mixed fluorine and chlorine derivatives of phosphorus, including some oxygen compounds, as well as those of three silicon compounds.

The diffraction patterns were obtained in the usual way,[5] whereby a beam of electrons traverses a sample of the vapor and the diffracted electrons are recorded on a photographic emulsion. The apparent maxima as well as some of the minima were measured visually on a comparator, and the observed diameters were converted to the s_0 values [equal to $4\pi (\sin \theta/2)/\lambda$] listed in the tables below. The s_0 values for the maxima were used with the visually estimated intensities, I_k, in the calculation of the functions shown in Figs. 1 and 8 representing the observed radial

distributions[6] of scattering matter for the various substances. In cases where the total range of estimated intensities was greater than ten to one, a "corrected intensity" was used, namely, $s^2e^{-as^2}I_k$, with a given the value which made the range of "corrected intensities" equal to ten to one.[7] The principal peaks in the distribution functions correspond to internuclear distances in the molecules. While the positions of the peaks are most reliable in the curves based on eight or nine measured maxima, curves are shown for all of the substances having more than three measurable maxima in the photographs. For the sake of comparison the vertical lines in Figs. 1 and 8 mark the internuclear distances as determined with the aid of theoretical intensity curves; the heights of the lines show the relative scattering powers associated with the atom pairs.

The other figures show various theoretical intensity curves calculated from the approximate scattering function, $I = \Sigma_{ij} Z_iZ_j(\sin sr_{ij})/sr_{ij}$, in which the summation extends over all of the atoms in the molecule, Z_i is the atomic number of the ith atom and r_{ij} is the separation of the ith and jth atoms. A choice was made among the molecular models on the basis of the selection of the curve which best reproduces the qualitative features of the observed diffraction pattern. In the tables the s values, corresponding to the maxima and minima in the curve, are compared quantitatively with the s_0 values, and the r_{ij} values assumed in the model are multiplied by the average of the s/s_0 ratios to obtain the observed interatomic distances. Wherever the measured diameter is unreliable because of excessive back-intensity or a marked asymmetry in the maximum, the corresponding s/s_0 ratio has been excluded in taking the average.

The samples of POF_3, POF_2Cl, $POFCl_2$, and $PFCl_2$ were provided by Professor H. S. Booth, A. R. Bozarth, and Fred Dutton of Western Reserve University. For $POCl_3$ the commercial product was used after fractional distillation. Preparations of PF_5 and PF_3Cl_2 were made by V. Schomaker and J. B. Hatcher under the direction of Professor D. M. Yost in this Laboratory. The sample of Si_2Cl_6 was prepared by Dr. Fred Stitt, and those of Si_2H_6 and $SiHCl_3$ were furnished by Professor Warren C. Johnson of the University of Chicago.

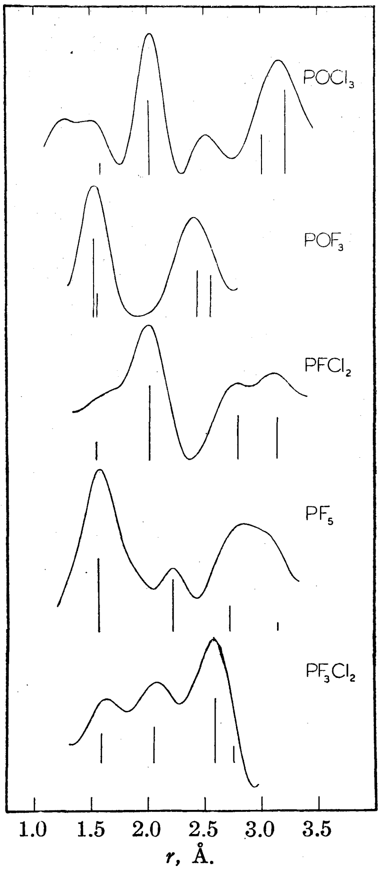

Fig. 1.—Observed radial distributions of scattering matter in the phosphorus compounds. The vertical lines represent the internuclear distances as determined by the comparison of the photographs with theoretical intensity curves.

[7] The significance of the correction factors will be discussed by V. Schomaker and C. Degard in a later paper.

Phosphorus Oxytrichloride.—The photographs of $POCl_3$ show nine rings with the relative intensities and s_0 values given in Table I. With the exception of the first and fourth maxima the decline in intensity is fairly regular. The fourth maximum is very faint in comparison with the third and fifth, while the sixth is relatively broad with a slight shelf on the outer edge. The radial distribution curve (Fig. 1) shows two principal peaks. The first at 2.02 Å. represents the P–Cl distance and the second near 3.2 Å. represents the O–Cl and Cl–Cl distances unresolved.

Six theoretical curves were calculated having the assumed distances P–Cl = 2.02 Å., P–O = 1.58 Å., and ∠ClPCl = 90, 100, 105, 107.5, 110, and 120°, respectively. The first and last failed to reproduce any of the distinguishing features of the observed diffraction pattern. The other four are shown in Fig. 2. The 100° model is incorrect because its curve shows a too strong fourth maximum and an extra maximum between the sixth and seventh. In the 110° curve the fourth maximum has turned into a shelf and an extra maximum appears between the fifth and sixth, and this, too, is incorrect. The best general agreement is given by a model lying between those for 105 and 107.5°; and on the basis of the observed appearance of the fourth and sixth maxima the ClPCl angles are fixed at 106 ± 1°. The data of Table I and the radial distribution curve lead to the distances P–Cl = 2.02 ± 0.03 Å., and Cl–Cl = 3.22 ± 0.03 Å. A preliminary value of 104 ± 4° for the angle was reported previously.[5]

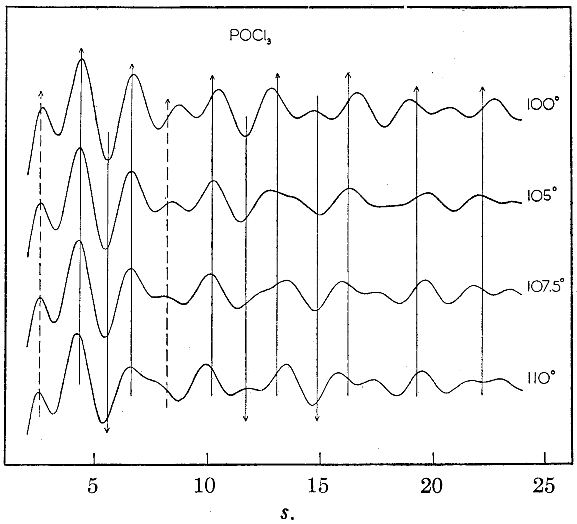

Fig. 2.—Theoretical intensity curves for phosphorus oxytrichloride. The arrows show the positions of the maxima and minima as measured on the photographs.

The low scattering power of the oxygen atom relative to that of the phosphorus and chlorine atoms means that its position cannot be as accurately fixed. The value, 3.01 Å., for the Cl–O distance occurring in the model accepted above is supported by the position of the second strong peak in the radial distribution curve. The displacement of this peak toward the Cl–Cl position is in agreement with the greater scattering power associated with the Cl–Cl terms. The corresponding P–O distance, 1.58 Å., is supported within 0.02 Å. by the more direct determination in POF_3.

Phosphorus Oxytrifluoride.—Photographs of POF_3 were obtained over the same range of scattering angle as observed for $POCl_3$, but on account of the smaller size of the POF_3 molecule only five maxima appeared. These are quite regular except for the shelf on the second. The five term radial distribution function shows peaks at 1.53 and 2.42 Å., the first representing P–F and P–O and the second F–F and O–F.

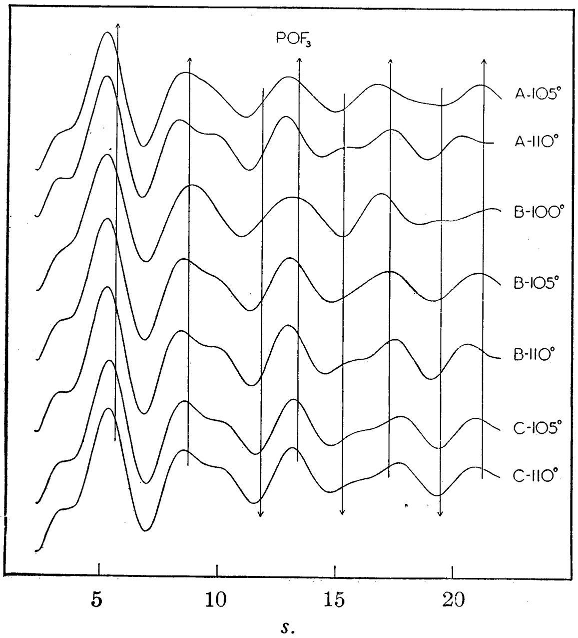

Fig. 3.—Theoretical intensity curves for phosphorus oxytrifluoride.

Thirteen intensity curves were calculated covering a range of the ratio P–O/P–F from 0.90 to 1.07° and a range of the FPF angle from 95 to 115°. The seven shown in Fig. 3 were calculated with the following parameter values: P–F = 1.56 Å., in all curves; A, P–O = 1.67 Å., ∠FPF = 105, 110°; B, P–O = 1.58 Å., ∠FPF = 100, 105, 110°; C, P–O = 1.49 Å., ∠FPF = 105, 110°. Among those not shown three curves were calculated having P–O = 1.40 Å. and P–F bond angles from 100 to 110°. These have two maxima instead of one between s = 14 and 19. The C curves with P–O = 1.49 Å. are somewhat better but the fourth maximum still lacks the symmetrical shape observed in the photographs. It may be noted that C-105° and C-110° are scarcely distinguishable because the change in angle has only the effect of interchanging the F–F and O–F distances. In the B curves (P–O = 1.58 Å.) the 100° model has no shelf on the second maximum, the 110° model has a faulty fourth maximum, while the 105° curve is reasonably satisfactory. In the A curves (P–O = 1.67 Å.) the small maximum preceding the fourth in the 110° model is incorrect, while the 105° curve is much better.

TABLE II

PHOSPHORUS OXYTRIFLUORIDE

Max.	Min.	I_k	s_0	s^a	s/s_0
1		8	(5.63)	5.23	(0.929)

3		8	13.35	12.92	.968
	4		15.27	14.67	.961
4		3	17.25	17.20	.997
	5		19.43	19.11	.984
5		1	21.24	20.84	.981
				Average	0.974
				P–F, Å.	1.519
				P–O	1.568
				F–F	2.442

[a] Calculated for P–F = 1.56 Å., P–O = 1.61 Å., and ∠FPF = 107°.

A survey of all the models shows that among those definitely eliminated are all those with FPF bond angles as large as 110° and those in which the O–F distances are not larger than the F–F distances. On the other hand, the angle is not less than 105°, so that the P–O distance cannot be appreciably less than the P–F distance. The most probable values for the P–O/P–F ratio and the FPF bond angle chosen for the best qualitative agreement between curve and photographs are 1.03 and 107°. In the table the s values for the model having these parameter values are compared with the s_0 values. The final results for the distances are P–F = 1.52 ± 0.02 Å., P–O = 1.56 ± 0.03 Å., and F–F = 2.44 ± 0.02 Å., with ∠FPF = 107 ± 2°.

Phosphorus Oxydifluorochloride and Oxyfluorodichloride.—Six rings were observed in the photographs of POF_2Cl and $POFCl_2$, but in each case a heavy background obscured the first three and only the outer ones were really distinctly resolved. Because of the lack of reliable measurements on the inner rings radial distributions were not calculated. For the same reason it was scarcely possible to make a complete treatment of the several parameters required to fix the molecular model. On the other hand, the occurrence of the same bond angles in $POCl_3$ and POF_3 suggested that there would be no appreciable variations in the structures of the two intermediate compounds. Accordingly, a theoretical curve was calculated for each with the distances and angles observed in the two previous cases, *i. e.*, P–Cl = 2.02 Å., P–F = 1.52 Å., P–O = 1.57 Å., and ∠FPF = ∠FPCl = ∠ClPCl = 106°.

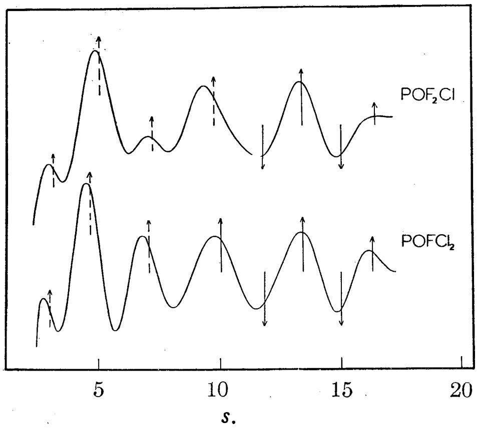

Fig. 4.—Theoretical intensity curves for phosphorus oxydifluorochloride and -fluorodichloride.

The two curves in Fig. 4 represent very well the qualitative feature in the photographs. In particular, the third ring in POF_2Cl is observed to be much weaker than the fourth, whereas in $POFCl_2$ the third and fourth rings are nearly equal. In the quantitative comparisons in Tables III and IV only the outer rings are used as indicated. Although the results for the two compounds differ by 1%, this is not significant in view of the probable experimental error which is estimated to be ±2% in this case. The values for POF_2Cl are P–Cl = 2.01 ± 0.04 Å., P–F = 1.51 ± 0.03 Å., P–O = 1.55 ± 0.03 Å., and ∠FPF = ∠FPCl = 106 ± 3°; for $POFCl_2$, P–Cl = 1.99 ± 0.04 Å., P–F = 1.50 ± 0.03 Å., P–O = 1.54 ± 0.03 Å., ∠FPCl = ∠ClPCl = 106 ± 3°.

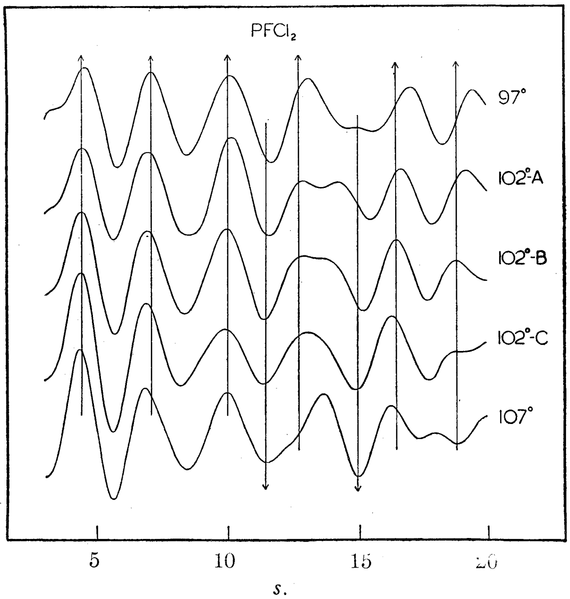

Fig. 5.—Theoretical intensity curves for phosphorus fluorodichloride.

Phosphorus Fluorodichloride.—The six term radial distribution function for $PFCl_2$ (Fig. 1) has a sharp peak at 2.01 Å., corresponding to the P–Cl distance in the molecule. The F–Cl and Cl–Cl distances are also represented but are not well enough resolved for distance determinations. In the calculation of theoretical curves the three bond angles were assumed to be equal and were varied from 90 to 120° with P–Cl = 2.02 Å. and P–F = 1.52 Å. Angle values outside of the range 97 to 107° (Fig. 5) were rejected because the curves showed extra maxima not observed in the photographs. The 97 and 107° curves are not satisfactory because they do not reproduce the rather broad fourth maximum followed by a sharp minimum. For the 102° curves the P–F distance has the assumed values A, 1.42 Å., B, 1.52 Å., C, 1.62 Å. A shows a doubled fourth maximum, which is not observed. Comparison of B and C suggests that the correct model lies between the two but nearer to B.

The data of Table V show how little the positions of the maxima are affected by the change in P–F distance in going from 102°-B to 102°-C (Fig. 5). This distance may be fixed within rather broad limits by the qualitative comparison. The final values are P–Cl = 2.02 ± 0.03 Å., P–F = 1.55 ± 0.05 Å., ∠FPCl = ∠ClPCl = 102 ± 3°. These are consistent with the observed radial distribution curve. The preliminary value for P–Cl reported earlier[5] has been increased by 0.02 Å. in the complete analysis.

					Cl–Cl	3.146	3.137
					F–Cl	2.774	2.832

[a] Calculated for P–Cl = 2.02 Å., P–F = 1.52 Å., bond angles = 102°. [b] Calculated for P–Cl = 2.02 Å., P–F = 1.62 Å., bond angles = 102°.

Phosphorus Pentafluoride.—In the six ring pattern observed in the PF_5 photographs the first ring is very heavy and broad and difficult to measure, while the fourth ring is the weakest of all those observed. The principal peak in the radial distribution function occurs at 1.58 Å., and is to be identified with the P–F distance.

Of the two types of molecular models considered the first is the trigonal bipyramid with the phosphorus atom at the center of an equilateral triangle of three fluorine atoms and the other two fluorine atoms on opposite sides of the phosphorus atom on a line perpendicular to the triangle. Curve A (Fig. 6) represents this model with P–F = 1.60 Å. The other models (designated B) are square pyramids with one fluorine atom at the apex and the other four at the corners of the square base. The angles between the P–F bond directed toward the apex and the bonds directed to the corners of the base were varied from 90 to 120°.

The B models with bond angles greater than 95° are unsatisfactory in that the fourth maximum is missing. Model B-90° and model A both show good agreement with the photographs; and since they differ only in the first maximum, which is poorly defined in the photographs, a choice between these two models cannot be made by means of the electron diffraction curves. It may be argued, however, that if the PF_5 molecule were based on a square pyramidal model the angles between the apex bond and the other bonds would be greater than 90° because of the unbalanced repulsions between the fluorine atoms. A simplified calculation based on Coulomb forces between the fluorine atom pairs leads to an angle value of 105° for the configuration of minimum potential energy. Such a model is definitely eliminated by the observed diffraction pattern.

TABLE VI

PHOSPHORUS PENTAFLUORIDE

				Average	0.982
				P-F, Å.	1.571

[a] Calculated for trigonal bipyramid with P–F = 1.60 Å.

The dipole moment of the gas has been measured and found to be zero.[8] This could be true of a square pyramidal model having equal bond moments only if the angle between the apex bond and the others were 104.5°, a value in disagreement with the diffraction evidence. The trigonal bipyramidal model, on the other hand, agrees both with the observed dipole moment and the electron diffraction pattern; and it may be concluded with certainty that this is the correct model for PF_5. The quantitative comparison of Table VI leads to a value of P–F = 1.57 ± 0.02 Å. in excellent agreement with the radial distribution curve.

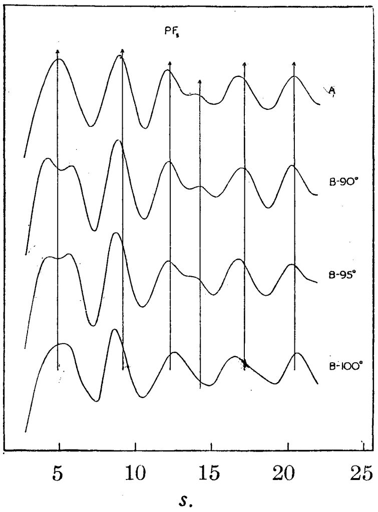

Fig. 6.—Theoretical intensity curves for phosphorus fluoride.

A preliminary report of this value was given in 1936.[5] In the meantime Braune and Pinnow[9] have investigated PF_5 by electron diffraction and have also chosen the configuration of the trigonal bipyramid. Their value for P–F is 1.54 Å., 2% smaller than reported in the present investigation.

Phosphorus Trifluorodichloride.—The eight rings observed in the PF_3Cl_2 photographs lead to a radial distribution curve with a sharp peak at 2.57 Å. and less reliable ones at 2.07 Å. and 1.63 Å. These correspond to F–Cl, P–Cl, and P–F distances. In the diffraction pattern the first five rings are much stronger than the last three. The third and fourth are weaker than the fifth, and the sixth is weaker than the seventh.

Because of the constancy of the bond angles in the PX_3 and in the POX_3 groups of compounds, it was assumed that the PX_5 group would also show no variation. Accordingly, only models of the trigonal bipyramidal configuration were calcu-

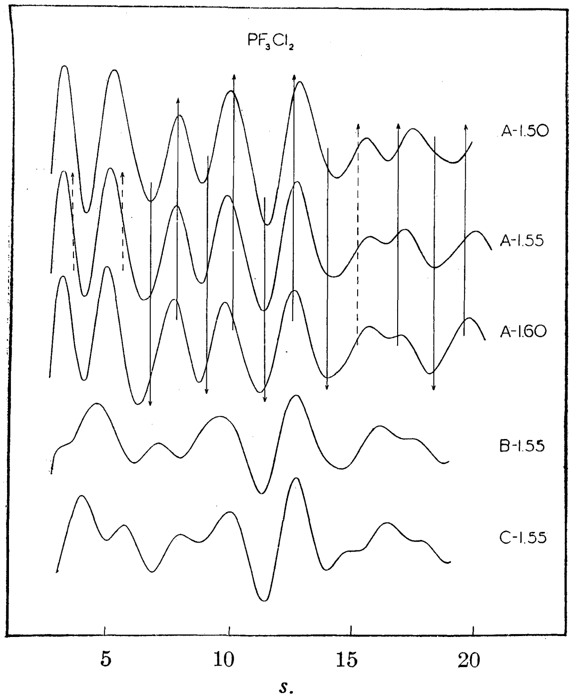

Fig. 7.—Theoretical intensity curves for phosphorus trifluorodichloride. The scale of the molecular models has been changed in plotting the curves by a factor of 1.023.

lated. In the A models (Fig. 7) the three fluorine atoms are in the equatorial plane and the two chlorine atoms at the poles, with P–Cl = 2.00 Å. and P–F = 1.50, 1.55, and 1.60 Å., as indicated. The B model has one chlorine atom in the equator with P–Cl = 2.00 Å., and P–F = 1.55, Å., and the C model has both chlorine atoms in the equator with P–Cl = 2.00 Å. and P–F = 1.55 Å.

The B and C models show pronounced qualitative disagreements with the photographs throughout the range observed; and it is evident that the agreement would not be much improved with any reasonable value for the P–F/P–Cl ratio. Model A-1.55 agrees quite well with the photographs; it is superior to A-1.50 and A-1.60 in the region of the sixth and seventh maxima. The final results based on the data of Table VII and the radial distribution curve are P–F = 1.59 ± 0.03 Å., P–Cl = 2.05 ± 0.03 Å., and F–Cl = 2.59 ± 0.03 Å.

3		15	8.69	8.74	1.006
4		8	11.49	11.08	0.964
	5		12.66	12.70	1.003
5		12	13.96	14.12	1.011
	6		15.47	15.50	1.002
6		5	16.69	16.78	1.006
7		3	19.26	19.10	0.992
				Average	0.995
				Si–Si, Å.	2.329
				Si–H	1.473

[a] Calculated for Si–Si = 2.34 Å., Si–H = 1.48 Å., ∠HSiSi = 109.5°.

For comparison with theoretical intensity curves five models were assumed with Si–Si distances of 2.34 Å., Si–H bond angles of 109.5°, and Si–H bond distances ranging from 1.35 to 1.55 Å. The H–H terms were neglected. The curves differ mainly in the fourth maximum, which is too strong in those corresponding to Si–H distances of 1.45 Å. or less, and too weak in those corresponding to Si–H distances of 1.50 Å. or more. The intermediate curve in Fig. 9 shows good agreement with the photographs. The final values for the interatomic distances are Si–Si = 2.32 ± 0.03 Å., Si–H = 1.47 ± 0.03 Å.

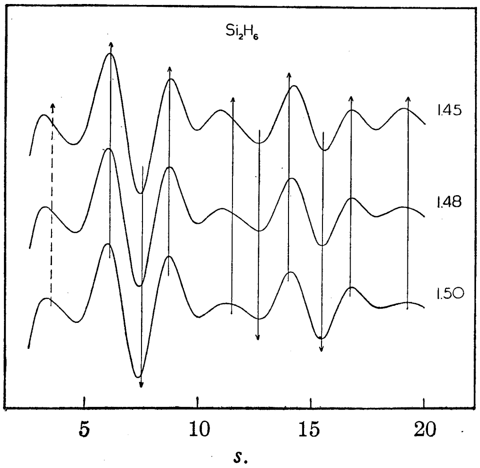

Fig. 9.—Theoretical intensity curves for disilane.

Trichlorosilane and Hexachlorodisilane.—The photographs of $SiHCl_3$ are exceptionally clear, showing a characteristic pattern of nine rings. Two well-resolved peaks in the radial distribution curve occur at 3.28 and 2.00 Å., corresponding to Si–Cl bond angles of 110°. Intensity curves (Fig. 10) were calculated for the molecular models having Si–Cl distances of 2.00 Å. and Si–Cl bond angles of 109.5 and 112°. The observed pattern is very well represented by the first of these, while in the second curve the third maximum is too strong relative to the second and the eighth is too strong relative to the seventh. While the bond angle may be 110° as suggested by the radial distribution curve, it can scarcely be as large as 112°.

In the comparison of s_0 and s values in Table IX it will be noted that the observations on the second and third maxima are displaced in opposite directions with respect to the corresponding s values. This is in accordance with the St. John effect previously observed when two maxima lie close together and are separated by only a shallow minimum. The s/s_0 values from these maxima are not included in the average value of the ratio. The values reported on the basis of the radial distribution curve and the quantitative and qualitative comparison of the intensity curves with the photographs are Si–Cl = 2.01 ± 0.03 Å., Cl–Cl = 3.29 ± 0.03 Å., ∠ClSiCl = 110 ± 1°.

(10) M. de Hemptinne and J. Wouters, *Nature*, **138**, 884 (1936); *ibid.*, **139**, 928 (1937).

value for Cl–Cl and that found in the present investigation is larger than the experimental error of the present result.

A sample of Si_2Cl_6 was photographed some time ago with a diffraction camera allowing a range of pattern only to $s = 11$. Five rings were observed in this range although the last was too faint to be measured. Since the inner rings show the usual displacement characteristic of measurements made at s values below about five, only two maxima could be measured well, and the radial distribution function was not calculated.

Tests were made, however, on two models. In each the assumed Si–Cl distance, 2.00 Å., was based on the observed values in $SiHCl_3$ and $SiCl_4$, the Si–Si distance was assumed to be 2.32 Å. from the value observed in Si_2H_6, and tetrahedral angles were used throughout. In the "*cis*" model the $SiCl_3$ groups were oriented so that the plane of each Si–Cl bond with the Si–Si bond also contained an adjacent Si–Cl bond in the other half of the molecule. In the "*trans*" model one $SiCl_3$ group was rotated by 60° around the Si–Si bond direction. In the "*cis*" curve the third maximum is partially resolved into two. The "*trans*" curve (shown in Fig. 10) is superior in this respect and it reproduces the qualitative features of the photographs. The quantitative measurements (Table X) suggest a decrease in the lengths of the more important interatomic distances. The curves calculated for the mixture of "*cis*" and "*trans*" molecules, most of the molecules being "*trans*," give somewhat better quantitative agreement with the photographs. This suggests that there is some freedom of rotation around the Si–Si bond. From the meager quantitative data it is impossible to determine the degree of freedom of internal rotation if the bond angles are different from the tetrahedral angle. A calculation of the steric repulsion of the six chlorine atoms indicates that the potential energy of the "*cis*" configuration is 650 cal./mole higher than that of the "*trans*" model. It may be concluded that the "*trans*" model is approximately correct with Si–Cl = 2.00 ± 0.05 Å. and Si–Si = 2.32 ± 0.06 Å.

Discussion

The observed bond distances and angles in the phosphorus compounds including PF_3 and PCl_3[3,6] are collected in Table XI.

The P–F bonds ranging in length from 1.50 to 1.59 Å. represent three types of molecules, but the variations in bond length accompanying the change from one to another of these types are much smaller than those occurring among the molecules ordinarily classed together in the PX_3 type. The PX_3 molecules represent the normal valence compounds of phosphorus; there are apparently two distinct types of bonding within this group according to whether the attached radical X has unshared electron pairs, which by "back coördination" to the phosphorus may under certain conditions produce a degree of double bond character in the P–X bonds. When X is a methyl radical or another phosphorus atom, the bond is a normal single covalent bond. The observed distances in P_4 molecule, 2.21 Å.,[11] and in phosphorus trimethyl, 1.84 Å.,[12] give a phosphorus radius of 1.10 Å. in agreement with the value in the table of covalent radii. The sum of this radius and that for fluorine, 0.64 Å.,[13] is 1.74 Å. and is the length of a normal single covalent P–F bond. The observed bond distances in PF_3 and $PFCl_2$ fall below this by 0.2 Å. and indicate a considerable departure from the bond type occurring in P_4 and $P(CH_3)_3$. While the present results throw no new light on the nature of this change in bond type, it is evident that the change in going from PX_3 to POX_3 and PX_5 with constant X is less pronounced than the change occurring among the different PX_3 molecules. These effects are shown to a lesser degree by the observed P–Cl bond lengths, whose deviations from their average value, 2.01 Å., are smaller than the fall below the P–Cl radius sum, 2.09 Å.

The apparent difference in the P–F bond lengths in PF_3 and $PFCl_2$ may have some significance in spite of the large experimental errors. It has

$POCl_3$		2.02 ± .03	(1.58)		106 ± 1°
POF_2Cl	1.51 ± .03	2.01 ± .04	1.55 ± 0.03	106 ± 3°	
$POFCl_2$	1.50 ± .03	1.99 ± .04	1.54 ± .03		106 ± 3°
PF_5	1.57 ± .02			90°; 120°; 180°	
PF_3Cl_2	1.59 ± .03	2.05 ± .03		120°	±180°

been observed that in the fluoromethanes and fluorochloromethanes[14] the C–F bond length decreases by about 0.05 Å. in going from the molecules with one fluorine atom to those with two or more. This effect may also occur in phosphorus compounds, but in the two substances investigated here having only one fluorine atom per molecule ($PFCl_2$ and $POFCl_2$) the more powerfully scattering chlorine atoms interfere with a precise location of the fluorine atom. Investigations are to be made on more suitable substances.

In the POX_3 compounds the P–X bond distances are not different from those in the PX_3 compounds for either fluorine or chlorine. From a comparison of the observed P–O distance, 1.56 Å., with the P–O double bond radius sum, 1.57 Å., and the P–O distances observed in phosphates, 1.56–1.61 Å., we conclude that the oxygen is held to the phosphorus atom by a double bond. The formation of the bond involves the previously unshared pair of electrons on the phosphorus atom and a pair from the oxygen atom, but in spite of the use of an additional bond orbital on the phosphorus atom the P–X bonds are not disturbed seriously.

While the increase in coördination number from three to four has no effect, the increase to five lengthens the bonds by 0.05 or 0.06 Å. In PF_5 the shortest F–F distances are just equal to that in CH_2F_2, 2.22 Å. This fact suggests that the mutual fluorine atom repulsions have lengthened the bonds in PF_5, but the conclusion is not certain because the tetrahedral bond angle in CH_2F_2 shows that at 2.22 Å. the fluorine atoms may not be as close as the critical distance of approach. In PF_3Cl_2 the P–F and P–Cl bonds have both been lengthened, and the F–Cl distance, 2.59 Å., is just that in CH_2FCl; but here again the lack of an increase in the bond angle in the substituted methane leaves the conclusion in doubt. An alternative explanation for the increase in the P–X bond lengths is that the degree of double bond character in each bond is decreased with the formation of additional bonds, *i. e.*, some of the 3*d* orbitals on phosphorus are utilized more easily than others.

The change of bond angles in going from PX_3 to POX_3 is of interest especially in view of the constant bond lengths. In the former compounds the XPX angles are close to 102° and in the latter they have risen to 106°. The angles between the P–O bond and the P–X bonds are 112°. This is additional evidence that the four atoms are not held by ordinary tetrahedral bonds. The small importance of repulsions between the attached atoms here is illustrated by the 106° ClPCl angle compared with the 112° OPCl angle.

There are many questions about the nature of phosphorus–halogen bonds which cannot be answered at the present state of information, and the problem remains of collecting data on many related substances before a complete discussion can be given.

The silicon compound measurements reported here illustrate the variation in bond type among the normal valence compounds of silicon. The Si–Si distance, 2.32 Å., observed in Si_2H_6 agrees with that in the crystalline form of the element, and the bond is of the normal single covalent type. In $SiHCl_3$ the SiCl bond is 2.01 Å. or 0.15 Å. less than the Si–Cl radius sum. The same situation exists in $SiCl_4$[3,6] with bonds of 2.00 Å. In Si_2Cl_6 the silicon atoms show both bond types in the same molecule. The Si–H distance, 1.47 Å., in Si_2H_6 leads to a hydrogen radius of 0.30 Å. in agreement with the values from other non-metallic hydrides. The bond angle of 110 ± 1° in $SiHCl_3$ does not show the increase above the tetrahedral value which is observed in $CHCl_3$. The increase in size of the central atom has increased the chlorine atom separations from 2.93 to 3.29 Å., and their mutual repulsions are not great enough to

distort the bond angles in the silicon compound.

We are indebted for the furnishing of materials to Professor H. S. Booth of Western Reserve University, Professor Warren C. Johnson of the University of Chicago, Professor D. M. Yost of this Laboratory, Dr. Fred Stitt, and their associates. We also wish to thank Messrs. V. Schomaker and K. J. Palmer for assistance in preparing some of the photographs. To Professor Linus Pauling we express our appreciation of unfailing encouragement and help.

Summary

The molecular structures of seven phosphorus compounds have been investigated with the results shown in Table XI. The P–F bond distances in the PX_3 and POX_3 molecules are all close to 1.52 Å., and in PF_5 and PF_3Cl_2 are 1.57 and 1.59 Å. An increase in bond length with coördination number occurs at coördination number five but not four. The observed lengths are all smaller than the covalent radius sum, 1.74 Å. The P–Cl bond lengths show similar variations but the decreases below the radius sum, 2.09 Å., are only from 0.04 to 0.08 Å.

The XPX bond angles increase by 4° in going from PX_3 (102°) to POX_3 (106°). The P–O bond, 1.56 Å. in length, is a double bond and stands at angles of 112° to the three P–X bonds.

In Si_2H_6 the Si–Si bond length is 2.32 ± 0.03 Å., within 0.02 Å. of the length in elementary silicon. In $SiHCl_3$ and Si_2Cl_6 the Si–Cl bonds are 2.01 ± 0.03 Å., and 2.00 ± 0.05 Å.; the same value has been observed in $SiCl_4$. This value is 0.15 Å. below the Si–Cl radius sum. The ClSiCl angle in $SiHCl_3$ is distorted from the tetrahedral value by less than 1°.

The Crystal Structure of Cesium Aurous Auric Chloride, $Cs_2AuAuCl_6$, and Cesium Argentous Auric Chloride, $Cs_2AgAuCl_6$

BY NORMAN ELLIOTT AND LINUS PAULING

The substances cesium aurous auric chloride, $Cs_2AuAuCl_6$, and cesium argentous auric chloride, $Cs_2AgAuCl_6$, discovered by Wells,[1] are of interest because of their jet black color, which has been ascribed[2] to the presence of the same element or two closely similar elements in two valence states.[3] In a preliminary investigation carried out some time ago[4] the substances were found to be diamagnetic, showing that they contain gold and silver in the univalent and trivalent oxidation states rather than the bivalent state. Powder photographs were also prepared with molybdenum X-radiation. These photographs, each with about fifteen lines, were interpreted as showing the crystals to have a structure closely related to the cubic perovskite type, the unit cube, with $a_0 \cong 5.33$ Å. for each substance, containing 1 Cs at 000, 1 (Au,Ag) at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$, and 3 Cl at $\frac{1}{2}\frac{1}{2}0$, $\frac{1}{2}0\frac{1}{2}$, $0\frac{1}{2}\frac{1}{2}$. Although the agreement between the intensities of X-ray reflection calculated for this structure and the observed values was good in general, there were one or two points of pronounced discrepancy for each substance, and the conclusion was reached that the structures are actually distorted somewhat from the ideal perovskite arrangement.

In the course of the investigation described below X-ray powder photographs were prepared with copper and iron radiation, giving greater dispersion, and it was found that cesium aurous auric chloride is tetragonal, and contains the complex ions $[AuCl_2]^-$, which is linear, and $[AuCl_4]^-$, which is square. A similar structure occurs for heat-treated samples of cesium argentous auric chloride, which also exists in a cubic modification involving some randomness in atomic arrangement.

The Determination of the Structure of Cesium Aurous Auric Chloride.—Powder photographs of cesium aurous auric chloride were prepared with copper Kα radiation filtered through nickel and with iron K radiation, the camera radius being 5.005 cm. The photographs show about fifty well-defined lines, occurring as multiplets near

the angles expected for reflections from a cubic crystal. This suggests that the unit of structure of the crystal is closely related to a cube. The observation that the cubic line {200} occurs as a doublet, with the outer component twice as strong as the inner one, suggests that the crystal is tetragonal. This is supported by the multiplet structure of the other lines, the octahedral reflections being single, reflections with two indices equal double, and those with all three indices different triple.

The tetragonal unit of structure with $a_0 = 7.49 \pm 0.02$ Å. and $c_0 = 10.87 \pm 0.02$ Å. accounts for the presence of all observed lines.[5] The lattice can be taken as body-centered, no reflections with $h + k + l$ odd being observed. No classes of planes other than those indicated by the lattice are absent on the photographs. The space group is accordingly $D_{4h}^{17} - I4/mmm$ or one of its subgroups with the same unit. It was found possible with the assumption of holohedry to determine an atomic arrangement which accounts completely for the X-ray data; it is accordingly probable that the space group of the crystal is D_{4h}^{17}.

The density of the substance was determined by displacement of benzene to have the value 4.57 g./cc. This corresponds to 1.94 $Cs_2AuAuCl_6$ per unit, the calculated value of the density for two molecules per unit being 4.72 g./cc. There are 4 Cs, 2 Au^{I}, 2 Au^{III}, and 12 Cl atoms to be located. The sets of equivalent positions for D_{4h}^{17} are[6]

2a: $000,\ \frac{1}{2}\frac{1}{2}\frac{1}{2}$
2b: $00\frac{1}{2},\ \frac{1}{2}\frac{1}{2}0$
4c: $0\frac{1}{2}0,\ \frac{1}{2}00,\ \frac{1}{2}0\frac{1}{2},\ 0\frac{1}{2}\frac{1}{2}$
4d: $0\frac{1}{2}\frac{1}{4},\ \frac{1}{2}0\frac{1}{4},\ \frac{1}{2}0\frac{3}{4},\ 0\frac{1}{2}\frac{3}{4}$
4e: $00z,\ 00\bar{z},\ \frac{1}{2}\frac{1}{2}\frac{1}{2}+z,\ \frac{1}{2}\frac{1}{2}\frac{1}{2}-z$
8h: $xx0,\ \bar{x}\bar{x}0,\ x\bar{x}0,\ \bar{x}x0,\ \frac{1}{2}+x\ \frac{1}{2}+x\frac{1}{2},\ \frac{1}{2}-x\frac{1}{2}-x\frac{1}{2},$
$\frac{1}{2}+x\frac{1}{2}-x\frac{1}{2},\ \frac{1}{2}-x\frac{1}{2}+x\frac{1}{2}$

together with 8f, 8g, 8i, 8j, and positions for sets of 16 and 32 equivalent atoms. The photographs show that the atoms are in positions close to those of the perovskite arrangement. This can be achieved only in the following way

2 Au^{III} in 2a
2 Au^{I} in 2b
4 Cs in 4d
4 Cl in 4e, with $z \cong 1/4$
8 Cl in 8h, with $x \cong 1/4$

(The assignment of Au^{III} to 2b and Au^{I} to 2a leads to the same structures.)

The parameters x and z were evaluated from the intensity data given in Table I. The ob-

[5] This unit is obtained from the small pseudo-cubic unit by rotating about c through 45° and doubling c_0. It corresponds to the dimensions $a_0 = 5.28$ Å., $c_0 = 5.44$ Å. for the small pseudo-unit, with axial ratio 1.03.

[6] "International Crystal Structure Tables."

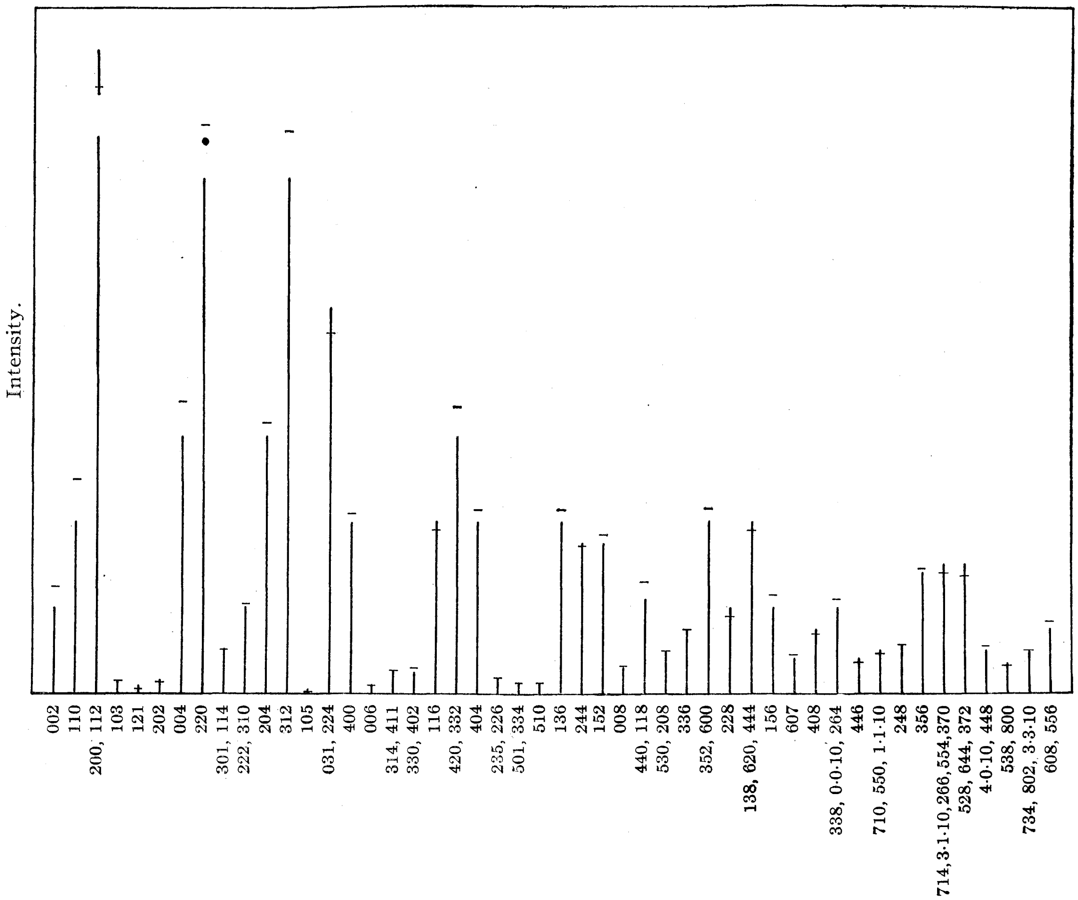

Fig. 1.—Calculated and observed intensities of reflections on powder photographs of cesium aurous auric chloride. The vertical lines show the observed values of the relative intensities, and the horizontal crossbars the calculated values.

served intensity values $I_{\text{obsd.}}$ were obtained from microphotometer records of the photographs and from visual estimates made on a series of photographs taken under identical conditions except for varied time of exposure. Intensity values were calculated with the equation

$$I_{\text{calcd.}} \sim \frac{1 + \cos^2 \Theta}{\cos \Theta \sin^2 \Theta} hF^2$$

in which h is the frequency factor and F the structure factor. F is given by the equation

$$F = f_{\text{Au}} + f_{\text{Au or Ag}} \cos 2\pi \frac{h+k}{2} + (-1)^{l/2} f_{\text{Cs}} \left\{ \cos 2\pi \frac{h}{2} + \cos 2\pi \frac{k}{2} \right\} + 2f_{\text{Cl}} \left\{ \cos 2\pi u(h+k) + \cos 2\pi u(h-k) + \cos 2\pi lv \right\}$$

Screening-constant f values were used,[7] without temperature correction. The parameter values obtained in this way, with especial emphasis on comparisons between adjacent lines on the photographs, are $x = 0.228 \pm 0.003$ and $z = 0.288 \pm 0.003$. The excellence of the agreement between observed and calculated intensities with these parameter values is shown in Table I and Fig. 1.

The Determination of the Structure of Cesium Argentous Auric Chloride.—Copper radiation photographs of samples of cesium argentous auric chloride which had been standing at room temperature since their preparation two to three years before were found to show only reflections (about thirty in number) which could be explained by a cubic unit of structure with $a_0 = 5.28 \pm 0.01$ Å., containing $\frac{1}{2}$ $Cs_2AgAuCl_6$. The lines on the photographs are sharp, and the absence of fine structure comparable in magnitude with the clearly resolved $CuK\alpha_1$-α_2 doublet for the wide-angle reflections shows that the approximation to a cubic structure is within 0.1%.

After the sample had been heated in a sealed evacuated tube at 350° for seventy-two hours and

---

[7] L. Pauling and J. Sherman, *Z. Krist.*, **81**, 1 (1932).

cooled slowly to room temperature over a period of about five hours, it gave quite different X-ray photographs, the cubic lines being split into components similar to those for the aurous-auric compound, but with still greater separation. The photographs could be indexed completely on the basis of a tetragonal unit with a_0 = 7.38 ± 0.02 Å. and c_0 = 11.01 ± 0.02 Å. The unit is body-centered, and the observed reflections correspond to the space-group $D_{4h}^{17} - I4/mmm$ or one of its subgroups. The atomic arrangement described above for $Cs_2AuAuCl_6$, with Ag^I replacing Au^I and with the parameter values $x = 0.220 \pm 0.03$ and $z = 0.285 \pm 0.003$, accounts completely for the observed intensities, as shown in Table II and Fig. 2.

Discussion of the Structures.—The structure found for the tetragonal form of cesium argentous auric chloride (after heating at 350°) is shown in Fig. 3. The structure is closely related to the perovskite structure, the arrangement of the large cesium and chlorine atoms corresponding approximately to cubic closest packing, with the silver and gold atoms alternating in positions at the centers of chlorine octahedra. The distortion from the ideal perovskite structure is such as to show the presence of $[AgCl_2]^-$ and $[AuCl_4]^-$ complexes. Each silver atom has two closest chlorine atoms at the distance 2.36 Å., which is just the sum of the covalent radii for silver (with coördination number two) and chlorine;[8] the other four chlorine atoms of the distorted octahedron are 2.92 Å. from the silver atom. The $[Cl\text{-}Ag\text{-}Cl]^-$ complexes are linear, and are oriented parallel to the *c* axis of the crystal. Each gold atom has four nearest chlorine neighbors, arranged about it at the corners of a square, at the distance 2.30 Å., which is the sum of the covalent radii of trivalent gold and chlorine. The distance from the gold atom to the two other chlorine atoms in its neighborhood is 3.13 Å.

The linear configuration of the $[AgCl_2]^-$ complex ion is expected, in view of the analogy of the complex to the linear $[Ag(CN)_2]^-$ complex in the crystal $KAg(CN)_2$, studied by Hoard.[9] The square configuration of the chloroaurate ion $[AuCl_4]^-$ is similar to that observed[10] for the isoelectronic chloroplatinite ion $[PtCl_4]^=$, and is ex-

pected from quantum mechanical considerations.[11]

From these results it is seen that cesium argentous auric chloride is a compound of cesium dichloroargentite, $CsAgCl_2$, and cesium tetrachloroaurate, $CsAuCl_4$, with the stability of the compound to be attributed to the close packing of the pseudo-perovskite arrangement. The formula of the compound might well be written as $CsAgCl_2 \cdot CsAuCl_4$ or $Cs_2AgCl_2AuCl_4$.

The cubic modification of the substance must involve some randomness of atomic arrangement, since the X-ray data show that silver and gold atoms are randomly distributed in such a way as to give no reflections requiring a larger unit. It is probable that the crystal contains linear $[AgCl_2]^-$ complexes and square $[AuCl_4]^-$ complexes with random distribution and random orientation relative to its three orthogonal axes.

The structure found for cesium aurous auric chloride is similar to that of the tetragonal modification of the argentous auric compound. The structure involves linear $[AuCl_2]^-$ groups, with Au^{I}–Cl = 2.31 Å., and square $[AuCl_4]^-$ groups, with Au^{III}–Cl = 2.42 Å. The longer Au–Cl distances are Au^{I}–Cl = 2.98 Å. and Au^{III}–Cl = 3.13 Å.

There is some evidence that the structure found for this substance represents some deviation from the ideal structure. The axial ratio c/a for tetragonal $Cs_2AgAuCl_6$ is 1.491, whereas that found for $Cs_2AuAuCl_6$ is 1.452, which is considerably closer to the value for no distortion from the cubic perovskite structure, 1.414. It is to be expected, however, because of the very small difference in radii of silver and gold atoms, that the structures of the substances would be identical. The low value of the axial ratio of the aurous auric compound suggests that in the sample of this substance used for preparing the photographs the ideal structure with completely oriented complex ions had not been achieved,

---

(11) L. Pauling, THIS JOURNAL, **53**, 1367 (1931).

and that some of the complexes were oriented in a random manner. Some further support for this idea is given by the value of the parameter x, which makes the Au^{III}–Cl distance 0.12 Å. larger than in the argentous auric compound; it seems likely that the change in intensities of the lines caused by the partial randomness of the structure has caused a small error in the parameter determination. An effort to test this hypothesis was made by heating the sample of $Cs_2AuAuCl_6$ to 350° for twenty-four hours; the photograph obtained of the sample after this treatment was identical with the earlier ones, however, showing that the partial randomness of structure, if it exists, represents the stable state at ordinary temperatures and not a metastable state.

An investigation of cesium aurous auric chloride and cesium argentous auric chloride has been reported recently by Ferrari,[12] leading to results different from ours. Ferrari reported the substances to give powder photographs (taken with iron radiation) corresponding to cubic units with a_0 = 5.23 Å. in each case, except that a few very faint lines were observed indicating the true units to have values of a_0 twice as large. He suggested a structure involving distortion from the ideal perovskite arrangement such as to give $[AuCl_6]^{=}$ complexes with the configuration of a regular octahedron. It seems to us improbable that this complex exists; and we believe that the samples studied by Ferrari represent random structures, as described above, with admixture of the tetragonal ordered modifications in sufficient amounts to give the faint extra lines which he observed.

Summary

Crystals of tetragonal cesium aurous auric chloride have a body-centered unit of structure, with $a_0 = 7.49 \pm 0.02$ Å., and $c_0 = 10.87 \pm 0.02$ Å. containing 2 $Cs_2AuAuCl_6$. The space group is $D_{2h}^{17} - I4/mmm$, and the atoms are in the following positions of this space group: 2 Au^{III} in 2a; 2 Au^{I} in 2b; 4 Cs in 4d; 4 Cl in 4e, with $z = 0.288 \pm 0.003$; 8 Cl in 8h, with $x = 0.228 \pm 0.003$. Tetragonal cesium argentous auric chloride, $Cs_2AgAuCl_6$, has a similar unit, with

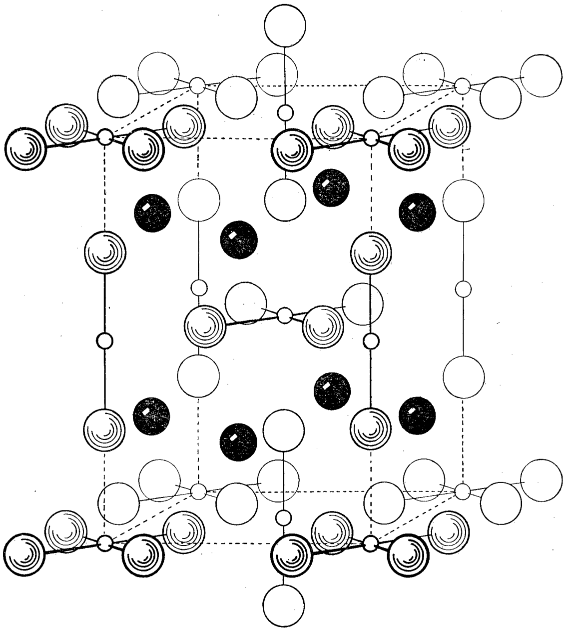

Fig. 3.—The atomic arrangement in tetragonal crystals of $Cs_2AgAuCl_6$ and $Cs_2AuAuCl_6$. Large full circles represent cesium atoms, large open circles chlorine atoms, and small circles gold and silver atoms.

$a_0 = 7.38 \pm 0.02$ Å., and $c_0 = 11.01 \pm 0.02$ Å., and a similar atomic arrangement (with Ag^{I} replacing Au^{I}), the parameter values being $z = 0.285 \pm 0.003$ and $x = 0.220 \pm 0.003$. These crystals contain linear $[AgCl_2]^-$ and $[AuCl_2]^-$ ions, similar to $[Ag(CN)_2]^-$, and square coplanar $[AuCl_4]^-$ ions, similar to the $[PdCl_4]^{=}$ and $[PtCl_4]^{=}$ ions.

In addition a metastable cubic modification of $Cs_2AgAuCl_6$, capable of conversion into the stable tetragonal modification by heating, was studied. The apparent unit of structure of this is cubic, with $a_0 = 5.28 \pm 0.01$ Å. It contains $\frac{1}{2}$ $Cs_2AgAuCl_6$, and appears to have the perovskite structure, with $\frac{1}{2}$(Ag + Au) at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$, Cs at 000, 3 Cl at approximately $\frac{1}{2}\frac{1}{2}0$, $\frac{1}{2}0\frac{1}{2}$, $\frac{1}{2}\frac{1}{2}0$. It is probable that the crystal contains $[AgCl_2]^-$ and $[AuCl_4]^-$ complexes with random distribution among the positions and orientations provided by the perovskite structure. Evidence for the existence of a similar modification of $Cs_2AuAuCl_6$ is given by the work of Ferrari.

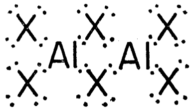
The Electron Diffraction Investigation of Aluminum Chloride, Bromide, and Iodide

BY K. J. PALMER AND NORMAN ELLIOTT

The unusual physical and chemical properties of aluminum chloride, bromide, and iodide lend considerable interest to the electron diffraction investigation of these compounds in the gas phase. Vapor density measurements have shown that in the gaseous state below approximately 400° the substances exist as the dimeric molecules Al_2Cl_6, Al_2Br_6, and Al_2I_6.

The same configuration is suggested for these molecules by considerations based on the extreme ionic and the extreme covalent points of view. The radius ratio of the ions Al^{3+} and Cl^- is 0.40 (ratio of univalent radii[1]), which corresponds to tetrahedral coördination. This can be achieved for a molecule Al_2X_6 by the sharing of an edge between two tetrahedra, as shown in Fig. 1. From the covalent point of view this configuration would be expected as the result of the tendency of the aluminum atoms to complete their octet valence shells, the electronic structure of the molecule being



The suggestion of this as a possible structure for the aluminum halides was made by Fajans.[2]

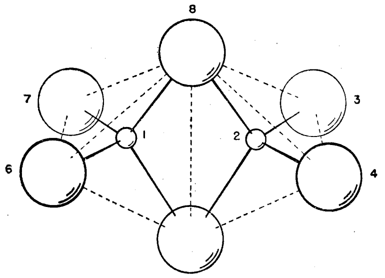


Fig. 1.—The spatial configuration of the dimeric molecule Al_2X_6. Positions 1 and 2 correspond to the aluminum atoms; the remaining positions are occupied by halogen atoms.

We have carried out the study of these substances by the electron diffraction method, and have verified the double-tetrahedral configuration of Fig. 1, with some deformation of the tetrahedra, as described below.

Experimental

The electron diffraction photographs were obtained and interpreted in the usual way.[3] The wave length of the electrons was 0.0613 Å. and the camera distance 10.85 cm. for the chloride and bromide and 20.16 cm. for the iodide.

The strong tendency of the aluminum halides to hydrolyze made it necessary to transfer the samples to the high temperature nozzle inside a moisture proof box. The nozzle[4] could then be sealed and inserted into the electron diffraction apparatus, the sample not being allowed to come into contact with moist air. This procedure proved to be satisfactory, as was verified by inspection of the nozzle after the exposures were made. In no case was there any sign of decomposition.

Merck C. P. aluminum chloride was used without further purification. The aluminum bromide was made by the method of Richards and Krepelka.[5] The aluminum iodide was prepared by heating iodine with excess aluminum in an evacuated glass tube held in a vertical position. The temperature was maintained at 300° for six hours, in which time the color due to the iodine vapor had disappeared completely. The aluminum iodide which collected in the lower part of the tube along with the excess aluminum was separated from the latter by distilling it to the upper part of the tube and then sealing the tube off at the center. The product appeared in the form of colorless highly refractive crystals. There was no evidence of any iodine vapor being present either during or after the distillation. These crystals were used without further purification.

Aluminum Chloride.—The photographs of aluminum chloride show nine maxima. The averaged values of s_0, I (the visually estimated intensities), and C (equal to $Is_0^2e^{-as_0^2}$) are given in Table I. The qualitative appearance of the photographs is well represented by curve F of Fig. 3

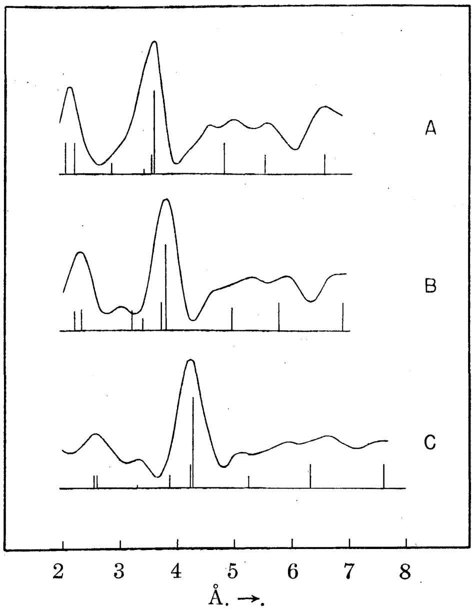

Fig. 2.—Radial distribution curves for (A) aluminum chloride, (B) aluminum bromide and (C) aluminum iodide.

which was calculated for the finally accepted model. The radial distribution curve,[6] curve A of Fig. 2, calculated using the values of C (Table I) in place of I, shows principal peaks at 3.56 and 2.11 Å. These values are interpreted as the Cl–Cl and the short Al–Cl distances, respectively. The ratio of these, 1.69, is close to that (1.633) for a regular tetrahedral arrangement of chlorine atoms about the aluminum atoms. Strong support for this structure is provided by the simplified theoretical intensity curve calculated for the regular tetrahedral model (curve A of Fig. 3), which shows good, although not complete, agreement with the characteristics of the photographs.

In order to find a model in which the ratio of Cl–Cl to Al–Cl is 1.69, all of the edges of the two tetrahedra except the shared edge were assumed to have the value 3.56 Å., and the eight smallest Al–Cl distances the value 2.11 Å. The shared edge would then have the value 2.58 Å. Although this distance is much less than the distance of closest approach (2.86 Å.) observed for two non-bonded chlorine atoms, a theoretical intensity curve was calculated for this model (curve B, Fig. 3), which again is in good but not complete agreement with the photographs. Curves C and D, Fig. 3, were calculated for models in which the shared edge has the value 2.75 and 2.85 Å., respectively. The other ten edges have the values 3.56 Å. in model C and 3.54 Å. in model D and the smallest Al–Cl distances the values 2.12 and 2.11 Å., respectively. These curves do not agree with the photographs quite so well as does curve B.

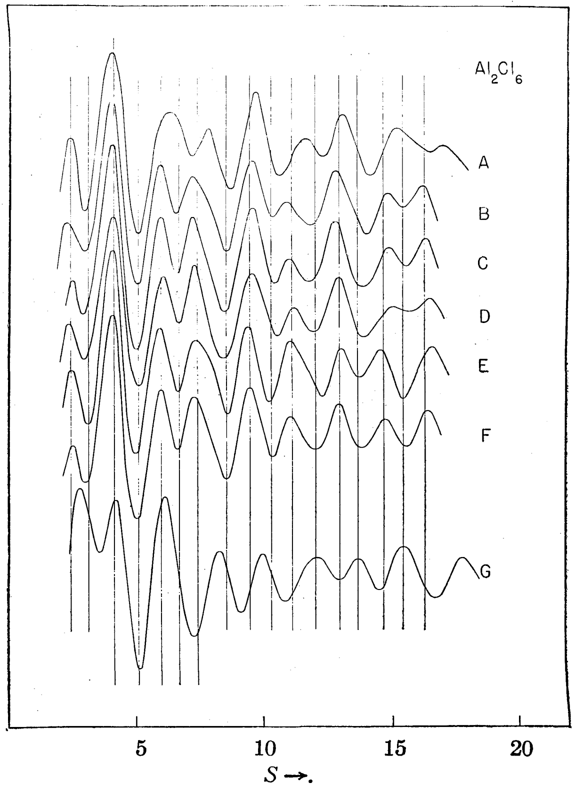

Fig. 3.—Theoretical intensity curves for aluminum chloride.

A very large decrease in the value of the shared edge is necessary in order to obtain the ratio 1.69 when at the same time one keeps the other edges of the tetrahedron about equal to 3.56 Å. and the short Al–Cl distances all equal to 2.11 Å. Thus it is evident that the models so far assumed have been oversimplified, and that the stable configuration, although approximating two regular tetrahedra sharing an edge, is in reality considerably distorted. In order to obtain an insight into the type of distortion to be expected the following calculation was made.

The molecule is assumed to be completely ionic, and to be represented by the potential function

$$V = -\sum_{ij} \frac{e_i e_j}{r_{ij}} + \sum_{ij} \frac{B_{ij} e_i e_j}{r_{ij}^n}$$

in which r_{ij} is the distance between the ith and jth atoms, B_{ij} is the Born coefficient, n is a con-

---

[6] L. Pauling and L. O. Brockway, THIS JOURNAL, **57**, 2684 (1935). The use of the values of C in place of I has been suggested by V. Schomaker and C. Degard. They will publish an account of their investigation soon in THIS JOURNAL.

stant, taken to have the value 9 for this calculation, and e_i, e_j are the charges on the ith and jth atoms, taken equal to -1 and $+3$ for chlorine and aluminum, respectively. It was further assumed that the ratio of the B's is given by the expression

$$\frac{B_{\text{Al-Cl}}}{B_{\text{Cl-Cl}}} = \frac{(R_{\text{Al}} + R_{\text{Cl}})^8}{(2R)_{\text{Cl}}{}^8}$$

where R_{Al} and R_{Cl} are the ionic radii of aluminum and chlorine, respectively. The absolute magnitudes of the B's were obtained by setting $\partial V/\partial r = 0$ and using r_{ij}'s corresponding to two regular tetrahedra with all short Al–Cl distances equal to 2.11 Å. The values so obtained are $B_{\text{Al-Cl}} = 48.15$ and $B_{\text{Cl-Cl}} = 1755$. These values were retained throughout the calculation.

A method of successive approximations was used to carry out the calculation. Each of the four independent parameters necessary to specify the structure was successively varied, the process being repeated once. The final values of the parameters so obtained indicate the type of distortion to be expected in such a structure. With a charge of $+3$ assumed to reside on each of the two aluminum atoms the repulsion between them is very strong, and the most notable changes in going from two regular tetrahedra to the final equilibrium configuration are the decrease in the length of the shared edge and the increase in the Al–Al distance. This latter effect changes the values of the short Al–Cl distances by a large amount. The final values of the interatomic distances calculated in this way are Al_1–Al_2 = 3.60, Al_2–Cl_3 = 1.99, Al_2–Cl_8 = 2.31, Al_2–Cl_6 = 4.89, Cl_3–Cl_4 = 3.49, Cl_3–Cl_8 = 3.57, Cl_5–Cl_8 = 2.90, Cl_3–Cl_7 = 5.52, Cl_3–Cl_6 = 6.52 Å. The subscripts on the atomic symbols refer to the position of the atoms as given in Fig. 1. The average of the four Al_2–Cl_3 distances, equal to 1.99 Å., and the four Al_2–Cl_8 distances, equal to 2.31 Å., (refer to Fig. 1) is 2.15 Å., in fair agreement with the radial distribution peak at 2.11 Å. However, if this were the correct model, the two shortest Al_2–Cl distances probably would appear as separate peaks in the radial distribution curve. Moreover, the intensity curve calculated for this model (curve E, Fig. 3) does not agree qualitatively with the photographs; the sixth maximum is too high and the eighth and ninth minima are not of equal depth.

Seven additional intensity curves were calculated for models in which the four parameters were varied. The model finally selected gives an intensity curve (curve F, Fig. 3) which reproduces the qualitative features of the photographs in every respect. The values of the interatomic distances for this model are listed in Table II. Table I gives the values of s and s_0 and their ratio, s/s_0, for model F.

TABLE II

INTERATOMIC DISTANCES IN ALUMINUM CHLORIDE

	Distance, Å.	Number of times distance occurs in molecule
Al_2–Cl_3	2.06 ± 0.04	4
Al_2–Cl_8	2.21 ± .04	4
Cl_5–Cl_8	2.83 ± .10	1
Cl_3–Cl_4	3.53 ± .04	2
Cl_3–Cl_8	3.56 ± .02	8
Al_1–Al_2	3.41 ± .20	1
Cl_3–Cl_7	5.49 ± .05	2
Cl_3–Cl_6	6.52 ± .05	2
Al_2–Cl_6	4.77 ± .15	4

Aluminum Bromide.—The photographs of aluminum bromide show seven well-defined rings and have the same qualitative features as those for aluminum chloride. The radial distribution curve has two well-defined peaks at 2.28 and 3.77 Å. The ratio of 3.77 to 2.28 is 1.65, indicating that the tetrahedra in this molecule probably are not distorted to so great an extent as for the chloride. Curve A of Fig. 4 was calculated for two regular tetrahedra sharing an edge. The curve is in good but not complete qualitative agreement with the photographs. Curves B and C of

Fig. 4 were calculated for models having the same type of distortion as that found for the chloride, but smaller in magnitude. The two models are essentially the same except for the length of the shared edge. In model B this edge was assumed to be 3.36 Å. and in model C 3.20 Å. The Al_2–Br_3 and Al_2–Br_8 distances were taken equal to 2.21 and 2.33 Å., respectively, in model C, and 2.21 and 2.35 Å. in model B.

The qualitative agreement of curve C with the photographs is better than that of curve B in that the fifth maximum in the former is slightly more intense than the fourth, in agreement with the appearance of the photographs. The differences in these two curves are, however, very slight in spite of the fact that the Br_5–Br_8 distance has been changed by 0.16 Å. The insensitiveness of the intensity curves to variations in this parameter makes it necessary to assign to it a large probable error. In Table III there are listed the values of I, C, s_0, s (for model C), and the ratio of s/s_0, and in Table IV there are given the values of the interatomic distances for the molecule and their estimated probable errors.

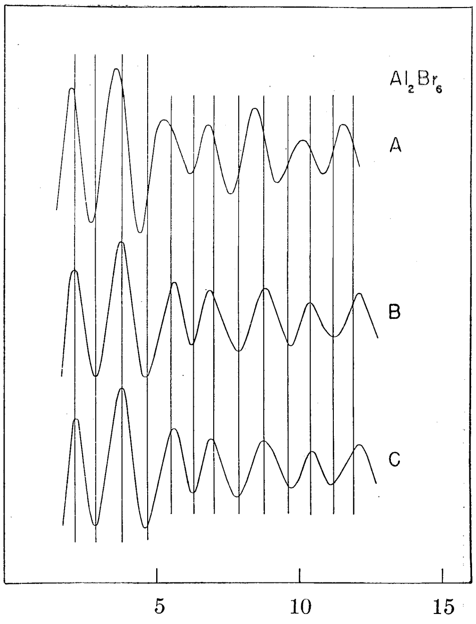

Fig. 4.—Theoretical intensity curves for aluminum bromide.

Aluminum Iodide.—The photographs of aluminum iodide, taken with a camera distance of 20.16 cm., show seven well-defined maxima, the general appearance of the photographs being closely similar to that for the chloride and bromide. This similarity is strong evidence for the assumption that the structures of the three molecules are similar in configuration.

The radical distribution curve (curve C, Fig. 2), shows principal peaks at 2.58 and 4.23 Å. The ratio of the latter to the former distance is 1.64, indicating that the structure is very nearly that of two regular iodine tetrahedra sharing an edge.

The ratio of the scattering due to the iodine atoms to that due to the aluminum atoms is very large in aluminum iodide; this makes the determination of the positions of the aluminum atoms with any degree of accuracy impossible. The intensity curves shown in Fig. 5 were calculated for models approximating those described for aluminum bromide. Curve A is for undistorted tetrahedra, and curves B and C for tetrahedra whose shared edge has the value 4.00 and 3.85 Å., respectively, and for which the Al_2–I_3 and Al_2–I_8 distances have the values 2.58 and 2.54 Å., respectively. Curve A does not agree with the photographs in that the relative intensities of the maxima are unsatisfactory. Curve C gives a somewhat better representation of the appearance of the photographs than curve B, but the differences in these two curves, namely, the variation of the intensities of the third, fourth, and fifth maxima, are so small that, as in the case of the bromide, it is impossible to determine the length of the shared edge with much accuracy.

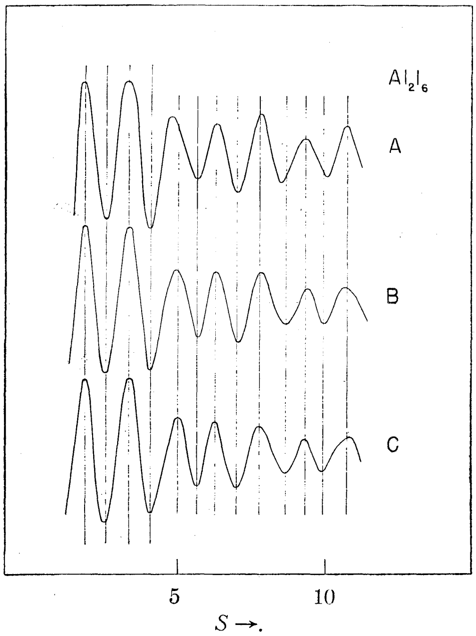

Fig. 5.—Theoretical intensity curves for aluminum iodide.

The values of the interatomic distances with their estimated probable errors are given in Table VI. The quantitative comparison of the s values obtained from curve C with the observed s_0 values is given in Table V.

Al_2–I_6	5.22 ± .15	4

Discussion

The only report on the structures of aluminum chloride, bromide, or iodide previous to the present one is that of Ketelaar[7] on the structure of aluminum chloride crystals. He found that the chlorine atoms are in hexagonal closest packing, this arrangement being compatible with that found for the gas molecule in this investigation. However, he chose to place two aluminum atoms inside an octahedron of chlorine atoms, and only 0.56 Å. apart, rather than one each inside of two tetrahedra sharing an edge, both of these possibilities being provided by the hexagonal closest packed arrangement. The extent to which the X-ray data can be accounted for by this latter configuration is being investigated by one of us. Curve G, Fig. 2, is the simplified theoretical intensity curve calculated for the "octahedral" model of Ketelaar; it is apparent from a comparison with curve F that this model cannot represent the structure of the gas molecule.

The large difference in electronegativity between aluminum and the halogen atoms leads one to expect that the Al–X bond will be largely ionic, and this is confirmed by the observed contraction of the shared edge. The percentage decrease in length of the shared edge is found to be largest in the chloride and least in the iodide, which is in accordance with expectation.

The sums of the tetrahedral radius of aluminum and the normal radii for the halogen atoms are 2.25, 2.40, and 2.59 Å. for the chloride, bromide, and iodide, respectively. These values are to be compared with the observed values, 2.06, 2.21, and 2.53 Å., which are the Al_2–X_3 distances, and 2.21, 2.33, and 2.58 Å., which are the Al_2–X_8 distances, for the chloride, bromide, and iodide, respectively. The observed shortening in the case of the Al_2–X_3 distances is probably due to the excited structures in which an X_3 halogen atom

(7) J. A. A. Ketelaar, *Z. Krist.*, **90**, 237 (1935).

swings in a pair of electrons and forms a double bond with the aluminum atom. This type of resonance is not expected to occur to the same degree for halogen atoms forming two bonds, which accounts for the fact that the observed Al_2–X_8 distances are nearly equal to the sum of the appropriate radii.

It is interesting to note that the observed values of the Al_2–X_3 distances show a greater tendency for the chlorine and bromine atoms to form double bonds than of iodine atoms; this is compatible with the results of other investigations.

We wish to express our thanks to Professor Linus Pauling for his aid and helpful criticism during the course of this investigation.

Summary

It is shown that in the gaseous state the dimeric molecules of aluminum chloride, bromide, and iodide consist of two tetrahedra sharing an edge with six halogen atoms at the corners, each tetrahedron containing one aluminum atom. The final values of the interatomic distances are as follows

The subscripts on the atomic symbols refer to their positions in the molecule as given in Fig. 1.

	Al_2Cl_6	Al_2Br_6	Al_2I_6
Al_1–Al_2	3.41 ± 0.20 Å.	3.39 ± 0.10 Å.	3.24 ± 0.15 Å.
Al_2–X_3	2.06 ± .04	2.21 ± .04	2.53 ± .04
Al_2–X_8	2.21 ± .04	2.33 ± .04	2.58 ± .04
Al_2–X_6	4.77 ± .15	4.93 ± .10	5.22 ± .15
X_3–X_4	3.53 ± .04	3.72 ± .03	4.20 ± .03
X_3–X_8	3.56 ± .02	3.78 ± .03	4.24 ± .02
X_5–X_8	2.83 ± .10	3.20 ± .10	2.90 ± .15
X_3–X_7	5.49 ± .05	5.76 ± .10	6.24 ± .15
X_3–X_6	6.52 ± .05	6.86 ± .10	7.54 ± .10

Photochemical Studies. XXVI. A Further Study of the Fluorescence of Acetone Vapor and its Relationship to the Photochemical Decomposition

BY MAX S. MATHESON AND W. ALBERT NOYES, JR.

The fluorescence of acetone vapor was reported by Damon and Daniels,[1] who stated that it is greenish and is changed to blue by the presence of small amounts of oxygen. The oxygen disappears during illumination and this fact has been used as a means of determining small amounts of this substance.[2]

Two regions, one extending from 4100 to 4820 Å. (maximum 4580 Å.) and the other from 4990 to the limit of plate sensitivity (5210 Å.), were found by Damon and Daniels.[1] Norrish, Crone and Saltmarsh[3] report three bands of fluorescent emission (all diffuse) with maxima at 5117, 5572 and 6095 Å. More recently Padmanabhan[4] has found that the bands are not devoid of structure but consist of diffuse bands superimposed upon a continuous spectrum. Ten bands, two considered to be doubtful, were reported.

Herzberg[5] first found a discrete structure in the near ultraviolet absorption of acetone vapor and this has been confirmed by other workers.[3,6] The detailed analysis of these bands and their interpretation is still lacking, but the existence of such a structure is in conformity with the fact that fluorescence is observed. However, structure is difficult to observe in many polyatomic molecules even though fluorescence is found. Such seems to be the case with ethyl methyl ketone[7] and diethyl ketone.[8]

All authors who have studied the quantum yield of acetone decomposition in the near ultraviolet at room temperature agree that it is low.[9] The explanation of this fact is not complete. Damon and Daniels[1] state that the fluorescence is too weak to be the primary cause of this effect. However Fisk and Noyes[10] studied the fluorescence excited by the 3130 Å. line of mercury and found (with the very low intensities used) a Stern–Volmer mechanism to be obeyed. At moderate pressures it was found that the number of quanta absorbed was roughly equal to the sum

of the three quantities: (a) number of molecules which fluoresce; (b) number of molecules which dissociate; (c) number of activated molecules deactivated by collision. However, the mechanism used to accomplish this balance disagreed quite definitely with some of the photochemical facts, particularly with the supposed decrease in quantum yield with acetone pressure.

That the mechanism of acetone photodecomposition may be quite complex is suggested by the work of Spence and Wild.[11] These authors find approximately one molecule of carbon monoxide for each molecule of ethane at 3130 Å., but a considerable deficiency of carbon monoxide at shorter wave lengths. This agrees with the fact, first reported by Barak and Style,[12] that appreciable amounts of biacetyl are formed at room temperature during photodecomposition of acetone. At 60° the amount of biacetyl was found to be negligible, due perhaps to the instability of the CH_3CO radical at that temperature.

To attempt to elucidate the phenomenon of a low quantum yield coupled with a relatively small amount of fluorescence it was thought desirable to study the fluorescence over as wide a range of conditions as practicable. Unfortunately the absorption coefficient of acetone is so low at 3130 Å. that it did not prove feasible to use pressures low enough to permit a decision to be made as to the effect of collisions on this reaction.

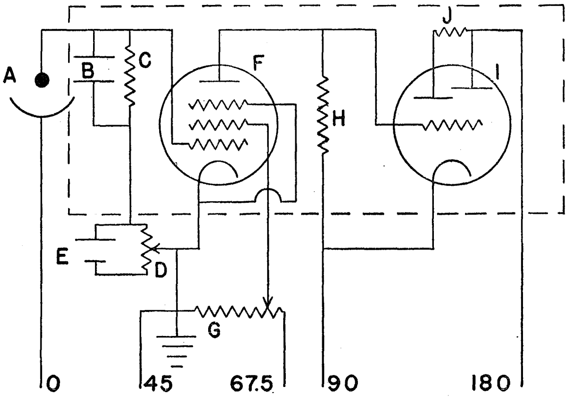

Fig. 1.

Experimental

Purification of Acetone.—Reagent quality acetone was purified by the method of Shipsey and Werner[13] by crystallizing from an acetone solution of anhydrous sodium iodide. The acetone was distilled from the salt over a steam-bath and then carefully fractionated, the middle portion boiling at 55.8° (uncorr.) being retained. After placing in the vacuum line, it was refluxed for forty-eight hours over boron trioxide at low temperatures and then fractionated. No stopcocks or joints involving grease were present in the line.

Purification of Biacetyl.—Biacetyl (Eastman) was fractionally distilled three times, the final middle fraction boiling at 87–88° being retained. After placing in the vacuum line, it was subjected to five low pressure fractionations at room temperature, the first three condensations taking place at liquid air temperatures and the last two with dry ice.

The Fluorescence Cells.—Two all-quartz cells having a T shape were used at different times. These were sealed to the rest of the line with graded seals. The length of the main limb was 4 cm. and the windows were 2 cm. in diameter.

The Light Source.—A General Electric H3 quartz high pressure mercury arc operated at 85 watts was used. A hole was blown in the glass envelope surrounding the arc to permit the exit of wave lengths below 3500 Å.

The light was passed through a water-cooled Red Purple Corex A filter and then through either one or two quartz plates lightly silvered (by sputtering) according to the directions given by R. W. Wood.[14] A quartz lens was used to bring the radiation to a focus at the center of the cell, although the beam was nearly parallel.

The radiation transmitted by the optical system was photographed with an E3 Hilger spectrograph on Eastman 33 plates. Microphotometer tracings[15] showed the following distribution of radiation: (a) 3130 Å., 79%; (b) 3340 Å., 8%; (c) 3650 Å., 12%; (d) all others less than 1%. (No trace of lines below 3130 Å. could be found on the plates which were microphotometered.)

The Measurement of the Incident Radiation.—For some runs the incident radiation was measured by a cesium oxide photoelectric cell with quartz envelope. For others a similar cell with Pyrex envelope was used. One or the other of these cells was placed on the exit side of the long limb of the T so that transmitted radiation was measured.

The current from this photoelectric cell was amplified and measured by the circuit shown in Fig. 1.[16] The photoelectric cell is shown at A. F is a Sylvania type 77 vacuum tube. I is a 6E5 magic eye radio tube. D is a student potentiometer. C is a 10-megohm composition resistor and B is a 0.1 microfarad condenser. H is a 1 megohm composition resistor and J is a 0.5 megohm composition resistor. G is a 10^5-ohm screen potentiometer. E is a battery of three dry cells. The figures at the bottom refer to voltages obtained by the use of four B batteries.

This amplifier was used as a null point indicator, the null point used being the just closed condition of the fan-shaped shadow on the fluorescent screen of the 6E5 tube (I). The change in the reading of the student potentiometer D necessary to just close the shadow gave a measure

of the intensity of light falling on the photoelectric cell. The linearity of amplification was tested by use of the inverse square law of intensities obtained from a filament lamp placed at distances of two meters or greater.

Since the fraction of radiation transmitted by the exit window of the fluorescence cell was constant, it was possible to calculate quantities proportional to the incident intensity with the use of the known absorption coefficients of acetone vapor.[17] Absorption of the mercury line at 3130 Å. was alone considered.

The Measurement of the Fluorescent Radiation.—The fluorescent radiation was measured by a photoelectric cell with quartz envelope and having a plane window in front of the cathode. Current from this photoelectric cell was measured with a DuBridge circuit using an FP54 tube.[18]

Sample Experiment.—The method of introducing acetone from a cooled reservoir until it reached the desired pressure was used previously.[10] Biacetyl, when used, was introduced from calibrated volumes where the pressure was known. At low pressures the ratio of pressures could be determined exactly even if the absolute pressure was uncertain.

Both amplifiers and the arc were turned on and a half hour allowed to elapse in order to obtain steady conditions. The DuBridge and Brown[18] amplifier was balanced as described by these authors in order to minimize the drift of the galvanometer.

A shutter in front of the light source prevented any decomposition of acetone vapor while the pressure of the latter was being adjusted. Since the DuBridge and Brown amplifier had a lag of about three minutes, the transmitted and the fluorescent radiation were both measured over an interval of four or five minutes at least. Table I shows a sample set of readings.

TABLE I

DATA OF A TYPICAL EXPERIMENT

Time	G_f		G_t	Operation
3:33 P. M.	−11.40		1078.0	Light shut off from cell
3:34	−11.40	(−11.40)	1078.5	(Pressure acetone = 152.8 mm.)
3:35	+14.00	(13.99)	972.0	Light on, P = 152.8 mm.
3:36	14.72	(14.69)	971.0	
3:37	15.12	(15.08)	971.5	
3:38	14.99	(14.93)	972.0	
3:39	4.20	(4.13)	956.0	Light on, P = 0 (liquid air on trap)
3:40	3.25	(3.17)	954.5	
3:41	3.00	(2.90)	954.5	
3:42	3.05	(2.94)	954.5	
3:43	−10.70	(−10.83)	1077.5	Light off
3:44	−11.20	(−11.34)	1077.5	
3:45	−11.25	(−11.40)	1077.5	

G_f is measure of fluorescence intensity. G_t is obtained from measurements of transmitted intensity.

Under G_f it is seen that a drift of the readings toward more positive values has taken place during the experiment. Experimentally this drift was found to be nearly uniform. The drift per minute is, therefore, (11.40–11.25)/11. The figures under G_f are then corrected for drift with the results given in parentheses. The value 14.93 obtained at 3:38 is due to scattered plus fluorescent radiation, while the value 2.94 obtained at 3:42 is due to scattered radiation alone. The difference (11.99) is proportional to the intensity of the fluorescence. At low acetone pressures the scattered radiation may be a large fraction of the total measured, so that the accuracy is small.

The average of G_t at 3:34 and 3:44 is 1078.0 and is the value with the light off. By subtracting the reading at 3:42 one obtains 123.5, which is proportional to the radiation transmitted when no acetone is in the cell.

Since the amount of 3130 Å. radiation absorbed is small it will vary nearly linearly with the path length. From the geometry of the system the length of path from which radiation could be incident on the photoelectric cell measuring the fluorescence is 2.8 cm., but since relative results only are necessary this figure is not very critical.

Let A be the fraction of the radiation transmitted by the back window, D_t the measured intensity at 0 acetone pressure (=123.5 above), D_t' the intensity in front of the back window and D_t'' the intensity in back of the front window both with acetone in the cell.

Then

$$D_t'' = D_t/A \qquad (1)$$

From Beer's law

$$D_t' = D_t'' \exp.(-kcl) = D_t/A \exp.(-kcl) \qquad (2)$$

where l is the cell length (4 cm.), c is the concentration in moles per liter and k = 6.63 for 3130 Å. radiation.[17] Using the perfect gas law one finds (omitting A which is constant)

$$D' = D_t \times 10^{-61.735 \times 10^{-5}P} \qquad (3)$$

where P is in millimeters.

The effective path (2.8 cm.) begins 0.5 cm. back of the front window. Use of Beer's law indicates that the absorbed intensity is given by

$$I_a = D_t \times 10^{-61.735 \times 10^{-5}P} (10^{5.41 \times 10^{-4}P} - 10^{0.996 \times 10^{-4}P}) \qquad (4)$$

where the quantity in parentheses is the fraction of the light absorbed in the effective path (2.8 cm.).

In the above example

$$I_a = 17.28 \qquad (5)$$

and

$$I_a/I_f = 1.44 \text{ (at } P = 152.8 \text{ mm.)} \qquad (6)$$

A series of values of I_a/I_f could be made. As shown previously[10] the intensity units cancel

when a plot is made of this quantity against the pressure and the slope is divided by the intercept.

The estimated accuracy of I_a/I_f is about ±5%, although this tends to increase at low pressures of acetone where the fluorescence is very weak.

When biacetyl was mixed with the acetone or used alone the procedure was exactly similar to that described above, except that with pure biacetyl the fraction of light absorbed was assumed to be proportional to the pressure since accurate absorption coefficients of this substance have not been obtained.

Discussion of Results

It should be kept in mind that the incident intensity in the present work was much larger (100 to 1000 times) than that used in the previous experiments.[10]

Since it was the object of the present work to ascertain what effect collisions have in deactivating acetone molecules, values of I_a/I_f were desired over a large pressure range and particularly at low pressures. However, it became evident quite early that measurements below pressures of 1 to 2 cm. were unreliable due to the small absorption by the acetone and consequent weak fluorescence.

Attempts to verify the previous work[10] at higher pressures by plotting I_a/I_f against pressure and dividing the slope by the intercept gave not only results differing from those published, but the results were erratic and not reproducible. Figure 2 shows plots of I_a/I_f *vs.* P (cm.) for two different runs in which each point involved an exposure of the acetone to the radiation during ten minutes. Both of these runs were made by starting at low acetone pressures and adding acetone for each successive point without, however, evacuating the line between points.

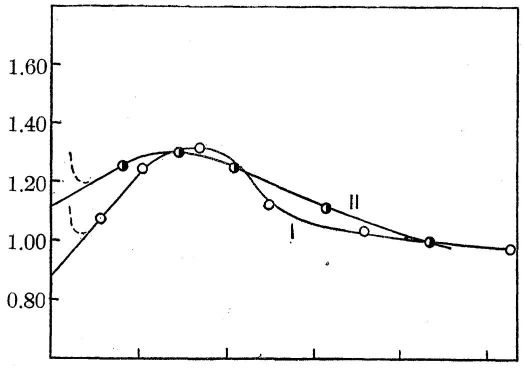

Fig. 2.

As stated above, experiments at low pressures are accompanied by a large error, although it may be significant that I_a/I_f apparently increased at pressures of a centimeter or below as indicated roughly by the dotted lines.

In the previous work it was found that

$$\text{Slope/Intercept} = 0.052\ (\text{Av.})^{10}\ (P \text{ in cm.}) \quad (7)$$

In the present experiments many values of slope/intercept were found which agree approximately with this figure providing one considers only points at low pressures obtained before the acetone had been subjected to a long exposure to the radiation. Thus in Fig. 2, 0.134 and 0.036 (approximately) were obtained for slope/intercept for the lower points. It seems evident that the conclusions of Fisk and Noyes[10] need not be seriously modified, although they were based on data obtained over a limited range of experimental conditions.

However, it should be pointed out that in every case the I_a/I_f *vs.* pressure curve passes through a maximum (see also Fig. 3). Although the data obtained previously indicate that the slope tends to become less at higher pressures, this fact had not been observed.

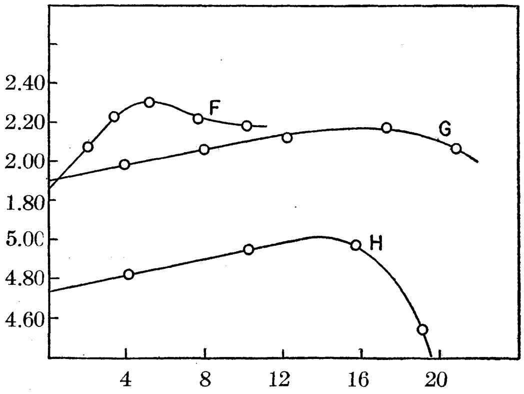

Fig. 3.—F, 2-minute exposure; G, D_t one-fourth that for F, same exposure time; H, D_t same as for F, 4-minute exposure, fresh acetone used for each point.

The following observations are also important:

(1) As the intensity is increased the value of I_a/I_f decreases, this effect being more noticeable with long than with short exposures. Previously it had been found (for very low intensities) that I_a/I_f was approximately independent of intensity, although the data were not very satisfactory on this point.

(2) At a given pressure and a given intensity I_a/I_f decreases with increasing time. However, if

the acetone is condensed with liquid air the value of this ratio returns almost exactly to its initial value. This indicates that some relatively nonvolatile substance is responsible for this phenomenon, since the mere interposition of a shutter did not produce this effect.

(3) When short exposures were used for the measurement of each point (curves F, H and G, Fig. 3) the point of inflection tended to come at higher pressures than was the case with long exposures. A greater displacement was observed with low intensities (curve G). (It should be kept in mind that with the exception of H (Fig. 3) successive points were obtained by adding acetone without intervening evacuation.)

(4) If the line was evacuated between successive points (curve H, Fig. 3) the maximum was displaced toward higher pressures even though high intensities were used.

(5) Results obtained by starting at a high pressure and removing acetone to reduce the pressure between points did not agree with those obtained by the procedure normally used.

All of these facts point to the formation during illumination of some substance which has a marked effect in increasing the fluorescence.

Neglecting secondary reactions of relatively minor importance at room temperature, the photochemical decomposition of acetone proceeds mainly in two ways

$$(CH_3)_2CO = C_2H_6 + CO^{1,3,11} \qquad (8)$$

$$2(CH_3)_2CO = (CH_3CO)_2 + C_2H_6{}^{11,12} \qquad (9)$$

(In the presence of water Damon and Daniels[1] state that diacetone alcohol may be formed.)

Of the products in (8) and (9) biacetyl would be the least volatile and from other considerations might be expected to be the one responsible for the phenomena discussed above. It was decided, therefore, to examine the effect of biacetyl on the fluorescence of acetone.

Table II presents results obtained during one run in which the acetone pressure and the incident intensity were maintained nearly constant.

TABLE II

EFFECT OF DIACETYL ON FLUORESCENCE OF ACETONE

Acetone press., mm.	69.6	69.8	69.0	69.2	69.9	70.7	68.7
Biacetyl press., mm.	0.50	0.34	0.23	0.16	0.11	0.07	0
ft	29.08	23.22	24.05	25.68	25.24	25.41	4.68
(D	148.0	142.0	141.0	137.5	135.3	135.75	133.0
D_t/I_f	5.1	6.1	5.9	5.4	5.4	5.3	28.4

(D_t/I_f is very closely proportional to I_a/I_f)

Biacetyl alone at the pressures shown in Table II would absorb an amount of radiation too small to measure and yet it seems to increase the apparent amount of fluorescence five or sixfold. This large effect at once raises the question as to whether acetone itself fluoresces.

The decisive answer to the question here raised cannot be made at once, but the following facts point to a fluorescence of acetone itself:

(1) After condensation by liquid air the fluorescence diminishes and reproduces the value obtained at the beginning of illumination. Several minutes of illumination are necessary, except at higher acetone pressures where the absorption is high, before the fluorescence begins to increase markedly.

(2) The fluorescence changes from green to blue when oxygen is present.[1] The interpretation of this fact is tentative and will be discussed later.

The conclusions to which the above experimental evidence seemed to lead necessitated an investigation of the fluorescence spectrum. The spectrum was photographed both with a small Hilger glass prism spectrograph and with an E3 spectrograph with glass train. The silvered quartz plates were removed from the optical system (see above) so that the incident radiation was less monochromatic than in the rest of the experiments. Cramer Iso Presto and Wratten and Wainwright panchromatic plates were used.

The following results were obtained:

(1) With pure acetone (102 mm.), frozen down every seven minutes to lessen the effect of biacetyl and a three-hour exposure with the small spectrograph, two bands at approximately 5100 and 5600 Å. were observed. These are almost certainly the bands at 5117 and 5572 Å. reported by Norrish, Crone and Saltmarsh.[3] When photographed with the larger spectrograph the band at 5117 Å. seemed to consist of several maxima as found by Padmanabhan.[4]

(2) With pure biacetyl (45 mm.), two-hour exposure with the small spectrograph, the same bands as in (1) appeared and in addition a faint band about 6100 Å. The latter is probably the band at 6095 Å. reported by Norrish, Crone and Saltmarsh.[3]

(3) Acetone (65 mm.) and biacetyl (0.5 mm.) and a two-hour exposure with the small spectrograph showed the same bands as in (1).

No trace of the region extending from 4100 to 4800 Å. reported by Damon and Daniels[1] could be found, but this means in all probability that it is weak compared to the fluorescence at longer wave lengths. (The plates used by Damon and Daniels were not sensitive at wave lengths longer than 5200 Å.) The blue color of the fluorescence when oxygen is present indicates that wave lengths below 5000 Å. must be present. The observed bands at longer wave lengths, which were alone observed by Norrish, Crone and Saltmarsh,[3] are evidently much more intense than any fluorescent emission in the blue region.

These results seem to indicate beyond any question that the supposed emission of acetone is the same as that of biacetyl with the possible exception of wave lengths below 5000 Å. The effect of oxygen on the fluorescence of biacetyl and of acetone was observed visually. With acetone oxygen weakened the fluorescence considerably and changed its color from greenish to blue in agreement with the results of Damon and Daniels.[1] With biacetyl the fluorescence was weakened and became less yellow although it did not acquire the characteristic blue of acetone. At the same time biacetyl gave a heavy deposit on the windows.

If the emitter is the same for both biacetyl and acetone the following possibilities suggest themselves:

(1) Acetone may dissociate into CH_3 and CH_3CO, the latter being either formed in an excited state or raised to an excited state by collisions of the second kind with excited molecules. Biacetyl would perhaps dissociate to give two CH_3CO radicals.

The energy required to dissociate acetone by the equation

$$(CH_3)_2CO = CH_3CO + CH_3 \qquad (10)$$

is uncertain, but is probably not less than 75 kcal. Quanta of 3130 Å. radiation correspond to about 91 kcal. per mole. Thus neither free radical could possess enough potential energy to be capable of fluorescing in the visible spectrum (approximately 50 kcal. per mole would be required at 6000 Å.). Roughly the same discrepancy would exist for dissociation and subsequent fluorescence of biacetyl.

Thus if emission by the CH_3CO radical takes place this must follow an activation by a collision of the second kind. A detailed mechanism considering the possible secondary reactions leads to a kinetic expression too complex to be capable of any sort of rigorous test. The enhancement of the fluorescence due to the addition of small amounts of biacetyl would have to be due to the dissociation of the latter into CH_3CO radicals by collisions of the second kind with excited acetone. Thus two excited acetone molecules would be necessary in each sequence of events leading to fluorescence. Whether or not the incident intensity would appear as the square in the expression for the fluorescent intensity would depend on other steps used in the mechanism.

(2) The major portion of the fluorescence may be due to excited biacetyl molecules. This substance absorbs[19] at least to 4700 Å. If excited biacetyl molecules are reduced to the zero vibration level by collisions prior to fluorescence,[20] the operation of the Franck–Condon principle *might* cause the maximum intensity of fluorescent emission to lie at longer wave lengths than the long wave absorption limit at room temperature.

If (2) is the correct explanation, the effect of oxygen is to prevent the formation of biacetyl and the weak blue fluorescence observed with oxygen present[1] would be due to acetone itself. The second explanation may be expressed by the following mechanism

$$\begin{array}{llrcll}
k_1 I & & \mathrm{Ac} + h\nu & = & \mathrm{Ac}_1 & (11) \\
k_2 & & \mathrm{Ac}_1 & = & \mathrm{M} & (12) \\
k_3 & & \mathrm{Ac}_1 & = & \mathrm{Ac} + h\nu_1 & (13) \\
k_4 & & \mathrm{Ac}_1 + \mathrm{Ac} & = & 2\mathrm{Ac} & (14) \\
k_5 & & \mathrm{Ac}_1 + \mathrm{B} & = & \mathrm{B}_1 + \mathrm{Ac} & (15) \\
k_6 & & \mathrm{B}_1 + \mathrm{Ac} & = & \mathrm{B} + \mathrm{Ac} & (16) \\
k_7 & & \mathrm{B}_1 & = & \mathrm{B} + h\nu_2 & (17) \\
k_8 & & \mathrm{B}_1 & = & \mathrm{N} & (18)
\end{array}$$

Ac represents a normal and Ac_1 an excited acetone molecule. B is a normal and B_1 an excited biacetyl molecule. M and N are dissociation products. These equations lead to

$$I/I_f = \frac{(k_2 + k_3 + k_4(\mathrm{Ac}) + k_5(\mathrm{B}))(k_6(\mathrm{Ac}) + k_7 + k_8)}{k_1k_3(k_6(\mathrm{Ac}) + k_7 + k_8) + k_1k_5k_7(\mathrm{B})} \qquad (19)$$

Since biacetyl has a very large effect on the fluorescence, this equation probably reduces to

$$k_1I/I_f = (k_6(\mathrm{Ac}) + k_7 + k_8)/k_7 \qquad (20)$$

and I/I_f is independent of biacetyl pressure unless the latter is very low. This is in accord with the facts.

In order to find an expression for the effect of intensity and time on the ratio of I/I_f, it is necessary to introduce a rate of biacetyl formation. If this is assumed to be of such a nature that

$$(\mathrm{B}) = KI_0(\mathrm{Ac})t \qquad (21)$$

---

(19) *Cf.* Sponer, "Molekülspektren," Verlag von Julius Springer, Berlin, 1935, Vol. I, p. 117.

(20) *Cf.* Gradstein, *Z. physik. Chem.*, **22B**, 384 (1933).

where I_0 is the incident intensity and t is the time, equation (19) becomes

$$I/I_f = \frac{(k_2 + k_3 + k_4(\mathrm{Ac}) + k_5KI_0(\mathrm{Ac})t)(k_6(\mathrm{Ac}) + k_7 + k_8)}{k_1k_3(k_6(\mathrm{Ac}) + k_7 + k_8) + k_1k_5k_7KI_0(\mathrm{Ac})t} \tag{22}$$

This equation is a quadratic in (Ac) divided by a first order expression in (Ac) and may be made to fit the data presented. When I_0t is very small, (22) reduces to

$$k_1I/I_f = 1 + (k_2 + k_4(\mathrm{Ac}))/k_3 \tag{23}$$

which is the equation used by Fisk and Noyes.[10]

Therefore it is possible to explain the observed facts by means of the mechanism included in equations (11) to (18), but it is unsafe to conclude that fluorescence of the acetyl radical does not take place or may not be mainly responsible for the phenomena described.

The Raman spectrum of biacetyl has not been investigated very completely.[21] Except, possibly, for the line at 1725 cm.$^{-1}$, no close agreements are found with differences in wave numbers among the bands found by Padmanabhan.[4] However, this is not evidence at present against the interpretation given since the electronic spectrum of this molecule has not been analyzed.

Acetone seems to have no effect on the fluorescence of biacetyl, when the latter is at a pressure of about 50 mm. and the former at a pressure of a few millimeters. Thus the seemingly good resonance for deactivation of acetone by biacetyl does not carry over to the deactivation of biacetyl by acetone. This is not incompatible with the mechanism suggested.

The various facts concerning the photochemical decomposition of acetone and the fluorescence phenomena discussed above, indicate that the following reactions take place

$$(\mathrm{CH_3})_2\mathrm{CO} + h\nu = ((\mathrm{CH_3})_2\mathrm{CO})_1 \tag{24}$$
$$((\mathrm{CH_3})_2\mathrm{CO})_1 = (\mathrm{CH_3})_2\mathrm{CO} + h\nu_1 \tag{25}$$
$$= \mathrm{CH_3CO} + \mathrm{CH_3} \tag{26}$$
$$\mathrm{CH_3CO} + \mathrm{CH_3CO} = (\mathrm{CH_3CO})_2 \tag{27}$$
$$\mathrm{CH_3} + \mathrm{CH_3} = \mathrm{C_2H_6} \tag{28}$$
$$\mathrm{CH_3CO} = \mathrm{CH_3} + \mathrm{CO} \tag{29}$$
$$((\mathrm{CH_3})_2\mathrm{CO})_1 + (\mathrm{CH_3CO})_2 = ((\mathrm{CH_3CO})_2)_1 + (\mathrm{CH_3})_2\mathrm{CO} \tag{30}$$
$$((\mathrm{CH_3CO})_2)_1 = 2\mathrm{CH_3CO} \tag{31}$$
$$= (\mathrm{CH_3CO})_2 + h\nu_2 \tag{32}$$
$$(\mathrm{CH_3})_2\mathrm{CO} + ((\mathrm{CH_3CO})_2)_1 = (\mathrm{CH_3CO})_2 + (\mathrm{CH_3})_2\mathrm{CO} \tag{33}$$
$$(\mathrm{CH_3})_2\mathrm{CO} + ((\mathrm{CH_3})_2\mathrm{CO})_1 = 2(\mathrm{CH_3})_2\mathrm{CO} \tag{34}$$

It is possible that methyl radicals may react with acetone

$$\mathrm{CH_3} + (\mathrm{CH_3})_2\mathrm{CO} = \mathrm{C_2H_6} + \mathrm{CH_3CO} \tag{35}$$

Direct dissociation instead of the formation of active molecules doubtless takes place in the continuum.

That the $\mathrm{CH_3CO}$ radical is relatively unstable is indicated by the almost total absence of biacetyl formation at 60°[11] and the fact that the photochemical decomposition of biacetyl at 100° gives almost solely ethane and carbon monoxide.[22]

Spence and Wild[11] find the ratio of ethane to carbon monoxide to increase with intensity when radiation in the continuum is absorbed by acetone, approaching a limiting value of 2.5. This is to be ascribed to the influence of reaction (27). In the full arc this ratio passes through a maximum and then decreases toward a limiting value of about 1.5. This would be due to (30), (31) and (29). In the banded region also the $\mathrm{C_2H_6/CO}$ ratio is nearly one, which would be ascribed to the high efficiency of (30) and the subsequent reactions (31) and (29). Thus biacetyl would have little chance of continued existence in the presence of excited acetone molecules.

While reactions (24) to (35) account for many of the experimental facts, the resulting kinetic expression would be so complex that it cannot be tested with data now available.

The effect of biacetyl formation is to tend to lower the ratio of slope to intercept in the previous work.[10] The calculated mean life for excited acetone would be, if anything, too small and, as concluded previously for other reasons, the value of 4×10^{-10} sec. is a lower limit.

In conclusion the authors wish to express their appreciation to Dr. C. F. Fisk, who built the DuBridge and Brown amplifier and made some preliminary runs on the work herein presented.

Summary

1. An apparatus for studying the fluorescence of gases is described.

2. The ratio of absorbed to fluorescent intensity of acetone is a function both of incident intensity and of time of exposure. Only at very low intensities is a Stern–Volmer equation obeyed.

3. The fluorescence spectra of acetone and of biacetyl are identical at wave lengths longer than 5000 Å. The fluorescence in the blue, which alone appears when oxygen is present, is much weaker than the fluorescence at longer wave lengths and could not be photographed.

---

(21) Kohlrausch and Pongratz, *Ber.*, **67B**, 976 (1934).

(22) Porter, Ramsperger and Steel, THIS JOURNAL, **45**, 1827 (1923).

4. Small amounts of biacetyl greatly increase the fluorescence of acetone.

5. It is concluded that the fluorescent emitters are the same for both acetone and biacetyl, at least as regards the bands at 5000 Å. and longer wave lengths.

6. Mechanisms to account for these facts are advanced. An adequate explanation is based on a very probable deactivation of excited acetone molecules by biacetyl, the excited biacetyl being responsible for the fluorescence. However, fluorescence of the CH_3CO radical cannot be excluded.

The Absorption Spectrum of Biacetyl between 1500 and 2000 Å.

BY VICTOR R. ELLS

In connection with work on the spectroscopy and photochemistry of ketones it was thought advisable to study the absorption spectrum of biacetyl. This substance is formed during the photochemical decomposition of acetone[1] and is a possible product, along with other diketones, during the irradiation of ethyl methyl ketone. Since absorption coefficients of the ketones below 2000 Å. are far higher than in the near ultraviolet, it was hoped that the absorption spectrum might be used to detect even small amounts of biacetyl.

As would be expected the juxtaposition of two chromophoric groups causes a displacement of the absorption spectrum toward longer wave lengths. Thus in the near ultraviolet biacetyl vapor absorbs to 4670 Å.,[2] whereas acetone[3] and ethyl methyl ketone[4] show absorption to only between 3200 and 3300 Å. Below these absorption regions both biacetyl and the other ketones show a broad zone of transmission extending to below 2000 Å., where an intense absorption takes place.

Biacetyl shows bands with fine structure from 4670 to 4400 Å. at which point the bands become diffuse. Continuous absorption is observed below 2800 Å.[2] and extending to about 2500 Å.

Lardy[5] and Luthy[6] have investigated the spectra of biacetyl and of glyoxal, respectively, in hexane solution. In biacetyl four bands occur between 4512 and 4054 Å., a wide band at 2800 and another at 1950 Å. being observed also. Glyoxal between 4613 and 3119 Å. shows seventeen bands and in addition there are bands at 2800 and 1950 Å. The substitution of a CH_3 group for a hydrogen atom widens the narrow bands, reduces their number and increases the absorption coefficient.

Experimental

The biacetyl (Eastman) was fractionated several times before being introduced into the storage bulb, after which it was again fractionated three times at low pressures in the vacuum line. Calcium chloride was used as a drying agent and the boiling point of the fraction taken was 87–88°. The freezing point was approximately −4°, although no value is recorded in the literature. No vapor pressure data could be found, but the observed vapor pressures were about 0.01 mm. at −70°, 1 mm. at −30° and 13 mm. at 0°.

A quartz cell with relatively thin windows was interposed between the hydrogen discharge tube and the slit of the vacuum spectrograph to avoid introducing the biacetyl directly into the spectrograph. Thus an absorbing column about 15 cm. in length and vapor pressures from 0.01 to 15 mm. were used. The spectrograph has been described.[3] Ilford I plates were used.

The dispersion of the spectrograph with the setting used was found to be 8.48 Å. per mm. in the first order. The 1931.027 Å. line of C III and a number of the fourth positive bands of carbon monoxide were used[7] as wave length standards. Since a quartz cell was employed, the lower limit of observation was about 1550 Å.

Results

Twenty-six bands of biacetyl were found in all. These are listed in Table I, together with rough estimates of the intensities based on the pressure at which the bands appeared and their visually estimated intensities on the plates. The red edges of the bands appeared to be most sharp and are reported. Most of the bands were sufficiently

sharp so that the error should not exceed ten wave numbers, although a few of the more diffuse bands may not be accurate to better than 30 cm.$^{-1}$. Bands measured only once may be considered to be somewhat doubtful.

TABLE I

BIACETYL BANDS, 1600–2000 Å.

Wave length, Å.	Wave number cm.$^{-1}$	Relative intensities	No. times measured
1691.45	59121	75	8
1705.09	58648	50	8
1720.13	58135	20	2
1730.88	57774	40	8
1745.35	57295	100	9
1883.77	53085	2	3
1905.45	52481	3	5
1928.08	51865	4	3
1951.07	51254	12	11
1960.78	51000	1	1
1962.44	50957	4	5
1963.56	50928	4	4
1964.64	50900	4	4
1965.95	50866	5	8
1967.30	50831	1	1
1968.16	50809	3	1
1969.05	50786	3	1
1970.06	50760	4	3
1970.99	50736	8	8
1972.08	50708	6	12
1973.09	50682	12	12
1974.45	50647	12	15
1975.82	50612	2	3
1977.14	50578	2	2
1982.87	50432	1	1
1984.40	50393	1	1

One upper electronic state probably leads to all the bands in the table except the first five. These twenty-one bands are found in three regions, as are those from 50,634 to 53,119 cm.$^{-1}$ in ethyl methyl ketone[4] and those from 51,000 to 54,954 cm.$^{-1}$ in acetone (four regions). The bands present many similarities in all three compounds.

In biacetyl, as in the other two ketones, the structure is sharpest in the region of longest wave length and very diffuse in the other two.

From intensity considerations the 50,647 band is probably the origin of the system. Absorption is practically complete above 56,000 cm.$^{-1}$ at the optimum pressure for observing the bands from 50,600 to 54,000.

The prominent bands in the three regions referred to above are separated by about 1200 cm.$^{-1}$ as follows:

50,647 51,865 53,085
1218 1220

It is true that frequency differences very close to this seem to be found in other ketones,[8] but it is less clear with biacetyl whether this difference is significant, since it is possible to put five of the important bands in a progression using a frequency approximately half as great:

50,647 51,254 51,865 52,481 53,085
607 611 616 604

However, similarities to the spectra of the other ketones would indicate the 1200 cm.$^{-1}$ frequency to be characteristic of the upper state of the carbonyl group, especially since the bands 50,647, 51,865 and 53,085 belong in different regions.

The Raman spectrum of biacetyl is probably not known in detail, although Kohlrausch and Pongratz[9] have found the following frequencies (intensities in parentheses): 375 (0), 690 (2), 1275 ($^1/_2$), 1444 (0), 1725 (2), 2940 (3), 3023 ($^1/_2$). Frequency differences of 375 and 690 do not occur prominently, if at all, in the bands in Table 1. Therefore it is impossible to identify, even tentatively, any transitions from upper vibration levels in the ground state.

Some eight differences of approximately 220 cm.$^{-1}$ occur. This is rather low to be a fundamental frequency of either the upper or lower state and may possibly be ascribed to a difference between upper and lower state fundamentals. Further attempts at a vibration analysis seem inappropriate at present.

The first five bands in Table I doubtless involve a second upper electron state as do the bands 60,086 to 62,529 in acetone and 58,110 to 59,360 in ethyl methyl ketone. 1350 occurs twice and 475 occurs twice as frequency differences among these bands, but the significance of these numbers is uncertain.

Since a quartz cell was used, the spectrum below 1550 Å. was not investigated. In acetone Duncan[10] found a Rydberg series among the bands at shorter wave lengths, but such a series, if it exists, could not have been found in the present experiments.

As the pressure is increased continuous absorption appears at the shorter wave lengths studied and gradually spreads until it reaches 2000 Å. In this respect biacetyl somewhat resembles the other ketones.

(8) Henri, *Compt. rend.*, **199**, 849 (1934); **203**, 67 (1936); Eastwood and Snow, *Proc. Roy. Soc.* (London), **A149**, 434 (1935); see Noyes, *J. Phys. Chem.*, **41**, 81 (1937).

(9) Kohlrausch and Pongratz, *Ber.*, **67B**, 976 (1934).

(10) Duncan, *J. Chem. Phys.*, **3**, 131 (1935).

Certain of the bands of biacetyl occur, as would be expected, at longer wave lengths than similar bands for the other ketones hitherto investigated. Since absorption coefficients in the absorption regions below 2000 Å. are, generally speaking, very high, it probably would be possible to use these bands for a semi-quantitative as well as a qualitative estimate of the amount of biacetyl present along with acetone and ethyl methyl ketone.

In conclusion the author wishes to express his appreciation to Dr. W. A. Noyes, Jr., who suggested this problem.

Summary

The absorption spectrum of biacetyl vapor has been investigated with a vacuum grating spectrograph between 2000 and 1550 Å. Absorption regions are found which correspond in general to those in acetone and ethyl methyl ketone, although they are displaced to longer wave lengths as would be expected due to the juxtaposition of two carbonyl groups. A prominent frequency difference of about 1220 cm.$^{-1}$ is found in the upper state, although the presence of another difference almost exactly half as great renders the interpretation ambiguous. Certain bands occur at wave lengths sufficiently displaced from those in acetone and ethyl methyl ketone to permit them to be used for the identification of biacetyl in the presence of these other substances.

Phase Rule Studies of Soap Systems.
I. Applicability of the Phase Rule

By J. W. McBain, R. D. Vold and M. J. Vold*

The purpose of this introductory paper is to justify the application of the phase rule to soap systems.

It has been shown[1] that many colloid systems are formed spontaneously from their crystalloidal components, and exhibit properties which are independent of previous history and are solely dependent upon composition and temperature, and that they are thermodynamically stable in the same sense as are crystals or solutions of sugar or salts. It will be shown that therefore the phase rule in its usual form, ($F = C + 2 - P$), must apply to all thermodynamically stable colloid systems, without the introduction of any new variable.

Empirically, it has been found in many contributions since that of McBain and Burnett in 1922 that the behavior of systems of soap, water and electrolytes can be represented quantitatively on the usual Gibbs triangular diagram.[2] A large body of knowledge has been thus assembled and the work of previous authors[3] also has been found to fit into the same systematic description and analysis. The results have led to a greatly clarified understanding of the processes and phenomena of soap-boiling.

The same phases occur for sodium palmitate,[4] potassium laurate,[5] and potassium oleate.[6] The observations of temperatures at which phase changes occur and the analytical data on the composition of separated phases fit into the phase rule diagrams. Similar results have been obtained in experiments on the mixed fatty acids from coconut oil and in the experiments of Elford with commercial oils and fats on a full commercial scale. Ferguson and Richardson[7] likewise found that the phases of commercial soaps are the same as those in soaps from a single fatty acid.

It was an important finding,[2] confirmed by all subsequent work, that for practical purposes, apart from processes involving graining or salting out, the complex contents of the soap kettle may be regarded as a three-component system of soap, water and electrolyte.[7,8]

All this work together with the papers which presently are being communicated illustrates the utility of the phase rule in giving a comprehensive quantitative description of the behavior of soap systems. The very different methods used in these studies: namely, analysis of separated phases, visual observation of temperatures and concentrations at which phases appear and disappear, observations with the microscope and the polarizing microscope with heating stage,[9] vapor pressures, and dilatometer, are all in complete agreement.

The Phase Rule and Colloids

Theoretically, the phase rule may be regarded as an extension to chemistry of the algebraic principle that n equations are needed for a unique determination of n independent variables. In heterogeneous equilibria the variables are temperature, pressure and composition of the phases, and the relations between them are derived from the thermodynamic criterion of equilibrium that the chemical potential or partial molal free energy of each component must be the same in all phases throughout the system. The phases must be effectively homogeneous, uninfluenced by "capillarity," and in true equilibrium with each other.

No phase is homogeneous on an atomic or molecular scale, and the difficulty is often felt to be accentuated when colloidal particles are present. Büchner[10] has given a satisfactory answer by pointing out that heterogeneity has only a relative and not an absolute meaning and that heterogeneous systems are not necessarily two-phase systems. Even optically heterogeneous colloid systems become homogeneous in the Gibbsian sense if the volume element selected is large compared with the micelle instead of the molecule.

A colloid is thermodynamically a single phase only if its external properties such as vapor pressure, freezing point, distribution ratio, etc., etc., are solely and completely defined by temperature, pressure and composition. Although the effects of capillarity are explicitly excluded in the deduction of the phase rule,[11] yet since temperature, pressure and concentration in a stable reversible colloidal system coincidentally determine the capillary state of the system, there is no effect upon the application of the phase rule to external equilibria.[12]

Attainment of Equilibrium

It is a prerequisite for the legitimate application of the phase rule that true reversible equilibrium is attained and is thereafter independent of time. The same final state should be attainable from higher and lower concentrations or from higher and lower temperatures. Of course, the phase rule applies to reversible metastable equilibria as well, just as it applies to the solubility curve of anhydrous sodium sulfate or even of the slowly hydrolyzing substance ethyl acetate where hydrolysis is slow in comparison with the measurement. It is essential to show not only that the system has been brought into equilibrium but that this has not been displaced or distorted by the method of examination. Mere cooling of a soap system may introduce a phase which only slowly disappears again and may thus be misleading. This is one source of the experimental discrepancies which have been discussed at length in the German literature.[12]

Phases and Nomenclature in Soap Systems

Apart from false "equilibria," much of the denial of the applicability of thermodynamics to soap systems has arisen from the great confusion in the terminology employed in describing them, especially in translation. For clarity, therefore, the phases of soap systems will be listed.[13] It is helpful to refer to the two component diagram of Fig. 1, and to the schematic three component diagram, Fig. 2, where the corners represent soap, water and salt, respectively, and the composi-

Likewise, Kruyt and de Jong hesitate to give the name phase to the liquid layers separating out in colloid systems, rejecting the phase rule and terming the process "coacervation," the colloid richer liquid "coacervat" and the liquid poor in colloid "liquide d'équilibre"; H. G. Bungenburg de Jong, "La Coacervation, les Coacervats, et leur Importance en Biologie," Tomes I and II, Actualités Scientifiques et Industrielles No. 397, Herman et Cie., Paris, 1936.

(13) For full descriptions, see J. W. McBain in Alexander's "Colloid Chemistry," Vol. I, 1926, Chapter 5, p. 138; J. W. McBain and M. C. Field, THIS JOURNAL, **55**, 4776 (1933). For examples of German terms, see E. L. Lederer, "Kolloidchemie der Seifen," Th. Steinkopff, Dresden, 1932, p. 299.

tions are proportional to the distances from these corners.

1. Clear Isotropic Solution. Nigre. Lye.—It is seen from Fig. 1 that there is only one body of isotropic solution which at sufficiently high temperatures embraces all proportions of soap and water, as they are completely miscible above the true melting point of the soap. Nevertheless in Fig. 2, which refers to a single temperature, it is evident that there is a region, which may be called the isotropic bay region,[14] where two portions of the isotropic solution may exist in equilibrium with each other as separate liquid phases. The one containing much salt with but little soap is called lye, or "Unterlauge," or "dünne Lauge." The other containing a moderate concentration of soap is the soap boilers' nigre, or "Leimniederschlag," "schwärzliche Flüssigkeit," "Leimseife," or "Leim." The isotropic solution in general is commonly called soap solution, "isotrope Seifenlösung," "isotrope homogene Lauge," or "Seifensol."

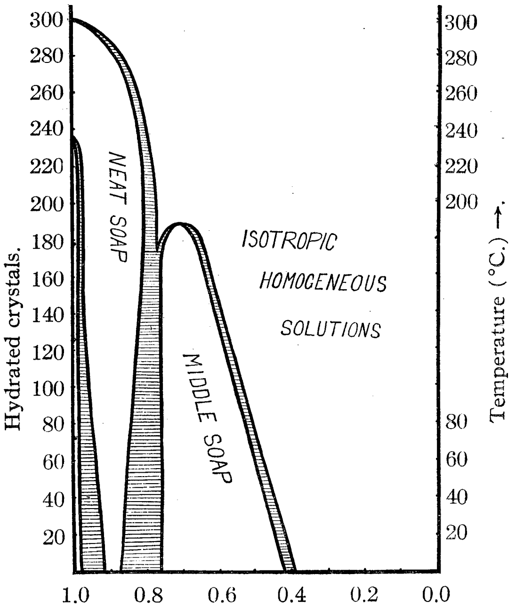

Fig. 1.—Equilibrium diagram for the two-component system potassium oleate–water (from McBain and Elford[6]).

In the middle of the isotropic region some soaps become highly viscous or set to an isotropic jelly.[15] This is not a separate phase and has no separate boundary. The jelly is clear, transparent and elastic, and may flow slowly. It is unfortunate that the term "Seifen-Gallerte" has been employed to designate a wholly different opaque mixture of phases leaving no German term to indicate the true soap jellies. Soap jellies,[15] like middle soap,[4] were previously unknown.

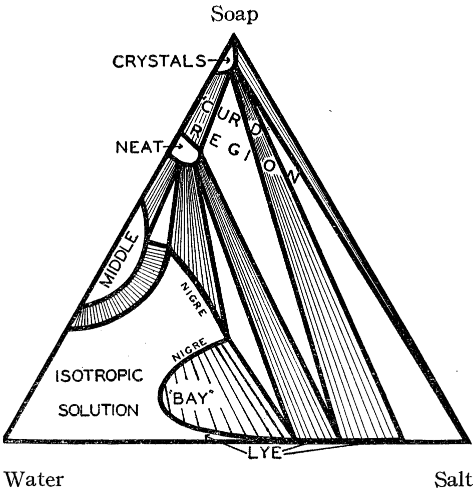

Fig. 2.—Schematic equilibrium diagram for a system soap–salt–water near 100°.

2. Neat Soap.—Neat soap is a doubly refracting clear or translucent liquid crystalline soap phase. It includes the soap boilers' fitted and settled soap (while hot), or "geschliffene Kernseife," "Kernseife auf Leimniederschlag," "abgesetzte Kernseife," "klare Seife," or "glatte Kernseife." Curd soap, or "Kernseife auf Unterlauge," is, when hot, the same phase, neat soap; except where the concentration of electrolyte is so high as to cause separation of curd fibers, which anyway appear on cooling (see below).

3. Middle Soap.—This is another conic anisotropic liquid or clear doubly refracting liquid crystalline phase, immiscible with neat soap, and of lower soap content. It sometimes has been mistakenly confused with "Leimniederschlag" or nigre which is wholly different.

4. Crystalline Phases. A. Lamellar Crystals.—These very thin six-sided transparent colorless crystals, giving a highly developed X-ray pattern, occur sometimes with sodium soaps, or sediments of acid soaps, but more frequently with potassium, ammonium and hydrogen soaps, forming the fig in soft soaps. Since they gen-

---

(14) A similar bay is found for gelatin, F. Kellogg and J. W. McBain, *J. Gen. Physiol.*, **12**, 1 (1928). A diagram rather similar to Fig. 2 is also obtained for serum globulin with pseudoglobulin and euglobulin occupying the positions of neat and middle soap; J. W. McBain and E. Jameson, *Trans. Faraday Soc.*, **26**, 768 (1930).

(15) M. E. Laing and J. W. McBain, *J. Chem. Soc.*, **117**, 1506 (1920); *Kolloid-Z.*, **35**, 18 (1924).

erally are not found as a stable phase in the case of sodium soaps they do not appear on any of the phase-rule diagrams in this or the following paper.

B. Curd Fibers.—This second crystalline phase, showing with X-rays[16] a three-dimensional spacing, is the same as the *curd phase* of Vold and Ferguson.[17] It is the common crystalline form of sodium soaps and is the phase which is referred to as hydrated crystals on many of the diagrams. They are white fibers, "Kernfasern," often several centimeters long, but usually consisting of bundles of fibers which are ultramicroscopic except in length. They have been photographed in the ultramicroscope by Zsigmondy and Bachmann[18] and by McBain, Darke and Salmon.[19] Curd fibers may be anhydrous but usually contain water. It is not certain whether they form definite hydrates or are of continuously variable composition. Although submicroscopic fibers may be present, this crystalline phase is sometimes granular in appearance rather than fibrous.

Soap Systems: Multiphase Equilibria

According to the phase rule, in any three component system, three liquid or solid phases may coexist at any one temperature, with vapor, as is shown by the triangles within Fig. 2, whose corners represent the phases in contact; at least one of these four phases will be of continuously variable composition or concentration with change in temperature. Ostwald and Erbring[12] have mistakenly regarded the coexistence of three condensed phases over a temperature range as a disproof of the applicability of the phase rule. The coexistence of pairs of phases, both of variable composition at any one temperature, is likewise shown in Fig. 2 in the areas shaded with tie lines whose ends connect the phases in contact. Five phases of fixed composition are required for any invariant three component system.

Soap curd, or simply **curd** (not to be confused with commercial curd soap boiled on lye, especially not with curd fibers) is a mixture of phases which occurs in the curd region indicated on Fig. 2, and consists of a white, more or less opaque, mass of solid containing curd fibers, with or without solution or liquid crystalline material. Dry curd consists entirely of curd fibers. Curd has been variously designated "geronnener Kern," "kristallines hydratisiertes Gerinnsel," "Gerinnsel," "Koagel," "Kernseife," or "Seifengel"; it is not "Kernseife," which is neat soap. The formation of curd has been called "Erstarrung" or "Gelatinierung," which has been confusing because gelatinization is usually reserved for the formation of true jellies.

Curiously, McBain's suggestion that soap curd may consist of a mixture of definite hydrates of crystalline curd fibers has been regarded[12] (see also Lederer[13]) as evidence that the phase rule does not apply to soap systems. It is supposed that the water content of curd fibers varies continuously, with the *non sequitur* that McBain's suggestion leads to the conception of curd fibers as consisting of an infinite number of phases. The correct alternative is a single phase of continuously variable composition. The confusion may be due to failure to distinguish between curd and curd fibers, the former being the heterogeneous masses indicated in Fig. 2 in the curd region and the latter consisting either of a few definite crystalline hydrates or of one or two series of crystals containing variable amounts of water, as in the zeolites.

Summary

1. It is shown that the phase rule is applicable in its usual form to thermodynamically stable colloid systems in true equilibrium.

2. It is pointed out that the phase rule does in fact describe the actual behavior of soap systems.

3. Since reported discrepancies appear to have been due to misunderstanding of the phases and systems discussed, these are listed and defined.

Phase Rule Studies of Soap.
II. The System Sodium Laurate–Sodium Chloride–Water

By J. W. McBain, G. C. Brock, R. D. Vold and M. J. Vold

In the preceding paper a review has been made of existing phase rule studies of soap systems. This paper, extending the work begun by one of us in collaboration with A. J. Burnett[1] adds the system sodium laurate–sodium chloride–water to the list of those whose behavior has been investigated over a wide range of temperature and composition. In the present work emphasis has been placed on verifying the strict applicability of the phase rule and on ascertaining the experimental conditions necessary for establishing true reversible equilibrium.

Experimental Procedure

Three different standard methods have been employed. The first, the synthetic method, consists of observing the temperatures at which phase changes occur in systems of known composition. The second, the delimiting method, is an isothermal procedure having the consequent advantage that observations on the same tube can be made at intervals over a period of time. It consists of preparing, by trial and error, pairs of systems whose compositions lie very close together, one on each side of the boundary to be determined, and placing the boundary between them. The third method consists of analyzing the separated phases.

The sodium laurate used was a special preparation made for us by Kahlbaum (it contained less than 0.3% excess fatty acid). The soap was dried in an air oven at 105° from time to time and periodic checks made of its water content, which was always taken into account in making up tubes. Kahlbaum dry sodium chloride "for analysis" was used throughout. The water was freshly distilled, and in the case of dilute systems special precautions were taken to exclude carbon dioxide.

In all cases the calculated quantities of salt, water and soap, in the order named, were weighed into heavy-walled Pyrex glass tubes which were sealed off immediately to prevent changes in composition.

For application of the synthetic method the following procedure was adopted. The tube was first heated to a temperature such that its contents formed a homogeneous isotropic solution. A "Mazola" oil-bath was employed for temperatures up to 230°. Temperature was measured by means of a calibrated mercury thermometer. Above 230° an electrically heated oven provided with mica windows was used. Temperature was measured by means of a calibrated thermocouple pyrometer. Then the tube was allowed to cool slowly and the temperature (T_i) recorded at which the first turbidity appeared due to the formation of droplets of a second phase. Finally, the tube was cooled to room temperature and the temperature (T_c) recorded at which, on slow reheating, the last trace of crystal or curd fibers just disappeared.

For application of the delimiting method, the following procedure was found to be most desirable. Spurious results that may be obtained by superficially innocent variations of this procedure are described later. First the tube was heated to homogeneity as described under the synthetic method. It was then cooled to the desired temperature and allowed to stand for a few days, undisturbed except for periodic gentle mixing of the separated phases. The number and nature of the phases present was determined by inspection.

For the analytical work larger samples were used; consequently, because of the increased danger of explosion, these tubes were not heated to homogeneity. The tubes were allowed to stand at 90° for three months. Since the results obtained were in good agreement with those obtained by the other two methods, we are confident that equilibrium was reached. The analyses were carried out in the following manner. A tube was removed from the thermostat and quenched by immersion up to the level of the soap sample in a salt–ice–water freezing mixture. Each of the separated phases was analyzed for soap content by decomposition with a known amount of sulfuric acid, extraction with ether and titration with sodium hydroxide solution of the weighed lauric acid recovered from the ether extract, as well as back titration of the acid in the aqueous layer. Salt content was determined by titrating, with silver nitrate, the neutralized aqueous layer from which the fatty acid had been extracted.

The System Sodium Laurate–Water

In the two component system sodium laurate–water, the observations of temperatures at which phase changes occur can be plotted directly on a temperature–composition diagram. The data obtained are recorded in Table I and Fig. 1. Curve ABCD is drawn through points representing the upper temperature limit of existence of liquid crystalline soap phases (T_i). Curve EFGHDJO is drawn through points representing the upper temperature limit of the existence of crystalline soap (T_c).

At all points above the curve ABCDJ the soap system consists of homogeneous isotropic solution. In the composition range from F to G and also that from H to D, the temperature of disappearance of crystalline soap is constant. Consequently, by direct application of the phase rule, four phases are present in each of these regions. These phases are crystalline soap, middle soap,

neat soap and vapor in the case of region FG; and crystalline soap, middle soap, isotropic solution and vapor in the case of region HD.

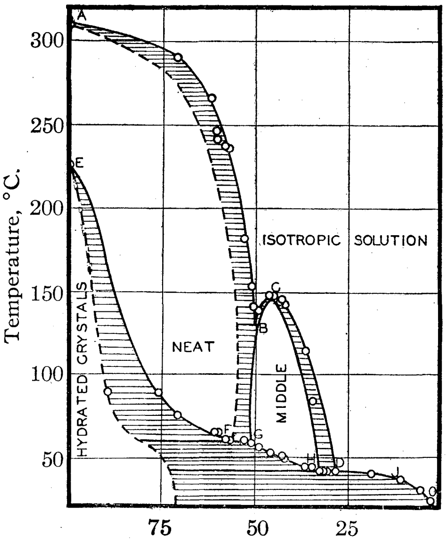

Fig. 1.—The system sodium laurate–water.

These observations make the further course of the diagram clear even though the boundaries that have not been quantitatively determined throughout are drawn with dashed lines. No conclusion concerning the constitution of the crystalline form or forms can be drawn from the work included in the present communication, but it is a definite result from vapor pressure studies at 90° (which will be communicated shortly) that it does not consist of anhydrous sodium laurate. Further vapor pressure measurements designed to ascertain the number and nature of the crystalline phases are now under way in this laboratory. Meanwhile, to facilitate interpretation of the diagram, a tentative boundary has been drawn in (dotted line, Fig. 1).

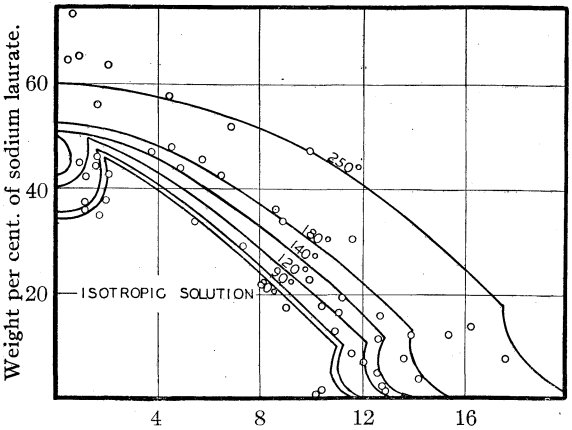

Fig. 2.—The boundaries of the field of aqueous isotropic solutions at definite temperatures (curves), as deduced from T_i determinations (circles) made at intermediate temperatures.

The phase behavior of sodium laurate and water is entirely similar to that of other soap systems.[2] The nature of the phases and the various equilibria have been described in these earlier communications. At point C middle soap is in equilibrium with an isotropic solution of the same composition (NaL + 14.4 H_2O, or 3.85 N_W solution). This point does not indicate compound formation; it has the same nature as a maximum point of

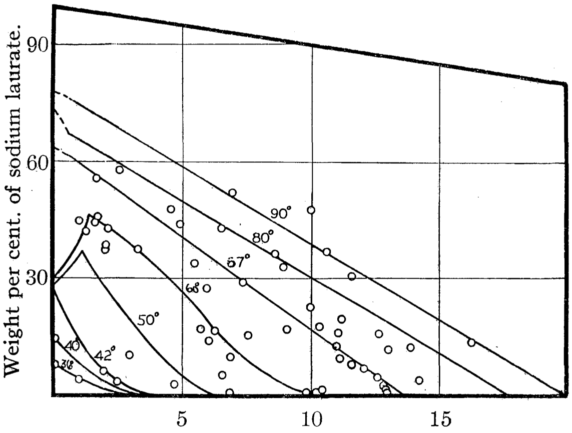

Fig. 3.—The limiting solubilities of hydrated crystalline soap at definite temperatures (curves), as deduced from the T_c determinations (circles) made at intermediate temperatures.

Table II gives the temperatures, T_i, at which, on cooling, tubes having the indicated composition first separated a second phase. The table has been subdivided according to the nature of the separating phases. The data in this table determine the boundary of the field of isotropic solution except at temperatures and compositions such that the isotropic solution is in equilibrium with a crystalline soap phase. In Fig. 2 all these data have been plotted on a single triangular diagram.[4] The number of points is sufficient to permit drawing in the isotherms. Since such a procedure in-

---

(3) A. Findlay, "The Phase Rule," Longmans, Green and Co., New York, N. Y., seventh edition, 1931, p. 120.

(4) The right triangle used in place of the more customary equilateral triangle retains all the geometrical properties of the latter except that the water content is derived by subtracting from 100 the sum of the percentages of soap and salt.

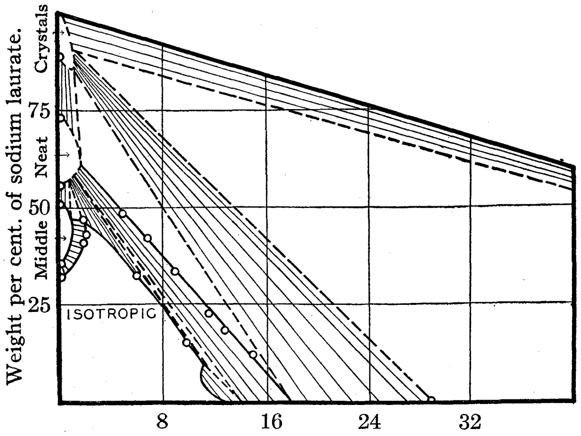

Fig. 5.—The system NaL–NaCl–H_2O: equilibria at 80°.

volves a certain degree of arbitrary choice, as does any purely graphical method, a uniform method of extrapolation was devised and used in the construction of the isotherms appearing in Fig. 2. A given isotherm is made to pass as closely as possible through all points obtained by linear interpolation or extrapolation from the compositions of pairs of points found to lie on the same boundary, although at somewhat different temperatures. For example, as is indicated in Fig. 2, a tube containing 12.5% soap and 11% salt separates neat soap at 93°; a tube containing 17% soap and 9.1% salt separates neat soap at 71°; consequently the neat–nigre boundary at 80° passes through the point 15.2% soap, 9.9% salt. Even where the experimental points are quite widely separated, the isotherms can be drawn in correctly. For example, it can be seen that a nigre–lye bay must exist in this system even at 250°.

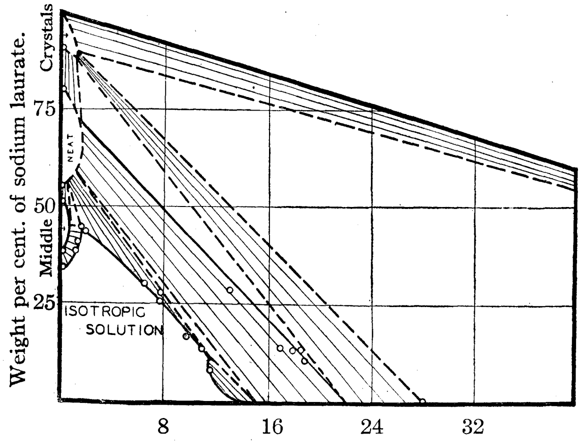

Fig. 6.—The system NaL–NaCl–H_2O: equilibria at 100°.

The course of the neat–nigre boundary at salt contents up to 9%, which is accurately determined by the experimental points, precludes the possibility of nigre's containing, for example, 18% each of salt and soap existing in equilibrium with a neat soap of any composition whatsoever, since the line corresponding to such an equilibrium cannot reach the soap axis below 100% soap without cutting across the established field of homogeneous solution.

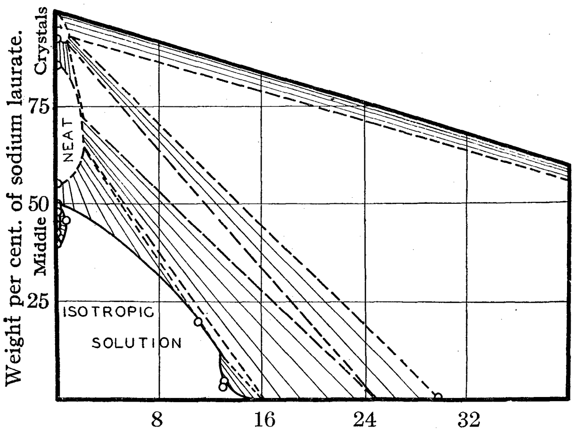

Fig. 7.—The system NaL–NaCl–H_2O: equilibria at 140°.

Table III gives the temperatures, T_c, at which, on slow heating, the last trace of crystal just dissolves in systems of indicated composition; the points have been sorted according to the number and nature of the phases remaining. All these data have been plotted on a single triangular diagram in Fig. 3. The isotherms are of three types. Below 42° the solubility isotherms are identically the isotropic solution boundaries. Above 61° the

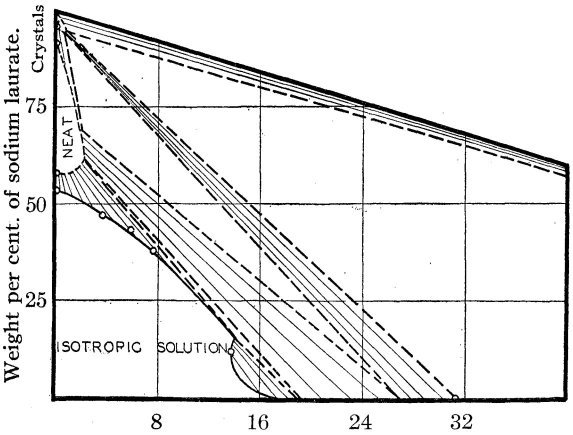

Fig. 8.—The system NaL–NaCl–H_2O: equilibria at 180°.

solubility isotherms trace out the neat–lye edge of the triangle, hydrated crystal–neat soap–lye, and a part of the neat soap boundary. At temperatures between 42 and 61° the crystalline soap phase dissolves to form either middle soap or middle soap and isotropic solution. The isotherms were constructed in the same manner as those of Fig. 2.

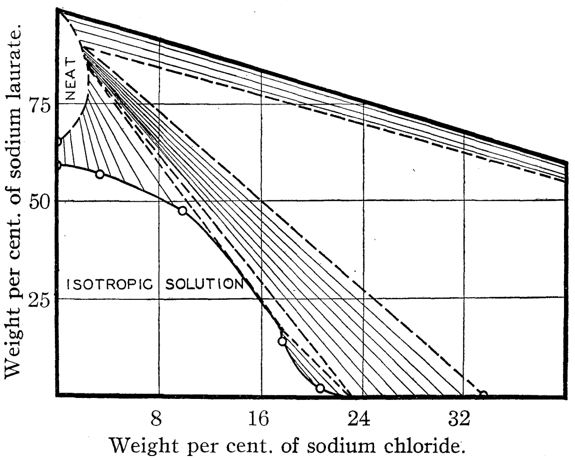

Fig. 9.—The system NaL–NaCl–H_2O: equilibria at 250°.

On the basis of the data derived from Tables II and III, the diagrams appearing in Figs. 4 to 9 were constructed. Boundaries that have not been delimited experimentally are dotted in. The authors wish to emphasize the tentative nature of the boundaries given for the crystalline soap region. They are based entirely on analogy with the course of this boundary in the case of sodium palmitate at 90°[5] and the determination by McBain and Salmon[6] of the water content at the apex of the triangle, salt–lye–crystalline soap, at 90°.

The phase behavior of the system at 90° is given in Fig. 10. For this one temperature, the exact courses of the crystalline soap boundary and upper neat soap boundary are the only uncertainties. The additional data available at this temperature are summarized in Tables IV and V. The results of the delimiting experiments fix the position of the triangle, neat–nigre–lye. They also substantiate the validity of the neat–nigre boundary obtained by the synthetic method. The analytical results confirm the correctness of the composition of lye in the triangle, neat–nigre–lye, found using the delimiting method, and also establish the directions of the tie lines in the neat–lye region. The compositions of the two phases and that of the total system lie in each case on a straight line, as is required if the analyses are accurate; the slope of

[a] These points lie on the tie-lines but usually not on the neat soap boundary because of incomplete separation of phases. [b] This tube contained 3 layers, neat, nigre and lye. Only the lye layer could be obtained free from contamination. In addition to salt, it was found to contain only 0.2% soap.

the tie lines is consistent with the slope of the neat–lye edges of the triangles, neat–nigre–lye and neat–crystalline soap–lye.

The work at 90° shows how well results obtained by entirely independent experimental methods fit together in complete harmony on a standard phase rule diagram, and gives further weight to the assertion[7] that the phase rule does in fact apply to soap systems.

Experimental Tests of the Applicability of the Phase Rule.—We have emphasized[7] that the applicability of the phase rule to any system is conditioned by whether or not the state of the system is completely fixed by temperature, pressure and composition, independent of time and of the previous history of the particular specimen examined. The experiments of Ostwald and Erbring,[8] of Lester Smith,[9] and of Ferguson,[10] as well as some results obtained in this Laboratory, had led to the supposition that such a reversible equilibrium might not be realizable in all soap systems. The work of Smith was concerned with metastable equilibria that exist in systems supersaturated with respect to curd fibers. Both Ostwald and Erbring and Ferguson were concerned with the nigre–lye bay and the triangle neat–nigre–lye at temperatures around 90°. The following experiments also deal with these latter regions.

Experiment 1.—Salt, water, and soap were weighed into tubes in the order named, the salt being all dissolved before the soap was added. The tubes were then sealed off, mixed thoroughly and suspended in a thermostat at 90°. After three hours, during which they were twice mixed gently, the nature of the phases present was entirely in accord with the equilibrium diagram (Fig. 10). The tubes were then allowed to stand undisturbed, except for periodic momentary removal from the thermostat for observation, for a period of three weeks. During this period the volume of the nigre layer in some systems lying within the triangle changed gradually, and a layer of neat soap formed on the surface of all systems lying within the nigre–lye two phase region. Their final condition could not be made to harmonize with any equilibrium phase diagram. Hence further experiments were planned to elucidate the behavior.

Experiment 2.—Our diagram for the phase behavior of the system sodium laurate–sodium chloride–water at 100° showed that Tube No. 14 (Table VI) should consist of homogeneous nigre. At 90° it consisted initially of nigre over lye and had acquired a small surface layer of neat soap on standing for three weeks. It was found that the neat soap layer persisted for at least a day at 100°, but that it could be destroyed by gentle mixing with the nigre and, once destroyed, did not form again at 100°.

Experiment 3.—The lesson of Experiment 2, that the highly viscous neat soap, once formed, can persist over long periods, suggested that the changes observed in Experiment 1 might have been due to the formation of a small amount of neat soap from nigre in the brief interval during which the tubes were removed from the thermostat for observation, with the gradual accumulation into a visible layer of the neat soap formed during successive observations. All tubes were therefore subjected to periodic gentle mixing carried out with the tubes out of the thermostat for not longer than ten seconds. The neat soap layers that had formed disappeared, and all the tubes returned to their original condition. No further change in the nature or relative volumes of the phases took place over a period of ten days.

It appears that neat soap forms easily from nigre, and disappears only with difficulty. This single simple fact may be in large measure responsible for the results reported above,[8,10] to the effect that variations with time occur and that results of analysis of separated phases are not in accord with the boundary determined by the delimiting method.

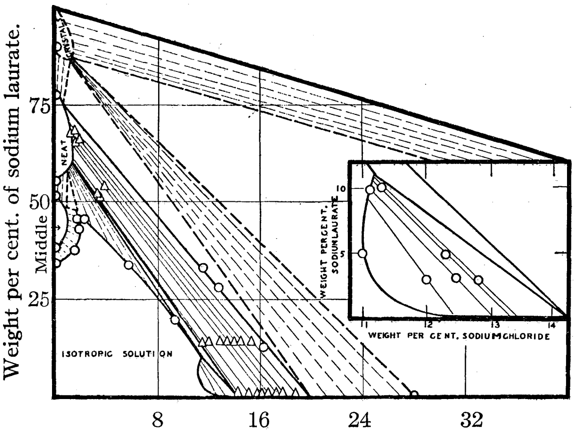

Fig. 10.—The system NaL–NaCl–H_2O: equilibria at 90°. (○), Points derived from the data of Tables I, II and III. (△), Points from Table V. Insert: the nigre–lye bay. Tie lines plotted from Table VI.

Experiment 4.—The technique described in Experiment 3 as "gentle mixing" was adopted primarily to minimize the formation of foam. However, the final equilibrium state is completely independent of the mechanical treatment of the sample as long as adequate mixing is achieved, as is proved by the following result. Gentle mixing was replaced by violent vertical shaking which produced complete emulsification of the separated phases in each other and filled the tubes with a macroscopically homogeneous foamy mass. Although there were considerable differences in the rates of settling out of different phases, every tube returned within twenty-four hours to the same state[11] as

[11] In tubes such as No. 14 containing nigre nearly saturated with respect to neat soap, the foam proved very persistent. When it did finally collapse, a small ring of neat soap was deposited on the glass above the nigre meniscus. This trace of neat soap could be dissolved in the nigre by patient gentle agitation.

was reached under "gentle mixing" conditions both with respect to the phases present and their relative volumes.

Experiment 5.—It was demonstrated that in every tube (23 in all) the same final state was reached on cooling to 90° from such a temperature (160°) that the contents had formed a single homogeneous isotropic liquid, as was reached on heating to 90° from room temperature.

Discussion

The isothermal diagrams shown in Figs. 4 to 10 are for representative temperatures over the complete range from 60° to the melting point of anhydrous sodium laurate. Similar diagrams at any desired temperatures could be drawn on the basis of the data given in Tables II and III. The changes in phase behavior that occur as the temperature is raised have been described fully[2a] for the case of sodium palmitate. The behavior of sodium laurate is entirely similar as can be seen directly from the diagrams.

In experiments 1 to 5 the fact that the number and relative volumes of the separated phases was determined only by temperature and composition was regarded as sufficient proof of the applicability of the phase rule to this portion of the system. However, the measurements of relative heights of the different phases can be used in an approximate calculation verifying in further detail the conformity of the observed behavior to the requirements of the phase rule.

In the two phase "bay" the relative weights of the nigre and lye are inversely proportional to the distances measured along the tie line from the point representing the total composition of the system. Consequently, since the phases have nearly the same density, the relative volumes of nigre and lye can be used to deduce the direction of the tie lines in this region. Systems no. 14 and no. 23 happen to lie on nearly the same tie line. That the relative volumes of nigre and lye are in accord with the number calculated from the delimiting curve can be taken as verification of conformity with the requirement of the phase rule that systems lying on the same tie line must separate into phases of the same composition. An enlarged section of the "bay" is inserted in Fig. 10, and the numerical data on which the tie lines are based appear in Table VI.

Table VI

[a] The relative volumes of the phases were estimated by measuring their heights in the tube.

From any point in a three-phase triangle, such as neat–nigre–lye, the relative weights of the three phases can be calculated from the compositions of the corners. Since the neat–nigre–lye triangle is very narrow, the values of the relative weights are extraordinarily sensitive to very small changes in composition. Nevertheless, these calculated relative weights are in accord within the limits of experimental error (±0.1% in salt content) with the relative volumes observed, as can be seen in Table VII.

[a] The relative volumes of the phases were estimated by measuring their heights in the tube.

[b] The compositions of the triangle corners are (a) neat: 60.0% sodium laurate, 1.50% sodium chloride, (b) nigre: 11.15% sodium laurate, 11.15% sodium chloride, (c) lye: 0.20% sodium laurate, 14.07% sodium chloride.

Summary

1. Diagrams have been constructed showing the phase behavior of the two component system, sodium laurate–water, and of the three component system, sodium laurate–sodium chloride–water, at various representative temperatures from 60° to the melting point of anhydrous sodium laurate (310°). Data are tabulated that make possible construction of the diagram at any intermediate temperature.

2. Results obtained by synthetic, delimiting and analytical methods are in quantitative agreement.

3. It has been shown experimentally that true reversible equilibrium independent of time is reached in this system, and that this equilibrium is described exactly by the phase rule.

Kinetics of the Pyrolysis of Isobutyl Iodide

BY J. LESLIE JONES

This work concerns the kinetics of the thermal decomposition of gaseous isobutyl iodide in the temperature range of 550 to 600°K. Jones and Ogg[1] investigated the pyrolysis of *n*-propyl iodide and *n*-butyl iodide in the temperature range of 584 to 627°K. They found that the rate-determining step could be represented in the case of *n*-propyl iodide by the equation

$$-\frac{d(C_3H_7I)}{dt} = k(C_3H_7I)(I_2)^{1/2} \qquad (1)$$

The kinetics of the decomposition of the *n*-butyl iodide was qualitatively the same but could not be treated quantitatively. The same authors[2] found that the rate of disappearance of isopropyl iodide was governed by a unimolecular rate expression

$$-\frac{d(C_3H_7I)}{dt} = k(C_3H_7I) \qquad (2)$$

Ogg[3] studied the thermal decomposition of gaseous *s*-butyl iodide in the temperature range 511 to 549°K. He found that the results were best fitted as a combination of a unimolecular reaction plus an iodine catalyzed decomposition of the iodide

$$-\frac{d(C_4H_9I)}{dt} = k_1(C_4H_9I) + k_2(C_4H_9I)(I_2)^{1/2} \quad (3)$$

In view of the varying rate determining equations found for the various homologs, it seemed profitable to investigate additional members of the series with the view of correlating the possible mechanisms involved in the several decompositions. The possibility of certain reactions of free radicals has been strengthened by this generalization of mechanisms. Much evidence indicates that the dissociation energy of the C–I linkage is approximately equal to the activation energy of the above unimolecular reaction,[4] *e. g.*, 43,000 cal.

Experimental Section

The isobutyl iodide employed was an Eastman product. It was dried over calcium chloride and phosphorus pentoxide, then distilled *in vacuo*. The product remained colorless.

The apparatus and procedure employed were described in a previous publication.[1] A slight change was made in this apparatus, substituting a small bore greased stopcock for the Bodenstein greaseless valve. The capillary tubing leading out of the thermostat to the stopcock was heated electrically to prevent condensation of iodine. There was apparently no effect on the rate of decomposition of the alkyl iodide due to this change in apparatus.

Homogeneity of the Thermal Decomposition.—In order to test the homogeneity of the reaction the surface–volume ratio of the system was changed. The major number of experiments were carried out in a 500-cc. Pyrex bulb. Two sets of rate measurements were made in a 280-cc. Pyrex bulb packed with Pyrex glass tubing. The bulbs had surface–volume ratios of 0.63 cm.$^{-1}$ and 8.8 cm.$^{-1}$, respectively. No increase in the rate of reaction was found for the experiments carried out in the packed bulb. As will be shown later, the rate-determining step in the decomposition is of the one-half order with respect to iodine; therefore the agreement of the rate constants for the packed bulb with those in the unpacked bulb indicates the absence of appreciable wall reaction. This result is in agreement with the investigations previously cited for the homologous alkyl iodides.[1,3]

Experimental Results

Nature of the Over-all Reaction.—Glass and Hinshelwood[5] made two runs on the decomposition of isopropyl iodide and analyzed the products of complete reaction. They found that the reaction proceeded in accordance with the equation

$$2\,C_3H_7I \longrightarrow C_3H_8 + C_3H_6 + I_2 \qquad (4)$$

This was proved by a determination of the iodine formed in the reaction and an analysis of the permanent gases. The ratio of final to initial pressure, P_∞/P_0, was 1.54 at 351° and 1.45 at 301°. The ratio of P_∞/P_0 was 1.47 for *s*-butyl iodide, 1.55 for *n*-propyl iodide and 1.49 for isopropyl iodide. The present work yielded 1.55 as the value of P_∞/P_0 for isobutyl iodide. There was no apparent trend of the ratio with temperature, although it was difficult to determine accurately the values of P_0 at the highest temperatures employed.

No gases were formed which were not condensable in liquid air, thus eliminating the possibility of appreciable amounts of methane and hydrogen as products. The amount of iodine formed on complete decomposition was determined by two methods which checked with the above equation. The first method was the direct titration of the

iodine formed while the second involved the condensation of all products in the side-arm of the reaction vessel by liquid air, then allowing the side-arm to warm to room temperature during evacuation of the reaction vessel. Thus the butylenes and butanes were removed from the vessel, but the iodine, due to its low vapor pressure, remained condensed in the side-arm. The stopcock was closed and the iodine vaporized. Various experiments were frozen out before completion and tested for hydrogen iodide. In most cases none was found, but a few per cent. at most. If the reaction mixtures were allowed to stand for several hours after practical completion, hydrogen iodide formed to the extent of 5 to 10% of the iodine.

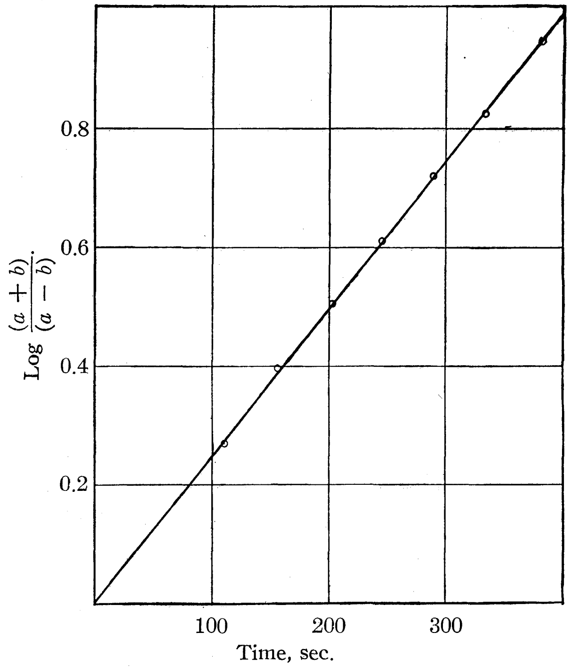

Fig. 1.—Run 24, P_0 = 42.0 mm. T = 319.5°.

All evidence points to the same over-all reaction for the decomposition of *n*-propyl iodide, isopropyl iodide, *n*-butyl iodide, *s*-butyl iodide and isobutyl iodide. This is quite remarkable in view of the fact that the rate determining step varies from case to case.

The Rate-Determining Step of the Thermal Decomposition of Isobutyl Iodide.—A rate expression fitting the data was obtained by testing various empirical equations which seemed likely. The data obtained fitted most closely the simple expression

$$-\frac{d(C_4H_9I)}{dt} = k(C_4H_9I)(I_2)^{1/2} \qquad (5)$$

The pressure of isobutyl iodide at any time t was given by

$$(C_4H_9I) = \frac{1.55\ P_0 - P_t}{0.55} \qquad (6)$$

and in the absence of initial iodine concentration

$$(I_2) = \left(\frac{0.50}{0.55}\right)(P_t - P_0) \qquad (7)$$

if it was assumed that all iodine was present as butyl iodide or free iodine. On integration and evaluation of the integration constant, the rate constant k was given by

$$k = \frac{1}{0.953(0.55)P_0^{1/2}t} \ln \left\{\frac{(0.55P_0)^{1/2} + (P_t - P_0)^{1/2}}{(0.55P_0)^{1/2} - (P_t - P_0)^{1/2}}\right\} \qquad (8)$$

The rate constants were determined by plotting the value of the logarithmic factor of equation (8) against the time. However, the slope of the line was not constant initially, generally being greater over the first 10%. A typical example is given in Fig. 1, where a well-fitting straight line was obtained after the first 10% decomposition. It was noted that the slope of the initial section of the curves fell off more rapidly with increasing temperature and in the majority of experiments well fitting straight lines were obtained after not

[a] Runs in packed flask.

more than 10% decomposition. The ordinate intercepts tended toward zero with increasing temperature, indicating that the initial rate determining step has a lower activation energy than the slow reaction predominating after 10% decomposition. Those experiments at the higher temperatures and pressures had zero intercepts. There was no definite trend to the values of k with increasing initial pressure. The experimental values of k are listed in Table I. All results have been included with the exception of the first experiment.

To obtain the activation energy for the rate-determining step, the term (log k) was plotted against $1/T$ and the best fitting straight line drawn through the experimental points (Fig. 2). The activation energy was 37,800 cal./mole with an estimated accuracy of ±2000 cal./mole.

Discussion

As in the case of n-propyl iodide the rate-determining expression (5) may be written as

$$-\frac{d(C_4H_9I)}{dt} = k_1K_{I_2}^{1/2}(C_4H_9I)(I) \qquad (9)$$

where K_{I_2} is the equilibrium constant for the dissociation of iodine. Two probable mechanisms based upon equation (9) can be rejected as contradictory to experimental facts. The mechanisms are

MECHANISM (a)

$C_4H_9I + I \longrightarrow C_4H_8I + HI$ (slow) (a-1)
$C_4H_8I \longrightarrow C_4H_8 + I$ (a-2)
$C_4H_9I + HI \longrightarrow C_4H_{10} + I_2$ (a-3)
$2I + M \longrightarrow I_2 + M$ (a-4)

MECHANISM (b)

$C_4H_9I + I \longrightarrow C_4H_9 + I_2$ (b-1)
$C_4H_9 + I_2 \longrightarrow C_4H_8 + HI + I$ (b-2)
$HI + C_4H_9I \longrightarrow C_4H_{10} + I_2$ (b-3)
$2I + M \longrightarrow I_2 + M$ (b-4)

In each case these mechanisms are intended to represent the main reaction occurring after about 10% decomposition of the alkyl iodide. In each mechanism reactions (a-1) and (b-1) are the slow rate-determining steps, accounting for the dependence of the experimental rate upon the square root of the iodine concentration.

Consideration of reaction (a-3) or (b-3) indicates that both of these mechanisms are probably invalid. Ogg[4] studied the reaction for the case of methyl, ethyl and n-propyl iodides. He found that the rate of reaction decreased in going from the ethyl iodide to the n-propyl iodide, hence the rate of reaction in the case of isobutyl iodide would be slower. If Ogg's value of the bimolecular constant (his k value) is corrected by a factor of 10^{-1}, the error arising in conversion of the concentration units from mm. to (mole/cc.), the value of the absolute rate of the reaction (a-3) or (b-3) may be calculated. Since the rate of the reaction for the case of ethyl iodide is approximately 0.43 that of n-propyl iodide, it will be assumed that the rate of the corresponding reaction for isobutyl iodide is 0.43 the rate of the reaction for n-propyl iodide. At 550°K. the rate constant for n-propyl iodide is 37.6 (mole/cc.)$^{-1}$ sec.$^{-1}$. Assuming an alkyl iodide concentration of 40 mm. and a hydrogen iodide pressure of 10 mm., the absolute rate of n-propyl iodide disappearance is 1.28×10^{-11} mole/cc./sec. At 550°K. the value of k for isobutyl iodide is 0.637 (mole/cc.)$^{-1/2}$ sec.$^{-1}$. Assuming an alkyl iodide concentration of 40 mm. and an iodine concentration of 10 mm., the absolute rate of disappearance of isobutyl iodide is 3.95×10^{-10} mole/cc./sec. Hence one may consider the experimental rate of disappearance of isobutyl iodide as 72 times the rates of disappearance as calculated for reaction (a-3) or (b-3). Assuming the same concentration values at 585°K., the absolute rate of reaction (a-3) for n-propyl iodide is 5.18×10^{-11} mole/cc./sec. and the experimental rate of disap-

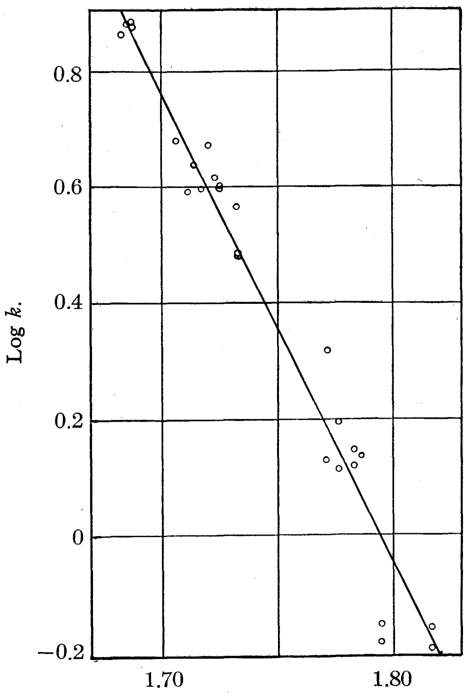

Fig. 2.

pearance of isobutyl iodide is 2.86×10^{-9} mole/cc./sec. Therefore, at 585°K. the experimental rate of disappearance of isobutyl iodide is 127 times the rate of disappearance as calculated for the reaction (a-3) or (b-3).

Evidence[2,4] indicates that the energy required to break the C–I linkage is 43 kcal., and the heat of dissociation of hydrogen iodide is 70.7 kcal. The reverse of reaction (a-1) (for *n*-propyl iodide) is thought to possess an activation energy[3] of 14 kcal. These data yield a value of the carbon–hydrogen linkage of 74.7 kcal. This value is quite low in comparison with the value of 94.5 kcal. calculated by Kistiakowsky and Gershinowitz[6] from the dissociation of cyanogen into cyanide radicals. Such a low value for the C–H bond does not seem plausible even in the possible case of a secondary hydrogen linkage. This constitutes a second serious objection to mechanism (a).

MECHANISM (c)

$$\begin{aligned} C_4H_9I + I &\longrightarrow C_4H_9 + I_2 && \text{(c-1)} \\ C_4H_9 + C_4H_9I &\longrightarrow C_4H_{10} + C_4H_8I && \text{(c-2)} \\ C_4H_8I &\longrightarrow C_4H_8 + I && \text{(c-3)} \\ 2I + M &\longrightarrow I_2 + M && \text{(c-4)} \end{aligned}$$

This mechanism is quite probably the one which prevails in the decomposition of *s*-butyl iodide (with the addition of a simple unimolecular rate determining step). The absolute rate of the iodine atom catalyzed reaction for *s*-butyl iodide at 549°*K*. and the previous concentration units is 1.86×10^{-10} mole/cc./sec. Compare this with the experimental absolute rate of disappearance of isobutyl iodide, *e. g.*, 3.95×10^{-10} mole/cc./sec. at 550°K. The structure of isobutyl iodide with regard to the carbon–iodine bond is similar to the normal alkyl iodide. In the case of *n*-propyl iodide[4] the reaction between free propyl radical and iodine molecule is more rapid than reaction (c-2). Hence, on the basis of the similar rate-determining steps one can rule out this mechanism as it is also improbable for *n*-propyl iodide.

Mechanism (d).—A mechanism was presented in the paper on *n*-propyl iodide which adequately described the decomposition. This mechanism may be generalized to account for the pyrolysis of isobutyl iodide.

The reaction rate constant is comparatively high for the first 10% decomposition, decreasing meanwhile to give a constant value over the remainder of the pyrolysis. Comparison of the unimolecular rate data for *s*-butyl iodide and *n*-propyl iodide yields some interesting results. At 550°K. and the given concentration units, the absolute rate of disappearance of *s*-butyl iodide is 2.42×10^{-10} mole/cc./sec. and for *n*-propyl iodide 2.62×10^{-10} mole/cc./sec. On this basis one can account for the rate of the initial decomposition of isobutyl iodide by the mechanism proposed for *n*-propyl iodide, *e. g.*

$$\begin{aligned} C_4H_9I &\longrightarrow C_4H_9 + I && \text{(d-1)} \\ C_4H_9 + C_4H_9I &\longrightarrow C_4H_{10} + C_4H_8 + I && \text{(d-2)} \end{aligned}$$

Reaction (d-2) is a comparatively slow reaction, the rate constant of the reaction of the free radical with iodine molecule probably being larger.

Due to the reaction between *n*-propyl radicals and iodine molecules the equilibrium (d-3) is established quite rapidly. On this basis the main mechanism is

$$\begin{aligned} i\text{-}C_4H_9I &\rightleftarrows i\text{-}C_4H_9 + {}^1/_2\, I_2\text{(equil.)} && \text{(d-4)} \\ i\text{-}C_4H_4 + I_2 &\longrightarrow \underline{\underline{C_4H_9I}} + I\text{(slow)} && \text{(d-5)} \\ i\text{-}C_4H_9 + \underline{\underline{C_4H_9I}} &\longrightarrow C_4H_{10} + C_4H_8 + I\text{(rapid)} && \text{(d-6)} \\ 2I + M &\longrightarrow I_2 + M \end{aligned}$$

The formula $\underline{\underline{C_4H_9I}}$ represents an activated molecule whose spatial configuration is not necessarily that of isobutyl iodide. This activated molecule reacts with an isobutyl radical, simultaneously losing a hydrogen atom and an iodine atom to form butene. Calculations below indicate that reaction (d-4) has a steric factor of about 10^{-4}. This factor can represent the infrequent occurrence of the proper internal phase conditions necessary for the formation of the activated molecule which has the opportunity of colliding with an isobutyl radical. In the case of *n*-propyl iodide it was considered[1] that the slow step (d-4) resulted in the formation of isopropyl iodide whose rate of decomposition is known[2] to be faster than that of *n*-propyl iodide. Calculations which are presented above indicate that the absolute rate of decomposition of *s*-butyl iodide is less than that of isobutyl iodide; hence, *s*-butyl iodide could not be a possible isomerization product of isobutyl iodide. In addition the isomerization would involve a shift of a carbon atom, a process requiring high activation energy. Isomerization to *t*-butyl iodide would require only the shift of a hydrogen atom; however, *t*-butyl iodide decomposes[7] to form isobutylene and hydrogen iodide and the hydrogen iodide would accumulate in concentrations greater than the experimental values.

---

[6] Kistiakowsky and Gershinowitz, *J. Chem. Phys.*, **1**, 432 (1933).

[7] Jones and Ogg, THIS JOURNAL, **59**, 1942 (1937).

Some interesting calculations can be made concerning the rate of reaction (d-5). Since the equilibrium constant K for (d-4) is

$$\frac{(I_2)^{1/2}(i\text{-}C_4H_9)}{(i\text{-}C_4H_9I)} = K$$

then

$$-\frac{d(i\text{-}C_4H_9I)}{dt} = k_5(i\text{-}C_4H_9)(I_2) = k_5K(i\text{-}C_4H_9I)(I_2)^{1/2}$$

The experimental value k is equal to k_5K. As the equilibrium constant K is given by $K = e^{\Delta S^0/R}\,e^{-Q/RT}$, where ΔS^0 is the standard entropy change for reaction (d-4), the rate constant k_5 can be calculated if the entropies of the compounds involved in the reaction are known.

The value of ΔS^0 is calculated at 570°K. The entropy of the iodine molecule at 570°K. (62.53 e. u.) is calculated from the spectroscopic data of Murphy[8] and the Sackur–Tetrode equation. As an approximation, the entropy of the isobutyl radical is taken to be that of isobutane, the data of Pitzer[9] being used to calculate the translational plus rotational entropy of the molecule. The value is 65.64 e. u. at 570°K. Since the calculation of ΔS^0 is primarily concerned with the breaking of the carbon–iodine bond, it will be assumed that the remaining vibrational entropy of isobutyl iodide and isobutyl radical will cancel in the reaction. Hence, only the vibrational entropy ascribed to the carbon–iodine bond is calculated,[10] using 503 and 260 cm.$^{-1}$ (doubly degenerate) as the proper frequencies. The total value of the vibrational entropy ascribed to the bond is 4.41 e. u. The rotational and translational entropy of isobutyl iodide is calculated as 74.01 e. u. where the moments of inertia are taken as 9.0×10^{-39}, 61.0×10^{-38} and 61.0×10^{-38} g. cm.^{2}.

The value of ΔS^0 is 15.52 e. u. at 570°K. and the value of $e^{\Delta S^0/R}$ is 2.48×10^3. The data of Murphy give the heat of dissociation of iodine at 570°K. as 36.65 kcal./mole. The probable heat of dissociation of the primary carbon–iodine bond is 43 kcal. Hence, the value of the heat of reaction Q for the equilibrium (d-4) is 24.7 kcal. So

$$K = 2.48 \times 10^3 e^{-24,700/RT}\ (\text{mole/cc.})^{1/2}$$

The critical increment E_5 for the reaction (d-4) is related to the true activation energy Q_5 by the relation $E_5 = Q_5 + {}^1/_2RT$ (simple bimolecular reaction theory). As E_5 is 13.1 kcal./mole, Q_5 is 12.5 kcal./mole. The temperature dependent equation for k_5 is given by $k_5 = 3.39 \times 10^9\ T^{1/2}e^{-12,500/RT}$ (mole)$^{-1}$/(cc.) sec.$^{-1}$. This equation gives an effective collision diameter of 9.1×10^{-10} cm. Assuming a "true collision diameter" of 6×10^{-8} cm., this corresponds to a steric factor of approximately 2.3×10^{-4}. This value of the steric factor is probably accurate to a factor of 10^2.

On the basis of the above experimental data the reaction

$$i\text{-}C_4H_9 + I_2 \longrightarrow i\text{-}C_4H_9I + I$$

may be considered to have the same activation energy as (d-5). Previous work indicates that the reaction

$$s\text{-}C_4H_9 + I_2 \longrightarrow s\text{-}C_4H_9I + I$$

has an activation energy of 14.2 kcal. and the reaction

$$C_2H_4I + I_2 \longrightarrow C_2H_4I_2 + I$$

has an activation energy of 11.2 kcal. On the basis of the above discussion the reaction

$$n\text{-}C_3H_7 + I_2 \longrightarrow n\text{-}C_3H_7I + I$$

has an activation energy of 12.6 kcal.

On the whole a consistent interpretation can be given to the thermal decomposition of the alkyl iodides based upon a large amount of experimental data. It is felt that the work indicates that the reactions of free radicals require appreciable activation energy, in accord with other existing experimental evidence. At the present there is no evidence which indicates that the strength of the primary carbon–iodine bond is not approximately 43 kcal.

Summary

An experimental study is presented on the kinetics of the thermal decomposition of gaseous isobutyl iodide in the temperature range of 550 to 600°K. The rate of disappearance of isobutyl iodide is expressed by

$$-\frac{d(C_4H_9I)}{dt} = k(C_4H_9I)(I_2)^{1/2}$$

Several proposed mechanisms are shown to be invalid. A mechanism consistent with the experimental data and also explaining the decomposition of n-propyl iodide is in the main

$$i\text{-}C_4H_9I \rightleftarrows i\text{-}C_4H_9 + {}^1/_2\ I_2(\text{equil.}) \qquad (\text{d-4})$$
$$i\text{-}C_4H_9 + I_2 \longrightarrow \underline{\underline{C_4H_9I}} + I(\text{slow}) \qquad (\text{d-5})$$
$$i\text{-}C_4H_9 + \underline{\underline{C_4H_9I}} \longrightarrow \overline{C_4H_9} + C_4H_{10} + I(\text{fast}) \qquad (\text{d-6})$$
$$2I + M \longrightarrow I_2 + M$$

The equilibrium constant K for reaction (d-4) is

The Synthesis of Disubstituted Acetylenes

BY JOHN R. JOHNSON, A. M. SCHWARTZ AND THOMAS L. JACOBS

In pursuing an investigation of the reactions of certain acetylenic systems, a number of disubstituted propynes of the type R—C≡C—CH$_2$—R′ were required. The present paper reports a study of synthetic methods for the preparation of pure individuals of known structure.

The alkylation of monosubstituted acetylenes was investigated as a promising preparative method. Nef[1] reported the methylation of phenylacetylene by heating it with methyl iodide and potassium hydroxide, and Morgan[2] effected ethylation of phenylacetylene by heating the sodium derivative with ethyl iodide. Both reactions were carried out in sealed tubes at relatively high temperature (140°) and the yields were low. Preliminary studies of these methods indicated that neither would be satisfactory for preparative purposes. In attempting to employ the method of Morgan, it was found that the sodium derivatives of typical alkyl- and arylacetylenes were surprisingly inert toward alkyl halides. At temperatures sufficiently high to bring about a reaction, vigorous deep-seated decomposition occurred. The substituted acetylides are evidently much less reactive than the monosodium derivative of acetylene itself, which reacts smoothly with alkyl halides at low temperatures.[3] Attempts to effect metathetical reactions between alkyl halides and other metallic derivatives of monosubstituted acetylenes (such as the bromomagnesium, cuprous, silver, and mercuric compounds), in a variety of solvent media, were also unsuccessful.[4]

In an investigation of the action of alkyl *p*-toluenesulfonates on organomagnesium halides, Gilman and Beaber[5] reported the synthesis of β-chloroethylphenylacetylene from the bromomagnesium derivative of phenylacetylene and β-chloroethyl *p*-toluenesulfonate. We have employed their method with excellent results for the preparation of several alkyl derivatives of phenylacetylene. However, the modification of Truchet,[6] in which the sodium derivatives of the acetylenes are used, is advantageous in one respect. When the organomagnesium halide is used, two moles of the sulfonic ester is consumed in producing one equivalent of the alkylated acetylene, since one mole of the ester is converted to the corresponding alkyl bromide (reaction I);[7] but with the sodium acetylides only one equivalent of the sulfonic ester is required (reaction II).

$$\mathrm{R{-}C{\equiv}C{-}MgBr + 2R'{-}OSO_2{-}C_7H_7 \longrightarrow R{-}C{\equiv}C{-}R' + R'{-}Br + Mg(OSO_2{-}C_7H_7)_2} \quad \text{(I)}$$

$$\mathrm{R{-}C{\equiv}C{-}Na + R'{-}OSO_2{-}C_7H_7 \longrightarrow R{-}C{\equiv}C{-}R' + NaOSO_2C_7H_7} \quad \text{(II)}$$

The sodium derivatives were used with satisfactory results for the alkylation of phenylacetylene and *n*-octylacetylene, to obtain the following disubstituted acetylenes: ethyl-, *n*-butyl-, and γ-chloropropylphenylacetylene; ethyl- and γ-chloropropyl-*n*-octylacetylene. The sodium derivatives appeared to be particularly advantageous in the aliphatic series, but there are certain limitations. Attempts to effect syntheses using phenylethynylsodium and benzyl or β-chloroethyl *p*-toluenesulfonate were unsuccessful. In these instances, however, the desired compounds were obtained by the use of phenylethynylmagnesium bromide.

The structures of the disubstituted acetylenes were checked by several methods. In some instances oxidation with aqueous potassium permanganate was employed and the resulting acids

were identified; in others, the hydrocarbons were hydrated with mercuric sulfate and sulfuric acid to the corresponding ketones. The halogenated hydrocarbons were identified by replacement of the halogen atom by carboxyl, by way of the nitrile, and oxidation of the resulting acetylenic acid.

$$\begin{aligned}&\mathrm{R{-}C{\equiv}C{-}(CH_2)_{\mathit{n}}{-}Cl} \longrightarrow \\ &\mathrm{R{-}C{\equiv}C{-}(CH_2)_{\mathit{n}}{-}C{\equiv}N} \longrightarrow \mathrm{R{-}C{\equiv}C{-}(CH_2)_{\mathit{n}}{-}CO_2H} \\ &\mathrm{R{-}C{\equiv}C{-}(CH_2)_{\mathit{n}}{-}COOH} + \mathrm{H_2O} + 3[\mathrm{O}] \longrightarrow \\ &\qquad\qquad \mathrm{R{-}COOH} + \mathrm{HOOC{-}(CH_2)_{\mathit{n}}{-}COOH}\end{aligned}$$

In all cases the compounds behaved like pure individuals and the structures corresponded with those anticipated.

Experimental

Ethylphenylacetylene (1-Phenylbutyne-1).—In a three-necked flask fitted with a mechanical stirrer, reflux condenser and separatory funnel, were placed 75 cc. of anhydrous ether and 4.6 g. (0.2 mole) of clean sodium wire. With vigorous stirring, 21 g. (0.2 mole) of phenylacetylene was added slowly. The reaction started spontaneously and the phenylacetylene was added at such a rate that the ether refluxed gently. The mixture was refluxed for two hours and the ether was then removed completely by warming on a steam-bath. The solid phenylethynylsodium was covered with 75 cc. of anhydrous di-*n*-butyl ether, the mixture was warmed to 60°, and 40 g. (0.2 mole) of freshly distilled ethyl *p*-toluenesulfonate was added dropwise, while stirring vigorously. A spontaneous exothermic reaction occurred and the temperature was maintained below 70° by external cooling. After two hours at 60–70°, the reaction mixture was cooled and treated with a large volume of water. The upper layer was separated, washed with dilute hydrochloric acid and finally with water. After drying, the product was fractionated under reduced pressure. After removal of a small quantity of unreacted phenylacetylene and of di-*n*-butyl ether, the ethylphenylacetylene distilled sharply at 82–83° (5 mm.). After redistillation the product weighed 20 g. (77% yield); b. p. 82° at 5 mm., d^{20}_{4} 0.9210.

This preparation was also carried out using toluene as the reaction medium; in this modification the phenylethynylsodium was prepared directly in toluene. Using the quantities of reactants given above, about 5 g. of phenylacetylene was recovered and 18–20 g. of ethylphenylacetylene was obtained.

The structure of this compound was checked by hydration to *n*-butyrophenone. Five grams of the hydrocarbon in 15 cc. of ethyl alcohol was treated with 2 g. of mercuric oxide, and 15 g. (8 cc.) of concd. sulfuric acid was added dropwise with shaking. After cooling to 20°, the mixture was poured into water and the product extracted with ether. The resulting ketone distilled at 220–223° (740 mm.), and was identified as *n*-butyrophenone through the oxime, m. p. 47°, and the semicarbazone, m. p. 187–188°.

β-Chloroethylphenylacetylene (1-Phenyl-4-chlorobutyne-1).[5]—An ethereal solution of phenylethynylmagnesium bromide was prepared by refluxing 21 g. (0.2 mole) of phenylacetylene with slightly more than the calculated quantity of ethylmagnesium bromide (in approximately molar solution). The resulting solution was added dropwise, with vigorous stirring, to 94 g. (0.4 mole) of β-chloroethyl *p*-toluenesulfonate. The mixture was refluxed gently for eight hours and after cooling was decomposed by iced hydrochloric acid. The ethereal layer was separated and washed successively with water, sodium bicarbonate solution, and water. After drying over calcium chloride the ether was removed and the residue was fractionated under reduced pressure. A large fraction which distilled below 50° at 25 mm., was refractionated at atmospheric pressure and gave 5 g. of phenylacetylene and 25 g. of ethylene chlorobromide (86% of the calculated amount). The remainder gave 15 g. (46% yield) of β-chloroethylphenylacetylene: colorless liquid, b. p. 95° (3 mm.); d^{20}_{4} 1.0763, n^{20}_{D} 1.5724, n^{20}_{C} 1.5657, n^{20}_{F} 1.5882; MR_{D} calcd., 47.6, obsd. 50.52.

Anal. Calcd. for $C_{10}H_9Cl$:Cl, 21.58. Found: Cl, 21.52, 21.56.

This compound was not obtained when phenylethynylsodium was used in place of phenylethynylmagnesium bromide. In this case the phenylacetylene was recovered unchanged after the reaction mixture was hydrolyzed, but none of the sulfonic ester was recovered.

γ-Chloropropylphenylacetylene (1-Phenyl-5-chloropentyne-1).—This substance was prepared according to the procedure given under ethylphenylacetylene, using 50 g. (0.2 mole) of γ-chloropropyl *p*-toluenesulfonate instead of the ethyl ester. The yield of purified product was 27 g. (75% yield). When toluene was used as the reaction medium, a large quantity of phenylacetylene was recovered and only 9 g. (25% yield) of the disubstituted acetylene was obtained.

A redistilled specimen of γ-chloropropylphenylacetylene had the following constants: b. p. 125–127° (4 mm.); d^{20}_{4} 1.0576, n^{20}_{D} 1.5615, n^{20}_{C} 1.5555, n^{20}_{F} 1.5761; MR_{D} calcd., 52.2, obsd. 54.70.

Anal. Calcd. for $C_{11}H_{11}Cl$: Cl, 19.88. Found: Cl, 19.76, 19.84.

The structure of this compound was checked by conversion to 6-phenyl-5-hexynoic acid, and oxidation of the latter to benzoic and glutaric acids. A solution of 5 g. of the chloropropylphenylacetylene in 50 cc. of 90% alcohol was refluxed with 10 g. of pulverized potassium cyanide for thirty hours. After cooling, the mixture was poured into a large volume of water and the oily layer of nitrile was separated. This was refluxed with an excess of 10% potassium hydroxide solution until no oily drops remained. After cooling, the solution was poured into an excess of iced hydrochloric acid, whereupon the acetylenic acid separated as an oil. The latter was extracted with ether and the solvent was distilled off. No attempt was made to purify the intermediate acid. The crude acid was allowed to stand for twenty-four hours at room temperature with a slight excess of 1% aqueous potassium permanganate, with occasional shaking. Oxidation occurred readily and a clear colorless solution was obtained after filtering off the manganese dioxide. The solution was concentrated to a small volume and poured into an excess of iced acid. An oily mixture of acids was precipitated, from which benzoic and glutaric acids were isolated by repeated partition between ether and water. Benzoic acid was identified by a mixed melting point with an authentic specimen. The glutaric acid melted at 97–98°; neutralization equivalent, 68 (calcd., 66); anilide, m. p. 218–219°.

***n*-Butylphenylacetylene (1-Phenylhexyne-1).**—Phenylethynylsodium was prepared by adding slowly 51 g. (0.5 mole) of phenylacetylene to 11.5 g. (0.5 gram atom) of sodium wire in toluene at 35–40°. Higher temperatures must be avoided or the sodium derivative is converted to a gelatinous mass in the presence of toluene. To the suspension of the sodium derivative, 114 g. (0.5 mole) of *n*-butyl *p*-toluenesulfonate was added slowly, with stirring, while the temperature was maintained at 70°. The reaction mixture was treated in the usual way and the product was fractionated through a 30-cm. heated Vigreux column under reduced pressure. A small amount of phenylacetylene was recovered and 51–55 g. (65–70% yield) of *n*-butylphenylacetylene was obtained. The redistilled product had the following constants: b. p. 94–95° at 4 mm. (bath 110–115°), 109–110° at 12 mm. (bath 129–133°); d^{20}_4 0.9024; n^{20}_C 1.5292, n^{20}_D 1.5347, n^{20}_F 1.5485, n^{20}_G 1.561; *MR*D calcd., 52.0, obsd. 54.8.

On hydration in the usual way there was obtained *n*-amyl phenyl ketone (*n*-caprophenone), m. p. 24°, b. p. 137–139° (15 mm.); the semicarbazone of the ketone, after one crystallization from 50% alcohol, melted at 131.5–132° (reported, 127–128° and 131–132°).[8]

Ethyl-*n*-octylacetylene (Dodecyne-3).—Twenty-eight grams (0.2 mole) of pure *n*-octylacetylene[9] in 80 cc. of di-*n*-butyl ether was treated with 8 g. (0.2 mole) of sodamide, previously pulverized under di-*n*-butyl ether. The mixture was heated at 100° for two hours, with stirring, to complete the formation of the sodium derivative, and after cooling to 60° was treated dropwise with 40 g. (0.2 mole) of ethyl *p*-toluenesulfonate. The reaction mixture was heated at 70° for three hours, cooled and treated with cold water. The product was isolated by fractionation under reduced pressure. There was obtained 21 g. (63% yield) of ethyl-*n*-octylacetylene, b. p. 95° (12 mm.); d^{20}_4 0.7871, n^{20}_D 1.44415, n^{20}_C 1.44236, n^{20}_F 1.45162; *MR*D calcd., 55.6, obsd. 55.65.

Anal. Calcd. for $C_{12}H_{22}$: C, 86.65; H, 13.35. Found: C, 86.59, 86.63; H, 13.33, 13.35.

The structure of this hydrocarbon was checked by oxidation with 1% aqueous potassium permanganate, as described above, which gave propionic and pelargonic acids. The former boiled at 138°, and gave propionanilide, m. p. 105°; this anilide showed no depression of the m. p. when mixed with an authentic sample of propionanilide. Pelargonic acid was identified by formation of the amide, m. p. 90°, which showed no depression when mixed with the amide obtained from a sample of synthetic pelargonic acid.

3-Chloropropyl-*n*-octylacetylene (1-Chlorotridecyne-4).—This compound was prepared according to the directions given for ethyl-*n*-octylacetylene, using 50 g. (0.2 mole) of γ-chloropropyl *p*-toluenesulfonate in place of the ethyl ester. The yield of purified product was 65% of the theoretical. A redistilled sample of 3-chloropropyl-*n*-octylacetylene had the following constants: b. p. 123–124° (3 mm.), d^{20}_4 0.9275, n^{20}_D 1.47073, n^{20}_C 1.46810, n^{20}_F 1.47749; *MR*D calcd., 65.1, obsd. 65.0.

Anal. Calcd. for $C_{13}H_{23}Cl$: Cl, 16.54. Found: Cl, 16.40, 16.48.

The structure of this compound was checked by conversion to 4-tetradecynoic acid, and oxidation of the latter with 1% aqueous permanganate, following the procedure given under γ-chloropropylphenylacetylene. There were obtained pelargonic and glutaric acids, which were identified as described above.

Summary

A study has been made of the alkylation of metallic derivatives of monosubstituted acetylenes. The action of alkyl *p*-toluenesulfonates on the sodium or bromomagnesium derivatives of alkyl or arylacetylenes has been found to be a satisfactory procedure for the preparation of a variety of disubstituted acetylenes.

ITHACA, N. Y. RECEIVED APRIL 25, 1938

---

[8] Truchet (ref. 6b, p. 400) reported that the semicarbazone of the ketone obtained by hydration of *n*-butylphenylacetylene melted at 164–165°, in agreement with the reported value for the semicarbazone of *n-amylacetophenone*. This is evidently an error since the acetylene in question should yield the lower homolog, *n*-butylacetophenone, as we have found.

A Study of Propyne-Allene Tautomerism. 1,3-Diphenylpropyne (Benzylphenylacetylene) and Related Compounds

BY JOHN R. JOHNSON, THOMAS L. JACOBS AND A. M. SCHWARTZ

The best known examples of prototropic triad systems are those involving a double bond, and the tautomeric change can be expressed by a simple general equation

$$\mathrm{H{-}X{-}Y{=}Z} \rightleftarrows \mathrm{X{=}Y{-}Z{-}H}$$

in which X, Y and Z represent atoms of carbon, nitrogen or oxygen (occasionally, sulfur). Analogous prototropic systems containing a triple bond are encountered less frequently and have not been studied extensively. These may be represented by means of two general equations, corresponding to the presence of one or two mobile protons in the particular system.[1]

$$\mathrm{H{-}X{-}Y{\equiv}Z} \rightleftarrows \mathrm{X{=}Y{=}Z{-}H}$$

$$\mathrm{H_2X{-}Y{\equiv}Z} \rightleftarrows \mathrm{H{-}X{=}Y{=}Z{-}H} \rightleftarrows \mathrm{X{\equiv}Y{-}ZH_2}$$

This type of prototropic system is of particular interest in view of the circumstance that one of the tautomeric forms is a 1,2-dienoid structure of the allene or ketene type.

The existence of proton mobility in the system $\mathrm{R{-}CH_2{-}C{\equiv}N}$ is well recognized, and the metallic derivatives of these compounds exist largely in the ketene-imine form. The reverse change is demonstrated by the observation that the Hofmann degradation of phenylpropiolic amide ($\mathrm{C_6H_5{-}C{\equiv}C{-}CO{-}NH_2}$), which would be expected to produce phenylethynylamine, actually yields benzyl cyanide.[2]

$$\underset{\text{ethynylamine}}{\mathrm{C_6H_5{-}C{\equiv}C{-}NH_2}} \longrightarrow \underset{\text{ketene-imine}}{\mathrm{C_6H_5{-}CH{=}C{=}NH}} \longrightarrow \underset{\text{nitrile}}{\mathrm{C_6H_5{-}CH_2{-}C{\equiv}N}}$$

The present investigation deals with the preparation and reactions of several 1,3-diarylpropynes, which contain a potentially prototropic system of the type $\mathrm{C_6H_5{-}CH_2{-}C{\equiv}C{-}C_6H_5}$. This system is related structurally to the arylpropynes studied by Bourguel,[3] and to certain trisubstituted propynes that have been observed to undergo propyne–allene transformations.[4]

The first compound chosen for study was the parent structure itself, 1,3-diphenylpropyne (benzylphenylacetylene). Owing to the identity of the terminal substituents in this particular compound, the possible prototropic change involves only two individuals: 1,3-diphenylpropyne (I) and 1,3-diphenylallene (II).

$$\underset{\text{I}}{\mathrm{C_6H_5{-}CH_2{-}C{\equiv}C{-}C_6H_5}} \qquad \underset{\text{II}}{\mathrm{C_6H_5{-}CH{=}C{=}CH{-}C_6H_5}}$$

The desired disubstituted acetylene could not be prepared by the action of benzyl halides on sodium phenylacetylide but was finally obtained by the reaction of phenylethynylmagnesium bromide with an excess of benzyl *p*-toluenesulfonate.[5] Subsequently, another specimen of the hydrocarbon was prepared by the interaction of phenylmagnesium bromide and phenylpropargyl bromide, according to the general method of Lai,[6] and this sample was found to be identical with the other.

1,3-Diphenylpropyne reacted with two atoms of bromine or iodine (in carbon tetrachloride solutions) to give a dihalide, and underwent autoxidation slowly in the air. The hydrocarbon was unaffected by heating with metallic sodium in an inert medium and gave a negative result in the Zerewitinoff test for active hydrogen,[7] using ethylmagnesium bromide in di-*n*-butyl ether.

To obtain evidence bearing upon the subject of propyne–allene tautomerism, the hydrocarbon was hydrated to a ketone by means of sulfuric acid and mercuric oxide, and was subjected to oxidation. The product of hydration proved to be benzylacetophenone (1,3-diphenyl-1-propanone), which would be expected from the acetylenic form since all of the known alkyl phenylacetylenes produce ketones of the type $\mathrm{C_6H_5{-}CO{-}CH_2{-}R}$ upon hydration. None of the isomeric compound, dibenzyl ketone, which might have been produced from 1,3-diphenylallene, could be detected in the reaction product. The fact that the hydrocarbon does not polymerize readily may

---

[1] These *prototropic* transpositions are the counterpart of the analogous *anionotropic* changes of the type: $\mathrm{R_2CBr{-}C{\equiv}CR} \longrightarrow \mathrm{R_2C{=}C{=}CRBr}$, and $\mathrm{R_2COH{-}C{\equiv}CR} \longrightarrow \mathrm{R_2C{=}CH{-}CO{-}R}$.

[7] It is of interest to note that Grignard and Lapayre [*Compt. rend.*, **192**, 250 (1931)] obtained a positive Zerewitinoff test with compounds of the type $\mathrm{R{-}C{\equiv}C{-}CH_2{-}C{\equiv}C{-}R}$, and other related structures.

be taken as further evidence against the allene structure, since allenes of this general type are known to form dimers with great ease.[4]

Oxidation of the hydrocarbon with cold 1% potassium permanganate solution gave a large amount of benzoic acid (0.96 equivalent) and a much smaller quantity of phenylacetic acid (0.15 equivalent). Ozonation of the hydrocarbon and hydrolysis of the ozonide gave benzoic acid (1.2 equivalents) and phenylacetic acid (0.10 equivalent). Treatment of the ozonide with aqueous potassium iodide, followed by sodium thiosulfate, gave benzyl phenyl diketone in 25% of the theoretical yield.[8] The allene form would have been expected to give benzaldehyde upon ozonolysis, but it is not certain that a small quantity of benzaldehyde would have survived the experimental procedure.

The chemical evidence indicates that 1,3-diphenylpropyne exists largely, if not entirely, in the acetylene form but the possibility of a small proportion of the allene form is not excluded. Conclusive evidence on this point was obtained through the study of a pair of isomeric derivatives of 1,3-diphenylpropyne, in which the terminal aryl groups were not identical. Owing to the circumstance that both of the isomeric propynes (III and V) would give rise to the same allene (IV), it is evident that active prototropy in the system would result in an interconversion of the two propynes. Prototropic change in the 1,3-diarylpropenes and 1,3-diarylmethylene-azomethines has been investigated in this way by Ingold and his collaborators,[9] who found that isomeric diarylpropenes possessing structures VI and VII existed as separate static individuals.

$$BrC_6H_4—CH_2—C{\equiv}C—C_6H_5$$

III

$$BrC_6H_4—CH{=}C{=}CH—C_6H_5$$

IV

$$BrC_6H_4—C{\equiv}C—CH_2—C_6H_5$$

V

$$CH_3O—C_6H_4—CH_2—CH{=}CH—C_6H_5$$

VI

$$CH_3O—C_6H_4—CH{=}CH—CH_2—C_6H_5$$

VII

Each gave rise only to its own oxidation products but interconversion (equilibration) could be effected by heating with alcoholic sodium ethoxide at 85°.[10]

The compounds chosen for the present study were *p*-bromobenzylphenylacetylene (III) and benzyl-*p*-bromophenylacetylene (V). If interconversion did not occur, the former should result from the interaction of *p*-bromobenzyl *p*-toluenesulfonate and phenylethynylmagnesium bromide (reaction A) and the latter from benzyl *p*-toluenesulfonate and *p*-bromophenylethynylmagnesium bromide (reaction B).

$$\text{(A)}\quad 2BrC_6H_4CH_2—OSO_2T + C_6H_5C{\equiv}C—MgBr \longrightarrow \underset{\text{III}}{BrC_6H_4CH_2—C{\equiv}C—C_6H_5} + BrC_6H_4CH_2Br + Mg(OSO_2T)_2$$

$$\text{(B)}\quad 2C_6H_5CH_2—OSO_2T + BrC_6H_4C{\equiv}C—MgBr \longrightarrow \underset{\text{V}}{C_6H_5CH_2—C{\equiv}C—C_6H_4Br} + C_6H_5CH_2Br + Mg(OSO_2T)_2$$

The two syntheses were carried out successfully, and the products were examined carefully to establish their constitution and to discover whether interconversion had occurred.

The compound (III) obtained by reaction A was a crystalline solid which melted at 42–44°. It gave a dibromide, m. p. 108–108.5°, and on hydration produced a ketone which was shown to be *p*-bromobenzylacetophenone, m. p. 68.5–69°. The isomer (V) obtained by reaction B was a liquid that could not be crystallized. Its dibromide melted at 87°, and the ketone obtained by hydration was identified as benzyl-*p*-bromoacetophenone, m. p. 98–99°. The structure of the isomeric ketones was established by the synthesis of authentic specimens, and mixed melting point determinations with the ketones and with suitable derivatives.

$$\text{III} \xrightarrow[HgO]{H_2SO_4} BrC_6H_4CH_2CH_2COC_6H_5$$

$$\text{V} \xrightarrow[HgO]{H_2SO_4} C_6H_5CH_2CH_2COC_6H_4Br$$

The chemical evidence therefore indicates that the three-carbon system of the simple 1,3-diarylpropynes is not actively prototropic, and that these compounds are distinct individuals which do not exist in dynamic equilibrium with the isomeric allenes. Proton mobility in the 1,3-diarylpropyne system is evidently quite low, since the isomeric bromodiphenylpropynes were not interconverted by contact with a Grignard re-

---

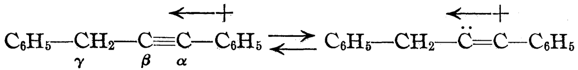
agent nor with hot aqueous potassium hydroxide solution.

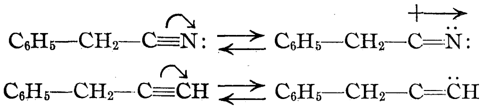
A consideration of structural features of the 1,3-diarylpropyne system, on the basis of current electronic theories of tautomeric change,[9] affords a suitable explanation of the observed low proton mobility. The ability of the aryl group at C_α to facilitate dynamic electron release toward the acetylenic system, leads to the inference that the significant activation of the molecule involves withdrawal of an electron pair of the multiple bond by the central atom (C_β). This view is in agreement with the fact that hydration of arylacetylenes to ketones invariably leads to a combination of protons at C_β and oxygen at C_α.



$$C_6H_5—\underset{\gamma}{CH_2}—\overset{\longleftarrow +}{\underset{\beta\quad\alpha}{C\equiv C}}—C_6H_5 \rightleftarrows C_6H_5—CH_2—\overset{\longleftarrow +}{\ddot{C}=C}—C_6H_5$$

active configuration

The direction of this displacement is favorable for the transfer of an anion from C_γ to C_α but is definitely unfavorable for the shift of a proton to C_α, since the increased electron density at C_γ tends to hold the available protons more firmly *and* the active configuration fails to provide an unshared electron pair at C_α to serve as a seat for available protons. This view of the 1,3-diarylpropynes is supported by comparison with benzyl cyanide and 3-phenyl-1-propyne.



$$C_6H_5—CH_2—C\overset{\curvearrowright}{\equiv N}: \rightleftarrows C_6H_5—CH_2—\overset{+\longrightarrow}{C=\ddot{N}}:$$
$$C_6H_5—CH_2—C\overset{\curvearrowright}{\equiv CH} \rightleftarrows C_6H_5—CH_2—C=\ddot{C}H$$

In these structures the activation involves electron withdrawal from C_β and results in a configuration that is favorable for prototropic change.[11] The decrease of electron density at C_γ increases the proton escaping tendency, and an unshared electron-pair is available to furnish a proton-seat at the α-position; consequently these systems are relatively mobile.

The behavior of the 1,3-diarylpropynes indicates that they are less mobile than benzyl cyanide or 3-phenyl-1-propyne, and that the group $—C\equiv C—C_6H_5$ has less activating effect on a methylene group than $—C\equiv N$ or $—C\equiv CH$.

Experimental

Benzylphenylacetylene (1,3-Diphenylpropyne)

Preparation.—An ethereal solution of 0.6 mole of phenylethynylmagnesium bromide was added dropwise, with stirring, to a gently refluxing solution of 330 g. (1.25 moles) of benzyl *p*-toluenesulfonate in 900 cc. of absolute ether. After the addition was completed (about two and one-half hours), the mixture was refluxed gently for six hours and hydrolyzed with cold dilute hydrochloric acid. The ethereal layer was washed with water, sodium carbonate, and finally with water. After removal of the solvent the residual oil was treated with 15% aqueous potassium hydroxide solution and the whole subjected to steam distillation. The distillate, containing benzyl bromide and benzyl alcohol, was discarded. The residual oil was taken up in ether, washed thoroughly with water, dried over anhydrous potassium carbonate, and distilled in an atmosphere of nitrogen. There was obtained 84 g. (72% yield) of benzylphenylacetylene, b. p. 150–160° (4 mm.). Redistillation gave a pale yellow, highly refringent liquid; b. p. 128–129° (1–2 mm.), $d^{20}{}_4$ 1.0273, $n^{20}{}_D$ 1.5946, $n^{20}{}_C$ 1.5881, $n^{20}{}_F$ 1.6113; *MR*D, calcd. 62.2, obsd. 63.5.

Anal. Calcd. for $C_{15}H_{12}$: C, 93.7; H, 6.3. Found: C, 93.68, 93.50; H, 6.44, 6.45.

Benzylphenylacetylene was prepared also by the general procedure of Lai,[6] but this method is much less convenient. A filtered solution of 0.32 mole of phenylmagnesium bromide was added dropwise over a period of two hours to a stirred solution of 62.5 g. (0.32 mole) of phenylpropargyl bromide in 150 cc. of absolute ether. The mixture was refluxed for three hours and hydrolyzed with cold dilute hydrochloric acid. Repeated fractionation under reduced pressure, under nitrogen, gave 14 g. (27% yield) of benzylphenylacetylene; b. p. 134–135° (1–2 mm.), $d^{20}{}_4$ 1.0408, $n^{20}{}_D$ 1.607. This specimen, although slightly less pure, was substantially identical with that obtained by the first method. Both samples gave the same ketone, benzylacetophenone, when subjected to hydration with sulfuric acid and mercuric oxide.

Benzylphenylacetylene absorbs oxygen slowly from the air but no definite product was isolated. Oxidation of 5 g. of the acetylene with cold 1% aqueous potassium permanganate solution gave 3.0 g. (48%) of benzoic acid and 0.5 g. (15% yield) of phenylacetic acid. Details of the ozonization experiments have been reported.[8]

Hydration to Benzylacetophenone (1,3-Diphenyl-1-propanone).—Two grams of mercuric oxide was mixed with a solution of 5 g. of benzylphenylacetylene in 10 cc. of 95% ethyl alcohol, and 15 g. (8 cc.) of cold concd. sulfuric acid was added slowly with shaking. The hot solution was allowed to cool to 20° and poured into a large volume of cold water. The resulting ketone, after two crystallizations from ethyl alcohol, weighed 3 g. (50% yield) and melted at 72–73°; the oxime melted at 82–83°. Benzylacetophenone is reported to melt at 72–73°, and its oxime at 82°.

Conversion to the Dibromide (1,2-Dibromo-1,3-diphenyl-1-propene).—A solution of 3 g. of the acetylene in 10 cc. of carbon tetrachloride was treated with a solution of 1 g. of bromine. Evaporation gave a mass of white needles; after crystallization from methyl alcohol and from petroleum ether, the product melted at 60°.

Anal. Calcd. for $C_{15}H_{12}Br_2$: Br, 45.41. Found: Br, 45.38, 45.41.

The acetylene readily absorbed two atoms of iodine in carbon tetrachloride solution but the resulting product was a viscous oil which could not be induced to crystallize.

---

(11) The predicted direction of electron displacement is confirmed by the fact that hydration of benzyl cyanide and 3-phenyl-1-propyne yields, respectively, phenylacetamide and phenylacetone.

Benzyl-*p*-bromophenylacetylene

Preparation.—*p*-Bromophenylacetylene was obtained conveniently from *p*-bromoacetophenone by the procedure of Dufraisse and Desquesnes.[12] The product boiled at 71–72° (3 mm.) and melted at 62–63°.

p-Bromophenylacetylene (64 g., 0.35 mole) was converted to the bromomagnesium derivative by warming with a slight excess of ethylmagnesium bromide, and the resulting homogeneous solution was added slowly to an excess (185 g., 0.7 mole) of benzyl *p*-toluenesulfonate in ether solution. The procedure was essentially the same as that employed for benzylphenylacetylene. There was obtained 25 g. (26% yield) of crude benzyl-*p*-bromophenylacetylene, b. p. 170–180° (3 mm.); redistillation gave a pale yellow liquid, b. p. 175–180° (3 mm.). The product was characterized by means of the solid dibromide, and by hydration to a solid ketone.

A solution of 2 g. of the acetylene in 10 cc. of carbon tetrachloride was treated with slightly more than two equivalents of bromine in the same solvent. The solvent was evaporated at 20° and the crude product recrystallized from ethyl alcohol. There was obtained 2 g. (63% yield) of the dibromide; white needles, m. p. 87°.

Anal. Calcd. for $C_{15}H_{11}Br_3$: Br, 55.66. Found: Br, 55.70, 55.71.

Hydration to Benzyl-*p*-bromoacetophenone.—In the usual way 5 g. of benzyl-*p*-bromophenylacetylene was treated with sulfuric acid and mercuric oxide, in the presence of ethyl alcohol. The resulting ketone after crystallization from ethyl alcohol weighed 2 g.; white leaflets, m. p. 98–99°. The semicarbazone of the ketone crystallized from alcohol in white needles, m. p. 163–164°. The ketone formed an oxime which crystallized readily from alcohol but showed a wide melting range; m. p. 115–125°. The ketone produced in the hydration reaction was shown to be the expected compound, benzyl-*p*-bromoacetophenone, by direct comparison with an authentic specimen, as described below.

Synthesis of Benzyl-*p*-bromoacetophenone.—A solution of 18.2 g. (0.1 mole) of pure *p*-bromobenzonitrile in absolute ether was added with stirring to a solution of 2-phenyl ethylmagnesium bromide (0.1 mole) and the mixture was refluxed gently for three hours. The reaction mixture was treated with a large excess of cold 15% sulfuric acid and the ether was distilled off without separating the aqueous acidic layer. The oily reaction product crystallized on cooling and after recrystallization from ethyl alcohol formed glistening white plates, m. p. 98–99°. The melting point was not changed by admixture with the ketone obtained by hydration of benzyl-*p*-bromophenylacetylene.

Anal. Calcd. for $C_{15}H_{13}OBr$: Br, 27.67. Found: Br, 27.62, 27.65.

The semicarbazone of the synthetic ketone melted at 164–165°, and showed no depression when mixed with the specimen obtained from the acetylene.

p-Bromobenzylphenylacetylene

Preparation.—A mixture of 54 g. (0.3 mole) of pure *p*-bromobenzyl alcohol (m. p. 77–78°), 54.5 g. (0.3 mole) of redistilled and recrystallized *p*-toluenesulfonyl chloride, and 500 cc. of anhydrous ether was cooled to −10° and treated with 24 g. (0.43 mole) of finely powdered potassium hydroxide, in small portions and with good stirring. The mixture was stirred vigorously for several hours, removed from the cooling bath, and treated with water. The ethereal layer was washed with water, dried over anhydrous potassium carbonate, and concentrated under reduced pressure. The crude *p*-bromobenzyl *p*-toluenesulfonate was precipitated by the addition of petroleum ether and was purified by recrystallization from ether and petroleum ether. The purified product (55% yield) formed large transparent plates, m. p. 74–75°.

An ethereal solution of 79.5 g. (0.23 mole) of *p*-bromobenzyl *p*-toluenesulfonate was treated with 0.115 mole of phenylethynylmagnesium bromide, and the reaction and purification were carried out as described for benzylphenylacetylene. There was obtained 15.5 g. (50% yield) of a pale yellow liquid boiling at 167–171° (1–2 mm.). Redistillation gave 12.5 g. of pure *p*-bromobenzylphenylacetylene; b. p. 166–169° (1–2 mm.), m. p. 42–44°.

Anal. Calcd. for $C_{15}H_{11}Br$: Br, 29.49. Found: Br, 29.88, 30.05.

Treatment of the acetylene with two equivalents of bromine in carbon tetrachloride gave a crystalline dibromide, which melted at 108–108.5° after two crystallizations from ethyl alcohol.

Hydration to *p*-Bromobenzylacetophenone.—To a solution of 5.8 g. of *p*-bromobenzylphenylacetylene in 10 cc. of ethyl alcohol, 2 g. of yellow mercuric oxide was added and 15 g. (8 cc.) of concd. sulfuric acid was introduced dropwise, with cooling and stirring, over a period of ten minutes. The temperature of the flask was raised to 50° for thirty minutes and finally to 95° for fifteen minutes. The reaction mixture was cooled and poured into 250 cc. of cold water. The crude ketone (5.2 g.) was recrystallized from ethyl alcohol and finally from methyl alcohol; m. p. 68.5–69°. The semicarbazone melted at 161–162°. A mixture of this compound with the semicarbazone of the isomeric ketone from benzyl-*p*-bromophenylacetylene, m. p. 163–164°, was found to melt at 133–142°.

The identity of the product of hydration of *p*-bromobenzylphenylacetylene was established by comparison of the ketone and of its semicarbazone with a synthetic specimen of *p*-bromobenzylacetophenone and its semicarbazone.

Synthesis of *p*-Bromobenzylacetophenone.—Several methods were investigated before a satisfactory synthesis of this ketone was found. The preparation was finally effected in an unequivocal manner by the interaction of *p*-bromophenylpropionyl chloride and diphenylzinc. We are greatly indebted to Mr. Stephen Hubard for carrying out the following preparations.

β-Phenylpropionic acid was brominated according to the general directions of Göring[13] and the mixture of brominated products was crystallized three times from 50% alcohol and once from a 1:1 mixture of benzene and petroleum ether. The resulting *p*-bromophenylpropionic acid melted at 131.5–134° (reported, 135°). The constitution of the acid was confirmed by oxidation with aqueous

---

[12] Dufraisse and Desquesnes, *Bull. soc. chim.*, [4] **49**, 1880 (1931).

potassium permanganate, which produced *p*-bromobenzoic acid, m. p. 245–246.5°.

Twenty-five grams of *p*-bromophenylpropionic acid was refluxed gently for five hours with four equivalents of thionyl chloride, and the excess of thionyl chloride was removed by distillation. The residual acid chloride was taken up in 75 cc. of benzene and the solution was added slowly, with stirring, to an excess of diphenylzinc. The latter was prepared by the addition of 27 g. (0.2 mole) of anhydrous zinc chloride in 25 cc. of absolute ether, to 0.45 mole of phenylmagnesium bromide.[14] After the reaction had been completed the mixture was hydrolyzed with dilute acid; the benzene–ether layer was separated, washed with dilute alkali, and finally with water. After removal of the solvent the crude product was recrystallized from ethyl alcohol, and finally from methyl alcohol. The purified ketone formed white needles, m. p. 68–69°. This material was identical with a small sample of the ketone which had been obtained by treating the sodium derivative of ethyl benzoylacetate with *p*-bromobenzyl bromide and saponifying the resulting ethyl benzoyl-*p*-bromobenzylacetate.

Anal. Calcd. for $C_{15}H_{13}OBr$: C, 62.30; H, 4.50. Found: C, 61.89; H, 4.78.

The semicarbazone of the synthetic ketone melted at 160–161.5°, and the 2,4-dinitrophenylhydrazone at 67–67.5°. The synthetic ketone and its semicarbazone showed no depression of the melting point when mixed with the specimens obtained from *p*-bromobenzylphenylacetylene.

Summary

1,3-Diphenylpropyne (benzylphenylacetylene) and two isomeric bromo derivatives have been prepared, and their chemical reactions investigated.

It has been shown that active prototropy of the propyne–allene type does not occur in these compounds, and that the 1,3-diarylpropynes exhibit low proton mobility.

Comparison with benzyl cyanide and 3-phenyl-1-propyne indicates that the phenylethynyl group has less activating effect than —C≡N or —C≡CH, which is in agreement with the anticipated order.

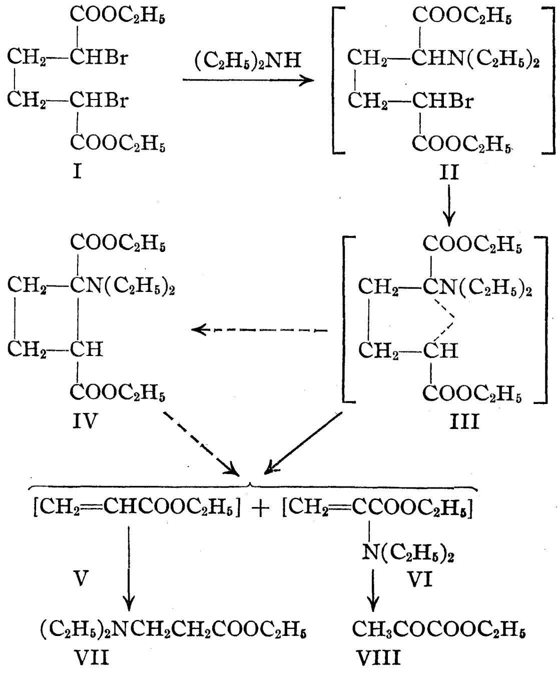
The Mechanism of the Cleavage of Ethyl α,α'-Dibromoadipate by Diethylamine

BY REYNOLD C. FUSON AND WM. E. LUNDQUIST

The cleavage of ethyl α,α'-dibromoadipate (I) by secondary amines, discovered by von Braun, Leistner and Münch,[1] may be interpreted in the light of Criegee's recently proposed theory of chain cleavages.[2] This postulate suggests that the cleavage may be explained by the formation of a 1,4-biradical. According to Criegee such radicals may stabilize themselves in two ways: (1) by closure to a four-membered ring or (2) by chain fission between atoms 2 and 3 to give two molecules of olefinic character. Applied to the cleavage of ethyl α,α'-dibromoadipate (I) by diethylamine this theory suggests that the biradical (III) may be produced from the intermediate bromoamino ester (II) by the loss of hydrogen bromide. The biradical might be expected to decompose to give ethyl acrylate (V) and ethyl α-diethylaminoacrylate (VI). The products actually isolated were ethyl β-diethylaminopropionate (VII) and ethyl pyruvate (VIII)—compounds which may be regarded as transformation products of V and VI, respectively. The formation of these compounds constitutes an example of the second mode of stabilization of the biradical.

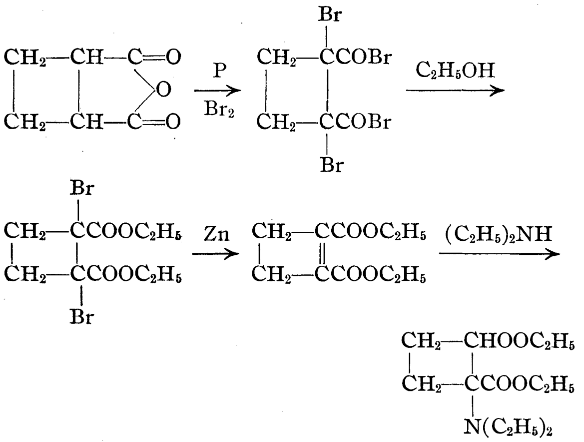


---

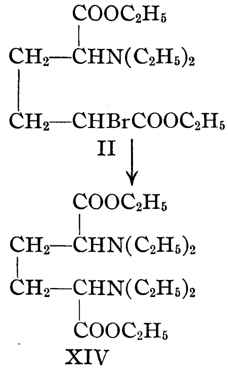
[1] Von Braun, Leistner and Münch, *Ber.*, **59**, 1950 (1926).

[2] Criegee, *ibid.*, **68B**, 665 (1935).

If the biradical stabilized itself by the first mode, *i. e.*, by closure to a four-membered ring, the product would be ethyl 1-diethylamino-1,2-cyclobutanedicarboxylate (IV). Although none of this compound was isolated, it was important to determine whether it might be a possible intermediate in the cleavage as was suggested by Fuson[3] in 1928. We have made this compound (IV), and have tested its thermal stability. The synthesis was carried out by the following sequence of transformations



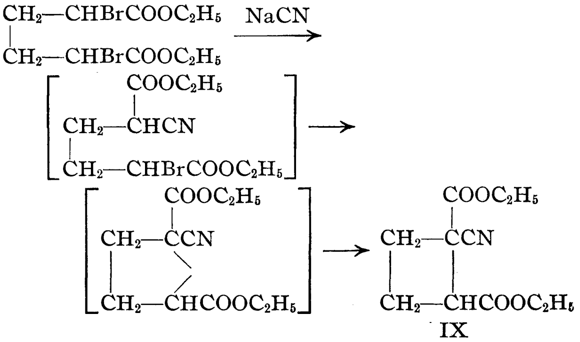
The amino ester was analyzed, and its molecular refraction and parachor were determined as a check on its identity. Its picrate was also prepared and characterized. The amino ester was found to be stable toward aqueous acid and alkali and could be distilled under diminished pressure without decomposition. It is therefore extremely unlikely that it is an intermediate in the cleavage of ethyl α,α'-dibromoadipate by diethylamine. This conclusion lends support to Criegee's theory.



II

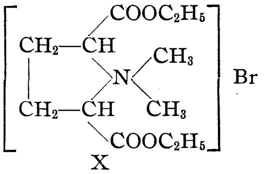
XIV

It is interesting to note that on the strength of his original theory—a theory which is no longer tenable—Fuson predicted that ethyl α,α'-dibromoadipate should react with sodium cyanide to give a cyclobutane derivative, and experiments showed that good yields of a stable cyclized product (IX) could be obtained.[4] This formation of a four-membered ring appears to be an example of the stabilization of a 1,4-biradical by ring closure. Thus the reactions of ethyl α,α'-dibromoadipate with sodium cyanide and diethylamine may be interpreted as examples of two ways in which 1,4-biradicals can stabilize themselves.

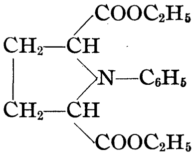


IX

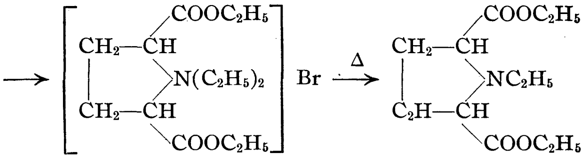
It might be expected that ethyl α-bromo-α'-diethylaminoadipate (II), postulated as the first product of the reaction, would tend to form the corresponding pyrrolidinium bromide. Ethyl α,α'-dibromoadipate reacts with dimethylamine in alcohol to give a pyrrolidinium bromide (X),[5] and with aniline,[6] ethylaniline,[7] and diethylaniline[8] at 100° or above to give ethyl 1-phenyl-2,5-pyrrolidinedicarboxylate (XI). The work of Menschutkin[9] on the velocity of the reaction of triethylamine with ethyl iodide in various solvents suggests that ethyl α,α'-dibromoadipate might be converted to a pyrrolidine derivative (XII) if the treatment with diethylamine were carried out in a suitable solvent.



X



XI



XII

XIII

The reaction was therefore repeated using acetone, ethyl alcohol and benzene as diluents in

comparable runs. The ethyl alcohol and acetone would be expected to hasten the formation of the intermediate, II, and the further reaction of II with more diethylamine to give the diamino product (XIV) or with itself by ring closure to give the quaternary pyrrolidinium salt (XII). The reaction in benzene would be expected to proceed in much the same manner as if there were no solvent;[10] that is, cleavage should result. It was found that the solvents had the expected effect. In ethyl alcohol the pyrrolidine derivative (XII) was formed with no evidence of any cleavage. In acetone the pyrrolidine derivative was also obtained but there was evidence of a small amount of cleavage. In benzene only a small amount of pyrrolidine was formed and both of the cleavage products (VII and VIII) were found. The salt, XII, was not isolated as such but rather as its thermal decomposition product, XIII.

The effect of solvents on the course of the reaction between diethylamine and ethyl α,α'-dibromoadipate made it seem necessary to reinvestigate the reaction of the ester with dimethylamine. It had been carried out in benzene solution by von Braun and Münch[11] who obtained a 20% yield of ethyl α,α'-tetramethyldiaminoadipate (XV). Fuson and Connor[5] using alcohol obtained small amounts of the diamino ester (XV) and the pyrrolidinium bromide (X). To favor cleavage the reaction was carried out rapidly and without a solvent. Dimethylamine and ethyl α,α'-dibromoadipate were heated in a sealed tube on a steam-bath for one-half hour and the crude reaction product was distilled. In this way there was obtained a 35% yield of ethyl 1-methyl-2,5-pyrrolidinedicarboxylate (XVI) with no evidence of any cleavage products.

Experimental

Ethyl 1-Diethylamino-1,2-cyclobutanedicarboxylate.—The anhydride of 1,2-cyclobutanedicarboxylic acid[12] was treated with bromine and red phosphorus[13] and then with ethyl alcohol to produce ethyl 1,2-dibromo-1,2-cyclobutanedicarboxylate. Dehalogenation with zinc in ether[14] gave ethyl Δ'-1,2-cyclobutenedicarboxylate.[15] The properties found for this substance are: b. p. 92–94° (2 mm.); $n^{20}\text{D}$ 1.4610; $d^{20}{}_4$ 1.081; γ^{20} 33.8 dynes/cm.;[16] $M\text{D}$ 50.3; P, 442.1. Calcd. for $C_{10}H_{14}O_4$: $M\text{D}$ 49.51;[17] P, 442.2.[18]

Diethylamine was added to this unsaturated material by the method of Körner and Menozzi.[19] Two grams of ethyl Δ'-1,2-cyclobutenedicarboxylate, 2 g. of diethylamine, and 5 cc. of absolute alcohol were heated at 100° in a sealed tube for five hours. The alcohol and excess diethylamine were removed by distillation, and the amine was then dissolved in ether leaving the amide behind. The amine was extracted from the ether with cold dilute sulfuric acid, and the aqueous solution was washed well with ether. Sodium hydroxide liberated an oil which was removed by ether extraction. The ethereal solution was washed well with water to remove much of the coloring matter, and was then dried with magnesium sulfate. Removal of the ether left a red oil which distilled under diminished pressure to give a clear colorless oil; b. p. 100–101° (2 mm.); $n^{20}\text{D}$ 1.4540; $d^{20}{}_4$ 1.016; γ^{20} 29.7 dynes/cm.[16]

Anal. Calcd. for $C_{14}H_{25}O_4N$: C, 61.97; H, 9.28; $M\text{D}$ 72.56;[17] P, 638.8.[18] Found: C, 62.25, 62.25; H, 9.43, 9.27; $M\text{D}$ 72.3; P, 623.4.

The picrate of the amine was prepared by adding 1 g. of ethyl 1-diethylamino-1,2-cyclobutanedicarboxylate to a saturated solution of 1 g. of picric acid in ethyl alcohol. The yellow crystals which soon appeared were recrystal-

lized several times from ethyl alcohol; m. p. 125–130.5°. The crystals are sensitive to direct sunlight.

Anal. Calcd. for $C_{20}H_{28}O_{11}N_4$: C, 48.00; H, 5.64; N, 11.20. Found: C, 47.96; H, 5.67; N, 11.22.

Ethyl 1-Ethyl-2,5-pyrrolidinedicarboxylate.—This substance was prepared by the method of von Braun and Seemann.[6] Thirty-six grams (0.1 mole) of ethyl *meso*-α,α'-dibromoadipate and 50 g. of dry benzene containing 13.5 g. (0.3 mole) of ethylamine were placed in a sealed tube. The tube soon became warm, and ethylamine hydrobromide began to separate. After standing at room temperature for twenty-four hours the bomb was warmed in a steam-bath for four hours. It was then cooled and the solution was filtered to remove ethylamine hydrobromide. The filtrate was diluted with ether and was extracted with an excess of cold dilute sulfuric acid to remove the basic fraction. The aqueous solution was washed with ether and was then made alkaline with sodium bicarbonate. The oil which separated was removed by ether extraction, the ethereal solution was washed with water and dried, and the ether was removed by distillation. Vacuum distillation of the residual oil gave 7 g. (30% of the theoretical amount) of a colorless oil, b. p. 108–114° (2 mm.). Redistillation gave a fraction boiling at 108–109° (2 mm.); $n^{20}\text{D}$ 1.4508; d^{20}_4 1.052; γ^{20} 32.5 dynes/cm.[16]

Anal. Calcd. for $C_{12}H_{21}O_4N$: C, 59.24; H, 8.70; *M*D 62.84;[17] *P*, 557.7.[18] Found: C, 59.33, 59.34; H, 8.56, 8.63; *M*D 62.2; *P*, 552.2.

The chloroplatinate of the pyrrolidine was prepared by treating 0.8 g. of ethyl 1-ethyl-2,5-pyrrolidinedicarboxylate with 0.7 g. of platinic chloride and 1 cc. of concd. hydrochloric acid in 20 cc. of ethyl acetate. The product was recrystallized from a mixture of equal volumes of ethyl alcohol and ethyl acetate to obtain pale orange crystals; m. p. 133.5–135.5°.

Anal. Calcd. for $(C_{12}H_{21}O_4N)_2\cdot H_2PtCl_6$: Pt, 21.77. Found: Pt, 21.70, 21.70.

Reaction of Diethylamine with Ethyl α,α'-Dibromoadipate. Reaction in Alcohol.—Thirty-six grams of ethyl α,α'-dibromoadipate and 60 cc. of diethylamine were added to 150 cc. of 95% ethyl alcohol and the mixture was allowed to stand at room temperature. At the end of one day all of the dibromo ester had not dissolved so the mixture was warmed until solution was complete. The solution was then let stand at room temperature for an additional forty hours. The solvent and excess diethylamine were removed from the solution by distillation through a 12-in. (30-cm.) Widmer column, and the residue was then heated under diminished pressure to liberate as much material as possible from the diethylamine hydrobromide. The crude distillate obtained in this way was redistilled to obtain 6.5 g. (27% of the theoretical amount) of ethyl 1-ethyl-2,5-pyrrolidinedicarboxylate, boiling at 113–114° (3 mm.).

Reaction in Acetone.—Thirty-six grams of ethyl α,α'-dibromoadipate and 60 cc. of diethylamine were dissolved in a mixture of 145 cc. of acetone and 5 cc. of water, and the solution was allowed to stand at room temperature for two days. The solvent was then removed by distillation and the residue was distilled under reduced pressure. The crude distillate obtained was redistilled to get about 0.5 cc. of a product boiling at 90–95° (18 mm.) and 3 cc. of ethyl 1-ethyl-2,5-pyrrolidinedicarboxylate, boiling at 143–145° (18 mm.).

Reaction in Benzene.—Thirty-six grams of ethyl α,α'-dibromoadipate and 60 cc. of diethylamine were dissolved in 150 cc. of benzene and the solution was allowed to stand at room temperature for sixty hours. It was then filtered to obtain 30 g. of crude diethylamine hydrobromide (the theory calls for 30.8 g. of diethylamine hydrobromide). The diethylamine and benzene were removed from the filtrate by fractional distillation through a 12-in. (30 cm.) Widmer column. The residue was then distilled under diminished pressure to obtain 7 g. of a product boiling at 83–88° at 16 mm. pressure. This was allowed to stand with a slight excess of cold dilute hydrochloric acid for an hour, and it was then extracted with ether. Evaporation of the ether from this extract left a small quantity of an oil which was shown to be ethyl pyruvate by conversion to its phenylhydrazone.

The acid solution was made alkaline with sodium hydroxide and the liberated amine was removed by extraction with ether. The ether solution was dried and the ether was removed by distillation. The residual oil was distilled under diminished pressure to give 3.5 g. (20% of the theoretical) of ethyl β-diethylaminopropionate boiling at 85–86° (15 mm.); $n^{20}\text{D}$ 1.4268.

The crude diethylamine hydrobromide was heated under reduced pressure to yield a small amount of an oil which on redistillation gave about 0.5 cc. of ethyl 1-ethyl-2,5-pyrrolidinedicarboxylate boiling at 110° (2–3 mm.).

Reaction of Dimethylamine with Ethyl α,α'-Dibromoadipate.—Eighteen grams of ethyl α,α'-dibromoadipate was placed in a glass tube and the tube was cooled in a dry ice–acetone bath. Dimethylamine, prepared by dropping a commercial aqueous solution on solid potassium hydroxide and dried by passing the gas over solid potassium hydroxide, was condensed and added to the tube until the weight of the tube had increased by 13.5 g. The tube was then sealed and allowed to warm up to room temperature. A spontaneous reaction occurred and after fifteen minutes the tube had become hot. It was heated for an additional half hour in a steam-bath, cooled and opened. The excess dimethylamine quickly vaporized and the remainder of the product was then distilled under diminished pressure. Redistillation of the crude product obtained gave 4 g. (35% of the theoretical) of ethyl 1-methyl-2,5-pyrrolidinedicarboxylate boiling at 138–141° (20 mm.). This when redistilled had the following properties: b. p. 114–115° (4 mm.), $n^{20}\text{D}$ 1.4515, d^{20}_4 1.072.

Summary

Ethyl 1-diethylamino-1,2-cyclobutanedicarboxylate has been prepared and found to be stable at ordinary temperatures. It is therefore concluded that this ester cannot be an intermediate in the cleavage of ethyl α,α'-dibromoadipate by diethylamine.

The reaction of diethylamine α,α'-dibromoadipate has been carried out using ethyl alcohol, acetone and benzene as solvents in comparable

runs. It has been found that the solvent affects the course of the reaction; ethyl 1-ethyl-2,5-pyrrolidinedicarboxylate is produced in these solvents. It is therefore concluded that 1,1-diethyl-2,5-dicarbethoxypyrrolidinium bromide cannot be an intermediate in the cleavage.

The 1,4-biradical theory of Criegee offers a satisfactory explanation of the facts.

The reaction of dimethylamine and ethyl α,α'-dibromoadipate carried out without a solvent gives a 35% yield of ethyl 1-methyl-2,5-pyrrolidinedicarboxylate with no evidence of any cleavage.

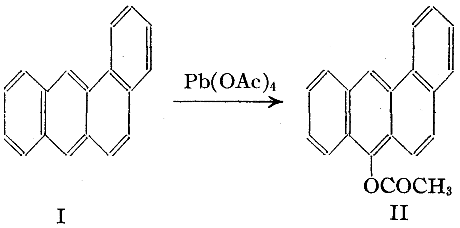
Substitution Reactions and Meso Derivatives of 1,2-Benzanthracene

BY LOUIS F. FIESER AND E. B. HERSHBERG[1]

Among various miscellaneous observations reported in this paper is a study of the action of lead tetraacetate on 1,2-benzanthracene and two related carcinogenic hydrocarbons. The idea of investigating the action of this oxidizing agent on polynuclear aromatic hydrocarbons was suggested by an observation of K. H. Meyer[2] which heretofore has attracted little attention. Schulze[3] at an early date had investigated the action of lead dioxide on anthracene in acetic acid solution, but it remained for Meyer to interpret the reaction correctly and to show that with two moles of oxidizing agent the chief product is hydroxyanthrone acetate. Using one mole of lead dioxide, Meyer obtained anthranyl acetate in 40–50% yield and noted that this was the first instance of the direct oxidation of a hydrocarbon to a phenol derivative. It occurred to us that this method of hydroxylation might have preparative value, that it might afford a useful method of probing for centers of reactivity in polynuclear compounds, and that the reaction would form an interesting model for a possible hydroxylation of carcinogenic hydrocarbons introduced into the animal organism.

In trial experiments lead tetraacetate was found to act as well as lead dioxide and it is a generally superior reagent. The reaction of one mole of lead tetraacetate with 1,2-benzanthracene in glacial acetic acid is complete after short heating on the steam-bath, and the purified reaction product, isolated in 52% yield, was found to be identical with synthetic 1,2-benzanthranyl-10-acetate[4] (II). The chief point of attack in the oxidation therefore is at the less hindered meso position 10.



I II

Little previous work has been done on the orientation of 1,2-benzanthracene in monosubstitutions. Cook and Hewett[5] found that the chief product of the Friedel and Crafts reaction with acetyl chloride at a low temperature is a meso ketone, but a distinction between the 9- and 10-positions was not made. With oxalyl chloride, Dansi[6] obtained besides a diketone a small amount of an acidic substance regarded as 1,2-benzanthracene-10-carboxylic acid. Barnett and Matthews[7] prepared a mononitro compound which they regarded as a 9- or 10-derivative, but they did not investigate the structure. We prepared a sample of the nitro compound by their method and reduced it to the amine. The same amine was obtained in good yield from 1,2-benz-10-anthranol[4] by the Bucherer reaction, from which it is evident that the nitration product prepared by Barnett and Matthews is 10-nitro-1,2-benzanthracene. The nitration of the hydrocarbon thus follows the same course as the oxidation with lead tetraacetate. Since 10-substituted derivatives of 1,2-benzanthracene are of particular interest in connection with the problem of carcinogenesis, it is significant that such compounds are available by the route of direct substitution reac-

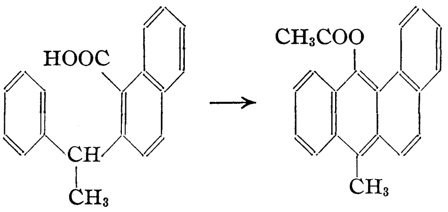
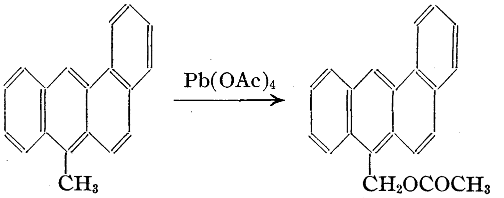
tions.[8] Two additional 10-derivatives described in the Experimental Part are 3,10-dimethoxy-1,2-benzanthracene, prepared by methylation of the MgBr-salt of the corresponding 10-hydroxy compound, and a glycol dibenzoate resulting from the action of the silver benzoate–iodine compound[9] on 10-allyl-1,2-benzanthracene.

Lead tetraacetate reacts somewhat less smoothly with 10-methyl-1,2-benzanthracene than with the parent hydrocarbon, but a crystalline reaction product (m. p. 151°) was isolated in a pure condition if in rather low yield. The substance has the composition of a monoacetoxy compound, and it seemed possible that oxidation had occurred in the available meso position 9. The hitherto unknown 9-acetoxy-10-methyl-1,2-benzanthracene (IV) was therefore synthesized for comparison by the acetylative cyclization[4] of the previously described[10] acid III with zinc chloride catalyst in acetic acid–anhydride, but the synthetic acetate (m. p. 154°), gave a marked depression when mixed with the product of oxidation. We next prepared the 3-acetoxy derivative of 10-methyl-1,2-benzanthracene, since a sample of the hydroxy compound was available from earlier work,[4] but this acetate melted much higher (215°) than the compound in question. The substance was finally identified as 10-acetoxymethyl-1,2-benzanthracene (VI) by direct comparison with a sample of this substance kindly provided by Professor J. von Braun, who in unpublished work has prepared the acetoxy compound by a method leaving no doubt as to the structure. The oxidation of an alkyl side chain is not without parallel, for Dimroth and Schweizer[11] obtained benzyl acetate in about 12% yield on refluxing toluene with lead tetraacetate for four hours, and Criegee[12] found that tetralin is converted by the reagent into the 1-acetoxy derivative (one hour). The oxidation of the hydrocarbon V is complete after fifteen minutes, but whether or not this indicates a special reactivity of the 10-methyl group cannot be determined until more data are available. At all events it is very surprising that the methyl group is attacked in preference to oxidation at the free meso position. In comparison with the meso reactivity of anthracene, and that manifested at the 10-position in 1,2-benzanthracene, the 9-position of the hydrocarbon in question appears to be definitely inert. We are inclined to attribute this effect to steric hindrance, and it may be noted that the 9-position of 1,2-benzanthracene corresponds to position 4 in the phenanthrenoid system present in the molecule and that there are definite indications of hindrance at this position in phenanthrene.[13] While 4-substitution is not unknown,[14] it is extremely rare.



III IV



V VI

In 1,2,5,6-dibenzanthracene both meso positions should be subject to any blocking effect which may be exerted by an angular ring and, in line with the expectations from the behavior of 10-methyl-1,2-benzanthracene, it was found that the tetracyclic hydrocarbon is more resistant to attack by lead tetraacetate than 1,2-benzanthracene. From the reaction of the pure, colorless hydrocarbon with one mole of reagent we invariably recovered some unchanged material, and no homogeneous reaction product was isolated. In the course of the experiments it was observed that the yellow chrysogen (1,2,6,7-dibenzanthracene[15,16]) present in crude 1,2,5,6-dibenzanthracene is oxidized more readily than this hydrocarbon by lead tetraacetate and converted into more soluble products. This suggested a method for the purification of the widely used carcinogenic hydrocarbon which has been found very convenient and efficient. The yellow material

is refluxed for a short time in benzene–acetic acid with about 0.1 mole of lead tetraacetate, and after concentrating and cooling the solution there is obtained very satisfactory, colorless 1,2,5,6-dibenzanthracene in over 80% yield. In our experience this method is considerably more rapid and sparing of material than preferential sulfonation of the chrysogen,[17] reaction with maleic anhydride,[15,18] or chromatographic adsorption.[16]

The lead tetraacetate reaction offers promise of providing information of value concerning the reactivity of various types of polynuclear aromatic hydrocarbons, with or without side chains and alicyclic rings, and the investigation of the reaction is being extended. The conversion of 3,4-benzpyrene and methylcholanthrene into monoacetoxy derivatives, m. p. 208.5–209°, corr., and m. p. 179.5–180.5°, corr., will be described at a later date.

In connection with the acetylative cyclization of the acid III, mentioned above, to an enol acetate (IV), the present paper reports a few additional observations concerning the application of this method[4] of ring closure. The most novel result is the cyclization of γ-(3-acenaphthyl)-butyric acid[19] by the catalytic method to 1-keto-1,2,3,4-tetrahydro-8,9-acephenanthrene[18] in 78% yield. Reference is also made below to a dimolecular product previously obtained[4] from 1,2-benz-10-anthranol.

Experimental Part[20]

Oxidation of 1,2-Benzanthracene.—A solution of 0.5 g. of colorless 1,2-benzanthracene and 1.5 g. of lead tetraacetate in 20 cc. of glacial acetic acid (distilled from permanganate) was warmed on the steam-bath for fifteen minutes and diluted with water to the point of saturation. On cooling there was obtained 0.43 g. (69%) of crude **1,2-benz-10-anthranyl acetate,** m. p. 130–140°, which yielded 0.33 g. (52%) of pure material, m. p. 160–163°, on crystallization from benzene–ligroin. This did not depress the melting point of the previously described sample.[4]

10-Acetoxymethyl-1,2-benzanthracene (VI).—The reaction was conducted as above at the steam-bath temperature, using 1.2 g. of 10-methyl-1,2-benzanthracene in 50 cc. of glacial acetic acid and 2.2 g. of lead tetraacetate in 50 cc. of this solvent. After fifteen minutes the solution was cooled well and diluted with two volumes of ice water. The precipitated material was collected and washed in the cold (otherwise it becomes gummy), dried in vacuum at 50°, and taken into ether–petroleum ether. An amorphous solid was obtained after concentrating the solution, and on three crystallizations from methanol the product formed pale greenish-yellow needles, m. p. 150.5–151.5°; yield, 0.25 g. (17%).

Anal. Calcd. for $C_{21}H_{16}O_2$: C, 83.98; H, 5.37. Found: C, 83.95; H, 5.53.

The substance did not depress the melting point of a sample of 10-acetoxymethyl-1,2-benzanthracene (of nearly identical m. p.) obtained from Professor J. von Braun.

Cyclization Experiments.—Following the exact procedure described[4] for the cyclization of 2-(α-naphthylmethyl)-benzoic acid, *o*-benzylbenzoic acid gave satisfactory **anthranyl-10-acetate** in 73% yield. It was not found easy to obtain material of constant melting point either from this source or from a sample prepared from anthrone; the best material melted at 134.5–135.5°. With 2-(4′-methyl-1′-naphthylmethyl)-benzoic acid[21] (5 g.), the amount of acetic anhydride was cut in half and the time of heating extended to one and one-half hours; the yield of **3-methoxy-10-acetoxy-1,2-benzanthracene,**[21] m. p. 193–194°, was 4.15 g. (86%). Two further crystallizations from glacial acetic acid gave colorless needles, m. p. 194–194.5°. Using the standard procedure,[4] γ-(3-acenaphthyl)-butyric acid[19] was converted in 78% yield into **1-keto-1′,2′,3′,4′-tetrahydro-8,9-acephenanthrene,**[19] m. p. 143–145°, and 2-(α-methylbenzyl)-1-naphthoic acid[10] (III) afforded **9-acetoxy-10-methyl-1,2-benzanthracene** (see below), m. p. 152.5–153.5°, in 95% yield.

9-Acetoxy-10-methyl-1,2-benzanthracene (IV).—Recrystallization of the cyclization product just mentioned from methanol gave small, colorless prisms, m. p. 153.5–154°. When mixed with 10-acetoxymethyl-1,2-benzanthracene the m. p. was depressed to 130–133°.

Anal. Calcd. for $C_{21}H_{16}O_2$: C, 83.98; H, 5.37. Found: C, 83.77; H, 5.33.

3-Acetoxy-10-methyl-1,2-benzanthracene.—The free hydroxy compound[4] was refluxed with acetic anhydride and fused sodium acetate and the product crystallized from methanol. It formed pale yellow prisms, m. p. 214–215°.

Anal. Calcd. for $C_{21}H_{16}O_2$: C, 83.98; H, 5.37. Found: C, 83.55; H, 5.49.

3,10-Dimethoxy-1,2-benzanthracene.—A mixture of 2.5 g. of 3-acetoxy-10-methyl-1,2-benzanthracene in 50 cc. of benzene and the Grignard reagent from 4.3 g. of *n*-butyl bromide in ether was refluxed for one hour, treated with 12 g. of dimethyl sulfate in 50 cc. of benzene, and refluxed for three hours. After hydrolysis with dilute acid a benzene solution of the product was passed through a tower of alumina to remove any hydroxy compound escaping methylation and the filtrate was evaporated. The residual material was very soluble in methanol or petroleum ether (b. p. 20–40°) and from the latter solvent it separated as transparent yellow cubes, m. p. 84–87°; yield, 1.2 g. (53%). This appeared to be a metastable form of the compound, for on being rubbed it changed to an opaque solid considerably less soluble than before. On recrystallization from ligroin (b. p. 60–70°) there was obtained 0.95 g. of light yellow, diamond-shaped prisms, m. p. 145–146.5°. Two more crystallizations from this solvent and one from methanol brought the melting point to 146–146.5°.

Anal. Calcd. for $C_{20}H_{16}O_2$: C, 83.31; H, 5.60. Found: C, 83.08; H, 5.80.

9-Methoxy-10-methyl-1,2-benzanthracene.—This was prepared from the acetoxy compound IV (0.85 g.) by cleavage with the Grignard reagent from *n*-butyl bromide (1.95 g.) and methylation (8 cc. of dimethyl sulfate, several hours), as above, except that at the end of the reaction the mixture was treated with alkali and stirred for two hours and then acidified. From the benzene solution there was obtained material which after one crystallization from methanol melted at 143–144°; yield, 0.46 g. (60%). The substance formed thin, pale greenish-yellow, square plates and recrystallization did not alter the melting point.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.20; H, 5.92. Found: C, 88.11; H, 6.00.

Purification of Yellow 1,2,5,6-Dibenzanthracene.—A warm solution of 0.6 g. of lead tetraacetate in 150 cc. of glacial acetic acid was added in small portions to a solution of 3 g. of bright yellow commercial hydrocarbon in 150 cc. of benzene. The addition must be made slowly to prevent precipitation of the hydrocarbon. After refluxing for one-half hour, the solution was concentrated in the course of one hour to a volume of about 100 cc. and allowed to cool. There was obtained 2.5 g. (83%) of 1,2,5,6-dibenzanthracene in the form of colorless leaflets melting at 265–266° and having a blue fluorescence in ultraviolet light. In other experiments in this Laboratory with larger amounts of a new lot of crude hydrocarbon the recovery has been somewhat lower. On comparing samples of hydrocarbon purified and recrystallized in various ways, the best material was found to melt at 266–266.5°.

10-Amino-1,2-benzanthracene. (a) **From the Nitro Compound.**—The hydrocarbon (4.6 g.) was nitrated at room temperature according to Barnett and Matthews[7] and the crude product (2 g.) crystallized twice from alcohol (100 cc. per g.). There was obtained 1.38 g. (25%) of **10-nitro-1,2-benzanthracene,** m. p. 164–165°.

Hydrogenation of the nitro compound (1.26 g.) in ethyl acetate (75 cc.) was conducted in the presence of Adams catalyst (25 mg.), and the filtered solution was concentrated and treated with ligroin. The solid which separated afforded on recrystallization from ether–ligroin 0.6 g. (54%) of the amine in the form of yellow leaflets, m. p. 174–175°. This did not depress the melting point of the analytical sample described in the next section.

(b) **From the Hydroxy Compound.**—A mixture of 0.5 g. of 1,2-benz-10-anthranol, 5 cc. of concentrated ammonia solution, 2.5 g. of sodium bisulfite in 5 cc. of water, and 2 cc. of dioxane was heated in a sealed tube at 150° for fifty hours. After dilution with water the precipitated solid was dried in vacuum and crystallized from ether–ligroin, giving in all 0.37 g. (74%) of product melting in the range 163–168°. Three more crystallizations gave material melting constantly at 174.5–175.5°. Depending on the relative proportions of ether and ligroin, the amine separated as yellow leaflets or as long yellow needles.

Anal. Calcd. for $C_{18}H_{13}N$: N, 5.76. Found: N, 6.00.

3-(1,2-Benz-10-anthryl)-1,2-propylene Glycol Dibenzoate.—A mixture of 0.93 g. of 10-allyl-1,2-benzanthracene, 1.59 g. of silver benzoate, and 0.88 g. of iodine in 25 cc. of dry benzene was refluxed for fifteen hours on the steam-bath, the solution was filtered. concentrated, and treated with ligroin. This gave 1.5 g. (85%) of satisfactory material, m. p. 148–151°. Two further crystallizations from benzene gave clusters of fluffy, colorless needles, m. p. 152.5–153.5°.

Anal. Calcd. for $C_{35}H_{26}O_4$: C, 82.33; H, 5.13. Found: C, 82.44; H, 5.03.

?-Chloro-1,2-benz-10-anthrone(ol?).—A suspension of 1 g. of powdered 1,2-benz-10-anthranol in 10 cc. of dry ether was treated with 0.6 cc. of *t*-butyl hypochlorite and shaken for about ten minutes, when the orange solid had been converted into a yellow microcrystalline product. Collected and washed with ether, in which it is practically insoluble, the material weighed 0.87 g. (76%) and melted at about 125–130° with decomposition. After three crystallizations from ethyl acetate it melted constantly at 197–198°, dec., when inserted in a bath at 193° and heated rapidly. The substance contains chlorine and forms colorless, highly refractive prisms. It becomes yellow on storage or on being heated.

Anal. Calcd. for $C_{18}H_{18}OCl$: C, 77.58; H, 3.98. Found: C, 77.37; H, 3.94.

Dimolecular Product from 1,2-Benz-10-anthranol.[22]—The above chloro compound was converted on attempted crystallization from methanol into a sparingly soluble chlorine-free product. The same substance was obtained on shaking a suspension of 0.5 g. of 1,2-benz-10-anthranol in 20 cc. of methanol with 0.3 cc. of *t*-butyl hypochlorite for fifteen minutes and boiling the mixture for five minutes. The sparingly soluble material which precipitated (0.25 g.) on crystallization from acetic acid and from toluene formed fine, colorless needles, m. p. 261–263°, dec.

Anal. Calcd. for $C_{36}H_{24}O_2$: C, 88.49; H, 4.94. Found: C, 88.23; H, 4.73.

The substance gave no depression when mixed with the "condensation product" (m. p. 265–267°, dec.) previously described. The present method of preparation suggests that the substance is an oxidation product, and the composition, particularly as indicated by the earlier analyses, appears to be approximately that of a dianthrone (calcd. for $C_{36}H_{22}O_2$: C, 88.86; H, 4.56).

Summary

1,2-Benzanthracene reacts with lead tetraacetate to give the 10-acetoxy derivative, while with 10-methyl-1,2-benzanthracene the reagent attacks the methyl group and the product is 10-acetoxymethyl-1,2-benzanthracene. A very simple and effective method of removing the yellow impurity accompanying 1,2,5,6-dibenzanthrene prepared by the Elbs reaction consists in preferential oxidation with lead tetraacetate.

Various miscellaneous *meso*-substituted derivatives of 1,2-benzanthracene are described in this paper, and it is shown that nitration of the hydrocarbon gives the 10-nitro compound.

Sterols. XLI. Reduction of Naphtholic Steroids to Phenolic Steroids. Equilenin

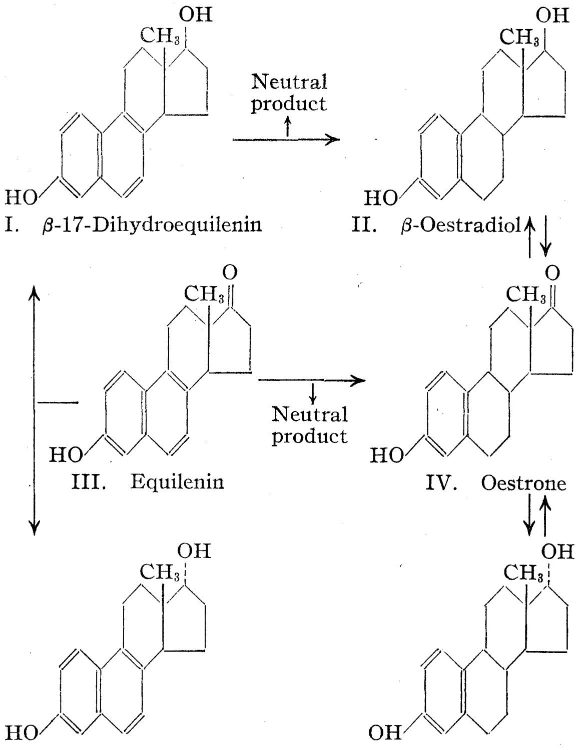
BY RUSSELL E. MARKER

Some time ago we reported the preparation of oestrone from ergosterol.[1] Although no details of the synthesis could be included in that short note, we felt that since the entire synthesis had been checked by two of us, and since the oestrone was shown to be identical in all respects with the natural hormone, no doubt could exist as to the validity of our preparation. However, soon after the appearance of our note, Windaus and Deppe[2] reported that they had been unable to duplicate our preparation of the phenolic tetrahydrodehydroneoergosterol by the reduction of dehydroneoergosterol with sodium and amyl alcohol; in fact, they claimed to find almost no phenolic products in the reduction mixture. As a result of this paper, a number of authors[3–6] have questioned our claim to have prepared synthetic oestrone.

We are now prepared to present a series of papers showing that, contrary to the claims of Windaus and Deppe, β-naphtholic steroids can be reduced to give substantial yields of phenolic steroids as well as larger amounts of neutral steroids. These reductions, which have been carried out by the same general procedure as that used to prepare the phenolic steroid used in our synthesis of oestrone, are actually an extension of the classic studies of Bamberger and co-workers,[7] studies which apparently were overlooked by Windaus.

In this paper we shall describe the reduction of equilenin and of the isomeric 17-dihydroequilenins. The accompanying chart shows the transformation involved.

Since the products sought for in the reduction experiments included oestrone derivatives, great care was taken to purify the equilenin used in this work. Equilenin, m. p. 252°, obtained by repeated crystallizations was first converted into its picrate, and then into its benzoate. Hydrolysis of the equilenin benzoate after repeated recrystallization finally gave equilenin, m. p. 257–258°, $[\alpha]^{25}\text{D} + 89°$, of very high purity.



I. β-17-Dihydroequilenin II. β-Oestradiol III. Equilenin IV. Oestrone V. α-17-Dihydroequilenin VI. α-Oestradiol

We have reported in a short note[8] that when equilenin is reduced with aluminum isopropylate and isopropyl alcohol, a mixture of α- and β-17-dihydroequilenins is formed. The β-17-dihydroequilenin, m. p. 215°, has been isolated as one component of the δ-follicular hormone, from mares' pregnancy urine, by Wintersteiner, Schwenk, Hirschmann and Whitman.[9] Since this substance does not precipitate with digitonin they suggested that it is configurationally related to β-oestradiol, for the latter, unlike α-oestradiol, also does not precipitate digitonin. Since Wintersteiner[10] has also suggested, on the basis of a com-

parison of physiological activities and melting points, that α-oestradiol and α-testosterone (*trans*-testosterone) are configurationally related, it follows that Wintersteiner's β-17-dihydroequilenin, m. p. 215–217°, has the structure I. We find that our β-17-dihydroequilenin, m. p. 215°, has the same properties as the natural hormone isolated by Wintersteiner; it forms a monobenzoate, m. p. 204°, and does not precipitate with digitonin. The less soluble α-17-dihydroequilenin, m. p. 248°, (V) forms a monobenzoate, m. p. 215°, and a diacetate, m. p. 124°. However, in contrast to the behavior of α-oestradiol, α-17-dihydroequilenin does not precipitate with digitonin. Tests[11] show that β-17-dihydroequilenin has an oestrogenic potency of 75–100 R. U. per mg. while the α-epimer has a somewhat greater potency, 250 R. U. per mg. Thus the two epimers are about one-fortieth to one-thirtieth, and one-twelfth as active as oestrone. This relatively low physiological activity of α-17-dihydroequilenin is contrary to the predictions of Wintersteiner, who thought he had isolated, in impure form, "α-dihydroequilenin" from mares' pregnancy urine. His product had a higher melting point than β-17-dihydroequilenin, and a high oestrogenic activity. Obviously, his product was contaminated with some highly active substance, possibly α-oestradiol. It is now evident that Wintersteiner's correlation of β-17-dihydroequilenin with β-oestradiol is correct, but his arguments—the non-precipitability with digitonin and low physiological activity of this, the lower melting epimeric 17-dihydroequilenin—have little bearing on the configuration, since the higher melting α-epimer is also not precipitated by digitonin, and also shows low oestrogenic potency. In this connection it should be emphasized that assignments of configuration based on a comparison of melting points are always to be regarded as only tentative, for the melting point relationships in a given type of epimeric steroids may be reversed by the introduction of double bonds. Thus while the melting points of *epi*-stigmastanol, *epi*-cholestanol, and similar *epi*-saturated steroids are considerably higher than for the corresponding β-epimers, this relationship is reversed in steroids of the type of cholesterol, sitosterol and stigmasterol, where the *epi*-forms melt somewhat lower than the β-forms. In most cases valid correlations of configurations can be made today only by actual chemical interconversions.

Accordingly, to establish the relationship of the 17-dihydroequilenin to the oestradiols, and to provide additional examples of the reduction of naphtholic steroids to phenolic steroids, the 17-dihydroequilenins were treated with sodium in boiling amyl alcohol according to the procedure developed by Bamberger[7] and used by us in the preparation of oestrone from dehydroneoergosterol.[1] By this method α-dihydroequilenin gave α-oestradiol, m. p. 176°, as proved by comparison of the product and its benzoate with authentic α-oestradiol and its monobenzoate. In addition, a small amount of another phenolic substance, m. p. 151–154°, was isolated in an impure state. The non-phenolic fraction from the reduction constituted the major portion of the reaction products, and yielded a substance of m. p. 172°, which will be described in a subsequent paper. Similarly, the reduction of β-17-dihydroequilenin yielded, besides larger quantities of non-phenolic material, β-oestradiol. The mother liquors, after conversion to the monobenzoate, on oxidation yielded oestrone monobenzoate. From the mother liquors of this experiment and a similar experiment using the α-epimer, a phenolic ketone, m. p. 222–225°, which analyzed for four double bonds was obtained. This may be equilin or one of its isomers. When equilenin was reduced with sodium in amyl alcohol, and the phenolic reduction product benzoylated and oxidized, oestrone benzoate was obtained.

In connection with the reduction of equilenin it should be noted that David[12] found that the action of sodium in amyl alcohol gave an oil of high oestrogenic potency. Since the 17-dihydroequilenins have very little potency it seems likely that he had also obtained reduction to phenolic substances, oestradiols, which gave his oil its high activity.

The details of our preparation of oestrone, which have been repeated many times in this Laboratory by different workers, will be reported as the last paper of this series on the reduction of naphtholic steroids.

I wish to thank Dr. Oliver Kamm and Parke, Davis & Company for their generous help and assistance in various phases of this work. I also express my thanks to Drs. Elmer J. Lawson, Eugene L. Wittle, Thomas S. Oakwood, Harry

Experimental

Purification of Equilenin.—The equilenin used in this work was separated from oestrone as well as possible by crystallization to give a product melting at 252°. Five grams of this product was dissolved in benzene and an equal volume of benzene saturated with picric acid was added. The solution was evaporated to one-half volume and let stand overnight in a refrigerator. The red picrate was filtered and recrystallized from a benzene solution saturated with picric acid. The picrate was dissolved in ether and shaken with ammonia diluted with an equal volume of water until it was washed free of picric acid. The ether was evaporated and the residue after one crystallization from 60% alcohol was shaken with 300 cc. of a 10% sodium hydroxide solution. At intervals benzoyl chloride was added until an excess was present. The insoluble benzoate was filtered, washed with water and recrystallized from ethanol to a melting point of 225°. This gave a depression in melting point when mixed with oestrone benzoate, m. p. 215°.

The purified equilenin benzoate was dissolved in ethanol and hydrolyzed by refluxing with an excess of potassium hydroxide for one hour. The equilenin was recrystallized from ethanol and then melted at 257–258° (uncorr.), $[\alpha]^{25}_{D}$ +89°.

The Dihydroequilenins.—To a solution of 4 g. of purified equilenin in 70 cc. of dry isopropyl alcohol was added 4 g. of powdered aluminum isopropylate. The mixture was refluxed for five hours and then concentrated to 20 cc. by slow distillation over a five-hour period. While the mixture was still warm, 2 g. of potassium hydroxide dissolved in 60 cc. of methanol was added. The mixture was let stand for thirty minutes, and then was poured into water and acidified with hydrochloric acid. The product was extracted with ether, the solvent removed and the residue crystallized from 100 cc. of 80% ethanol. After three crystallizations a constant melting point of 248° was reached which did not increase upon further crystallization. When mixed with equilenin it gave a depression in melting point to 215°. This compound is designated as α-dihydroequilenin.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.5; H, 7.5. Found: C, 80.3; H, 7.6.

Diacetate of α-Dihydroequilenin.—α-Dihydroequilenin (100 mg.) was refluxed for thirty minutes with 5 cc. of acetic anhydride. After removal of the excess acetic anhydride, the residue was crystallized from 50% ethanol to give needles melting at 124°.

Anal. Calcd. for $C_{22}H_{24}O_4$: C, 74.9; H, 6.9. Found: C, 74.8; H, 7.0.

Monobenzoate of α-Dihydroequilenin.—α-Dihydroequilenin (25 mg.) was shaken with 6 cc. of 10% sodium hydroxide solution and an excess of benzoyl chloride for twenty minutes. The benzoate was filtered and recrystallized from ethanol; m. p. 215°.

Anal. Calcd. for $C_{25}H_{24}O_3$: C, 80.4; H, 6.7. Found: C, 80.5; H, 6.7.

β-Dihydroequilenin (δ-Follicular Hormone).—The mother liquor from the crystallization of α-dihydroequilenin was diluted while hot with water until a concentration of 50% alcohol was reached. It was allowed to cool slowly to room temperature for one hour, and the precipitate filtered. This consisted chiefly of some additional α-dihydroequilenin. The filtrate was cooled in a freezing mixture of ice and hydrochloric acid. The product was filtered and recrystallized from 50% ethanol to give a product melting at 215°, which gave a depression in melting point to 180° when mixed with α-dihydroequilenin.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.5; H, 7.5. Found: C, 80.4; H, 7.7.

Monobenzoate of β-Dihydroequilenin.—This was prepared in a way similar to that described for the α-form. It was crystallized from alcohol to a constant melting point of 204°.

Anal. Calcd. for $C_{25}H_{24}O_3$: C, 80.4; H, 6.7. Found: C, 80.4; H, 6.7.

Reduction of α-Dihydroequilenin by Sodium in Amyl Alcohol.—To a solution of 1 g. of α-dihydroequilenin, m. p. 248°, dissolved in 100 cc. of *n*-amyl alcohol (dry) was added 8 g. of sodium. The amyl alcohol was refluxed until the sodium had dissolved (two hours). Water was added, and the alkaline solution was acidified with hydrochloric acid. The product was extracted with ether, and the solvent removed *in vacuo*. The residue was dissolved in ether and the ethereal solution was washed well six times with 100-cc. portions of 2% sodium hydroxide solution. The alkaline solution was acidified and extracted with ether. The ether was evaporated and the phenolic residue was sublimed in a high vacuum at 175° bath temperature. The sublimate weighed 194 mg. A small amount of tarry phenolic material did not sublime. The sublimate was crystallized from dilute ethanol to give a product melting at 176°. This was purified only with difficulty as there was present a second phenolic product which could not be crystallized beyond 151–154° (unsharply) because of the small amount of product and some difficulty of separation. This product is being investigated further. The 176° product gave no depression in melting point when mixed with oestradiol, m. p. 178°.

The total product was converted to its monobenzoate by shaking with sodium hydroxide solution and benzoyl chloride. The product after crystallization from dilute ethanol melted at 194°. When mixed with the monobenzoate of α-dihydrooestrone it gave no depression in melting point; yield 41 mg.

Anal. Calcd. for $C_{25}H_{28}O_3$: C, 79.5; H, 7.5. Found: C, 79.5; H, 7.5.

The neutral fraction from the reduction which was not extractable with alkali from an ethereal solution was recrystallized from acetone–water to give a product melting at 172°. A study of this compound will be reported later.

Reduction of β-Dihydroequilenin with Sodium in Amyl Alcohol.—One gram of β-dihydroequilenin was reduced with sodium in amyl alcohol as described for the α-compound. The phenolic material was removed by shaking an ethereal solution of the reduced product with 2% sodium hydroxide. This phenolic fraction was sublimed in high vacuum at 175° (bath temp.) to give 205 mg. of sublimate.

As there was present in the sublimate a product other than β-dihydrooestrone, separation by direct crystallization could not be accomplished. The total product was converted into the benzoate by shaking with sodium hydroxide and benzoyl chloride. This was crystallized from dilute ethanol to give a substance of indefinite melting point; upon hydrolysis of this product with potassium hydroxide in ethyl alcohol a product was obtained which after crystallization from dilute ethanol gave a melting point of 215–219°. When this substance was mixed with β-dihydrooestrone, m. p. 222°, no depression in melting point was observed. Only 11 mg. of this product was obtained. It gave a depression in melting point of 24° when mixed with β-dihydroequilenin, m. p. 215°.

The total mother liquors from this product was converted again into the benzoate and this was oxidized with 40 mg. of chromic oxide in acetic acid for one hour. Water was added and the product extracted with ether and washed with water and sodium carbonate solution. After removal of the ether, the residue was dissolved in 50 cc. of ethanol and refluxed for thirty minutes with 1 g. of Girard's reagent. Water and ether were added, the layers separated and the aqueous layer heated on a steam-bath for a few minutes with an excess of hydrochloric acid. The ketonic material was extracted with ether, and the residue after removal of the ether was hydrolyzed with alcoholic potassium hydroxide. The product thus obtained was sublimed in high vacuum at 160°. From the sublimate after crystallization from ethanol was obtained 28 mg. of oestrone, m. p. 255°. When it was mixed with authentic oestrone it showed no depression in melting point.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.9; H, 8.2. Found: C, 79.9; H, 8.3.

The mother liquors of this gave a product which after several crystallizations from dilute ethanol melted unsharply at 222–225°. This gave a depression in melting point when mixed with both oestrone and equilenin. The same product was obtained by the oxidation of the mother liquors from the α-dihydrooestrone obtained from the reduction of α-dihydroequilenin. This gave an analysis for a compound more unsaturated than oestrone, and is being studied further.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.5; H, 7.5. Found: C, 80.3; H, 7.5.

Reduction of Equilenin by Sodium in Amyl Alcohol.—One gram of equilenin was reduced by sodium in amyl alcohol as described for dihydroequilenin. The phenolic product of reduction was distilled in high vacuum, giving 123 mg. of distillate. This was converted to the benzoate and oxidized by chromic acid to give 31 mg. of oestrone after hydrolysis. It melted at 250–251°, and gave no depression in melting point when mixed with oestrone.

Reduction of Oestrone Benzoate with Aluminum Isopropylate.—To a solution of 500 mg. of oestrone benzoate dissolved in 20 cc. of dry isopropyl alcohol was added 1 g. of aluminum isopropylate and the reduction was carried out as described for the reduction of equilenin. The product which was obtained was dissolved in 25 cc. of ethanol and a solution of 2 g. of digitonin in 100 cc. of 65% alcohol was added. After standing overnight, the digitonide was filtered and washed with 70% ethanol. This after drying was warmed with pyridine on a steam-bath for thirty minutes. After removal of the pyridine and digitonin the product was crystallized from dilute ethanol and then melted at 195°. Upon hydrolysis it gave oestradiol of m. p. 178°.

The mother liquors from the digitonide of the α-form were concentrated to a small volume and shaken with water and ether. The ethereal solution was filtered and concentrated. The residue was hydrolyzed with alcoholic potassium hydroxide and gave after crystallization from dilute ethanol a product melting at 222°, which was β-oestradiol as shown by mixed melting points.

Summary

The reduction of equilenin by aluminum isopropylate gives a mixture of α- and β-dihydroequilenin which can be separated readily by crystallization. The latter compound is identical with the δ-follicular hormone. Upon reduction of either isomeric dihydroequilenin by sodium in amyl alcohol about 20% of phenolic substances are formed and from the α-form is obtained α-oestradiol whereas the β-dihydroequilenin yields β-oestradiol. Both yield about 75% of nonphenolic products which are being studied.

Sterols. XLII. The Isolation of Oestranediols from Human Non-Pregnancy Urine

BY RUSSELL E. MARKER, EWALD ROHRMANN, ELMER J. LAWSON AND EUGENE L. WITTLE

In an earlier paper in this series[1] it has been proposed that the numerous steroids present in urines and glandular extracts arise by reductive processes in the course of utilization of the sex and cortical hormones. On the basis of new experimental information to be presented in this paper, it now appears that the oestrogenic hormones suffer these same reductive processes when they are utilized as hormones in the non-pregnant woman, for from the urines of such subjects we have isolated two isomeric oestranediols.[2]

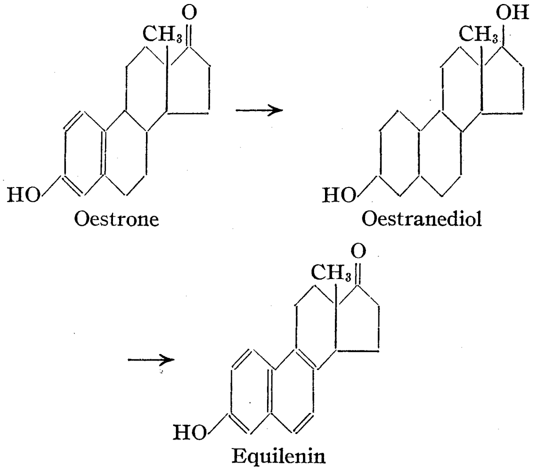

Fig. 1.

The mode of isolation of these diols was essentially the same as that described in earlier papers. Two hundred gallons (755 liters) of non-pregnancy human urine was extracted with butanol, and hydrolyzed with acid and alkali to yield a neutral fraction which was separated by means of succinic anhydride and Girard's reagent into carbinols, ketones, and inert substances. The carbinol fraction, corresponding to 40 mg. per gallon of urine, was treated with digitonin to separate the 3-βOH and 3-αOH sterols. The 3-βOH sterol fraction proved to be mainly cholesterol. From the carbinol fraction not precipitable by digitonin two alcohols, $C_{18}H_{30}O_2$, m. p. 242 and 204°, were isolated by fractional crystallization after removal of a small amount of pregnanediol. The structures of these diols as stereoisomeric oestranediols are proved by the following facts. Both diols form diacetates melting at 160° which show a decided depression in admixture. Both diols, when heated with platinum black, are dehydrogenated to give equilenin, although in poor yields because of the polymerization of the latter to equilenin red. Furthermore, the catalytic hydrogenation of oestrone in alcoholic solution containing a little hydrochloric acid[3] gives an oestranediol, m. p. 205°, identical with oestranediol-B, m. p. 204°. Since this oestranediol yields a different diketone, 170°,[3a] from the diketone, m. p. 124°, formed by oestranediol-A the two carbinols must differ at least in regard to their configuration at C_5 or C_{10}. Ample opportunity for isomerism is of course possible since the reduction of oestrone generates new asymmetric centers at C_3, C_5, and C_{10}. We have, indeed, indications of the presence of other possibly isomeric carbinols in the mother liquors from which the diols were isolated. Neither oestranediol-A, nor the less abundant and more soluble oestranediol-B, precipitates with digitonin, but this cannot be taken as indicating that these diols contain 3-αOH groups, for neither neoergosterol nor *epi*-neoergosterol form insoluble digitonides,[4] apparently, the presence of an angular methyl group at C_{10} is essential for the formation of insoluble digitonides.

The isolation of these stereoisomeric oestranediols from the urine of non-pregnant women throws considerable light on the manner of utilization of oestrone when it functions as a hormone in the organism. Large quantities of oestrone are excreted by the pregnant woman, probably because the hormone is not being utilized while the oestrus cycle is suspended. During this same period, however, no appreciable amount of progesterone is excreted for the latter is being used to control the development of pregnancy; instead large quantities of carbinols and ketones, which are reduction products of progesterone, are elimi-

nated. In the mature non-pregnant female, on the other hand, oestrone is being utilized to control the oestrus cycle, so almost none of this hormone is excreted in the urine;[5] instead, its reduction products, the oestranediols formed in the course of utilization of the hormone are excreted. In complete harmony with these facts is the small amount of pregnanediols in non-pregnancy urine. Furthermore, the oestranediols are not present in pregnancy urine, for their relative ease of isolation makes it highly improbable that they could have been overlooked in our extensive investigation of its steroid fraction.[6]

The presence of the oestranediols in non-pregnancy urine but not in pregnancy urine shows that they are formed, not by merely enzymatic processes, but in the actual utilization of oestrone. This view is supported by the results of some experiments on the enzymatic reduction of oestrone by the methods of Mamoli, Vercellone and Ercoli.[7] Enzyme extracts of hog ovaries, beef suprarenal glands and bull testes were mixed with oestrone and allowed to stand for thirty days. In none of these cases was any reduction product formed, the oestrone being recovered unchanged.

The investigation of steroids from non-pregnancy urine is being continued on a much larger scale. We wish to thank Dr. Oliver Kamm and Parke, Davis & Company for their generous help and assistance in various phases of this work. The micro-analyses were done by Dr. George H. Fleming of this Laboratory.

Experimental Part

Isolation of Total Sterol Fraction.—Two hundred gallons (756 liters) of human non-pregnancy urine was extracted thoroughly with butanol before hydrolysis. The aqueous portion was then hydrolyzed by heating with hydrochloric acid, and after hydrolysis this was again thoroughly extracted with butanol. The butanol was evaporated *in vacuo* from both extracts and the products worked up separately.

The product from the extraction of the non-hydrolyzed urine was heated on a steam-bath with 5 kg. of sodium hydroxide dissolved in 20 liters of water for one hour, then steam distilled until no more volatile material came over. This required six hours. The residue remaining in the flask was thoroughly extracted with ether, and the solvent evaporated. The residue was rehydrolyzed with alcoholic potassium hydroxide, and the neutral product so obtained weighed 17 g. after removal of the solvent.

The residue was dried by distillation with benzene. To this was added 25 g. of succinic anhydride and 50 cc. of pyridine and the mixture was heated for one hour on a steam-bath. Ice and ether were added and the pyridine was removed by shaking with dilute hydrochloric acid. The succinic esters were then removed from the ether solution by shaking with sodium carbonate solution. The aqueous layer was acidified and the succinic esters of the carbinols were extracted with ether. The ether was evaporated and the residue was hydrolyzed by heating with an excess of alcoholic potassium hydroxide solution. The hydrolyzed carbinol fraction weighed 8 g. after removal of the solvent. This residue was dissolved in 100 cc. of ethyl alcohol and 5 g. of Girard's reagent was added. The solution was heated for twenty minutes on a steam-bath, water was added and the product was well extracted with ether. The aqueous layer upon heating with hydrochloric acid gave only a small amount of ketones which were reserved for future investigation. The solvent was removed from the ethereal extract from the Girard's reagent treatment and the residue was dissolved in a small amount of ethyl alcohol. To this was added 250 cc. of a 2% digitonin solution in 90% ethyl alcohol, and the mixture allowed to stand overnight. The digitonide was filtered and dried. It gave 3.7 g. of digitonide which upon hydrolysis gave mainly cholesterol. The alcohol was distilled from the filtrate from the digitonide and the residue was thoroughly extracted with ether and filtered. The ether was evaporated giving a residue weighing 5 g.

The sterol fraction from the acid hydrolyzed fraction of the non-pregnancy urine was worked up to this point in a similar manner. This fraction was similar to the other in all respects, except that the cholesterol content appeared to be less. Four grams of carbinols remained after removal of the cholesterol, ketones and non-carbinol material.

Oestranediol-A.—The above sterol fractions were sublimed separately using a mercury vapor pump and the fraction subliming at 110–135° was collected over a period of twenty hours. The distillates upon cooling in acetone gave in both cases a crude crystalline product melting at 200–210° which did not depress in melting point when mixed, so the total distillates, weighing 3.9 g., were combined. This was dissolved in 15 cc. of acetone, cooled overnight in a refrigerator and then filtered. This fraction was principally pregnanediol. The filtrate was cooled in a mixture of ice and hydrochloric acid for two hours. The crystalline product was filtered and the mother liquors reserved for future investigation.

The crystalline material (1.2 g.) was recrystallized from acetone to give a substance of a constant melting point 242°; yield 295 mg. This, when pure, is quite insoluble in acetone and can also be crystallized from a mixture of benzene and ligroin. It gave a depression in melting point of 30° when mixed with pregnanediol and 25° when mixed with *allo*-pregnanediol.

---

(5) Loews and Lange, *Klin. Wochr.*, **5**, 1038 (1926), found very little oestrogenic activity in concentrates from non-pregnancy urine.

(6) At present we have worked over the steroid fraction of over 100,000 gallons (378,000 liters) of human pregnancy urine, whereas the oestranediols are easily isolated from small amounts of non-pregnancy urine.

(7) Mamoli and Vercellone, *Z. physiol. Chem.*, **245**, 93 (1937); *Ber.*, **70B**, 470 (1937); Vercellone and Mamoli, *Z. physiol. Chem.*, **248**, 277 (1937); Ercoli and Mamoli, *Ber.*, **71**, 156 (1938); Ercoli, *Ber.*, **71**, 650 (1938).

Diacetate of Oestranediol-A.—A solution of 25 mg. of oestranediol-A in 5 cc. of acetic anhydride was refluxed for thirty minutes. The acetic anhydride was evaporated and the residue was recrystallized from methanol to a constant melting point of 160°.

Anal. Calcd. for $C_{22}H_{34}O_4$: C, 72.9; H, 9.5. Found: C, 73.2; H, 9.7.

Oestranedione-A.—To a solution of 50 mg. of oestranediol-A in 20 cc. of acetic acid was added 40 mg. of chromic anhydride in 5 cc. of 90% acetic acid. After standing at room temperature for one hour, water was added and the product was extracted with ether. The ethereal solution was freed of acids by shaking with water and 2% sodium hydroxide solution, and evaporated. The residue was sublimed in high vacuum and the fraction distilling at 120° was recrystallized from 50% acetone to give 36 mg. of oestranedione-A, m. p. 124°.

Anal. Calcd. for $C_{18}H_{26}O_2$: C, 78.8; H, 9.5. Found: C, 79.2; H, 9.8.

Equilenin from Oestranediol-A.—A mixture of 150 mg. of oestranediol-A and 100 mg. of platinum black was melted in a stream of nitrogen. The temperature was then lowered to 215–225° and kept there for one hour, during which time bubbles of hydrogen were given off. The product was dissolved in ether and filtered. The ether was evaporated and the residue dissolved in 10 cc. of benzene. To this was added 10 cc. of a benzene solution saturated with picric acid and the solution concentrated to 10 cc. After standing in a refrigerator overnight the red crystalline picrate was collected and dissolved in ether. The ether solution was shaken with ammonia diluted with an equal volume of water until the color of picric acid was no longer present. The ether solution was then shaken with 5% sodium hydroxide solution. The alkaline solution was acidified and the product was filtered and washed with water. It was recrystallized from 50% alcohol to give 14 mg. of a product melting at 247–249°, giving a bright red color characteristic of equilenin when melted in the presence of oxygen. It gave no depression in melting point when mixed with an authentic sample of equilenin, m. p. 256°. It gave a depression in melting point to 233° when mixed with oestrone.

Oestranediol-B.—The mother liquors from the crystallization of oestranediol-A were concentrated to about 20 cc. and cooled in a refrigerator overnight. The crystalline material was filtered and the filtrate was evaporated to about 10 cc. and cooled in ice–hydrochloric acid mixture. The crystalline product was filtered and crystallized from benzene–ligroin mixture. It was then crystallized from acetone to a constant melting point of 204°, yield 43 mg.

A sample of octahydro-oestrone was prepared by the method of Dirscherl[3] by the catalytic reduction of oestrone in alcoholic–hydrochloric acid solution using platinum oxide as a catalyst. This melted at 204–205°, and gave no depression in melting point when mixed with oestranediol-B isolated from non-pregnancy urine. Oestranediols-A and -B gave a depression in melting point when mixed with each other.

Anal. Calcd. for $C_{18}H_{30}O_2$: C, 77.6; H, 10.9. Found: C, 77.6; H, 10.8.

Diacetate of Oestranediol-B.—A solution of 25 mg. of oestranediol-B in 5 cc. of acetic anhydride was refluxed for thirty minutes. The acetic anhydride was evaporated and the residue was crystallized from methanol to a constant melting point of 160°.

Anal. Calcd. for $C_{22}H_{34}O_4$: C, 72.9; H, 9.5. Found: C, 72.8; H, 9.5.

Oestranedione-B.—A solution of 30 mg. of oestranediol-B (prepared by the reduction of oestrone) was oxidized by 30 mg. of chromic anhydride as described for oestranediol-A. The product was sublimed *in vacuo* and the sublimate was recrystallized from 50% acetone to a melting point of 170°.

Anal. Calcd. for $C_{18}H_{26}O_2$: C, 78.8; H, 9.5. Found: C, 79.0; H, 9.6.

Equilenin from Oestranediol-B.—One hundred and fifty mg. of oestranediol-B (from oestrone) was dehydrogenated as described for oestranediol-A. The product was isolated and purified as described before. It melted at 247° with the formation of a red color. Mixed with equilenin of known purity its melting point was raised to 250–254°. Mixed with oestrone it depressed to 230°.

Attempted Enzymatic Reduction of Oestrone.—Fresh hog ovaries were autolyzed according to the procedure used by Mamoli with stallion testes.[7] Three hundred cc. of the resulting extract (equivalent to 150 g. of ovaries) was mixed with 200 mg. of oestrone and the mixture was allowed to stand at 37° with frequent shaking for a period of thirty days. Then the mixture was extracted with ether, the solvent was evaporated to a volume of 50 cc. and washed with a 5% sodium hydroxide solution. The separated aqueous washings were then acidified with hydrochloric acid and the crystalline precipitate filtered, thoroughly washed with water and dried. The weight of the dried precipitate was 140 mg. It melted at 240–250° and showed no depression in melting point with an authentic sample of oestrone.

Similar results were obtained with extracts from suprarenal glands of beef, and bull testes.

Summary

Two stereoisomeric oestranediols have been isolated from non-pregnancy urine. The occurrence of these oestranediols in non-pregnancy urine but not in pregnancy urine indicates that they are formed by non-enzymatic reductive processes in the course of utilization of oestrone as a hormone.

Sterols. XLIII. The 3(β)-Hydroxysteroids in Human Pregnancy Urine

By Russell E. Marker, Stephen B. Binkley, Eugene L. Wittle and Elmer J. Lawson

On the basis of a theory of the origin and interrelationships of the sex and cortical steroids[1] we have predicted the absence in glandular extracts and urines of 3(β)-hydroxy saturated steroids of the coprostanol type. The absence of this type of steroid from mare pregnancy urine already has been reported.[2] As further verification of this prediction, we are now able to report the absence of this type of steroid in human pregnancy urine. Our examination of the 3(β)-hydroxy steroid fraction from 1000 gallons (3780 liters) of human pregnancy urine has revealed the presence, in more than mere traces, of only cholesterol (4 mg. per gallon) and *allo*-pregnanediol-3(β),20(α) (1–1.5 mg. per gallon).

The carbinol fraction of 1000 gallons (3780 liters) of human pregnancy urine from which pregnanediol-3(α),20(α), and *allo*-pregnanediol-3(α),20(α) had been removed was treated with digitonin solution to isolate the 3(β)-hydroxysteroids. The 3(β)-hydroxysteroid fraction thus obtained was distilled and the fraction subliming up to a bath temperature of 170° was investigated. (The residue which did not distil, consisting of triols, tetrols and so forth, was too small to warrant investigation.) The distillate, consisting of mono- and dihydroxy steroids was separated into a saturated and unsaturated steroid fraction, making use of the fact that the unsaturated sterol dibromides do not precipitate with digitonin. Crystallization of the unsaturated sterol fraction yielded cholesterol, and an examination of the mother liquors from this showed the presence of only small amounts of other substances. Similarly, the saturated sterol fraction proved to be almost entirely *allo*-pregnanediol-3(β),20(α). To prove the absence of pregnanediol-3(β),20(α) and similar coprostanol derivatives, the sterols in the mother liquors from the isolation of *allo*-pregnanediol-3(β),20(α) were epimerized with sodium in boiling xylene, the cholestanol derivatives precipitated with digitonin, and the filtrate examined for the presence of *epi*-coprostanol type derivatives, but none were found present.

We wish to thank Dr. Oliver Kamm and Parke, Davis & Company for their generous help and assistance in various phases of this work.

Experimental Part

The carbinol fraction from 1000 gallons (3780 liters) of human pregnancy urine after removal of the preganediol, *allo*-pregnanediol and ketones was dissolved in a small amount of ethyl alcohol. To this was added a solution of 40 g. of digitonin in 2 liters of 90% ethyl alcohol. It was allowed to stand overnight; then the insoluble digitonide was filtered and washed with ethyl alcohol until colorless. After drying it weighed 38 g.

The digitonide was decomposed by heating for thirty minutes on a steam-bath with 150 cc. of pyridine and pouring into 2 liters of ether. The digitonin was filtered and the pyridine was removed by washing with hydrochloric acid. The ether was evaporated, giving a residue of 9.8 g. of sterols. This residue was sublimed *in vacuo* up to 170° using a mercury vapor pump for forty hours. Only mono- and dihydroxysterols distil up to this temperature. The distillate, weighing 7.0 g., was dissolved in 500 cc. of ethyl alcohol, cooled to 0° and enough bromine added to give a permanent yellow color. Then an excess of a 1% solution of digitonin in 90% alcohol was added. After standing overnight, the digitonide was filtered. Upon drying this weighed 6.4 g. From the filtrate was obtained, after debromination with zinc dust, 3.2 g. of cholesterol. The filtrate contained a considerable amount of cholesterol in addition to some other unsaturated steroids in smaller amounts. The insoluble digitonide was decomposed by pyridine as previously described. Upon crystallizing the liberated sterol from acetone, 0.8 g. of a product was obtained melting at 216°, which gave no depression in melting point when mixed with *allo*-pregnanediol-3(β),20(α) (m. p. 216°).

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 79.9; H, 11.4.

Oxidation of this gave *allo*-pregnanedione of m. p. 200° which showed no depression in melting point when mixed with a known sample.

To see whether the filtrate from the *allo*-pregnanediol-3-(β),20(α) contained any carbinols of the pregnane series with β-OH groups in the 3-position, the residue after evaporation of the solvent was epimerized by refluxing for nine hours with 5 g. of sodium in 100 cc. of xylene. The sodium was destroyed with aqueous alcohol and the product was extracted with ether. The solvent was removed and the residue dissolved in a small amount of alcohol. An excess of digitonin in 90% alcohol was added, and after standing overnight the digitonide was filtered. The alcohol was removed from the filtrate and the residue was extracted for twenty-four hours with ether. No residue remained after evaporating the ethereal solution, showing that all of the sterols in human pregnancy urine precipi-

table by digitonin and containing one or two hydroxyl groups are either unsaturated sterols or belong to the *allo*-saturated series, with none of the regular pregnane series present.

Summary

Cholesterol and *allo*-pregnanediol-3(β),20(α) were isolated from the digitonin precipitable fraction of human pregnancy urine sterols. No mono- or dihydroxy-steroids of the pregnane configuration at C-5 with 3(β)-OH groups were found present.

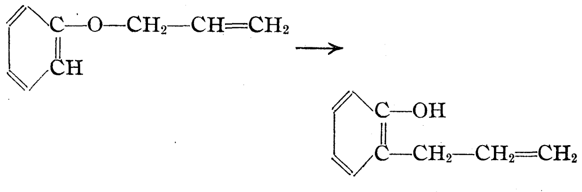
The Rearrangement of Vinyl Allyl Ethers

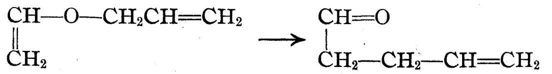
BY CHARLES D. HURD AND MAXWELL A. POLLACK

That phenyl allyl ether undergoes thermal rearrangement into *o*-allylphenol has been known for several years. Recent investigations have demonstrated the intramolecular nature of the process,[1] the inversion of the allyl group,[2] the failure of α,α-disubstituted allyl ethers to rearrange,[3] and the unusual rearrangement of γ-ethylallyl phenyl ether.[4]

That part of the aryl allyl ethers which is concerned in the rearrangement possesses the skeleton C═C—O—C—C═C



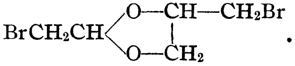
There is no previous mention in the literature of vinyl allyl ether, the simplest compound to possess this structure. It seemed important, therefore, to prepare it so that its pyrolytic behavior might be studied. If a comparable rearrangement occurred, allylacetaldehyde would be anticipated.



$$CH_2{=}CH{-}O{-}CH_2CH{=}CH_2 \longrightarrow CH(=O){-}CH_2{-}CH_2{-}CH{=}CH_2$$

The enol modification of this aldehyde, $CH_2{=}CH{-}CH_2{-}CH{=}CHOH$, would be analogous to the *o*-allylphenol.

Since neither vinyl allyl ether nor any of its simple analogs are known, several synthetical approaches were tested. One of these methods consisted in the condensation between allyl bromoacetal and sodium. A similar reaction had been employed successfully by Wislicenus[5] in the preparation of vinyl ethyl ether: $BrCH_2CH(OC_2H_5)_2 + Na \longrightarrow CH_2{=}CHOC_2H_5 + NaBr + C_2H_5ONa$, but in the present adaptation, the yield was trivial. When only one-fifth of the theoretical amount of sodium was added to the acetal, the reaction mixture became a thick brown mass, to which further addition of alkali metal proved ineffectual. No improvement was realized with xylene as solvent. Somewhat similar results were obtained by Hibbert and Hill[6] from the reaction between sodium and 3-bromo-1,2-propanediol bromoacetal,



$$BrCH_2CH\langle{}^{O-CH-CH_2Br}_{O-CH_2}$$

Another procedure tried was related to the last step in Boord's[7] synthesis of α-olefins from β-bromo ethers: $BrCH_2CHROC_2H_5 + Zn \longrightarrow CH_2{=}CHR + BrZnOC_2H_5$. Here again, however, the analogy was misleading for only slight yields of vinyl allyl ether were obtained following the action of zinc on allyl bromoacetal, $BrCH_2CH(OC_3H_5)_2$. With no solvent, very little reaction occurred below 148°, and above that temperature the violence of reaction led to the formation of a black tar. When boiling alcohol was used as a medium, it was found that the rate of reaction was very slow, only a small amount of ether being obtained in six hours.

Another approach to the synthesis of this material was based on the fact that enol ethers may be prepared by heating certain ketals in the presence of an acid catalyst.[8] When allyl acetal was heated with a trace of *p*-toluenesulfonic acid, a small amount of vinyl allyl ether was obtained, but most of the material remained unreacted.

$$CH_3\text{—}\overset{H}{\underset{OC_3H_5}{C}}OC_3H_5 \xrightarrow{ArSO_3H} CH_2\text{=}CHOC_3H_5 + C_3H_5OH$$

Killian, Hennion and Nieuwland were unable to obtain vinyl ethers by similar treatment of ethyl and propyl acetals.

One method which was found to be fairly serviceable involved heating allyl acetal with phosphorus pentoxide in a solvent such as quinoline or dimethylaniline.

$$CH_3CH(OC_3H_5)_2 + P_2O_5 \longrightarrow CH_2\text{=}CH\text{—}O\text{—}C_3H_5 + 2HPO_3$$

Yields of 12–19% were obtained. Claisen[9] used this general method in 1898 in preparing vinyl ethyl ether.

The best synthesis of vinyl allyl ether was found to be the reaction between β-bromoethyl allyl ether and powdered potassium hydroxide. A 51% yield was realized.

$$BrCH_2CH_2OCH_2CH\text{=}CH_2 + KOH \longrightarrow CH_2\text{=}CHOCH_2CH\text{=}CH_2 + KBr + H_2O$$

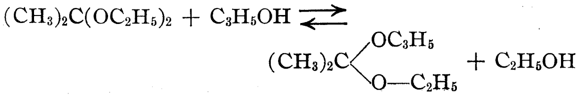
Bromoethyl allyl ether was prepared for this purpose by condensing the sodium salt of ethylene glycol with allyl bromide (77–81% yields), and treating the resulting β-hydroxyethyl allyl ether in pyridine with phosphorus tribromide.

$$HOCH_2CH_2ONa + BrCH_2CH\text{=}CH_2 \longrightarrow HOCH_2CH_2OCH_2CH\text{=}CH_2 \xrightarrow{PBr_3} BrCH_2CH_2OCH_2CH\text{=}CH_2.$$

Yields of 35–45% were obtained in this last reaction. There was considerable splitting of the ether during this treatment, which accounted for the low yield.

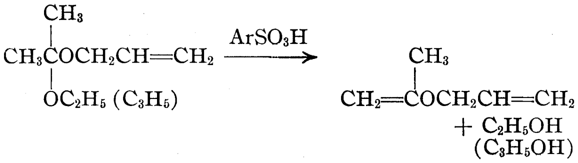
It will be recalled that the attempts to prepare vinyl allyl ether from allyl acetal were unsuccessful. A similar reaction with allyl dimethylketal, however, yielded acceptable quantities of α-methylvinyl allyl ether. For this synthesis, ethyl dimethylketal, $(CH_3)_2C(OC_2H_5)_2$, was required. It was obtained readily when acetone was condensed with ethyl orthoformate and ethyl alcohol in the presence of *p*-toluenesulfonic acid. When this ketal was heated for a few minutes with an excess of allyl alcohol and the same catalyst, an interchange of groups occurred and allyl dimethylketal was isolable from the reaction mixture in 38% yield. A smaller amount (12%) of the mixed ketal was also obtained.

$$(CH_3)_2C(OC_2H_5)_2 + 2C_3H_5OH \xrightleftharpoons{ArSO_3H} (CH_3)_2C(OC_3H_5)_2 + 2C_2H_5OH$$



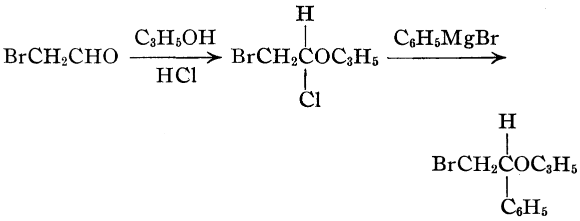
$$(CH_3)_2C(OC_2H_5)_2 + C_3H_5OH \rightleftharpoons (CH_3)_2C\begin{smallmatrix}OC_3H_5\\ O\text{—}C_2H_5\end{smallmatrix} + C_2H_5OH$$

When either of these allyl dimethylketals was distilled slowly from *p*-toluenesulfonic acid, α-methylvinyl allyl ether was obtained.



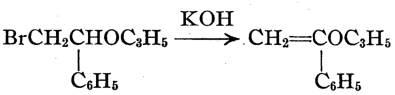
$$CH_3\overset{CH_3}{\underset{OC_2H_5\,(C_3H_5)}{C}}OCH_2CH\text{=}CH_2 \xrightarrow{ArSO_3H} CH_2\text{=}\overset{CH_3}{C}OCH_2CH\text{=}CH_2 + C_2H_5OH\ (C_3H_5OH)$$

The work of Boord and Lauer and their coworkers[10] on the preparation of vinyl ethers was adapted to this synthesis. α-Chloro-β-bromoethyl allyl ether, prepared by allowing dry hydrogen chloride and allyl alcohol to react with a mixture of bromoacetaldehyde and its trimer, was condensed with phenylmagnesium bromide. In this way, α-phenyl-β-bromoethyl allyl ether was formed.



$$BrCH_2CHO \xrightarrow[HCl]{C_3H_5OH} BrCH_2\overset{H}{\underset{Cl}{C}}OC_3H_5 \xrightarrow{C_6H_5MgBr} BrCH_2\overset{H}{\underset{C_6H_5}{C}}OC_3H_5$$

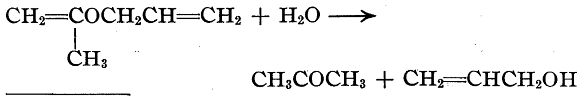
When it was heated with powdered potassium hydroxide, α-phenylvinyl allyl ether was produced.



$$BrCH_2\underset{C_6H_5}{C}HOC_3H_5 \xrightarrow{KOH} CH_2\text{=}\underset{C_6H_5}{C}OC_3H_5$$

Acid Hydrolysis of the Vinyl Ethers.—It is known[11] that allyl ethers hydrolyze readily when exposed to aqueous solution of acid. The three new vinyl ethers were also subjected to acid hydrolysis for purposes of characterization. Acetaldehyde, acetone and acetophenone were formed in turn.

$$CH_2\text{=}CHOCH_2CH\text{=}CH_2 + H_2O \xrightarrow{HCl} CH_3CHO + CH_2\text{=}CHCH_2OH$$



$$CH_2\text{=}\underset{CH_3}{C}OCH_2CH\text{=}CH_2 + H_2O \longrightarrow CH_3COCH_3 + CH_2\text{=}CHCH_2OH$$

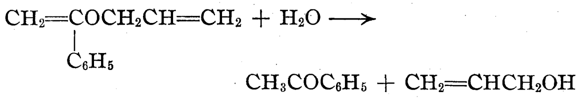
Allyl dimethylketal	61	26	1.4254	.870	45.93	46.11
Ethyl allyl dimethylketal	43–45	26	1.4090	.852	41.85	41.96
Allyl bromoacetal	102–104	23	1.4729	1.269	48.86	49.38
Allylacetaldehyde	103–104	749	1.4191	0.852	24.92	24.83

[a] Nieuwland and co-workers, THIS JOURNAL, **45**, 1552 (1923), and **52**, 2892 (1930), obtained materials with the boiling points of 162° (atm.) and 90–93° (16 mm.), n^{28}_D 1.4351, which he considered to be allyl acetal. However, in view of the discrepancies between these values and the ones found here, and the fact that no other constants or analyses were given by Nieuwland, it seems possible that the material obtained by him either was not the acetal or was a very impure sample.

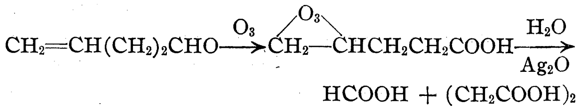


$$\mathrm{CH_2{=}\underset{\substack{|\\ C_6H_5}}{C}OCH_2CH{=}CH_2 + H_2O \longrightarrow CH_3COC_6H_5 + CH_2{=}CHCH_2OH}$$

Pyrolysis of the Ethers.—Heating in the liquid phase to 200–250° is the general method of bringing about the rearrangement of aryl allyl ethers into phenols. Whether or not vapor phase heating of vinyl allyl ether, necessitated by the low boiling point of the latter, would be comparable, could not be predicted. It was found, however, that the anticipated rearrangement into allylacetaldehyde occurred to the extent of 40–50% at 255°.

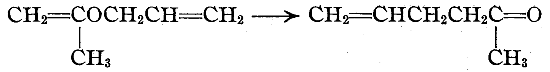
$$\mathrm{CH_2{=}CHOCH_2CH{=}CH_2 \longrightarrow CH_2{=}CHCH_2CH_2CHO}$$

No other products were formed, the remainder of the material being unchanged ether. At 215°, no rearrangement was observable. The identity of allylacetaldehyde was confirmed by analyses and by treatment with ozone, which gave rise to formic and succinic acids.



$$\mathrm{CH_2{=}CH(CH_2)_2CHO \xrightarrow{O_3} \overset{O_3}{CH_2{-}CH}CH_2CH_2COOH \xrightarrow[Ag_2O]{H_2O} HCOOH + (CH_2COOH)_2}$$

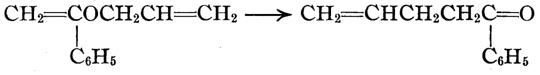
α-Methylvinyl allyl ether was found to be somewhat less stable to heat. There was practically complete conversion into allylacetone by heating in the vapor phase at 255°.



$$\mathrm{CH_2{=}\underset{\substack{|\\ CH_3}}{C}OCH_2CH{=}CH_2 \longrightarrow CH_2{=}CHCH_2CH_2\underset{\substack{|\\ CH_3}}{C}{=}O}$$

Indeed, a small amount of this ketone was isolated during the preparation of the ether, in which process the bath temperature reached 200°.

α-Phenylvinyl allyl ether appeared to be the least stable of these ethers. Mere distillation under reduced pressure (temperature below 175°) caused rearrangement into ω-allylacetophenone, and brief refluxing under atmospheric pressure brought about this reaction in a high yield.



$$\mathrm{CH_2{=}\underset{\substack{|\\ C_6H_5}}{C}OCH_2CH{=}CH_2 \longrightarrow CH_2{=}CHCH_2CH_2\underset{\substack{|\\ C_6H_5}}{C}{=}O}$$

Experimental Part

Bromoacetaldehyde.—Paraldehyde (125 g.) was brominated at −5 to −10° with bromine (360 g.) according to the directions of Hibbert and Hill.[12] The yields of the lachrymatory mixture of bromoacetaldehyde and its trimer were 39–53%.

Allyl Bromoacetal.—Seventy grams of the above bromoacetaldehyde mixture was placed in a 500-cc. three-necked flask, equipped with a mercury-sealed stirrer and a reflux condenser which was protected from moisture by a calcium chloride tube. To this were added 69 g. of allyl alcohol (b. p. 93–95°) and 0.4 cc. of 40% sulfuric acid. The resulting solution was refluxed, with constant stirring, for nine hours on the steam-bath. After cooling, it was taken up in an equal volume of ether and neutralized by shaking with a dilute sodium hydroxide solution. It was further washed with a small amount of sodium bisulfite solution, then washed with water, and dried over anhydrous sodium sulfate.

The ether solution was filtered and the ether removed under diminished pressure. The reddish-brown residual liquor was distilled under reduced pressure. Redistillation gave pure allyl bromoacetal, boiling at 102–104° at 23 mm. The material was colored slightly yellow when freshly distilled, but became colorless on standing. Constants for this compound, and for the other compounds to be described in this paper, are collected in Table I.

Anal. Calcd. for $C_8H_{13}O_2Br$: Br, 36.16. Found: Br, 35.94.

The yield obtained in this way was 20.5%. The yield

---

(12) Hibbert and Hill, THIS JOURNAL, **45**, 746 (1923).

was increased to 26.4% by removal of the water formed in the reaction. An experiment using 91.5 g. of the aldehyde, 90 g. of dry allyl alcohol and 0.55 cc. of 40% sulfuric acid was carried out. During a similar heating period of nine hours, 24 cc. of an alcohol–water constant-boiling mixture was removed, while 40 cc. of the alcohol was added. On working up the products as before, 43.4 g. of the acetal was obtained. If the allyl alcohol (53% of calcd.) was added directly to the bromination product of paraldehyde as soon as the color of bromine had disappeared from the solution, the yield of the acetal was 25%. In this reaction, stirring at −5° was maintained for two and a half hours before allowing the flask to warm up to room temperature. The lower layer was separated, dissolved in ether and purified as before.

Effect of Metals on Allyl Bromoacetal

Sodium.—Small pieces of sodium were added to 9.6 g. of allyl bromoacetal at 140–145°. About four drops of water-insoluble, odoriferous liquid, $n^{20}\text{D}$ 1.4105, was collected as distillate, which was identified later as vinyl allyl ether. When only 0.4 g. of sodium was added the reaction mixture set to a brown mass from which half of the original bromoacetal was recoverable (b. p. 103–105° at 27 mm.). Additional sodium rested on the surface of the brown mass without reacting. Xylene, as diluent, did not prevent the formation of this brown sludge.

Zinc.—Little or no reaction occurred between allyl bromoacetal and zinc dust up to 148°, but at this temperature a violent exothermic reaction ensued. A black tar was the only product.

A mixture of 20 g. of allyl bromoacetal, 50 cc. of alcohol and 14.7 g. of zinc dust was heated to reflux temperatures and stirred for three hours. Then 20 cc. of distillate (A) was taken off and 20 cc. of alcohol added for another refluxing period of three hours, after which all that would distil over (B) on the steam-bath was collected. Both A and B smelled strongly of allyl vinyl ether. When A was mixed with an equal volume of water, about 0.5 cc. of it separated, $n^{20}\text{D}$ 1.4101. No separation occurred when B was diluted. Much allyl bromoacetal was recovered from the higher boiling residue.

Allyl Acetal.—Twenty grams of dry calcium chloride was dissolved in 132 g. of allyl alcohol (b. p. 93–96°) by shaking in a tightly stoppered bottle. This solution was cooled to 0° and 50 g. (1.14 moles) of cold acetaldehyde was added. The bottle was restoppered and the mixture was shaken vigorously for ten minutes, at the end of which time two layers had formed.

The mixture was allowed to stand for thirteen and one-half hours with occasional shaking, before separating the clear upper layer. This was washed with 100 cc. of distilled water in three portions. The washed oil was allowed to stand for three hours to permit more water to settle out, and was then dried over anhydrous potassium carbonate for eighteen hours. After filtering, the material was distilled. Refractionation gave a total of 110.5 g. (68.2% yield) of allyl acetal which boiled between 146–150°. Other runs gave yields of 62.4 and 64.7%. The pure material boiled at 148–149°.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.61; H, 9.88. Found: C, 67.14, 67.37; H, 9.88, 9.95.

Decomposition of Allyl Acetal in the Presence of *p*-Toluenesulfonic Acid.—A mixture of 16 g. of allyl acetal and 0.045 g. of *p*-toluenesulfonic acid was heated to refluxing on an oil-bath. A small amount of tar appeared and the solution became red-brown in color. Subsequently, the material was heated at 105° for two and one-half hours and then at 130–140° for ten hours. During this latter heating period, 3 g. of liquid distilled over. Redistillation of this distillate gave 1.82 g. of crude vinyl allyl ether, collected between 48–98°. The usual ethereal odor was observed with this material. Its index of refraction $n^{20}\text{D}$ was 1.4107 ($n^{20}\text{D}$ for the pure ether, 1.4115). Evidence for its structure was obtained by hydrolysis of a small portion with dilute hydrochloric acid. To this resulting solution was added 5 cc. of an alcoholic solution of 2,4-dinitrophenylhydrazine. The hydrazone melted (without recrystallization) at 151–152°; mixed melting point with an authentic sample of the acetaldehyde derivative (m. p. 161–163°) was 157–158°.

Reaction between Allyl Acetal and Phosphorus Pentoxide.—Sixty grams of dimethylaniline (b. p. 190–191°) and 60 g. of phosphorus pentoxide were mixed thoroughly in a 500-cc. flask, after which 59 g. of allyl acetal was added. A 25-cm. empty Hempel column was placed on top of the flask and was connected to a condenser set for distillation. The mixture was heated slowly and kept at gentle refluxing until all of the easily-volatile material had distilled over. During this period a considerable amount of tarring occurred. The total weight of distillate was 28.8 g. Fractionation of this material through a 25-cm. Widmer column gave 6.8 g. (19.3%) of crude vinyl allyl ether (b. p. 56–70°). The other fractions consisted mainly of allyl alcohol (app. 60% of total), some allyl acetal and 1 g. of an unidentified substance boiling at 40–42°.

Other runs gave essentially the same products. The yields of vinyl allyl ether obtained in these other cases were: 15.5% (crude, using dimethylaniline as solvent) and 11.5% (pure, using quinoline as solvent). One redistillation through a good column sufficed for the purification of the ether, b. p. 65.0–65.2°.

Anal. Calcd. for C_5H_8O: C, 71.38; H, 9.59. Found: C, 71.30; H, 9.39.

β-Hydroxyethyl Allyl Ether.—To 158 g. of redistilled ethylene glycol 23.4 g. of sodium was added slowly in small pieces. After the reaction was over, the solution was heated with stirring on the steam-bath while 124 g. of allyl bromide was slowly added. The mixture was heated for two hours after the addition. The sodium bromide was filtered off and the filtrate distilled under reduced pressure. Redistillation through a 60-cm. Vigreux column gave 79.6 g. of pure material boiling between 63–64° at 18–19 mm., yield 77%.

Anal. Calcd. for $C_5H_{10}O_2$: C, 58.81; H, 9.87. Found: C, 58.45; H, 9.79.

Another run using 0.91 mole of sodium and 1.2 moles of allyl bromide wherein the ethylene glycol was separated from the β-hydroxyethyl allyl ether by ether–water partition, and the last of the hydroxy ether recovered by extracting the aqueous solution with ether, gave an 81% yield after the usual procedures of drying and distilling.

β-Bromoethyl Allyl Ether.—To 75.3 g. (0.278 mole) of phosphorus tribromide in a flask surrounded by an ice-bath was added slowly, with constant stirring, a mixture of 71 g. (0.695 mole) of β-hydroxyethyl allyl ether and 12.5 g. (0.156 mole) of dry pyridine. The mixture was stirred for one hour and then allowed to stand for an equal interval before distilling under reduced pressure. The distillate was washed twice with dilute sodium hydroxide, twice with dilute sulfuric acid, and once with water. After drying over anhydrous sodium sulfate, distilling and redistilling through a 60-cm. Vigreux column, a 40% yield of β-bromoethyl allyl ether was obtained. It boiled at 68.5–69° (36 mm.).

Anal. Calcd. for C_5H_9OBr: Br, 48.43. Found: Br, 48.19.

Using the Palomaa and Kenetti procedure,[13] which consists of the addition of the alcohol–pyridine mixture to cold phosphorus tribromide and allowing the reaction mixture to stand for a few hours, unmodified except that the crude bromide was distilled off under reduced pressure as soon as the addition was over, a 45% yield was obtained.

In another run, wherein the phosphorus tribromide was added to the mixture of β-hydroxyethyl allyl ether and pyridine at 0°, and the whole allowed to stand overnight, a 35% yield was realized.

Reaction between β-Bromoethyl Allyl Ether and Potassium Hydroxide.—Into a 125-cc. distilling flask was placed 42.5 g. of β-bromoethyl allyl ether, after which 43 g. of finely powdered potassium hydroxide was added. The mixture was heated slowly on an oil-bath to 110°, at which point volatile material began to distil. The bath temperature was raised slowly. When no more would come over (bath temperature was 174°), the heating was stopped. The distillate weighed 11.1 g. That this material was vinyl allyl ether was shown by the fact that practically all of it distilled at 65–66° (741 mm.). The refractive index, $n^{24}\text{D}$ 1.4101, was also in good agreement. The yield was 51%.

Upon taking up the residue in the flask with water, 12 cc. of impure bromoethyl allyl ether was recovered.

Ethyl Dimethylketal.—A mixture of 39 g. (0.26 mole) of ethyl orthoformate, 13 g. (0.23 mole) of dry acetone, 58 g. (1.3 moles) of absolute alcohol and 0.055 g. of *p*-toluenesulfonic acid was refluxed for ten minutes, neutralized with sodium ethoxide, cooled with running water and diluted with 400 cc. of distilled water. The upper layer which separated was washed three times with 50-cc. portions of distilled water and then allowed to dry over anhydrous potassium carbonate. After filtering, the material was distilled and the portion boiling between 113–115° was collected. The yield was 22.6 g. (75%).

Allyl Dimethylketal and Ethyl Allyl Dimethylketal.—To a mixture of 54 g. (0.41 mole) of ethyl dimethylketal and 160 g. of dry allyl alcohol was added 0.1 g. of *p*-toluenesulfonic acid. The whole was refluxed for ten minutes and then the color was discharged with sodium ethoxide. The alcohol mixture was distilled off slowly (up to a temperature of 97°), using a 60-cm. electrically heated Vigreux column with partial condensation head. The remainder was fractionated through this same column under reduced pressure. Refractionation gave 7 g. (12%) of ethyl allyl dimethylketal boiling at 43–45° at 26 mm., and 24 g. (38%) of allyl dimethylketal, boiling at 61° at 26 mm. (also 46–48° at 13–14 mm.).

Anal. of ethyl allyl dimethylketal. Calcd. for $C_8H_{16}O_2$: C, 66.62; H, 11.19. Found: C, 67.00; H, 11.23.

Anal. of allyl dimethylketal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.31. Found: C, 69.18; H, 10.35.

α-Methylvinyl Allyl Ether.—To 25 g. of allyl dimethylketal was added 0.1 g. of *p*-toluenesulfonic acid in a 50-cc. flask topped with a short Vigreux column connected to a water condenser set for distillation. The material was heated to gentle refluxing on an oil-bath, whereupon 21 g. of a volatile distillate was collected during a period of five hours. The bath temperature changed from 145 to 200° during this time. The distillate was shaken with four times its volume of distilled water, and the separated upper layer washed twice more with equal volumes of distilled water, after which the weight was 12 g. After drying over anhydrous potassium carbonate, the material was filtered and distilled through a 60-cm. Vigreux column. Three and one-half grams of α-methylvinyl allyl ether was collected, boiling at 87.5–88° (745 mm.). A small amount (1.5 g.) of allylacetone was separated at 126–129°. The residue was mainly unreacted allyl dimethylketal.

The allylacetone was characterized by its semicarbazone, m. p. 102–103° (reported[14] as 100–102°). The ether was analyzed.

Anal. Calcd. for $C_6H_{10}O$: C, 73.41; H, 10.28. Found: C, 73.02; H, 10.03.

Decomposition of Ethyl Allyl Dimethylketal in the Presence of *p*-Toluenesulfonic Acid.—A mixture of 6.4 g. of ethyl allyl acetonal and 0.04 g. of *p*-toluenesulfonic acid was heated as in the previous experiment. Five grams of material was collected while the bath temperature was raised slowly from 120 to 180°. The distillate was shaken with 50 cc. of distilled water, and the resulting upper layer washed twice with 10-cc. portions of water before drying over anhydrous potassium carbonate. After filtering, the material was distilled in a 2-cc. modified Claisen distilling flask at atmospheric pressure.

Fraction	B. p., °C.	Wt., g.	$n^{20}\text{D}$
1	82–88	0.10	..
2	88–90	.53	1.4155
Residue	..	.24	..

This distillate was chiefly α-methylvinyl allyl ether.

α-Chloro-β-bromoethyl Allyl Ether.—To 43.7 g. of a mixture of bromoacetaldehyde and tribromoparaldehyde at 0° was added 20.6 g. of dry allyl alcohol. At this temperature, dry hydrogen chloride was introduced with constant stirring until a 17.5 g. increase in weight was noted. At the end of the reaction two colorless layers had formed. The lower one was placed over anhydrous calcium chloride and the excess hydrogen chloride was evaporated under reduced pressure. A light-brown color appeared after standing for two days. After filtering, the α-chloro-β-bromoethyl allyl ether weighed 44 g. (62% yield).

In another run crystals of tribromoparaldehyde settled out during the reaction. The yield in this case (59.3%) was based on the unrecovered aldehyde.

α-Phenyl-β-bromoethyl Allyl Ether.—Phenylmagnesium bromide was prepared in the usual way from 176 g. (1.12 moles) of bromobenzene, 27 g. of magnesium and 400

---

[13] Palomaa and Kenetti, *Ber.*, **64**, 799 (1931).

[14] Von Braun and Stechele, *ibid.*, **33**, 1472 (1900).

cc. of dry ether. After cooling to 0°, a 1:1 dry ether solution of 134 g. of α-chloro-β-bromoethyl allyl ether was added with constant stirring. The material was added slowly enough so that the mixture remained cold. After the reaction was over, stirring at 0° was continued for twenty minutes before hydrolyzing with dilute hydrochloric acid. The ether layer was separated and dried over anhydrous calcium chloride.

After filtering, the ether was distilled off on the steam-bath, 3.5 g. of solid sodium hydroxide was added and the residue distilled under reduced pressure. Sixty-six grams (41% yield) of α-phenyl-β-bromoethyl allyl ether was obtained, distilling between 130–142° at 18–21 mm. Several refractionations were necessary in order to obtain a pure product, b. p. 129–130° (12 mm.). The major impurity was diphenyl.

Anal. Calcd. for $C_{11}H_{13}OBr$: Br, 33.16. Found: Br, 32.99. *Analysis* for unsaturation.[15] Subs., 0.2623; cc. of 0.5017 *N* $KBrO_3$–KBr soln. added, 6.43. Cc. of 0.1768 *N* $Na_2S_2O_3$ req. to back-titrate, 5.54. Double bonds per molecule, 1.03.

α-Phenylvinyl Allyl Ether.—To 18 g. of α-phenyl-β-bromoethyl allyl ether in a small distilling flask was added 4.5 g. of finely-powdered potassium hydroxide and the mixture allowed to stand for two hours. Heat was evolved during the addition and a red-brown color was developed. The system was placed under a pressure of 4 mm. and the bath was slowly heated up until gentle refluxing occurred. After one-half hour's refluxing, distillation was permitted to occur and 9 g. of material was collected. Since this gave a positive test for bromine in the sodium fusion test, it was treated further with 1.7 g. of finely powdered potassium hydroxide in a 12-cc. distilling flask. Under a pressure of 12 mm., the material was slowly heated up to refluxing, and maintained for one-half hour. Upon distillation, it was found that the entire distillate (3 g. or 25% yield) came over at 104–105° (12 mm.). A very small amount of water was collected also. The distillate was dried over anhydrous sodium sulfate and filtered therefrom. This unsaturated, colorless liquid gave no halogen test when fused with sodium.

Anal. Calcd. for $C_{11}H_{12}O$: C, 82.45; H, 7.56. Found: C, 82.01; H, 7.36.

Acid Hydrolysis of Vinyl Ethers

Vinyl Allyl Ether.—A few drops of vinyl allyl ether was dissolved in 5 cc. of 95% alcohol and two drops of concentrated hydrochloric acid was then added in order to hydrolyze the ether. After the addition of 5 cc. of a saturated solution of 2,4-dinitrophenylhydrazine in 95% alcohol, the mixture was boiled for one minute. Water was added to incipient cloudiness, and the hydrazone was permitted to crystallize. After two recrystallizations, the melting point of the orange crystals was 164–164.5°. A mixed melting point with authentic acetaldehyde 2,4-dinitrophenylhydrazone (m. p. 166°) showed the two materials to be identical (mixed m. p., 165–165.5°). A mixed melting point with the corresponding formaldehyde derivative (m. p. 165°) gave a thirty-degree depression.

α-Methylvinyl Allyl Ether.—This ether was treated in an identical manner. The 2,4-dinitrophenylhydrazone, after two crystallizations from alcohol, melted at 125°. The mixture m. p. with authentic acetone 2,4-dinitrophenylhydrazone (m. p. 125°) was 125°.

α-Phenylvinyl Allyl Ether.—A small amount of the ether was dissolved in dilute alcohol and semicarbazide hydrochloride was added. After gentle heating, the semicarbazone was permitted to form. The melting point, after one recrystallization from dilute alcohol, was 198–199°. A mixed melting point (199–200°) with authentic acetophenone semicarbazone (m. p. 200–201°) showed these two materials to be identical.

Pyrolysis of the Ethers

Vinyl Allyl Ether.—The method used here consisted in passing the vapors of the ether through a tube (16 × 0.7 cm.) which was heated to a constant temperature by the refluxing vapors of a proper bath material.

When naphthalene was used to provide a temperature of 215–218°, no rearrangement was observed. When 6.7 g. of vinyl allyl ether was passed through the tube during a period of twenty minutes, the 6.5 g. of recovered material proved to be unchanged ether.

When phenyl ether (b. p. 252–255°) was used, however, definite rearrangement was observed.

Run	Ether used, g.	Product	Time of run, min.
1	3.92	3.64	50
2	11.0	10.6	115

In these runs, 40–50% of a higher-boiling substance (b. p. 99–104°) was isolated from the recovered material, while the rest proved to be unreacted vinyl allyl ether. After several refractionations, 2.5 g. (approx. 50% of the combined fractions, b. p. 99–104°) came over constantly between 103–104° (749 mm.). This material had a pungent aldehyde-like odor and reacted immediately with Schiff's reagent. It was found to be much more soluble than vinyl allyl ether upon shaking with water. This fraction had the following constants: d^{20}_4 0.852; n^{20}_D 1.4191.

Anal. Calcd. for C_5H_8O: C, 71.38; H, 9.59. Found: C, 70.99, 71.08; H, 9.53.

The dimethone[16] derivative of allylacetaldehyde was prepared, and melted sharply at 98° after several recrystallizations from alcohol.

Anal. Calcd. for $C_{21}H_{30}O_4$: C, 72.79; H, 8.73. Found: C, 72.94; H, 8.62.

The 2,4-dinitrophenylhydrazone of allylacetaldehyde also was prepared. After three recrystallizations from alcohol, the melting point remained unchanged at 120°.

α-Methylvinyl Allyl Ether.—The same apparatus was used as in the case of vinyl allyl ether. The vapors of 3.6 g. of α-methylvinyl allyl ether were passed through the tube, which was heated to 255° by the refluxing vapors of phenyl ether, during the course of one hour. Three and three-tenths grams of material was recovered. On distillation, practically all of this distilled at 126–127° at 745 mm. Properties of allylacetone: n^{20}_D 1.4199; d^{20}_4 0.842; *MR* (found) 29.47, *MR* (calcd.) 29.45.

---

(15) Davis, Crandall and Higbee, *Ind. Eng. Chem.*, *Anal. Ed.*, **3**, 108 (1931).

(16) Klein and Linser, *Mikrochemie*, Pregl Festschrift, 204 (1929) "Methone" is a trade name for dimethyldihydroresorcinol.

The presence of the CH_3CO- group was indicated by the good iodoform test obtained from a drop of this material. Preparation of the semicarbazone (m. p. 103°) and the 2,4-dinitrophenylhydrazone[17] (m. p. 108–108.5°) further confirmed its identity.

α-Phenylvinyl Allyl Ether.—When 1.31 g. of this ether was refluxed gently under atmospheric pressure for fifteen minutes, a red-brown color developed. After cooling, the system was distilled at 12–13 mm. The entire volatile portion (0.93 g.) came over between 105–116°. A small amount of a deep red-brown, viscous material remained as residue. The refractive index $n^{20}D$ of the distillate was 1.5417.

The semicarbazone was prepared in the usual manner and found to melt, after two recrystallizations, at 156–157°. The oxime was also recrystallized twice and had the melting point of 53°.[18] A mixed m. p. with a sample of authentic acetophenone oxime (m. p. 57–58°) showed definitely that these two materials were different. Simple mixing gave a sticky mass, which was completely melted at 45.5°. This distillate is, therefore, identified as γ-butenyl phenyl ketone.

Ozonolysis of Allylacetaldehyde.—One gram of allylacetaldehyde was dissolved in 100 cc. of dry carbon tetrachloride and an excess of a 5% ozone-in-oxygen stream passed into the solution at 0°. The resulting ozonide was hydrolyzed in the presence of the solvent with 70 cc. of water and the reaction completed by refluxing for one and one-half hours. At this point, the freshly-prepared and well-washed silver oxide from 15 g. of silver nitrate was added and the mixture was further refluxed for one hour. After the evaporation of the carbon tetrachloride by gentle heating on the steam-bath, the mixture was filtered.

Most of this filtrate was distilled, the distillate made up to 110 cc., and a determination of the Duclaux values made.

	Cc. alkali required
Original 10 cc.	2.90
First 10 cc. distilled	1.20
Second 10 cc. distilled	1.30
Third 10 cc. distilled	1.40

Duclaux values found: 4.14, 4.48, 4.83. The theoretical values for formic acid are: 3.95, 4.40 4.55. This distillate slowly decolorized potassium permanganate solution.

After the formic acid had been distilled off, the residue was treated with excess of hydrochloric acid to precipitate the remaining silver. After filtering, the filtrate was evaporated to dryness.

A small amount of this residue was dissolved in water and neutralized with dilute sodium hydroxide. The *p*-bromophenacyl ester of the acid was prepared in the usual manner and was recrystallized from an alcohol–acetone mixture; m. p. 209–210°. A mixed melting point with authentic *p*-bromophenacyl succinate (m. p. 213.5–214°) showed the identity of the two materials. The value was 212–212.5°.

Summary

A number of methods of preparing vinyl allyl ethers have been investigated.

These ethers were found to rearrange smoothly upon heating at temperatures of 175–255°. Only one product was found to any appreciable extent in each case, indicating a clean-cut reaction. It was shown that allylacetaldehyde, allylacetone, and ω-allylacetophenone were formed in this way, respectively, from vinyl allyl ether, α-methyl vinyl allyl ether, and α-phenylvinyl allyl ether. These three ethers are listed in the order of decreasing thermal stability.

The rearrangement of vinyl allyl ether to allylacetaldehyde is analogous to the rearrangement of phenyl allyl ether to *o*-allylphenol.

The Polycondensation of Acrolein

BY EVERETT E. GILBERT[1] AND JOHN J. DONLEAVY

It has been shown[2] that in the presence of dilute aqueous alkalies, α-methylacrolein polycondenses by a Michael mechanism to yield hydroxy polyaldehydes. The purpose of this communication is to report a similar reaction for acrolein.

Several investigators have recorded the precipitation of a white solid upon the addition of alkalies to an aqueous solution of acrolein. McLeod[3] obtained a product softening at 83° and decomposing with evolution of gas at 94–95°. The substance was soluble in alcohol, but insoluble in water and in hydrocarbon type solvents. Upon heating, thermal depolymerization occurred with the formation of acrolein. Another observer[4] obtained a white powder softening at

[2] Gilbert and Donleavy, THIS JOURNAL, **60**, 1737 (1938).

[3] McLeod, *Am. Chem. J.*, **37**, 34 (1907).

[4] Nef, *Ann.*, **335**, 220 (1904).

115° and decomposing at 128–130°. A third group[5] described the powder as being converted to a viscous mass upon heating to temperatures between 80–110°; the solubilities were the same as those recorded above. No attempt ever has been made[6] to characterize any of the acrolein polymers.

A series of samples of the solid was prepared under widely varying conditions. They gave an immediate precipitate with Tollens' reagent, a definite although delayed test with Schiff's reagent, and an immediate precipitate of manganese dioxide with neutral aqueous permanganate at room temperature. The samples did not possess sharp melting points; decomposition temperatures were noted as low as 80° and as high as 125°.

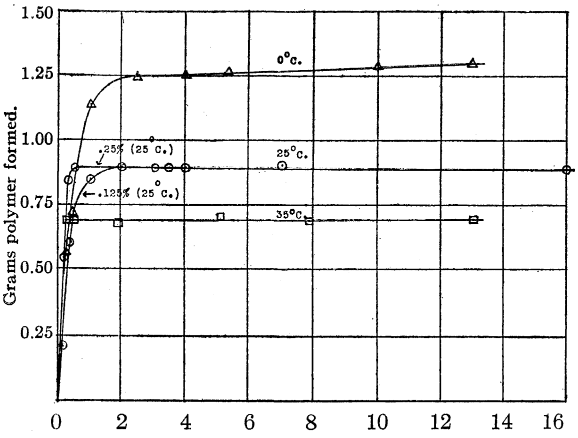

Fig. 1.

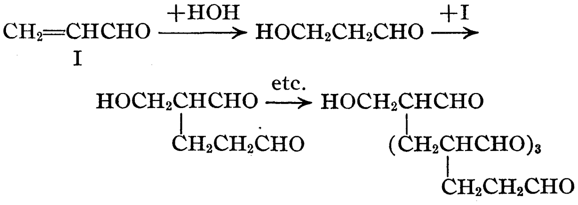
Analyses upon specimens variously prepared checked one another in being 4% lower in carbon than calculated for $(CH_2{=}CHCHO)_n$; the hydrogen was slightly higher than calculated. By analogy to the type of product similarly obtained from α-methylacrolein, it was concluded tentatively that the polyacrolein was a hydroxypolyaldehyde formed from five acrolein molecules and one water molecule. This was established by the preparation of a monoöxime (in the cold), and by the preparation of a tetra-2,4-dinitrophenylhydrazone (in the hot). A polyacrylic acid also was obtained by cautious oxidation with permanganate in the cold—followed by dehydration. Direct determinations of the molecular weight in freezing dioxane gave values which fell between one and two times the calculated molecular weight. Molecules possessing hydroxyl groups and such high densities of strongly polar aldehyde groups might be expected to associate.

Acrolein polycondenses by a Michael reaction in a manner similar to α-methylacrolein. The addition of water to acrolein yields hydracrylic aldehyde, the active methylene group of which condenses with acrolein by a Michael reaction producing a new active methylene group which again condenses by the Michael reaction with another acrolein molecule. These reactions are known to be catalyzed by alkalies; the reaction would continue until the formation of the pentamer. These steps are summarized in the equations



$$\underset{\text{I}}{CH_2{=}CHCHO} \xrightarrow{+HOH} HOCH_2CH_2CHO \xrightarrow{+\text{I}}$$

$$\underset{\textstyle CH_2CH_2CHO}{HOCH_2\underset{|}{C}HCHO} \xrightarrow{\text{etc.}} \underset{\underset{\textstyle CH_2CH_2CHO}{|}}{\underset{\textstyle (CH_2CHCHO)_3}{HOCH_2\underset{|}{C}HCHO}}$$

The above structure of the pentamer (containing acrolein units) would allow the formation of acrolein observed by McLeod[3] during thermal depolymerization.

A series of reaction velocity curves was obtained for the formation of the polymer under varying conditions to determine whether or not its mode of formation is consistent with the Michael mechanism advanced above. The values obtained are recorded in Table I; some of these are plotted in Fig. 1. The following conclusions were drawn from an examination of these

TABLE I

YIELD OF ACROLEIN POLYMER OBTAINED UNDER VARYING CONDITIONS

[6] C. Ellis, "The Chemistry of Synthetic Resins," Reinhold Publishing Corporation, New York, N. Y., 1935, p. 502.

data: (1) the reaction is an equilibrium type, since the curves become straight and parallel to the x-axis; (2) the rapidity with which equilibrium is reached depends upon the concentration of the alkaline catalyst (at a given temperature), although the position of the equilibrium point depends upon the temperature alone; (3) the equilibrium point is shifted to the left by a rise in temperature. It has been shown[7] that these phenomena are characteristic of the Michael reaction. It has also been shown[8] that substituents tend to hinder the Michael reaction. Thus acrolein yields a pentamer by the Michael polycondensation, while α-methylacrolein yields principally a trimer.

Experimental

The acrolein was used as received from Eastman Kodak Co.; it contained about 0.1% hydroquinone.

In determining the points for the velocity curves, the following procedure was employed. Two cubic centimeters of acrolein was dissolved in 20 cc. of distilled water. The stopper of the flask was then wired down securely. It was attached to the rotator of an isothermal bath (constant to within 0.03°), and was then rotated for fifteen minutes to attain the desired temperature. It was unstoppered quickly and 1 cc. of aqueous sodium hydroxide of specified strength was added. The flask was restoppered immediately and rotated for the desired time, after which it was removed from the bath. One cubic centimeter of dilute sulfuric acid was added to stop the reaction. The white precipitate was filtered on weighed filter paper, washed thoroughly with distilled water, and dried *in vacuo* for fifteen hours over concentrated sulfuric acid to constant weight. The data reported in Table I were obtained in this way.

The polymer is a white fluffy powder which cannot be crystallized; it was found to be soluble in alcohols, ketones and in dioxane, but insoluble in hydrocarbons and in water. These observations are in accord with previous work.[3-5]

Included among the specimens subjected to analysis were the following: (1) samples made by the addition of aqueous catalyst of the following strengths: 0.25, 0.5, and 1.0%; (2) samples made with 0.25% catalyst at 11, 25 and 40°; (3) white samples which had been filtered immediately, and those allowed to become yellow from longer exposure to the alkaline reaction medium; (4) specimens which had been reprecipitated from acetone by the addition of benzene. Nine samples were analyzed; the value cited below is the average from which no single analysis varied more than ±0.25%.

Anal. Calcd. for $C_{15}H_{22}O_6$: C, 60.40; H, 7.38. Found: C, 60.48; H, 7.37. (Calcd. for $(CH_2{=}CHCHO)_n$: C, 64.28; H, 7.14.) One sample prepared with 0.125% alkali analyzed to the tetramer. Calcd. for $C_{12}H_{18}O_5$: C, 59.50; H, 7.42. Found: C, 59.62; H, 7.50. These values were unchanged after reprecipitation from acetone with benzene.

The method of Oxford[9] was used for determining the molecular weights. The dioxane was dried and distilled over sodium, and the method was checked at intervals against naphthalene. Calcd. for the pentamer: mol. wt., 298. Found: mol. wt., 370, 376, 388, 472, 443, 485, 440, 582, 580. The same values were obtained at different concentrations.

Preparation of the Tetra-2,4-dinitrophenylhydrazone of the Polymer.—The method employed was essentially that suggested by Shriner and Fuson.[10] One equivalent of dinitrophenylhydrazine was employed for each aldehyde group. A brick-red solid was obtained upon cooling the reaction mixture. The crude product was fractionally crystallized from 250 cc. of 95% ethyl alcohol. The first crop was dried *in vacuo* for twelve hours over concentrated sulfuric acid. It decomposed at about 120° upon heating.

Anal. Calcd. for $C_{39}H_{38}N_{16}O_{18}$: C, 46.1; H, 3.74; N, 22.0. Found: C, 46.2; H, 3.55; N (Dumas), 21.63.

Preparation of the Monoöxime of the Polymer.—Two grams (0.007 mole) of the polymer was dissolved in 30 cc. of methyl alcohol. Two and one-half grams of hydroxylamine hydrochloride (0.36 mole) dissolved in methanol was added, and 2.9 g. (0.36 mole) of finely powdered sodium acetate also. The flask was sealed tightly and shaken vigorously at room temperature for three hours. The solution was then filtered free of sodium chloride and evaporated in a vacuum desiccator. During the evaporation more salt separated which was filtered. The solution was taken to dryness, and the white residue was thoroughly triturated with four fresh portions of distilled water. It was then dried *in vacuo* over concentrated sulfuric acid. Upon heating the oxime softened at 68° (uncorr.).

Anal. Calcd. for $C_{15}H_{23}NO_6$: C, 57.5; H, 7.35; N, 4.47. Found: C, 57.3; H, 7.20; N (Kjeldahl), 4.45.

Oxidation of the Polymer to Polyacrylic Acid.—One and seven-tenths grams (0.006 mole) of polymer was suspended in 50 cc. of distilled water; the suspension was cooled in an ice-bath. A solution of 3.2 g. (0.02 mole) of potassium permanganate and 0.4 g. of sodium hydroxide (0.01 mole) in 200 cc. of water was then added dropwise to the cooled suspension. Thorough mixing was ensured by the use of a stirring motor. The precipitation of manganese dioxide commenced almost immediately. Stirring was continued for about fifteen minutes after the addition was completed. The manganese dioxide was filtered by suction and thoroughly washed with three 20-cc. portions of hot water. The filtrate (placed in a large crystallizing dish) was put under vacuum over concentrated sulfuric acid. The solution was acidified after evaporation to a small volume. Since no precipitate formed, the evaporation was continued to dryness; a light brown resin separated. This was extracted thoroughly with four 30-cc. portions of boiling acetone and the acetone solution then filtered. Upon the addition of benzene, white flocks separated which were filtered and dried *in vacuo*. A white powder was obtained, yield 0.4 g. Upon heating it did not show a definite melting point, but began to sinter at about 70°. It was insoluble in dioxane and in hydrocarbons.

The Condensation of *n*-Butyraldehyde with 2-Butanone. II[1]

By S. G. Powell and Donald A. Ballard

In a previous paper[2] it was shown that *n*-butyraldehyde reacts with 2-butanone under the influence of dilute potassium hydroxide solution to form a ketol which yields 3-methyl-3,2-heptenone (I) upon dehydration. Eccott and Linstead[3] carried out a similar series of reactions with *n*-butyraldehyde and acetone and obtained 3,2-heptenone (A). When, however, they treated a mixture of the aldehyde and acetone with a strong solution of sodium hydroxide they obtained as a direct product of the reaction a substance which they concluded was a geometrical isomer of (A). The present investigation was undertaken in an attempt to prepare in a similar manner the isomeric forms of 3-methyl-3,2-heptenone.

When *n*-butyraldehyde was added to a mixture of 2-butanone and a strong solution of sodium hydroxide we obtained a substance (II) which gave the analytical figures for $C_8H_{14}O$. The semicarbazone of (II) after recrystallization from dilute methanol melted constantly at 141–142°, whereas that of (I) melts at 168°. The semicarbazone of α-ethyl-α-hexenal, which results from the condensation of two molecules of *n*-butyraldehyde, melts at 152°.[4]

The substance (II) was almost completely soluble in a solution of sodium sulfite and sodium bicarbonate, showing it to be an α,β-unsaturated ketone or aldehyde.

Upon reduction with sodium and moist ether (II) gave 3-methyl-2-heptanol, although in small yield. This led to the belief that the substance was in fact the isomer of (I), which also yields 3-methyl-2-heptanol upon reduction. In order to determine the configuration of their two substances Eccott and Linstead prepared a 3,2-heptenone from an α-hexenoic acid of known configuration. Following the same procedure we prepared a 3-methyl-3,2-heptenone from α-methyl-α-hexenoyl chloride and methyl zinc iodide and found it to be identical with (I). On oxidation with sodium hypobromite, (I) gave this same α-methyl-α-hexenoic acid. However, the same acid was obtained when (II) was oxidized. At this point the semicarbazone of (II) was recrystallized carefully from dilute ethanol instead of methanol and the semicarbazone of α-ethyl-α-hexenal was isolated. It was also possible to isolate the 2,4-dinitrophenylhydrazone of α-ethyl-α-hexenal from the products of the reaction between (II) and 2,4-dinitrophenylhydrazine. A current of air was then passed through a sample of (II) for several hours to oxidize part of the aldehyde. From the residue, after washing with alkali, it was possible to prepare the semicarbazone of (I). The substance (II) was therefore merely a mixture of (I) and α-ethyl-α-hexenal.

As α-ethyl-α-hexenal might also exist in two modifications, it was prepared both by the action of alkali upon *n*-butyraldehyde and by the dehydration of *n*-butyraldol with iodine. Both products gave the same semicarbazone.

In view of the foregoing it seemed advisable to study further the reaction between *n*-butyraldehyde and acetone. By following the procedure of Eccott and Linstead we obtained the substance (A) which gave a semicarbazone melting at 152°, as reported by these authors. However, this was found to be identical with the semicarbazone of α-ethyl-α-hexenal. As a further check we treated (A) with 2,4-dinitrophenylhydrazine and isolated the 2,4-dinitrophenylhydrazone of α-ethyl-α-hexenal and also one that was identical with that obtained from the 3,2-heptenone produced by dehydrating the ketol.

Experimental

The Direct Condensation of 2-Butanone with *n*-Butyraldehyde.—One hundred and forty-four grams of *n*-butyraldehyde was added in a slow stream to a mixture of 144 g. of 2-butanone and 1000 cc. of a 2.5% sodium hydroxide solution. The reaction was allowed to proceed until the first vigorous reaction had subsided and then the mixture was shaken for fifty-six hours. The upper layer was separated, washed with water and distilled. The fraction of b. p. 72–74° (20 mm.), 117 g., was shaken for fifteen hours with a mixture of 234 g. of sodium sulfite heptahydrate, 78 g. of sodium bicarbonate and 660 cc. of water. The aqueous solution was made alkaline with 40 g. of sodium hydroxide and distilled with steam. The oily portion of the distillate was separated, dried with calcium chloride and distilled; b. p. 77–78° (25 mm.); yield 77 g.

Anal. Calcd. for $C_8H_{14}O$: C, 76.12; H, 11.11. Found: C, 76.13; H, 11.30.

The semicarbazone was prepared in the usual manner from 1 g. of semicarbazide hydrochloride, 1.5 g. of sodium acetate and 0.8 g. of the ketone. The crude product melted at 137–140° and after recrystallization from dilute methanol at 141–142°.

Anal. Calcd. for $C_9H_{17}ON_3$: N, 22.94. Found: N, 22.9, 23.0.

Twenty-two grams of the condensation product was hydrogenated partially by passage with hydrogen over nickel at 200°. The partially reduced product (17 g.) was mixed with 100 cc. of ether and 250 cc. of water and treated with 7 g. of sodium. The material was worked up in the usual manner, yielding 10 g. of product, b. p. 70–90° (20 mm.). This was oxidized with a solution of 10 g. of sodium dichromate and 14 g. of sulfuric acid in 75 cc. of water, keeping the temperature below 50°. After stirring for several hours the mixture was steam distilled. The oily portion of the distillate was separated, dried with calcium chloride and distilled, yielding, beside high boiling substances, 2.5 g. of material, b. p. 57–62 (20 mm.). The semicarbazone of this melted at 82–84° after recrystallization from dilute methanol, as did a mixture of it with the semicarbazone of 3-methyl-2-heptanone.

3-Methyl-3,2-heptenone.—A solution of 12 g. of α-methyl-α-hexenoyl chloride in 20 cc. of dry benzene was added to the methyl zinc iodide prepared from 25 g. of methyl iodide and the resulting ketone isolated in the usual manner. The crude ketone (10 g.) was shaken for five hours with a mixture of 10 g. of sodium sulfite heptahydrate, 8 g. of sodium bicarbonate, and 60 cc. of water.[5] The mixture was extracted with ether and the aqueous portion made alkaline with 4 g. of sodium hydroxide and distilled with steam. The resulting ketone yielded a semicarbazone melting at 166–168°, identical with that obtained from the 3-methyl-3,2-heptenone formed by dehydrating the ketol.[2]

The α-methyl-α-hexenoyl chloride was prepared by the action of phosphorus trichloride on α-methyl-α-hexenoic acid, which in turn was prepared by the method of Kon, Linstead and McLennan.[6,7] The 2,4-dinitrophenylhydrazone, orange crystals, m. p. 137°, was prepared by the method of Allen.[8]

Anal. Calcd. for $C_{14}H_{18}O_4N_4$: N, 18.3. Found: N, 18.4, 18.5.

Oxidation of 3-Methyl-3,2-heptenone.—A solution of 55 g. of sodium hydroxide in 470 cc. of water contained in a one-liter flask was cooled to 0° and 80 g. of bromine added with constant stirring, keeping the temperature below 10°. The solution was again cooled to 0°, 21 g. of 3-methyl-3,2-heptenone (obtained by dehydration of the ketol) added, and the mixture stirred for four hours. The bromoform and carbon tetrabromide were then distilled off with steam. The residue was cooled to 60°, 67 cc. of sulfuric acid added, the mixture distilled with steam, and the distillate extracted three times with ether. The combined extracts were dried with calcium chloride, the ether removed, and the residue distilled, yielding 5 g. of acid, b. p. 127–130° (20 mm.); neut. equiv. calcd. 128; found 129.5.

***p*-Toluidide.**—The acid chloride was prepared and dissolved in benzene. Two equivalents of *p*-toluidine was added and the mixture heated to boiling for a few minutes. The benzene layer was washed with water, dilute hydrochloric acid, dilute sodium hydroxide, and finally with water again. The benzene was evaporated off and the residue recrystallized from petroleum ether, m. p. 85–88°.

Anal. Calcd. for $C_{14}H_{14}ON$: N, 6.45. Found: N, 6.37, 6.26.

A sample of the *p*-toluidide prepared in the same manner from the acid obtained by the method of Kon, Linstead and McLennan was found to be identical.

Oxidation of the Direct Condensation Product.—This was oxidized in the same manner as the 3-methyl-3,2-heptenone, yielding an acid b. p. of 130–135° (25 mm.); neut. equiv. 130; m. p. of the *p*-toluidide, 85–88°.

α-Ethyl-α-hexenal.—A solution of 12 g. of sodium hydroxide in 65 cc. of water was placed in a flask fitted with a reflux condenser and mechanical stirrer, and 72 g. of *n*-butyraldehyde rapidly added. Stirring was continued for thirty minutes, the oil separated, dried with calcium chloride and distilled; b. p. 75–82° (24 mm.); yield 40 g. The semicarbazone melted at 152° after recrystallization from dilute methanol.

α-Ethyl-α-hexenal was also prepared by heating 15 g. of *n*-butyraldol (prepared by the method of Grignard and Vestermann[9]) with a few crystals of iodine; yield 11 g., b. p. 71–74° (30 mm.). The semicarbazone melted at 152°.

The 2,4-dinitrophenylhydrazone melted at 124–125°.

Anal. Calcd. for $C_{14}H_{18}O_4N_4$: N, 18.3. Found: N, 18.4, 18.2.

Isolation of the Components of the Direct Condensation Product.—A stream of air was drawn through 60 g. of the product for twelve hours. It was then shaken with dilute sodium hydroxide solution, dried with calcium chloride, and again treated with air for twelve hours. The treatment with sodium hydroxide was repeated and then air drawn through the residue for thirty-six hours. At the end of this time the material was again shaken with sodium hydroxide solution and the residual oil dried and distilled, yielding 22 g., b. p. 70–90° (20 mm.), and 7 g., b. p. 90–

[7] The authors are indebted to Dr. T. R. Liston for the preparation of the necessary α-methyl-α-hexenoic acid and also for many valuable suggestions during the course of this investigation.

[8] Allen, THIS JOURNAL, **52**, 2956 (1930).

[9] Grignard and Vestermann, *Bull. soc. chim.*, **37**, 420 (1925).

140° (20 mm.). On redistillation the first fraction gave 10 g. of material of b. p. 70–75° (20 mm.). The crude semicarbazone of this fraction melted at 150–160°. After recrystallization it melted at 163–167° as did a mixture of it and the semicarbazone of 3-methyl-3,2-heptenone obtained by the dehydration of the ketol.

The sodium hydroxide extracts were combined and extracted with ether. The aqueous portion was acidified with dilute sulfuric acid and extracted with ether. The ether solution was dried, the ether removed, and the residue distilled. The acid boiled at 136–137° (20 mm.); neut. equiv., 145. The neutral equivalent of α-ethyl-α-hexenoic acid is 142.

The Direct Condensation of *n*-Butyraldehyde with Acetone.—This was carried out according to the directions of Eccott and Linstead.[3] The crude product was fractionated, yielding the following fractions: up to 90° (21 mm.), 62 g.; 90–130° (21 mm.), 17 g.; 130–180° (18 mm.), 43 g.; residue 30 g. The first fraction was carefully redistilled through a Podbielniak column, yielding 3 fractions.[10] The semicarbazones and 2,4-dinitrophenylhydrazones of each fraction were prepared and their melting points are given in Table I.

TABLE I

	B. p., °C. (19 mm.)	Wt., g.	M. p. (°C.) of crude semicarbazone	M. p. (°C.) of crude 2,4-dinitrophenylhydrazone
1	–65	3	110–120	95–100
2	65–69	29	123–133	99–110
3	69–71	11	143–148	120–122

By repeated crystallization of the crude derivative in each case, we were able to isolate a semicarbazone melting at 152°, identical with that of α-ethyl-α-hexenal. Fraction 3 was apparently almost entirely α-ethyl-α-hexenal. In order to identify the other component of fractions 1 and 2, the crude 2,4-dinitrophenylhydrazones were dissolved in alcohol, and the solution cooled, when crystals of the 2,4-dinitrophenylhydrazone of α-ethyl-α-hexenal separated. The mother liquor was evaporated to dryness and the residue dissolved in warm gasoline. When the solution was cooled a further crop of the 2,4-dinitrophenylhydrazone of α-ethyl-α-hexenal was obtained. The mother liquor was evaporated to dryness and the residue recrystallized from alcohol. This substance melted at 125–126° but was not identical with the 2,4-dinitrophenylhydrazone of α-ethyl-α-hexenal, m. p. 124–125°, as a mixture of the two melted at 100–110°.

A sample of 3,2-heptenone was prepared by dehydrating the ketol with oxalic acid, according to the method of Eccott and Linstead, and converted into the 2,4-dinitrophenylhydrazone. This substance melted at 125–126° and was identical with that obtained above.

Anal. Calcd. for $C_{13}H_{16}O_4N_3$: N, 19.2. Found: N, 18.9, 19.0.

Summary

1. An unsuccessful attempt was made to prepare *cis* and *trans* forms of 3-methyl-3,2-heptenone. An unsuccessful attempt was also made to prepare the *cis* and *trans* forms of 3,2-heptenone as described by Eccott and Linstead.

2. The 2,4-dinitrophenylhydrazones of α-ethyl-α-hexenal, 3,2-heptenone, and 3-methyl-3,2-heptenone were prepared.

3. The *p*-toluidide of α-methyl-α-hexenoic acid was prepared.

Researches on Nitrogenous Glucosides. IV. Some New Attempts to Synthesize Pyrimidine Glucosides

BY TREAT B. JOHNSON AND WERNER BERGMANN

The authors desire to report in this paper new data resulting from some special experiments applied in their researches on nitrogenous glucosides, which do not find their proper place in other papers to be published on this subject. The first contribution of importance from this Laboratory was made in 1930 when Hilbert and Johnson[1] synthesized successfully 3-glucosidouracil by interaction of 2,6-dimethoxypyrimidine with tetraacetylbromoglucose. The resulting acetyl derivative gave the desired nucleoside on hydrolysis. Later Hilbert[2] applied a similar reaction using 2-methoxy-6-aminopyrimidine and tetraacetylbromoglucose in order to obtain the corresponding glucoside of cytosine, but without success. It is of interest to note here that E. Fischer also failed in his attempts to prepare glucosides of both uracil and cytosine by the action of tetraacetylbromoglucose on the silver salts of these two pyrimidines.[3] Recognizing the limitations of this method of approach to practical methods of synthesizing nitrogenous glucosides, we next turned our attention to the study of techniques based on the use of sugar isocyanates and corresponding ureas as starting points. The only

[3] E. Fischer, *Ber.*, **47**, 1377 (1914).

sugar isocyanate derivatives recorded in the literature previous to our work were tetraacetylglucose isocyanate $C_{14}H_{19}O_9NCO$ and the corresponding isothiocyanate $C_{14}H_{19}O_9NCS$ described by E. Fischer in 1914.[3] This work of Fischer has been repeated in this Laboratory by different workers and several attempts have been made to utilize such simple sugar constructions for the preparation of nitrogenous glucosides in the hydantoin and pyrimidine series. Haring and Johnson[4] prepared Fischer's glucose isothiocyanate and showed that it adds as expected to α-amino acids or their esters, giving hydantoic acid derivatives which can be condensed smoothly to hydantoins. They prepared the first known glucoside derivatives of 2-thiohydantoin and hydantoin. Johnson and Bergmann[5] reëxamined Fischer's work on the preparation of tetraacetylglucose isocyanate $C_{14}H_{19}O_9NCO$ and its urea derivative, but failed in their attempts to synthesize pyrimidine glucosides from these simple sugar combinations.

In the experimental part of this paper is recorded the history of some interesting derivatives which have resulted from other types of reactions applied by the authors for the synthesis of new nitrogenous glucoside derivatives.

Experimental Part

Extension of Fischer's Isocyanate Work to Other Sugars.—We have found that as a rule the isocyanates of sugars are difficult to obtain in a pure form.[5] In most cases examined only amorphous products have been obtained in our researches. That these amorphous products sometimes contain considerable amounts of the desired isocyanate derivative can be demonstrated easily by their conversion into the corresponding ureas by the action of strong ammonia solution. The yields, however, are generally too low for service in practical synthesis.

1-Arabinose-isocyanate ⟶ 1-Arabinose-urea.—Triacetobromoarabinose was refluxed in dry xylene with twice the theoretical amount of anhydrous silver cyanate for several hours. After filtration and dilution of the xylene with petroleum ether an oil separated which solidified to a resin-like substance and from which no crystalline material could be obtained. The crude reaction product finally was suspended in concentrated ammonia solution when it dissolved immediately. The acetyl groups of the glucoside were removed by this treatment, and by application of a method of purification described in our previous paper we succeeded in isolating a beautiful crystalline urea derivative of 1-arabinose melting at 192°. It showed an optical rotation of $\alpha^{25}\text{D}$ +51.9° (0.1197 g. in 3.0686 g. of water gave d + 2.02°). This substance proved to be identical with 1-arabinose urea which has been described previously by Helferich.[6]

Xylose-isocyanate ⟶ sym-Dixylose-urea.—Triacetobromoxylose was refluxed as usual with silver cyanate in xylene for several hours. The amorphous reaction product which was obtained after filtration and addition of petroleum ether was treated with concentrated aqueous ammonia in the usual way. From the reaction mixture we separated a substance which crystallized in fine needles. It showed no sharp melting point, turning brown at 230° and charring at 250°. It gave an optical rotation of $\alpha^{25}\text{D}$ −20.5° (0.112 g. in 3.07 g. water gave d − 748°). The substance was identified as *sym*-dixyloseurea previously described by Helferich.[6]

Anal. Calcd. for $C_{11}H_{20}O_9N_2$: C, 40.73; H, 6.22. Found: C, 40.91; H, 6.39.

Heptaacetyllactose-isothiocyanate, $C_{12}H_{14}O_3(OCOCH_3)_7$-NCS.—As a rule it has been the authors' experience that the isothiocyanate derivatives of sugars are easier to obtain in a pure crystalline condition than the corresponding isocyanates. Seven grams of heptaacetylbromolactose was refluxed with 5 g. of silver thiocyanate in xylene for ten minutes. After addition of petroleum ether to the filtered solution crystals of the isothiocyanate began to separate. After purification by crystallization from chloroform and petroleum ether the isothiocyanate was obtained in the form of large prismatic crystals. It melted at 169–170°.

Anal. Calcd. for $C_{27}H_{35}O_{17}NS$: C, 47.82; H, 5.20. Found: C, 47.89; H, 5.39.

Heptaacetyllactose-ethylthiourethan, $C_{29}H_{41}O_{18}NS$.—This was prepared by refluxing the above isothiocyanate derivative in absolute ethyl alcohol. It crystallizes from hot alcohol in the form of needles melting at 119°. Like many other thiourethans it contains water of crystallization.

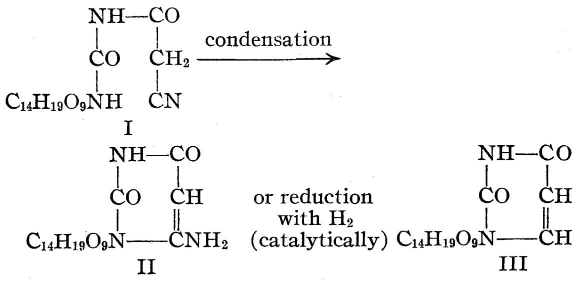
Anal. Calcd. for $C_{29}H_{41}O_{18}NS$: C, 46.94; H, 5.85. Found: C, 47.10; H, 5.81.

Heptaacetyllactosethioureido-ethyl acetate, $C_{31}H_{44}$-$O_{19}N_2S$.—One one-hundredth mole of the above isothiocyanate and 0.015 mole of ethyl glycine hydrochloride were refluxed in chloroform, containing a few drops of pyridine, for two hours. The excess of solvent was then expelled *in vacuo*, water added to the residue and the condensation product extracted with ether. After drying the ether solution, petroleum ether was added, when crystals of the reaction product separated. It deposited in the form of octahedra melting at 100°.

Anal. Calcd. for $C_{31}H_{44}O_{19}N_2S$: C, 47.68; H, 5.68. Found: C, 47.61; H, 5.73.

Attempts to Prepare Pyrimidine Glucosides in the Barbituric Acid Series.—The following proposed synthesis of a glucosido-uracil was studied:

A. Tetraacetylglucose-urea + cyanacetic acid



---

(4) Haring and Johnson, THIS JOURNAL, **55**, 395 (1933).

(5) Johnson and Bergmann, *ibid.*, **54**, 2360 (1932).

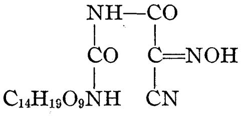
(6) Helferich, *Ber.*, **59**, 69 (1926).

Four grams of tetraacetylglucose-urea, 1 g. of cyanoacetic acid and 2 cc. of acetic anhydride were heated at 100° for ten minutes. On adding water to the cooled solution a crystalline substance separated. After crystallizing several times from dilute alcohol it melted constant at 135°.

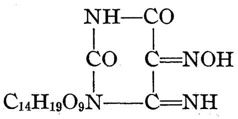
Anal. Calcd. for $C_{18}H_{23}O_{11}N_3$: C, 47.15; H, 5.27; N, 9.17. Found: C, 47.16; H, 5.24; N, 9.12.

Theoretically this substance could be either an acyclic or a cyclic compound (I or II). In order to determine its constitution molecular proportions of the compound and sodium nitrite were warmed in water for several minutes. The solution became yellow in color and on acidifying with acetic acid prismatic, plate-like crystals separated. After recrystallization from boiling water they melted at 179–180°. That we are dealing here with a nitroso derivative of the acyclic compound I as represented by formula IV is supported by the yellow color, and, furthermore, by the fact that cyanoacetic acid itself and sodium nitrite interact in a similar manner.

Anal. Calcd. for $C_{18}H_{22}O_{12}N_4$: C, 44.34; H, 4.75; N, 11.50. Found: C, 44.42; H, 4.74; N, 11.18.



IV



V

If the reaction product resulting from condensation with cyanoacetic acid is to be represented by the cyclic structure II, it should react with ammonia with removal of the acetyl groups and with formation of the stable cyclic glucoside. We found, however, that such treatment yielded smoothly glucose urea, leading to the conclusion that formula I and not II represents the correct constitution of the original condensation product.

Anal. Calcd. for glucose urea: C, 37.82; H, 6.35. For $C_{10}H_{15}O_7N_3$ (from II): C, 41.53; H, 5.22. Found: C, 37.93; H, 6.40; N, 12.36.

Under no conditions did we succeed in converting the ureide I into the pyrimidine II by the action of alkali.

We also attempted to effect ring closure of the ureide I by means of catalytic hydrogenation as previously applied successfully by Rupe,[7] and later by Johnson and Bergmann[8] for the preparation of uracil and thymine, respectively. We obtained no evidence of the formation of a uracil-glucoside derivative. An attempt finally was made to condense tetraacetylglucose-urea with malonic acid to obtain a barbituric acid glucoside derivative. Twelve grams of acetic anhydride, 10 g. of acetylglucose-urea and 2.7 g. of malonic acid were heated at 100° for thirty minutes. We obtained a deep orange colored solution. Dilution with water led to the precipitation of a crystalline substance from which we succeeded in separating a product that crystallized from methyl alcohol without coloration after treatment with norite. It melted at 206–207°. The results of analysis indicated that we were not dealing with a barbituric acid derivative, but with the acyclic compound *di-(tetraacetylglucose)-ureide of malonic acid*, $C_{14}H_{19}O_9NH\text{-}CONHCOCH_2CONHCONHC_{14}H_{19}O_9$.

Anal. Calcd. for $C_{33}H_{44}O_{22}N_4$: C, 46.68; H, 5.23; N, 6.60. Found: C, 46.51; H, 5.34; N, 6.86.

When this diureide was allowed to interact with alcoholic ammonia at ordinary temperature, glucose urea was formed.

Summary

1. Methods have been described for preparing 1-arabinose-urea, *sym*-dixylose-urea and heptaacetyllactose isothiocyanate and derivatives.

2. Condensation of cyanoacetic acid with tetraacetylglucose-urea leads to the formation of the ureide $C_{14}H_{19}O_9NHCONHCOCH_2CN$. Attempts to condense this to a pyrimidine construction were unsuccessful.

Fixation of Active Nitrogen by Organic Compounds

BY LOUIS B. HOWARD[1] AND GUIDO E. HILBERT

The most promising of various possible methods for directly introducing some form of elementary nitrogen into organic substances is the one utilizing active nitrogen[2] which consists essentially of atomic nitrogen. General experience has shown that molecular nitrogen is inert toward organic compounds and no catalyst has yet been discovered which will activate nitrogen to the extent that it will interact with organic materials. In this connection, it is noteworthy that practically all of many assumed reactions between nitrogen and organic molecules proceed with an increase in free energy.[3] In contrast to the ordinary form of nitrogen, atomic nitrogen, in view of its high reactivity, trivalent-like structure, $\left(\mathrm{N}\!\!<\right)$, and relatively long life, would be expected to interact

[3] We are grateful to Dr. R. Wiebe and Dr. R. T. Milner for having made many of these calculations.

with organic compounds. Practically the only work carried out in this direction has been done by Strutt, and by Willey and Rideal,[4] who examined superficially the behavior of a number of compounds toward active nitrogen produced by a condensed discharge. Relatively small amounts of materials[5] were worked with and apart from hydrogen cyanide the production of nitrogenous material of an organic nature[6] was not demonstrated.

In the investigation of the interaction of active nitrogen and organic materials, we were mainly interested in determining whether nitrogen can be fixed to yield a relatively complex product and, if so, what the nature of the product is, since this information is of value in elucidating the mechanism of the reaction. Diphenylacetylene was chosen as the organic partner in the reaction since the aromatic portion of the molecule was expected to confer properties to the nitrogenated material which would make it easy to handle, a matter of considerable importance as small quantities must of necessity be manipulated. Another apparent advantage in favor of diphenylacetylene is the vulnerability of the acetylenic linkage and this was expected *a priori* to be attacked to yield benzonitrile as follows

$$C_6H_5C{\equiv}CC_6H_5 + 2N\!\begin{smallmatrix}\diagup\\ -\\ \diagdown\end{smallmatrix} \text{ or } N_2^* \longrightarrow 2C_6H_5CN$$

In order to gain further information on the mechanism of the reaction the behavior of active nitrogen toward benzonitrile and toward tetrahydronaphthalene also was studied. The active nitrogen used in this investigation was produced by an uncondensed discharge except in two experiments where the nitrogen was activated by a condensed discharge.

Apparatus and Experimental Data

Apparatus.—After preliminary trials the apparatus shown in Fig. 1 was used in the final studies. It consists of three sections: (1) a purification train for removing, as far as possible, oxygen and water from the nitrogen, (2) a discharge tube for activating the nitrogen and (3) a reaction bulb with accessories for introducing the organic material and collecting the reaction products.

Purification of the nitrogen by the following method gave the best results. The nitrogen (Linde water-pumped) was conducted from the tank through tube A, 4 cm. in diameter and 50 cm. long, which was packed with pellets of potassium hydroxide, and then through B, which was heated electrically at 410°.[7] Tube B, 3 cm. in diameter and 100 cm. long, was packed with approximately 500 g. of copper wire, in pieces 0.16 mm. in diameter and 1 cm. long, which was repeatedly oxidized and reduced with air and hydrogen at about 410° to activate the surface. From this furnace the nitrogen was passed through trap C, cooled with liquid air and filled with copper turnings to turbulate the gas and increase the cold surface. The purified gas was then passed through two filed stopcocks into the activation chamber D. In a single run, nitrogen at flow rates up to 8 cc. per second and in volumes as great as 1000 liters could be handled conveniently. After completion of the experiment the copper in the tube B was readily regenerated by passing hydrogen gas through the three way stopcocks at either end.

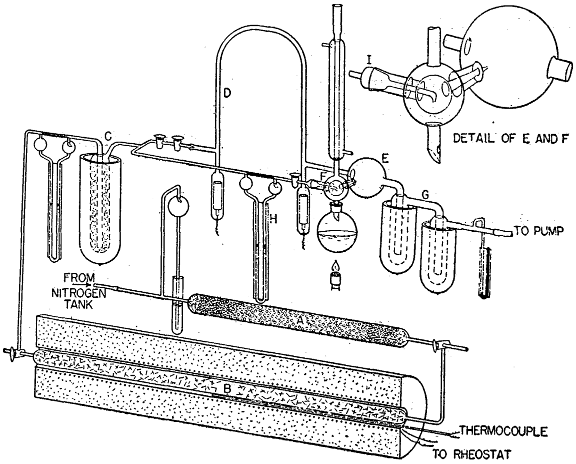

Fig. 1.—Apparatus for the fixation of active nitrogen by organic compounds.

The discharge tube D was fitted with hollow aluminum[8] electrodes, 2 cm. in diameter and 5 cm. long, mounted on tungsten leads. The path of the discharge between the electrodes was about 1 meter long and the current was produced by a General Electric sign transformer operating on 60 cycles and delivering a secondary current of 30 m. a. at 15,000 v.

From D the active nitrogen was conducted into E, where it mixed with the organic vapor which entered from the vaporizing bulb F. The two liquid air cooled traps G served to condense that portion of the reaction product which was not deposited on the walls of E. The unreacted nitrogen was eliminated from the apparatus by a Megovac pump. Bulb F (shown in detail in Fig. 1) consisted of a small jacketed chamber opening into E through a jet at right angles to the stream of excited nitrogen. The vapor

[5] Acetylene, benzene, naphthalene, pentane, heptane, methyl bromide, ethyl chloride and iodide, chloroform, bromoform, 1,1-dichloroethane and ethyl ether were investigated.

[6] In the reaction with benzene there was some indication that benzonitrile was formed. On the walls of the reaction chamber a brown-black solid was produced but no test for the presence of combined nitrogen was made.

[7] Under similar conditions, Stiehler, Chen and Clark, This Journal, **55**, 892 (1933), obtained nitrogen containing less than 2.4 × 10^{-6}% of oxygen.

[8] Tiede and Hey, *Ber.*, **66**, 85 (1933), tested several metals as electrode materials and found aluminum to give the highest concentration of active nitrogen.

pressure of the organic compound under study was controlled by refluxing a liquid with a suitable boiling point in the external heating system. Passage of the organic material into E was facilitated by a stream of purified nitrogen from C, the pressure of which was regulated by a filed stopcock and recorded by the flowmeter H. In order to recharge F, the glass tube between F and H was cut and the sealed in jet I removed.

Materials.—**Diphenylacetylene** (m. p. 60°) was prepared by the procedure of Schlenk and Bergmann.[9] After several recrystallizations from alcohol it was dried and stored over phosphorus pentoxide *in vacuo*. **Benzonitrile** from the Eastman Kodak Company was purified by triple extraction with dilute sodium hydroxide and dilute sulfuric acid. After drying over potassium carbonate, it was distilled and only the middle fraction collected; b. p. 191°. **Tetrahydronaphthalene** from the Eastman Kodak Company was purified by fractional distillation in which the middle of three fractions was collected: b. p. 208°.

Action of Active Nitrogen Produced by an Uncondensed Discharge on Diphenylacetylene

General Procedure for Carrying out the Reaction.—Diphenylacetylene in bulb F was heated to 100°, the discharge tube put in action, and the system adjusted with regard to pressure and flow rate of nitrogen (see Table II for the different pressures and flow rates used). When a strong lemon-yellow afterglow filled the reaction bulb E and the traps, the stopcock between H and I was opened slightly in order to facilitate the entrance of the organic material into E. Immediately thereafter a violet glow, suggestive of the cyanogen spectrum, filled the reaction bulb and the first liquid-air trap. As the amount of diphenylacetylene introduced was increased, the violet glow in the reaction bulb was quenched and only faintly visible at the point of entrance of the active nitrogen into E; an intense violet glow was, however, exhibited in the first trap. This condition remained constant even though the rate of introduction of the organic material was increased considerably. Generally the rate of flow of gas through F was so regulated that the violet glow in E was just quenched since it was desired to have an excess of diphenylacetylene in the reaction. Shortly after initiation of the experiment a yellowish-brown film was noticeable on E. Eventually E became wholly covered with a relatively thick layer of the brownish-black opaque product and considerable material was deposited in the two traps.

Isolation and Description of Reaction Products.—After all the sample had been introduced, the discharge was discontinued and the pressure brought up to atmospheric. The liquid air containers were removed from the traps and the system swept out for about four hours with purified nitrogen at a rate approximating 20 l. per hour. *Hydrogen cyanide* was collected in a solution of sodium hydroxide and determined by the Liebig method. The reaction bulb and traps were detached from the apparatus and had a distinct mixed odor of *benzonitrile*, *phenyl isocyanide* and hydrogen cyanide. Much of the *dark brown amorphous solid I*, which is the major product of the reaction, was removed by a combination of scraping and extraction with hexane.[10] Collection of the insoluble product on a filter was followed by thorough pulverization and repeated extraction with warm hexane to remove the last traces of the unreacted acetylene derivative. After drying *in vacuo* at 100° and weighing, it was submitted to elementary analysis. The solid material which could not conveniently be removed from E and G was dissolved in concentrated sulfuric acid and the nitrogen determined by the Kjeldahl method. An aliquot of the combined hexane extracts was likewise analyzed for nitrogen. In order to show the relative amounts of nitrogen obtaining in these fractions the representative results for experiment 3 (see Table II) are given in Table I.

TABLE I

NITROGEN DISTRIBUTION

Fraction	Nitrogen, mg.
Hydrogen cyanide	96
Recovered solid	250
Sulfuric acid solution	98
Hexane extracts	41

The sum of the amounts in the last three fractions is listed in Table II under the column "nitrogen fixed as solid." It is apparent that a relatively unimportant amount is extracted by hexane and this fraction was not further investigated.

The amount of benzonitrile formed in the reaction was so small that it could not be identified by chemical means. An alcoholic extract of some of the slightly pasty solid product formed in an experiment was distilled and the first fraction (one-third) diluted twenty-five times. The absorption bands of this solution were determined by using a quartz spectrograph and a hydrogen discharge tube as a source of light. Spectrographic results although suggestive that benzonitrile was present were not wholly satisfactory as the apparent presence of diphenylacetylene in the unknown tended to confuse the interpretation of the results.

The average of duplicate carbon, hydrogen and nitrogen analyses of (I) prepared under a variety of conditions is recorded in Table II. The percentages of nitrogen listed were determined by the Dumas method and were always from 0.2 to 1.0% higher than the values obtained by the micro Kjeldahl method in which the material was digested for twenty minutes as generally recommended. In a few cases, the percentage of oxygen present in the solid was determined by direct analysis,[11] in order to account for the fact that the sum of the carbon, hydrogen and nitrogen values did not total 100%. The value for oxygen obtained by direct analyses differed by 0.5 to 1.0% from the figure calculated by difference. We believe that the analyses for nitrogen by the Dumas method are low and responsible for this discrepancy. In this connection, it is of interest that certain high melting nitrogenous materials have been found by Milner and Sherman[12] to give low

---

[9] Schlenk and Bergmann, *Ann.*, **463**, 76 (1928).

[10] Most of the diphenylacetylene did not react and is to be found in this solution.

[11] Dr. R. T. Milner kindly carried out these determinations by his unpublished modification and adaptation to the semi-micro scale of the method by ter Meulen, *Rec. trav. chim.*, **43**, 899 (1924); **53**, 118 (1934).

[12] Milner and Sherman, *Ind. Eng. Chem., Anal. Ed.*, **8**, 331 (1936).

nitrogen values when determined by the Dumas method. Re-analysis of specimens prepared in experiments 1, 3 and 6 after they had stood from eighteen months to two years in stoppered containers from which no effort to exclude air was made, indicated that the products had been altered. The new results (see analyses f in Table II) were uniformly lower in carbon and nitrogen and higher in oxygen while hydrogen fluctuated but little.

When heated (I) showed a little shrinkage at 300° but remained unmelted at 320°. Upon much stronger heating it decomposed without melting to give ammonia, a small quantity of colorless oil and a considerable residue of charred material. The oil had a foul, isonitrile-like odor and appeared to be insoluble in dilute hydrochloric acid; the acid extract gave a negative color test for aniline with sodium hypochlorite.

Solubility tests showed (I) to be very slightly soluble in alcohol, ether, hexane, benzene and xylene, partially soluble in nitrobenzene and acetonitrile and readily soluble in benzonitrile, from which it was precipitated by hexane. It dissolved fairly readily in concentrated hydrochloric or glacial acetic acid from which solution it was not precipitated either by chilling or dilution with much water but only by making alkaline. The precipitated product was flocculent and continued washing resulted in an increased tendency of the solid to remain suspended, thus exhibiting a behavior quite similar to the peptization of a colloid. Its elementary analysis differed but slightly from the original; in accordance with a sodium ash of 3% the value for nitrogen was 3% less.

Some qualitative information on the mode of attachment of nitrogen in the molecule was secured by the following experiments. Emich's test[13] for the $>\!N-\overset{|}{\underset{|}{C}}-N\!<$ grouping by fusion of (I) with calcium oxide and subsequent formation of the characteristic yellow silver salt of cyanamide was positive. That some of the nitrogen can be removed as ammonia was shown by the following experiment. Weighed samples of about 0.05 g. each were heated for different lengths of time in Kjeldahl flasks with 2 *N* sodium hydroxide and the liberated ammonia collected in standard acid. The amount of nitrogen given off as ammonia after one, three and four hours of digestion was 2.60, 3.37 and 3.83%, respectively, of the weight of the sample. An attempt to hydrolyze the solid by heating 0.2 g. with 25 cc. of concentrated hydrochloric acid in a sealed tube at 180° for three hours was unsuccessful. No ammonium chloride or other crystalline material could be isolated from the acid solution. The insoluble material apparently differed from the original only in being much less soluble in cold concentrated sulfuric acid. Treatment with hot glacial acetic acid and zinc dust affected (I) only slightly. A brown flocculent solid was recovered and melted at 215–235° (dec.). In appearance and solubility it resembled the original product.

Oxidation with nitric acid yielded crystalline material, whereas chromic oxide in acetic acid and potassium permanganate in acetone did not give tractable products. Two grams of (I) was treated with a solution of 50 cc. of concentrated nitric acid and 75 cc. of water. A reaction occurred immediately with evolution of oxides of nitrogen and after twenty minutes of refluxing the solid was largely dissolved, giving a dark orange colored solution. After heating for two hours, the reaction mixture was cooled and the liquid fraction decanted from the insoluble tarry material. The acid solution was made alkaline and then slightly acidified with hydrochloric acid. *A buff colored solid (II)* (0.32 g.) separated and was collected on a filter, washed with cold water and dried. It was practically insoluble in benzene, slightly soluble in ether and partially soluble in alcohol. Extraction with benzene in a Soxhlet apparatus for one day left a residue of 0.12 g. (*Anal.* Found: C, 58.7; H, 3.2; N, 9.7, 9.6; ash, 4.8.) Evaporation of the benzene extract left only an intractable tar. The weakly acidic filtrate from (II) was extracted repeatedly with ether, and the extracts combined, filtered and evaporated to dryness *in vacuo*. The solid residue was subjected to fractional sublimation under diminished pressure at 100°; from the sublimed material there was obtained 0.15 g. of recrystallized *benzoic acid;* m. p. 122°. Continued sublimation at 135° yielded 0.1 g. of a light yellow crystalline material; m. p. 175–185°. Crystallization from water gave a nearly colorless product; m. p. 215–220° in a closed capillary.

Anal. Calcd. for $(C_{10}H_7NO_5)_x$: C, 54.3; H, 3.2; N, 6.3; O, 36.2. Found: C, 54.8, 55.1; H, 3.4, 3.6; N, 6.5; O (by difference), 35.3, 34.8. *Neutral equivalent.* Sub., 3.27 mg.: 2.54 cc. of 0.01 *N* NaOH. Found: 129.

Increased purification of the nitrogen used in the nitrogenation affected the composition of the solid reaction product and influenced the behavior of the discharge. Nevertheless, the reaction appeared to proceed in the same manner and the properties of (I) were not changed appreciably although the percentage of oxygen was lowered markedly. As the oxygen content of the nitrogen was diminished the discharge persisted at higher pressures. For example, when tank nitrogen without purification was used a pressure greater than 10 mm. extinguished the discharge, whereas when rigorously purified nitrogen was used pressures up to 25 mm. were attainable before the discharge failed. For comparison, the data from one of the experiments (No. 1) performed by using nitrogen containing an appreciable amount of oxygen have been included in Table II. In this case the nitrogen was passed over heated copper gauze and then through a liquid air trap. In all other recorded work (Table II) nitrogen purified by the scheme outlined earlier was used.

Variation in Stray Discharge.—In order to demonstrate the unimportance of stray discharge, which unavoidably leaks from the discharge tube to the reaction bulb, a sheath of copper foil cooled by an air blast was wrapped about the tube joining D and E and grounded to a water line. Although this did not completely eliminate the stray discharge it did materially lessen the amount reaching E. This was applied in experiment 4 which otherwise differed in no way from 3. Inspection of Table II shows that the yield of fixed nitrogen did not fall off.

Action of Active Nitrogen Produced by an Uncondensed Discharge on Benzonitrile.—The general procedure was similar to that already described in the experiments on diphenylacetylene. In this case owing to its high vapor pressure at room temperature it was not necessary to heat the benzonitrile. When the stopcock at I was closed, an in-

---

[13] Emich, *Monatsh.*, **10**, 321 (1889).

tense violet glow of excited cyanogen filled E. This was extinguished completely when the stopcock was opened slightly. Although some of the reaction product was deposited on the walls of E, the major portion, consisting essentially of a very dark brown solid partially dissolved in unchanged benzonitrile, collected in the traps. The hydrogen cyanide was swept out, collected and determined as in the diphenylacetylene experiments. The contents of the traps were filtered, and the solid thoroughly extracted with hexane. A current of nitrogen was continually swept over the product during these manipulations. The material was desiccated at 100° *in vacuo* for about three hours and immediately submitted to analysis (see expt. 7 in Table II). The filtrate from the solid was diluted with a large quantity of hexane and the flocculent material, which separated, reprecipitated from benzonitrile with hexane. It was dried and analyzed and appears to be identical with the first fraction. *Anal.* Found: C, 65.64; H, 3.73; N, 26.08. The hexane filtrates were combined and concentrated on the water-bath, giving an oil which by fractional distillation was found to consist almost wholly of unreacted benzonitrile; b. p. 190.5; n^{25}_{D} 1.5257.

The solid matter remaining in the traps was not taken up in concentrated sulfuric acid and determined for total nitrogen, since in this case such a value is not a measurement of the total nitrogen fixed. In one experiment, 9, the total yield of solid product was determined. The material that was easily separated was combined with the residue recovered from the acetonitrile, which was used to clean out E and G; weight 0.85 g.

Action of Active Nitrogen Produced by an Uncondensed Discharge on Tetrahydronaphthalene.—This run was carried out in exactly the same manner as that described for diphenylacetylene and in its general appearance differed only in that the cyanogen glow was much weaker and the trap contents at the end of the experiment were almost entirely liquid. After the hydrogen cyanide was swept out, the liquid in the traps was poured directly into hexane and the tar-like solid which precipitated triturated with hexane until a dark brown amorphous solid was obtained. It was collected on a filter in an atmosphere of nitrogen, dried *in vacuo* at 76° for one hour and immediately analyzed. The residues in the traps and from the hexane washings were dissolved in concentrated sulfuric acid and the nitrogen determined by the Kjeldahl method. The results are recorded in Table II.

Action of Active Nitrogen Produced by a Condensed Discharge on Diphenylacetylene.—Modification of the apparatus used in the previous experiments was effected by introducing three Leyden jars across the transformer and by connecting a spark gap in series with the discharge tube, the gap being quenched by a blast of air. Instead of being orange-yellow, the color of the discharge was more reddish-blue. Although unchanged with respect to color the after glow was markedly stronger. In Table II are tabulated results secured in two experiments, namely, 5 and 6. The formation of the solid on the walls of the reaction vessel appeared to take place more rapidly than in the corresponding experiments in which the uncondensed discharge was used. The properties and composition of the solid, however, were about the same.

Discussion

From the results shown in Table II it is concluded that active nitrogen reacts with diphenylacetylene, benzonitrile or tetrahydronaphthalene and initiates the formation of the organic nitrogenous material isolated. All other possible reactions which can account for the products seem to have been eliminated. For example, the early experiments in which the nitrogen used contained an appreciable amount of oxygen—one of these, 1, is recorded in Table II—gave products containing as much as 10% oxygen and were open to the criticism that nitrogen oxides instead of active nitrogen might have interacted with diphenylacetylene. That nitrogen oxides are not involved to any great extent in the later work is shown by experiments 2–4, where rigorously

[a] Uncondensed discharge. [b] Condensed discharge. [c] Stray discharge reduced considerably. [d] The nitrogen contained appreciably more oxygen than that used in the other experiments. [e] Purity of nitrogen was highest attained in this work. [f] Data obtained from reanalyses made eighteen to twenty-four months later. [g] This cannot be considered as representing only the nitrogen fixed in the reaction since the starting material contained 13.6% of nitrogen.

purified nitrogen was employed. The oxygen content of the products was lowered markedly (in 4 to 1%) without decreasing appreciably the amount of fixed nitrogen. Our experience indicates that it is a very difficult matter to prepare these nitrogenous products entirely free from oxygen, particularly for large scale experiments where the quantities of nitrogen required make impractical production of oxygen-free nitrogen from a chemical source. The contribution to the nitrogenous products by a reaction, between molecular nitrogen and the organic matter, induced by stray discharge is negligible. In no. 4 stray discharge was reduced considerably below that obtaining in no. 3 without affecting the yield of fixed nitrogen and in no. 2 the decrease in the pressure of the system diminished the yield of products, although in so far as stray discharge alone is concerned lowering the pressure in this range conduces to increased stray discharge.

Interaction of the aromatic compounds and active nitrogen yields essentially a polymerized nitrogenous solid and hydrogen cyanide. The yield of solid was greatly influenced by a change in the pressure of the system, thus increasing the pressure from 4 to 9 mm., increased the yield sevenfold. The ratio of nitrogen fixed by diphenylacetylene as hydrogen cyanide to nitrogen fixed as solid for the uncondensed discharge experiments 2–4 varies from 1:4 to 1:5. Experiments 5 and 6 in which a condensed discharge was employed also gave ratios varying from 1:4 to 1:5 and approximately the same yields of products. Averaging numerous determinations of carbon, hydrogen and nitrogen on specimens obtained under different conditions gives ratios of C:H:N that fluctuate from 4.4:3.3:1 (expt. 2) to 5.4:4.2:1 (expt. 7). Under the same conditions as obtained in the diphenylacetylene experiment, benzonitrile yields a solid similar in appearance and physical properties to the acetylene derivative but differing by containing 7% more nitrogen. In this case the yield of hydrogen cyanide is threefold greater. The action of active nitrogen on tetrahydronaphthalene was studied with the object of determining the mole ratio between the combined nitrogen and the original material in the reaction product and of determining the fate of the aliphatic hydrogen. The yield of hydrogen cyanide in this reaction is double that given by diphenylacetylene. Naphthalene is not formed and the solid product although physically similar has a much higher hydrogen content and an empirical formula close to $(C_{10}H_{10}N_2)_x$. It is to be noted that although the ratios of nitrogen to organic material in the reaction product obtained in the different experiments agree among themselves moderately well for a particular reactant, the ratio changes markedly from compound to compound. Thus, for every two molecules of the original aromatic compound,[14] the nitrogenated solid from the diphenylacetylene experiment contains about six atoms of nitrogen, that from the tetrahydronaphthalene experiment about four atoms of nitrogen and that from the benzonitrile experiment about three atoms of nitrogen. This change in the ratio is perhaps not surprising when it is considered that a decrease in this ratio was accompanied by an increase in the ratio of nitrogen fixed as hydrogen cyanide to nitrogen fixed as solid.

For comparative purposes, an exploratory experiment was performed to investigate the behavior of an aliphatic compound, isoprene, toward active nitrogen. A strikingly different result was secured. Practically no solid matter is formed and instead a nitrogenous low-boiling liquid in good yield and generating ammonia on hydrolysis is produced. In view of the apparent simplicity of this product, further studies with unsaturated aliphatic compounds, which are not being contemplated by us, would be expected to yield fruitful information.

The general mechanism of the reaction appears to involve a number of consecutive processes, (1) the interaction of atomic nitrogen and the aromatic compound to form an active intermediate, (2) stabilization of the intermediate to form the solid on the wall and (3) bombardment and further reaction of the solid with active nitrogen. In the collision between the organic molecule and active nitrogen it is not unlikely that a fragment is ejected. The structure of this fragment probably depends on the point of attack of the active nitrogen on the organic molecule and this view accounts, in part at least, for the formation of the simpler materials, hydrogen cyanide, excited cyanogen, (CN*), benzonitrile, etc. That a nitrogen-free, organic particle of relatively high molecular weight is not split off is suggested by the absence of this type of material in the products of the reaction. The most reasonable explanation

---

[14] We are, of course, assuming that the empirical formula of the original organic material has not suffered any great change on reacting with active nitrogen to form the solid.

for the high nitrogen content of the solid is that a considerable quantity of nitrogen is introduced by the reaction of active nitrogen with the solid on the walls of the vessel. The similar results secured by the employment of either a condensed or uncondensed discharge for the activation of nitrogen are in accord with the present concept that active nitrogen consists principally of atomic nitrogen, which most probably is the form taking part in the above reaction.

Comparison of the results of this work with those obtained by Kroepelin and Vogel[15] in the study of the action of atomic hydrogen on oleic acid and paraffin oil reveals a striking similarity in the course of the two reactions. (1) In both cases the initial reaction involves combination with the active element and the probable simultaneous formation of free radicals. (2) The active intermediates formed are subsequently stabilized and yield, to a certain extent, brown polymerization products. (3) The introduction of oxygen into the products can be avoided only by using an atmosphere absolutely free from oxygen.

Acknowledgment.—We are indebted to Drs. Wulf, Jones and Melvin for numerous experimental suggestions, to Dr. Wulf for the aid received in discussions on the theoretical aspects of this work and to Mr. Testa for the difficult and clever job of glass blowing on the apparatus.

Summary

Nitrogen activated by a condensed or uncondensed discharge reacts with diphenylacetylene to form a brown nitrogenous high-melting solid, hydrogen cyanide, excited cyanogen (CN*) and probably traces of benzonitrile and an isonitrile. From its physical and chemical properties, the brown solid, which is the major product of the reaction, appears to be a complex material of high molecular weight. It contains about 16–18% nitrogen, is resistant to acid hydrolysis, liberates ammonia on alkaline hydrolysis, yields benzoic acid and an unidentified, crystalline acid possessing nitrogen on nitric acid oxidation and seems to contain  $>N-\overset{|}{\underset{|}{C}}-N<$ group. Tetrahydronaphthalene and benzonitrile also react with atomic nitrogen to form amorphous solids having physical properties similar to the product from the acetylene derivative. The ratios of fixed nitrogen to organic material in the solid products from the three compounds decrease in the order diphenylacetylene, tetrahydronaphthalene, benzonitrile. In accordance with this, the ratios of nitrogen fixed as hydrogen cyanide to nitrogen fixed as solid decrease in the reverse order. In contrast to the behavior of the aromatic compounds, isoprene with active nitrogen gives instead of a polymerized solid a low-boiling nitrogenous liquid. The results are discussed with reference to the general mechanism of the reaction.

Condensations by Sodium. XIV. The Phthalic Acids and Some Factors Influencing Yields of Butyl- and Dimethylmalonic Acids

BY AVERY A. MORTON AND FRANKLIN FALLWELL, JR.

This paper describes the formation of all the phthalic acids in these reactions employing sodium and shows that they arise from two distinct sources. When phenylsodium, prepared by refluxing benzene with amylsodium, is carbonated, a third to a fifth of the total acids formed is a mixture of iso- and terephthalic acids, the remainder being benzoic acid. On the other hand preparing the same reagent, phenylsodium, in the presence of sodium benzoate, refluxing and treating the product with carbon dioxide gives the ortho isomer as the sole phthalic acid present. These results demonstrate clearly that there are two types of organosodium intermediates present. According to our common conventions one would be a *m*- or *p*-phenylenedisodium compound and the other sodium *o*-sodiobenzoate. The non-identity of their carbonation products provides a sharp distinction, the lack of which made tracking to the possible sources of butylmalonic acid[1] very difficult.

---

[1] Morton, Fallwell and Palmer, THIS JOURNAL, **60**, 1426 (1938).

Phenylenedisodiums, sources of the iso- and terephthalic acids, do not come from dimetalation of benzene by amylidenedisodium, a conclusion reached after a series of experiments with increasing ratios of benzene to amylsodium failed to show formation of these acids at the expense of butylmalonic acid (Fig. 1). This careful study was necessary because a chance agreement[2] in the yields of butylmalonic acid and these phthalic acids before and after addition of 150 ml. of benzene as well as the non-formation of the latter in a low temperature exchange had suggested such a possibility. The complete curve shows these products quite unrelated to each other. An earlier experiment[1] already has indicated that disproportionation of phenylsodium in boiling benzene does not occur appreciably, thus eliminating this possible source of phenylenedisodium. The plotted results of the present work show a slight maximum at 55 ml. of benzene which falls off somewhat as the quantity of benzene is increased. The mechanism field is therefore narrowed and includes the possibility that benzene has been attacked simultaneously or successively by two molecules of amylsodium. In addition this study had revealed a pronounced minimum for the combined yields of caproic and benzoic acids which corresponds with a slight maximum in the yield of phthalic acids. A molal ratio for benzene to amylsodium of two to one was present at this point, an interesting circumstance which together with the peculiarity for the existence of a minimum in the total acids and the failure to get more than 15% of the benzene converted into phenylsodium even under the most favorable circumstances, promises to make an interesting field for further study.

Abnormal reactivity and orienting influences prevail in this series. The sodium carboxyl group, for example, acts in the same manner as do the dimethylamino and methoxyl[3] groups in directing an entering sodium atom to the ortho position. Dimethylaniline and anisole have labile hydrogen atoms in the ortho rather than in the para position. Isophthalic acid predominates by four to one over terephthalic acid, a result calling for *m*-phenylenedisodium as the chief product of the double metalation of benzene. Such results emphasize the novelty in the behavior of these organosodium reagents. One characteristic difference marks these reactions from those in which the ordinary rules of orientation have been derived. In general chemical changes here occur on solid surfaces rather than in homogeneous solutions, a circumstance suggesting that the normal orienting influences may be shelved in the presence of a powerful reagent which operates through an initial adsorption of the molecule. The unpredicted nature of our results may be judged in the light of an observation of Gilman and Kirby[4] that a mixture of benzene, diethylmercury and potassium acted normally, giving phthalic and terephthalic acids after carbonation.

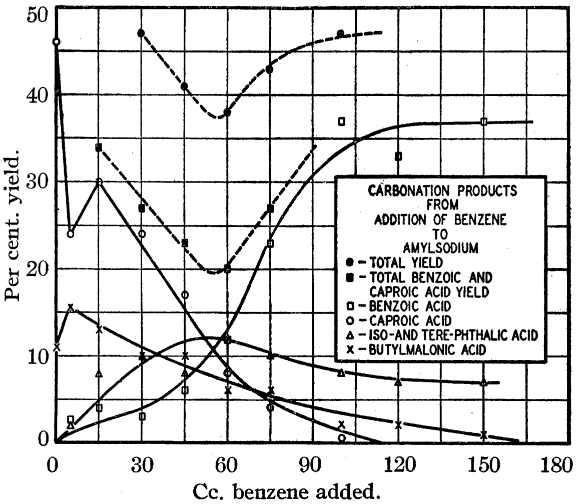

Fig. 1.

Another unusual feature in this work is the difference in the type of reaction which occurs on sodium benzoate when it is added before or after preparation of phenylsodium. The product in the former instance is largely phthalic acid and in the latter is chiefly triphenylcarbinol. Here also we believe the result is influenced by variations in the types of adsorption possible for we have observed that sodium benzoate is readily adsorbed on sodium, so much so in fact that it will completely block the reaction between sodium and amyl chloride if allowed to stand in contact with the metal for a few hours before addition of the chloride.

On the general principle that active nickel will labilize the hydrogen atom we attempted to improve the yield of phthalic acid by carrying out a reaction in the presence of this catalyst. A slight improvement only was realized. A similar experiment on sodium caproate, however, more than

doubled the yield of butylmalonic acid. Preparation of dimethylmalonic acid from sodium isobutyrate was not influenced by the use of nickel.

Experiments

Procedure.—The usual quantities consisting of 35 g. of fine sodium sand and 75 ml. of technical amyl chloride (Eastman Kodak Co.) were employed. The apparatus was the same as described in an earlier paper.[1] Unless otherwise noted the sand was activated prior to reaction by addition of about 5 ml. of *n*-amyl alcohol. This change in manipulation eliminated entirely a short induction period usually observed, changed the yields of caproic and butylmalonic acids to 35 g. (46%) and 5.5 g. (11%), respectively, and increased the ratio of mono- to dicarboxylic acid considerably. The usual amounts obtained without activated sand are around 30 and 16% for the two acids concerned. Two and one-half hours are required for addition of amyl chloride to the metal, one hour for stirring at 25–30° after addition, and one hour for carbonating at 35–40°. The solvent was petroleum ether except in those cases where benzene was used to provide phenylsodium as the organometallic reagent. Here also the use of activated sodium caused a small increase in the yield of benzoic acid.

Iso- and Terephthalic Acids.—Following the preparation of amylsodium as before described, 5, 15, 30, 45, 60, 75, 100, 120 and 150 ml. of thiophene-free benzene were added in separate experiments, the mixture in each case heated to 80° for two hours, and then cooled to below 40° for carbonation. Separation of the mixture of caproic and benzoic acids was accomplished first by petroleum ether and then by benzene extraction accompanied by distillation, that of the insoluble phthalic acids by filtration, and that of butylmalonic acids by extraction with ether. Corresponding yields for the amounts of benzene mentioned above are: for caproic acid, 17, 22, 17, 13, 6, 3, trace, 0, 0 g. (24, 30, 24, 17, 8, 4, trace, 0, 0%); for butylmalonic acid 7.7, 6.5, 5, 5, 3, 3, 1, 1, trace, g. (16, 13, 10, 10, 6, 6, 2, 2, trace, %); for benzoic acid, 2, 3, 2.5, 4.5, 9, 17, 28, 25, 28 g. (3, 4, 3, 6, 12, 23, 37, 33, 37, %); for phthalic acid, 1.2, 4, 5, 4, 6, 5, 4, 3.5, 3.5, g. (2, 8, 10, 8, 12, 10, 8, 7, 7%). For a graph of these results see Fig. 1. A single run in which 15 ml. of the benzene was present in the mixture before addition of amyl chloride produced 14 g. (19%) of caproic acid, 7.5 g. (15%) of butylmalonic acid, 3 g. (4%) of benzoic acid and 3 g. (6%) of the phthalic acid mixture.

Separation of the phthalic acid through the barium salts[5] is incomplete. On converting to the *p*-bromophenacyl[6] esters for identification, the insolubility of the tere- isomer in chloroform was noted. By one such separation the melting point of the crude iso- ester was 174–178° as compared with 179° for the pure material; that of the crude tere- isomer was 215–222° (pure compound is 225°). Products separated by means of the barium salts could be further purified by this method. The approximate composition was 80% iso- and 20% tere-.

Phthalic Acid.—Benzoic acid, 20 g., was added to 45 g. of sodium sand in benzene solution. Immediately after formation of sodium benzoate, 5 ml. of *n*-amyl alcohol was added and the mixture stirred for ten minutes. Amyl chloride, 15 ml., was next added to form the phenylsodium after the usual manner. The mixture was then heated for two hours at 80°. Upon cooling to about 30°, carbonating and decomposing, there was found 2.5 g. (6% referred to benzoic acid) of phthalic acid, decomposing at 160–180° followed by subliming as the anhydride in long white needles, m. p. 110–123 in the crude state (pure 128°). Neutralization equivalent of the crude product was 86 (pure 83). From the same reaction 1.5 g. (3%) of triphenylcarbinol was recovered. Repetition of the experiment using amylsodium instead of phenylsodium yielded 0.3 g. (1.0%) only of phthalic acid probably because the mixture could not be refluxed at so high a temperature.

Triphenylcarbinol.—Sodium benzoate was prepared in a separate container and then added to phenylsodium prepared in the customary manner in benzene as a solvent. After two hours of heating at 75°, carbonating and separating the products, 10.0 g. (24%) of triphenylcarbinol and 0.5 g. (1%) only of phthalic acid were obtained. Yields are calculated on the basis of the sodium benzoate added. Another method of introducing sodium benzoate after formation of phenylsodium was to pass carbon dioxide very slowly (two hours) into the organosodium reagent while the mixture was kept near 50°. Triphenylcarbinol, 7.5 g. (14%), calculated on the amyl chloride originally added was recovered. The amount of phthalic acid obtained was 0.8 g.

Catalytic Action of Nickel.—Raney nickel catalyst from 4 g. of the alloy was added in a benzene suspension to the mixture of sodium caproate and phenylsodium obtained by addition of 75 ml. of amyl chloride to sodium and sodium caproate (20 g. of the acid and 45 g. of metal) in benzene solution. After two hours of heating at 75° and subsequent carbonating, 10 g. (36% calculated on the caproic acid used) of butylmalonic acid, in addition to benzoic and recovered caproic acid, was obtained together with 0.8 g. of triphenylcarbinol. Use of double the amount of nickel (from 8 g. of the alloy) caused little change (9 g. or 33%) in the butylmalonic acid yield. The usual yield of this malonic acid in absence of nickel is 16.5%.

When sodium benzoate mixed with nickel was added to phenylsodium under the same conditions used for preparation of triphenylcarbinol above, the yield of ortho phthalic acid was 1 g. (2%). The yield of dimethylmalonic acid from sodium isobutyrate as described below was unaffected (28%) by addition of nickel.

Dimethylmalonic Acid.—A fine suspension of sodium isobutyrate, from isobutyric acid (20 g.) and sodium (10 g.) in benzene as a solvent, was added to phenylsodium prepared as before stated. After two hours of stirring at 75° the mixture was carbonated. Dimethylmalonic acid, identified by neutralization equivalent and decomposition point, was recovered along with a mixture of benzoic and unreacted isobutyric acid. The yield was 8.0 g. or 27% calculated on the basis of the isobutyric acid. Preparation of the sodium isobutyrate in a separate vessel was necessary in this case because its formation prior to addition of amyl chloride inhibited the latter reaction.

Summary

Iso- and terephthalic acids apparently are formed from phenylenedisodiums, which in turn

---

(5) Smith, This Journal, **43**, 1920 (1921).

(6) Kelly and Kleff, *ibid.*, **54**, 4444 (1932).

arise from sodium exchange reactions between benzene and two amylsodium molecules.

Phthalic acid is formed in these processes as a result of sodium benzoate being present during addition of amyl chloride to sodium in benzene solution.

If sodium benzoate is added after formation of phenylsodium the yield of phthalic acid is suppressed and that of triphenylcarbinol is increased.

Nickel as a catalyst causes a considerable increase in yield of butylmalonic acid, a slight increase for phthalic acid and no change in the quantity of dimethylmalonic acid.

The sodium metal can be activated by addition of a small amount of amyl alcohol. The total yield of acids and the proportion of caproic acid is thereby increased.

Bromo Ethers Derived from Hydantoins Having Terminal Ethylene Double Bonds in the C-5-Position

BY DOROTHY A. HAHN, MARGARET J. MCLEAN AND HELEN T. MURPHY[1]

The addition of bromine to each of two geometric isomers of ethyl N-3-methyl-C-5-benzalhydantoin-N-1-acetate, m. p. 50.5–51.5° and 121–122°, respectively, has been reported.[2] It was stated at that time that a molar quantity of bromine was decolorized as rapidly as added to a solution of either unsaturated hydantoin in carbon tetrachloride and that no evolution of hydrobromic acid took place until after the solution had been heated. In separating the product the carbon tetrachloride was replaced gradually by absolute alcohol and under these conditions a white crystalline compound, m. p. 113–113.5°, was precipitated which on analysis was found to contain one molecule of alcohol. The latter was obviously not present in the form of alcohol of crystallization since it could not be removed even by heating in a high vacuum. The formation of this compound was assumed tentatively to take place in the following way

$$\mathrm{C_2H_5OOCCH_2NCON(CH_3)COC{=}CHC_6H_5 \xrightarrow{Br_2} C_2H_5OOCCH_2NCON(CH_3)COCBrCHBrC_6H_5}$$

the latter compound then losing hydrobromic acid and adding ethanol to form

$$\mathrm{C_2H_5OOCCH_2NCON(CH_3)COC{=}CBrC_6H_5C_2H_5OH}$$

This interpretation of the reaction was based not only upon the results of analysis and the fact that dense fumes of hydrobromic acid had been evolved during the process of heating, but also upon references in the literature which established the formation of unsaturated monobromo derivatives following the addition of bromine to unsaturated hydantoins possessing analogous configurations.[3]

In repeating this experiment it was discovered that although both modifications of ethyl N-3-methyl-C-5-benzalhydantoin-N-1-acetate when treated in this way gave the same compound, m. p. 113–113.5°, a second and more soluble product, m. p. 92–94°, isomeric with the first was also formed in both cases. On the assumption that this represented a geometric modification of the higher melting compound, it was examined spectrographically since it was known that different types of unsaturated hydantoins could be identified readily, and that even isomers could be distinguished one from the other by means of their absorption curves.[4] The results of this investigation were very surprising since while the absorption curves of the two products indicated isomers, they also showed clearly that both belonged to the class of *saturated* and not unsaturated hydantoin derivatives.[5] This discovery led to a consideration of possible molecular configurations for compounds having the above composition that would account for the existence of isomeric saturated hydantoins. And since, due to the presence of two asymmetric carbon atoms, stereo

---

[1] The preparation of N-1,N-3-dimethyl-C-5-benzalhydantoin and its derivatives together with the investigation of their respective absorption spectra must be credited to Miss Helen T. Murphy, an honor student at Mount Holyoke College. The spectrographic work was carried out under the direction of Dr. Hildegard Stücklen, Assistant Professor of Physical Chemistry, to whom grateful acknowledgment is due.

modifications were to be expected[6] in the case of a molecule having the following arrangement of atoms

$$C_2H_5OOCCH_2NCON(CH_3)CO\underset{*}{C}(OC_2H_5)\underset{*}{C}HBrC_6H_5$$

the two isomers in question were finally assumed to represent, respectively, racemic modifications of this type.

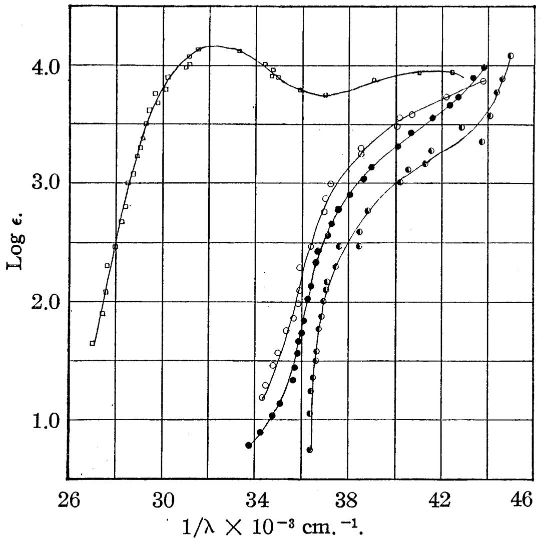

Fig. 1.—□-□-□ N-1,N-3-dimethyl-C-5-benzalhydantoin, $CH_3NCON(CH_3)COC{=}CHC_6H_5$,; N-1,N-3-dimethyl-C-5, 5-ethoxy-bromobenzylhydantoin, $CH_3NCON(CH_3)COC(OC_2H_5)CHBrC_6H_5$; o-o-o isomer, m. p. 141–143°; ●-●-● isomer, m. p. 119.5–121.5°; ◐-◐-◐ N-1,N-3-dimethyl-C-5-benzylhydantoin, $CH_3NCON(CH_3)COCHCH_2C_6H_5$.

Recently the behavior of N-1,N-3-dimethyl-C-5-benzalhydantoin, $CH_3NCON(CH_3)COC{=}CHC_6H_5$, has been investigated under conditions closely analogous to those which have just been described. Although only one of the two geometric isomers of this substance which are theoretically possible has as yet been isolated (p. 817),[5a] this reacts with bromine to form two isomeric compounds, m. p. 141–143° and 119.5–121.5°, which correspond in composition to the formula, $CH_3NCON(CH_3)CO\underset{*}{C}(OC_2H_5)\underset{*}{C}HBrC_6H_5$. These isomers again have been assumed to represent different racemic mixtures, respectively, since such an interpretation is in agreement with the results of analysis and also with the character of the absorption curves of the two compounds. The latter are not only closely analogous to those of the two isomeric ethoxybromo derivatives of ethyl N-3-methyl-C-5-benzalhydantoin-N-1-acetate[7] but both pairs of curves show a marked similarity to that of N-1,N-3-dimethyl-C-5-benzylhydantoin,[8] which can be prepared directly by reducing the corresponding unsaturated compound. On the other hand, they differ radically from the curve of N-1,N-3-dimethyl-C-5-benzalhydantoin.[9]

Due to the fact that the dibromo addition products, the formation of which precedes the formation of both of the above pairs of isomeric ethoxybromo derivatives, are extremely soluble and also very unstable compounds they have not as yet been isolated. It has been observed, however, that the corresponding addition products which are formed when C-5-benzalhydantoin and N-3-methyl-C-5-benzalhydantoin are treated, respectively, in carbon tetrachloride with molar quantities of bromine, are almost insoluble in neutral solvents. An attempt, therefore, is being made to prepare these compounds in pure condition, although they also are very unstable and are difficult to separate completely from the unacted upon unsaturated hydantoins from which they are obtained, since these too are relatively insoluble substances. Even at this stage of the investigation, however, it seems probable from a preliminary study of these products that the same general relationships can be shown to exist between unsaturated hydantoins of this type and their respective dibromo, alkoxybromo and oxybromo derivatives that have been reported recently to maintain in the case of 2,4-diketotetrahydropyrimidines and their corresponding derivatives.[10] This investigation is well under way and will be reported later in detail.

Experimental

Ethyl N-3-Methyl-C-5,5-ethoxy-bromobenzylhydantoin-N-1-acetate, $C_2H_5OOCCH_2NCON(CH_3)COC(OC_2H_5)CHBrC_6H_5$, exists in two isomeric modifications, m. p.

---

[6] Hahn and Seikel, THIS JOURNAL, **58**, 647 (1936).

[7] The spectra of ethyl N-3-methyl-C-5-benzalhydantoin-N-1-acetate and its derivatives were examined several years ago by Dr. Margaret K. Seikel (unpublished work). Since the absorption curves of these compounds are almost identical with those of the corresponding derivatives of N-1,N-3-dimethyl-C-5-benzalhydantoin, it has seemed more confusing than helpful to try to represent both sets in the same figure.

[8] *Cf.* ref. 5a, p. 817. This same compound is also formed when each of the two isomeric ethoxybromo derivatives of N-1,N-3-dimethyl-C-5-benzalhydantoin is reduced under the action of hydrogen iodide and red phosphorus.

[9] Compare the four curves in the accompanying figure.

[10] Johnson and Sprague, THIS JOURNAL, **59**, 2436 (1937).

113–113.5° and 92–94°, both of which are formed when either of the two geometric isomers of ethyl N-3-methyl-C-5-benzalhydantoin-N-1-acetate is treated with bromine under conditions which have already been described.[2] The lower melting and more soluble product was not isolated from the reaction mixture, however, until later when oily residues deposited from filtrates from the isomer, m. p. 113–113.5°, were examined. It was finally obtained by a process of fractional crystallization and when pure separated from concentrated alcohol solutions in the form of well-defined colorless prisms, which suffered no loss in weight when heated at 70°.

Anal. Calcd. for $C_{15}H_{15}O_4N_2Br{\cdot}C_2H_5OH$: N, 6.78; Br, 19.35. Found: N, 6.96, 7.05; Br, 19.88, 20.05.

It is interesting to note that in repeating these experiments and using "seed" to induce crystallization, 10.0 g. of the unsaturated ester, m. p. 50.5–51.5°, gave 6.2 g., m. p. 110–112°, as a first precipitate and 3.1 g., m. p. 80–84°, on concentrating the filtrate; while 10.0 g. of the unsaturated ester, m. p. 121–122°, gave 3.3 g., m. p. 110–112°, as a first precipitate and 6.1 g., m. p. 80–84°, on concentrating the filtrate.

N-1,N-3-dimethyl-C-5,5-ethoxy-bromobenzylhydantoin, $CH_3\overline{NCON(CH_3)COC}(OC_2H_5)CHBrC_6H_5$, exists in two isomeric modifications, m. p. 141–143° and 119.5–121.5°, both of which were formed under the following conditions. Bromine,[11] dissolved in chloroform (3.8 g. in 38 cc.), was added rapidly at room temperatures to a colorless solution of N-1,N-3-dimethyl-C-5-benzalhydantoin (p. 817)[5a] in the same solvent (5.0 g. in 15 cc.) until a permanent color remained after shaking. No hydrobromic acid was evolved during this process, which occupied only a few minutes, but when the solution was heated dense fumes of the mineral acid were given off. After the solution had been concentrated to a volume of 25 cc., an equal quantity of absolute alcohol was added and the mixture evaporated rapidly over a steam-bath to 25 cc. This process was repeated 5 or 6 times or until the odor of chloroform was no longer noticeable. The boiling solution (50 cc.) was then set aside to crystallize. The first precipitate, when filtered, washed with absolute alcohol and dried, weighed 4.22 g., m. p. 137–139°. A second precipitate, which was obtained by concentrating the filtrate and wash alcohol to 20 cc., consisted of 2.6 g., m. p. 103–106°. Small additional amounts of both products were obtained from the filtrate from the second precipitate, the combined weights of all representing a yield of more than 90% of the theoretical as calculated on the basis of the above formula. So far as could be observed there was no reason for suspecting the presence of any other substances in the reaction mixture. The two products were purified by recrystallization from absolute alcohol, in which the second is much the more soluble. Both separated from their boiling solutions, on cooling, in the form of large transparent hexagonal prisms or plates, which showed no loss in weight on heating.

Anal. Calcd. for $C_{14}H_{17}O_3N_2Br$: C, 49.28; H, 5.02; Br, 23.42. Found: (m. p. 141–143°) C, 49.41, 49.60; H, 5.01, 4.96; Br, 23.97, 23.86; (m. p. 119.5–121.5) C, 49.76, 49.58; H, 5.01, 5.26; Br, 23.47, 23.52.

Both compounds when heated for one hour at 110° with hydrogen iodide and red phosphorus were transformed into N-1,N-3-dimethyl-C-5-benzylhydantoin,[8] which was identified by comparison with an analyzed specimen.

The absorption curves of these two isomers, together with curves of the unsaturated hydantoin (p. 817)[5a] from which they were obtained and the corresponding saturated hydantoin[8] which resulted from their reduction, are represented in the accompanying figure. The spectrographic measurements were made by the Henri method[12] using a Hilger E2 quartz spectrograph. Each compound was dissolved in absolute alcohol which had been freed from all traces of benzene by fractional distillation with a Fenske column (3.5 × 1.5 cm.). The source of light was a copper-silver spark and Eastman No. 40 photographic plates were used except for the region below 2400 Å., when "Ultraviolet Spectrographic" plates were used.

Summary

N-1,N-3-dimethyl-C-5-benzaldehydantoin, when treated in chloroform solution with a molar quantity of bromine, gives an addition product which loses hydrobromic acid on heating and when the chloroform is replaced by absolute alcohol, is subsequently transformed into an ethoxybromo derivative. The latter exists in two isomeric modifications, both of which yield N-1,N-3-dimethyl-C-5-benzylhydantoin when heated with hydrogen iodide and red phosphorus.

The absorption curves of the two isomers, on comparison with those of N-1,N-3-dimethyl-C-5-benzylhydantoin and other saturated hydantoins of the same general type, indicate that both represent saturated compounds. Moreover, these two curves closely resemble those of the two isomeric ethoxybromo derivatives of ethyl N-3-methyl-C-5-benzalhydantoin-N-1-acetate which were obtained from the latter by means of similar transformations.

SOUTH HADLEY, MASS. RECEIVED JUNE 10, 1938

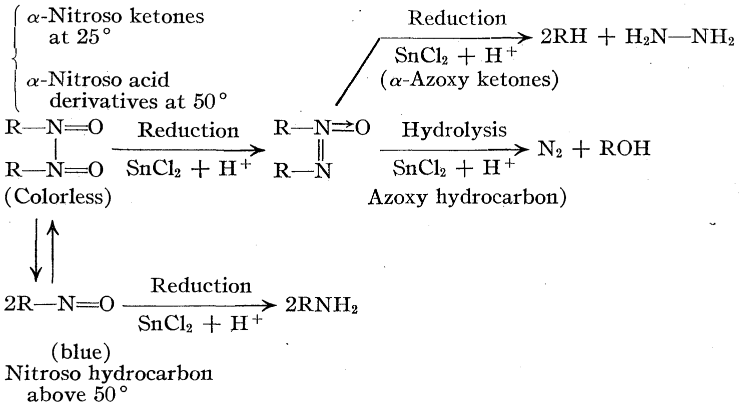
Aliphatic Azoxy Compounds. III. 2-Azoxy-2,5-dimethylhexane[1,2]

BY JOHN G. ASTON AND DAVID E. AILMAN

In order to study the reaction of the azoxy group in aliphatic organic compounds it was desirable to prepare an azoxy compound without any other functional groups. 2-Azoxy-2,5-dimethylhexane was chosen because of the availability of starting materials and lack of volatility with consequent ease of isolation of the product and intermediates.

It was soon found impossible to obtain this compound by reduction of the corresponding nitroso compound either at room temperature or at 57–60° with stannous chloride in acid solution. At room temperature the nitroso compound decomposed without reduction (see experimental section); at 57–60° a 58% yield of the corresponding amine was obtained. These results are important for above 55° the dissociation of the bis-nitroso compound is apparent. In the case of α-nitroso esters, where no such dissociation is evident at 55°,[1b,3] azoxy compounds may be obtained in good yields under similar conditions and no amine is produced. These facts indicate that the linkage in the bisnitroso compounds is through the nitrogens and that reduction to the amine proceeds through the monomolecular form since no amine has ever been found among the reduction products of aliphatic azoxy compounds.[1a]

The situation is made clear by the scheme



2-Azoxy-2,5-dimethylhexane eventually was prepared in 68–75% yield by condensing the corresponding nitroso compound with the corresponding hydroxylamine in the presence of solid potassium hydroxide at 50°. The use of concentrated sulfuric acid gave but 21% yield. Condensation of the corresponding nitro compound and amine in the presence of metallic sodium at reflux temperature gave a 10% yield. Both reactions are known in the aromatic series.[4]

Attempts to reduce this azoxy compound with stannous chloride and hydrochloric acid merely resulted in the hydrolysis of the compound to nitrogen, octenes, dimethylisoamylcarbinol and 2-chloro-2,5-dimethylhexane.

The accompanying mechanism seems plausible for this new type of decomposition as in the hypothetical intermediate II one sees a close analogy with the diazonium salts, the part enclosed by the dotted square being analogous to the $-\mathrm{N}^+\equiv\mathrm{N}$ of these salts.[5] While the hydrolysis occurs rapidly at reflux temperature in the presence of 6 *N* hydrochloric acid and stannous chloride, with 6 *N* hydrochloric acid alone (or with stannic chloride) the reaction is negligible.

The decomposition of the *bis*-nitroso compound by acid to yield nitrogen and nitrous oxide obviously can be formulated in a manner similar to the hydrolysis of the azoxy compound.

When treated with methylmagnesium iodide in diisoamyl ether at 100° for eighty minutes, less than 20% of addition was observed. This is hardly consistent with the open chain formula of the azoxy group since aromatic azoxy compounds seem to react as expected.[6] If the azoxy group in aliphatic compounds had the ring structure, the intermediate II postulated in the hydrolysis could be formed by ring cleavage.

It is hoped to report on the be-

havior of this compound with other reducing agents and the products of addition of organometallic compounds in the near future.

Experimental

Hydrolysis of 2-Nitroso-2,5-dimethylhexane.—Sixteen and four-tenths grams (0.115 mole, monomolecular basis) of nitroso compound was refluxed with 50 cc. of concentrated hydrochloric acid. The decomposition started explosively with the evolution of a large amount of nitrogen containing less than 2% of nitrous oxide. This gas sample, and all others in the work, was identified by distillation of the liquefied gas and vapor pressure measurements on the fractions. After refluxing for a half hour the oil was steam distilled. A tarry scum remained behind. The distillate gave, after drying with potassium carbonate, 0.85 g. (0.008 mole, 7% yield) of octenes, 6.0 g. (0.043 mole, 37% yield) of dimethylisoamylcarbinol and 2-chloro-2,5-dimethylhexane and 3.0 g. of high-boiling material, n^{20}_D 1.430. The octene fraction boiled at 106–120° (730 mm.), n^{20}_D 1.416, and gave positive reactions with bromine water and alkaline permanganate. From the carbinol-chloride fraction was obtained 4.6 g. of material boiling at 80–86° (100 mm.), n^{20}_D 1.4232–1.4240, which was nearly pure chloride.

Anal. Calcd. for $C_8H_{17}Cl$: Cl, 23.8; mol. wt., 148.6. Found: Cl (Stepanoff), 23.3, 23.9; mol. wt. (cryoscopic in benzene), 146.5, 147.3.

The pure chloride was obtained by passing gaseous hydrogen chloride into dimethylisoamylcarbinol keeping the mixture cool with tap water until constant weight was obtained. It boiled at 86° (100 mm.), n^{20}_D 1.4231.

The Action of Stannous Chloride and Concentrated Hydrochloric Acid on 2-Nitroso-2,5-dimethylhexane at 60°.—Six grams (0.042 mole) of 2-nitroso-2,5-dimethylhexane[7] was melted and added dropwise during twenty minutes to a rapidly stirred solution of 16 g. (0.071 mole) of crystalline stannous chloride dihydrate, in 50 cc. of concentrated hydrochloric acid held throughout the reaction at 57–60°. The blue color of the nitroso compound disappeared immediately with each addition; 90 cc. of 28% potassium hydroxide solution was added keeping the temperature below 45° to prevent loss of material by volatilization. Each addition of alkali precipitated basic tin salts which gradually redissolved. On neutralization and distillation of the solution 0.3 g. of octenes (0.0027 mole, 6.4% yield) and 0.54 g. (0.0039 mole, 9.2% yield) of a mixture of dimethylisoamylcarbinol and the corresponding chloride was obtained.

The solution was made strongly alkaline by the addition of 75 cc. more of 28% potassium hydroxide solution, and the amine was steam distilled. After drying with anhydrous potassium carbonate, distillation gave 3.17 g. (0.024 mole, 58% yield) of amine, b. p. 94° (150 mm.), 141.0° (733.6 mm.).[8]

Anal. Calcd. for $C_8H_{19}N$: C, 74.42; H, 14.73. Found: C, 73.63; H, 14.65.

The hydrochloride, after crystallization from alcohol, melted at 171°.

Anal. Calcd. for $C_8H_{20}NCl$: Cl, 21.5. Found: Cl (Volhard), 21.2.

A positive isonitrile test was obtained. The *p*-toluenesulfonamide[9] melted at 89.5–90°; mixed m. p. with an authentic sample showed no lowering.

The Action of Stannous Chloride and Concentrated Hydrochloric Acid on 2-Nitroso-2,5-dimethylhexane at Room Temperature.—A typical experiment is described; 8.5 g. (0.06 mole) of the solid *bis*-nitroso compound was added rapidly to a well-stirred solution of 8.3 g. (0.037 mole) of stannous chloride in 12.5 cc. of concentrated hydrochloric acid. The temperature, originally 27°, rose to 31° and fell slowly. The stirring was stopped as soon as the oily layer was colorless (not over ten minutes elapsed from the beginning of the addition). Nitrogen, containing a small amount of nitrous oxide, was evolved (the total gas was 5% of the nitrogen content of the sample).[10] Titration with permanganate showed that only 12% of the stannous ion had been oxidized. The mixture was diluted with 100 cc. of ice water and the oil was removed by solution in ether, washed with water, washed with sodium carbonate solution to remove acids, and dried with calcium chloride. Distillation gave 0.5 g. (0.0045 mole, 7.4% yield) of low-boiling material, n^{20}_D 1.419, (probably octenes); 2.5 g. (0.018 mole, 30% yield) of liquid boiling at 100–105° (150 mm.), n^{20}_D 1.422; and a residue amounting to 4.9 g. of a light yellow, very viscous oil, n^{20}_D 1.472, which contained tin and chlorine and which could not be distilled at 80° under the pressures of a mercury vapor pump.

The liquid, b. p. 100–105° (150 mm.), was evidently a

[9] Hinsberg and Kessler, *Ber.*, **38**, 906 (1906).

[10] If at this point the mixture is nearly neutralized with sodium hydroxide solution and steam distilled, the products are: 8% yield of low-boiling material (probably octenes), 53% yield of a mixture of dimethylisoamylcarbinol and chloride, and 3–9% yield of 2-amino-2,5-dimethylhexane.

mixture of dimethylisoamylcarbinol and the corresponding chloride. It was converted to the pure chloride, b. p. 98° (150 mm.), $n^{20}D$ 1.4230, by gaseous hydrogen chloride.

Anal. Calcd. for $C_8H_{17}Cl$: Cl, 23.8; mol. wt., 148.6. Found: Cl (Stepanoff), 24.0; mol. wt. (cryoscopic in benzene), 150.

When the viscous oil was boiled with concentrated hydrochloric acid, a blue color was visible in the refluxing oil for a short time. Nitrogen was evolved, and the oily material had the odor of dimethylisoamylcarbinol.

Preparation and Properties of 2-Azoxy-2,5-dimethylhexane.—Four grams (0.0276 mole) of 2-β-hydroxylamino-2,5-dimethylhexane[11] and 3.6 g. (0.025 mole) of 2-nitroso-2,5-dimethylhexane and 1.0 g. of anhydrous potassium carbonate were heated together at 50° for nine hours without apparent reaction; 1.0 g. of solid potassium hydroxide was added to the mixture. After eighteen hours more at 50° the reaction mixture was yellow green in color, showing that a reaction of the blue nitroso compound had taken place. Water was added to dissolve the salts and the oil was taken up in ether and dried with sodium sulfate. Distillation gave 5.1 g. (0.019 mole, 75% yield) of the colorless azoxy compound, b. p. 111° (5 mm.), $n^{20}D$ 1.4434, d^{20}_4 0.8564.

Anal. Calcd. for $C_{16}H_{34}ON_2$: C, 71.04; H, 12.68; N, 10.36; mol. wt., 270.3. Found: C, 70.67; H, 12.63; N (Dumas), 10.75; mol. wt. (cryoscopic in benzene), 273, 270.

2-Azoxy-2,5-dimethylhexane was also prepared by a procedure similar in every way to the above except that anhydrous magnesium sulfate followed by concentrated sulfuric acid were substituted for the potassium carbonate and potassium hydroxide, respectively. The yield of azoxy compound was 21%. The addition of the sulfuric acid caused some charring and not more than 0.5 cc. of acid was added. No other products were identified.

The Reaction of 2-Amino- with 2-Nitro-2,5-dimethylhexane in the Presence of Metallic Sodium.—Seven-tenths gram (0.03 gram atom) of sodium in the form of freshly cut chips was added gradually to a refluxing solution of 5.0 g. (0.039 mole) of the amine and 6.2 g. (0.039 mole) of the nitro compound. The products were worked up as above and gave 1.0 g. (0.0037 mole, 9.5% yield) of impure azoxy compound, b. p. 100–125° (4 mm.), $n^{20}D$ 1.4415, which was not redistilled. Other products were not identified.

The reaction of 2-azoxy-2,5-dimethylhexane with methylmagnesium iodide in the apparatus of Kohler and Richtmyer[12] showed the absence of active hydrogen and gave less than 20% addition during 80 minutes at 100°.

The Action of Stannous Chloride and Dilute Hydrochloric Acid on 2-Azoxy-2,5-dimethylhexane.—Ten and three-tenths grams (0.038 mole) of azoxy compound was mixed with 25 g. (0.11 mole) of stannous chloride in 225 cc. of 6 *N* hydrochloric acid solution. The mixture was refluxed for four hours in an apparatus for collecting the evolved nitrogen (generally about 60% of the theoretical) over 50% potassium hydroxide solution, and then the oil layer was steam distilled. Titration showed that less than 5% of stannous ion had been oxidized. The oily product, neutralized with sodium carbonate, and dried with calcium chloride, gave on distillation: 3.3 g. (0.03 mole, 38% yield) of octenes b. p. 113–120° (730 mm.), $n^{20}D$ 1.416; 3.6 g. (0.026 mole, 33% yield) of a mixture of dimethylisoamylcarbinol and 2-chloro-2,5-dimethylhexane, b. p. 98–103° (150 mm.), $n^{20}D$ 1.4221; and 0.6 g. (0.0022 mole, 6% yield) of recovered azoxy compound.

Individual octenes were not identified. Positive reaction with bromine water and with alkaline permanganate demonstrated their olefinic character. The octenes were converted to dibromides by reaction with bromine vapor and expulsion of excess bromine with dry air. Calcd. for $C_8H_{16}Br_2$: mol. wt., 272. Found: (cryoscopic in benzene), 274. Attempts to distil this dibromide gave a colorless oil, b. p. 100–113° (30 mm.), $n^{20}D$ 1.478, which rapidly turned red-brown and gave low analyses for bromine and mol. wt.

The carbinol–chloride mixture was analyzed. Calcd. for 65 mol. % $C_8H_{17}Cl$, 35 mol. % $C_8H_{18}O$: C, 67.5; H, 12.26; Cl, 16.20. Found: C, 66.7; H, 12.27; Cl, 16.21. The mixture was then converted with gaseous hydrogen chloride to pure chloride, b. p. 98° (150 mm.), $n^{20}D$ 1.423. Calcd. for $C_8H_{17}Cl$: mol. wt., 148.6. Found: (cryoscopic in benzene), 150.

Attempts to hydrolyze 0.5-g. samples of the azoxy compound with 6 *N* hydrochloric acid alone, or with stannic chloride, resulted in only negligible amounts of gas being evolved on refluxing for several minutes. With stannous chloride, a sample gave up its nitrogen almost quantitatively on refluxing for a half hour without oxidation of the stannous ion. The nitrogen was pure as shown by vapor pressure measurements. Evidently stannous chloride is a specific catalyst for the hydrolysis.

In conclusion we wish to thank Dr. G. H. Messerly for help with the distillation of the small quantities of gases and their identification by vapor pressure measurements.

Summary

1. 2-Nitroso-2,5-dimethylhexane was reduced to 2-amino-2,5-dimethylhexane in 58% yield with stannous chloride and concentrated hydrochloric acid at 60°.

2. The action of stannous chloride and concentrated hydrochloric acid on 2-nitroso-2,5-dimethylhexane at room temperature did not give appreciable reduction but only decomposition. Nitrogen, nitrous oxide, octenes, dimethylisoamylcarbinol, 2-chloro-2,5-dimethylhexane, and very small amounts of 2-amino-2,5-dimethylhexane were among the decomposition products.

3. The hydrolysis of 2-nitroso-2,5-dimethylhexane by refluxing with concentrated hydrochloric acid produced nitrous oxide, nitrogen, octenes, dimethylisoamylcarbinol and 2-chloro-2,5-dimethylhexane.

4. 2-Azoxy-2,5-dimethylhexane was prepared in excellent yield by condensing the corresponding

Aliphatic Azoxy Compounds. IV. The Preparation of Certain α-Azoxy Ketones. The Molecular Refractions and Parachors of Aliphatic Azoxy Compounds[1]

BY DAVID E. AILMAN

In order to study the molecular refractions and parachors of aliphatic azoxy compounds, additional liquid azoxy compounds are desirable. Ethyl 2-methyl-2-azoxy-propionate[2] and 2-azoxy-2,5-dimethylhexane[3] have been described elsewhere.

This paper describes the preparation and properties of ethyl α-azoxyisopropyl ketone and α-azoxyisopropyl isobutyl ketone of which only the former is a liquid whose molecular refraction and parachor have been compared with those of the compounds mentioned above.

Experimental

Ethyl α-Azoxyisopropyl Ketone.—Ten grams (0.039 mole, bimolecular basis) of bimolecular ethyl α-nitrosoisopropyl ketone[4] was reduced with 10.8 g. (0.048 mole) of crystalline stannous chloride $SnCl_2 \cdot 2H_2O$, in 15.8 cc. of concentrated hydrochloric acid,[5] keeping the temperature 30–36° for twenty minutes. A titration with permanganate showed that 0.040 mole of stannous ion had been oxidized. After nearly neutralizing the acid solution with sodium carbonate the liquid azoxy compound was removed by solution in ether, dried with potassium carbonate, and distilled, collecting 5.18 g. (0.021 mole; 55% yield), b. p. 126–126.5° (6 mm.), n^{20}_D 1.4587, d^{20}_4 1.0151.

Anal. Calcd. for $C_{12}H_{22}O_3N_2$: C, 59.45; H, 9.16; N, 11.57; mol. wt., 242.3. Found: C, 58.85; H, 9.09; N (Dumas), 11.72; mol. wt. (cryoscopic in benzene), 240, 241.

Reduction of Ethyl α-Azoxyisopropyl Ketone.—Eight grams (0.033 mole) of the azoxy compound on stirring with a solution of 31 g. (0.14 mole) of stannous chloride in 45 cc. of concentrated hydrochloric acid for seven hours at a maximum temperature of 65° (maintained for one hour), oxidized only 46% of the stannous ion (calculated for reduction to ketone and hydrazine[5]). (The excess stannous ion was determined by permanganate titration, which does not distinguish between stannous ion and hydrazine. This has been corrected for.) The isolation of 1.5 g. of a semicarbazone which melted a few degrees below the m. p. of ethyl isopropyl ketone semicarbazone (each recrystallization raised the m. p., but the amounts became too small to handle), together with the isolation of 0.5 g. of dibenzalazine (sharp m. p. and mixed m. p. with an authentic sample) showed that a reduction of the type observed with methyl α-azoxyisopropyl ketone[5] had occurred.

α-Azoxyisopropyl Isobutyl Ketone.—Eight grams (0.025 mole) of the *bis*-nitroso ketone[4] was reduced with 6.9 g. of stannous chloride in 13 cc. of concentrated hydrochloric acid. On chilling, after the reduction was complete, the oil crystallized. The product was recrystallized from lukewarm alcohol–water and then melted at 30–31°. The yield of purified product was 4.0 g. (0.013 mole, 52% yield).

Anal. Calcd. for $C_{16}H_{30}O_3N_2$: C, 64.39; H, 10.14; mol. wt., 298.2. Found: C, 63.97; H, 10.65; mol. wt. (cryoscopic in benzene), 310, 297, 300.

Molecular Refraction and Parachor

In Table I are given the properties of the liquid aliphatic azoxy compounds prepared to date. Densities were determined with a 2-cc. pycnometer. Surface tensions were measured with a DuNouy tensimeter which had been checked against water and alcohol.

TABLE I

No.	Compound	Mol. wt.	n^{20}_D	d^{20}_4	γ_{20}
1	2-Azoxy-2,5-dimethylhexane[3]	270.4	1.4434	0.8564	28.27
2	Ethyl α-azoxyisopropyl ketone	242.3	1.4587	1.0151	35.88
3	Ethyl 2-methyl-2-azoxypropionate[2]	274.3	1.4412	1.0562	33.56

In Table II are given in column 2 the observed molecular refractions; in column 3 the summation of Eisenlohr atomic refractivities,[6] exclusive of the azoxy grouping; and column 4 the refractivity

3	68.602	60.924	7.678
		Mean	7.647 ± 0.045

We may take the value of N_2 in aliphatic azo compounds as 6.32.[7] From other evidence it is known that the azoxy group in aromatic compounds has the open chain structure. The group refractivity should be obtained by adding the appropriate value for semipolar oxygen to the above value for N_2. Since the existing data do not yield a definite value, as a first try one adds the value for carbonyl oxygen, 2.211. The result is 8.531. A negative exaltation of about 0.9 unit is required to produce agreement with the measured value. Using the value for ether oxygen, 1.643, instead of that for carbonyl oxygen, gives a total of 7.96 units. This value, for no good reason, agrees well with our measured value of 7.65 when we consider that we have not taken into account the loss of the double bond of N=N in forming . It is interesting to note, however, that the molecular refraction of nitrous oxide is 7.58[8] and it has the open chain structure.

In order to calculate the value for aromatic compounds it seems reasonable to add the exaltations observed in aniline and nitrobenzene, 0.85 and 0.78 respectively, to the above value of 8.53, making a total for the azoxy group in aromatic compounds of 10.16. The observed value is 13.25 based on azoxybenzene.[7b] In other words a further positive exaltation of 3.1 units is necessary to produce agreement. Thus consideration of the results on a comparable basis uncovers a discrepancy of the order of 4 units between the experimental group refractivity in aliphatic compounds and in the unsubstituted aromatic compound if both had the same structure. Another method of comparison is to compare the difference of 1.33 between the above values for aliphatic azoxy and azo compounds with the difference of 0.61 between azoxy- and azobenzene.[9] The results obtained with meta substituted aromatic azo and azoxy compounds give a similar result but with ortho and para substituted compounds the difference is as much as two units lower (−1.4).[9] In the face of this big variation among aromatic compounds themselves, it might be said that the difference between azoxy and azo compounds in the aliphatic series is in accord with the difference in the aromatic series. The agreement however may be fortuitous. In view of this the value obtained for the molecular refraction of the azoxy group in aliphatic compounds is difficult to interpret.

In Table III (Col. 2) are given the parachors (*P*) deduced from the data of Table I. In column 3 of this table are given the parachors (P_1) calculated using Sugden constants[10] on the basis that the azoxy group has the structure $-N{=}\overset{|}{N}\longrightarrow O$ (*i. e.*, that the oxygen is semi-polar). The parachor value used for semi-polar oxygen was −1.6.

TABLE III

	P	P_1	P_2
2-Azoxy-2,5-dimethylhexane	729.2	724.8	719.9
Ethyl α-azoxy-isopropyl ketone	584.8	586.8	581.9
Ethyl 2-methyl-2-azoxy propionate	625.8	620.4	615.5

In column 4 are given the parachors (P_2) calculated on the basis that the azoxy group has its atoms arranged in a ring ().

The agreement is close between the experimental values and those calculated on the basis of the open chain structure.

Similar results have been obtained with aromatic azoxy compounds[10] (p. 119).

The difference between the measured values for aliphatic compounds and those calculated on the basis of a ring might be due to a different parachor value for the heterocyclic ring. This alternative is not particularly appealing but cannot be rejected.

One significant fact bearing on their constitution stands out from the chemical behavior of aliphatic azoxy compounds. It is that the azoxy group does not behave like that in aromatic compounds in which it has unquestionably the unsymmetrical open chain structure. The absence of color in all aliphatic azoxy compounds thus

---

[7] (a) Barrick, Drake and Lochte, THIS JOURNAL, **58**, 160 (1936), have measured the molecular refractions of 2,2′-azo-bispropane, 2,2′-azobisbutane, and isopropyl-azo-*s*-butane; (b) Auwers and Heimke, *Ber.*, **61**, 1030 (1938), have studied the methyl and ethyl esters of azoisobutyric acid. From these five compounds we have calculated the mean value of N_2 in azo compounds to be 6.32 ± 0.05.

[8] Brühl, *Z. physik. Chem.*, **25**, 647 (1898).

[9] Auwers, *Ber.*, **61**, 1042 (1928).

[10] Sugden, "The Parachor and Valency," Alfred A. Knopf, New York, 1930, pp. 38 and 116.

far prepared differentiates them from the aromatic azoxy compounds. However, this may be due to absence of conjugation. As a ring structure for the azoxy group in aliphatic compounds is not inconsistent with the data on molecular refraction, one must admit of this possibility, although it requires the assumption of a special parachor value for this ring.

The author wishes to thank Professor J. G. Aston for suggesting this problem.

Summary

1. Ethyl α-azoxyisopropyl ketone and α-azoxyisopropyl isobutyl ketone were prepared by reduction of the corresponding *bis*-nitroso compounds with stannous chloride in concentrated hydrochloric acid.

2. The molecular refractions and parachors of three liquid aliphatic azoxy compounds have been determined and yield a constant value for the azoxy groups.

3. There is no evidence that the azoxy group in aliphatic azoxy compounds has the unsymmetrical open chain structure rather than that of a three-membered ring.

Studies on Proteins in Liquid Ammonia. IV. On the Enzymatic Hydrolysis of Proteins Reduced by Metallic Sodium in Liquid Ammonia[1]

BY EVAN W. MCCHESNEY[2] AND RICHARD G. ROBERTS

Previous papers of this series[3] have shown that, of the reactions of proteins in liquid ammonia, perhaps the most interesting is that with metallic sodium. The proteins behave as acids, hydrogen gas is liberated, and sodium salts are formed. From these salts the sodium can be displaced by the addition of ammonium salts such as the chloride or sulfate. During the reaction with sodium reducible groups in the proteins, such as the —S—S— linkages in cystine, undergo reduction. This reaction has been demonstrated by du Vigneaud, Audrieth and Loring.[4]

Goddard and Michaelis[5] have shown that if keratins, such as wool, are treated with sodium thioglycolate in aqueous solution, they undergo reduction of the —S—S— linkages of the cystine residues, forming "kerateines" which are digestible by pepsin and trypsin, even if the resultant —SH groups are reoxidized during the course of the isolation of the kerateine. They postulate that the —S—S— groups act as "very firmly established cross links uniting the elementary fibers of polypeptide chains," and that reduction of the —S—S— groups destroys the fibrous pattern of the protein. Routh[6] has confirmed these observations and has extended them to show that powdered wool, produced by prolonged grinding of wool in a ball mill, is digested about half as fast as casein under comparable conditions.

It occurred to us that it would be of interest to determine whether proteins subjected to reduction by metallic sodium in liquid ammonia are altered with respect to their digestibility by enzymes, and to study proteins of several types, including silk fibroin. This protein is an albuminoid and has been shown[3a] to react rapidly with sodium in liquid ammonia to give a product soluble (as the free acid) in both ammonia and water. Its behavior should be of interest by comparison to wool, since the presence of cystine in the molecule has not been demonstrated.

In this work five substances have been studied: peptone, a substance previously digested by pepsin; egg albumin, a protein not readily digested by trypsin; casein, a protein readily digested by trypsin; wool, an albuminoid containing cystine; and silk fibroin, an albuminoid not containing cystine.[7]

Materials.—Commercial Witte's peptone, egg albumin (Merck impalpable powder), casein (Hammarsten), washed sheep's wool, and silk fibroin (prepared from silk noils supplied by the Cheney Bros. Silk Mills, South Man-

[7] Analysis by the Sullivan method showed that cystine is entirely lacking in silk fibroin.

chester, Conn.). The trypsin used was a commercial product (Digestive Ferments Co., Trypsin, 1:110).

Methods.—For the reduction experiments, 10 g. of the protein (dried for forty-eight hours at 80°) was suspended in about 200 cc. of liquid ammonia (dried over sodium) and 3 g. of metallic sodium was added. The reaction was allowed to proceed for two hours, then the equivalent amount of ammonium chloride (7 g., c. p. grade) was added. The ammonia was allowed to evaporate through a mercury seal, and the product was collected. It was then ground in a mortar, and dried in a desiccator over concentrated sulfuric acid until no odor of ammonia could be detected.

Half of the product was now dissolved, or suspended, in 100 cc. of water. A portion of 1 cc. was removed, and the amount of acid or alkali needed to bring the whole solution to a reaction just faintly acid to phenolphthalein was determined and added. Trypsin, 0.2 g., was added, and enough water to make a total volume of 200 cc. Amino nitrogen was immediately determined by the method of Van Slyke, after which toluene was added as a preservative, and the solution was incubated at 37°. Amino nitrogen was determined at intervals of one, three, seven, and fourteen days thereafter. Total nitrogen in solution was determined by the Kjeldahl method at the end of the fourteenth day.

The control experiments were of two types. In one type the native protein, 5 g., was brought into solution at *p*H 8, 2.5 g. of sodium chloride (c. p.) and 0.2 g. of trypsin were added, followed by enough water to make a total volume of 200 cc. The digestion and analyses were run as before. In the second type of control (referred to in the table as the "NH_3 control"), metallic sodium, 3 g., was dissolved in about 200 cc. of liquid ammonia and the exact equivalent of ammonium chloride (as judged by the disappearance of the blue color) was added immediately. Then the protein, 10 g., was added and the ammonia was allowed to evaporate. The product was powdered, dried over sulfuric acid, and analyzed as before.

Experimental Data.—The results are shown most conveniently in the form of tables.

TABLE OF RESULTS

	Amino nitrogen					
Days	Mg./cc.	% total sol. N	Mg./cc.	% total sol. N	Mg./cc.	% total sol. N

Discussion of Results

It is apparent that reduction of small molecules of the order of polypeptides, as in peptone, does not affect their digestibility by trypsin appreciably. Any changes such as tautomerization which occur during the reaction with sodium, would be expected to be reversed when the sodium is neutralized and the product is dissolved in water. Furthermore, the treatment with sodium would not be expected to alter significantly the structure of the molecules, their solubility, or the degree of their dispersion. For casein the results are somewhat difficult to interpret. The protein becomes more insoluble in water (at *p*H 8) as a result of the treatment with sodium in liquid ammonia, or with liquid ammonia alone, and its digestibility is decreased markedly in spite of the fact that the amount of the enzyme is greater relative to the amount of protein in solution. This would seem to indicate that the treatment in some manner causes the molecule to become more compact: decreases the extent of dispersion.

Egg albumin seems to be partly denatured by treatment with liquid ammonia since it is not completely soluble in water after having been suspended in ammonia. However, the treatment seems to open up the molecule in some way, since the increase in digestibility is very striking. The increase in the digestibility of reduced albumin probably, therefore, can be attributed to the action of the ammonia, not the sodium. The reason for the difference between the behavior of the two albumins (one reduced, one not, both ammonia-treated) is not apparent.

---

(8) Evidently analytical error.

The amount of digestion of native wool and silk fibroin by trypsin is of course practically negligible. Both ot these become digestible when treated with sodium in liquid ammonia, the results for wool being particularly striking. In the case of silk fibroin, it is evident that some dispersion occurs in both the reduced and the ammonia-control samples. The rate of digestion of the material actually in solution in the water is practically the same in both cases. The greater dispersion of the reduced material is probably due to some alteration in structure during the reaction with sodium. Sufficient information on the structure of silk fibroin is not available to make it possible to suggest what this alteration may be. However, if the molecular weight is as great as postulated by Bergmann and Niemann[9] (217,000), then it would seem as if some of the cross ties between the polypeptide chains must be ruptured. Since there are no —S—S— linkages, the rupturing would have to be (on the basis of present knowledge) by a reaction of the nature of ammonolysis.

The results with wool would be anticipated, perhaps, from the work of Goddard and Michaelis. Wool is only slightly dispersed in ammonia, and the product of the ammonia treatment is only slightly dispersed in water. However, that material which is dispersed digests about as rapidly as the reduced wool. The wool which is subjected to reduction is much more highly dispersed in water (not completely, however), probably due to reduction of the —S—S— linkages and consequent rupture of the cross ties between the polypeptide chains, hence digests rather rapidly.

It is worthy of note that in every case in which the protein was treated with sodium, the ratio of amino nitrogen to total nitrogen is increased (except in wool where the figures for the control are too small to be significant). This is strikingly demonstrated in the case of egg albumin where the native protein and the ammonia control each show about 4% of nitrogen in the amino form, while the reduced sample shows 11%. This would seem to indicate that some reaction of the nature of ammonolysis is occurring, with the rupture of some peptide bonds.

Acknowledgment.—We wish to thank Dr. W. D. Block of the University of Michigan for running the cystine analysis on silk fibroin.

Summary

The digestibility (by trypsin) of a number of proteins has been studied after treatment with sodium in liquid ammonia and compared with their behavior in the native state (or after treatment with liquid ammonia alone). Peptone is not affected by the treatment, and the digestibility of casein is decreased. The digestibilities of egg albumin, silk fibroin, and wool are increased by the treatment with sodium in liquid ammonia. Controls treated only with liquid ammonia appear to digest as rapidly as the reduced materials when one considers the smaller amount of the protein dispersed by the ammonia in *the cases of silk fibroin and wool.*

Saponins and Sapogenins. VIII. Surface Films of Echinocystic Acid and Derivatives

By C. R. Noller

Previous work[1] has indicated that echinocystic acid is a pentacyclic triterpenoid of the formula $C_{29}H_{45}(OH)_2COOH$. Nothing definite is known concerning the position of the functional groups. Since the same trimethylnaphthol is obtained by selenium dehydrogenation of echinocystic acid as has been obtained from hederagenin and oleanolic acid, it seems likely that all have one hydroxyl group in the same position. Moreover, the non-reactivity of the carboxyl group and of the double bond of these compounds indicates a similar location of these groups.

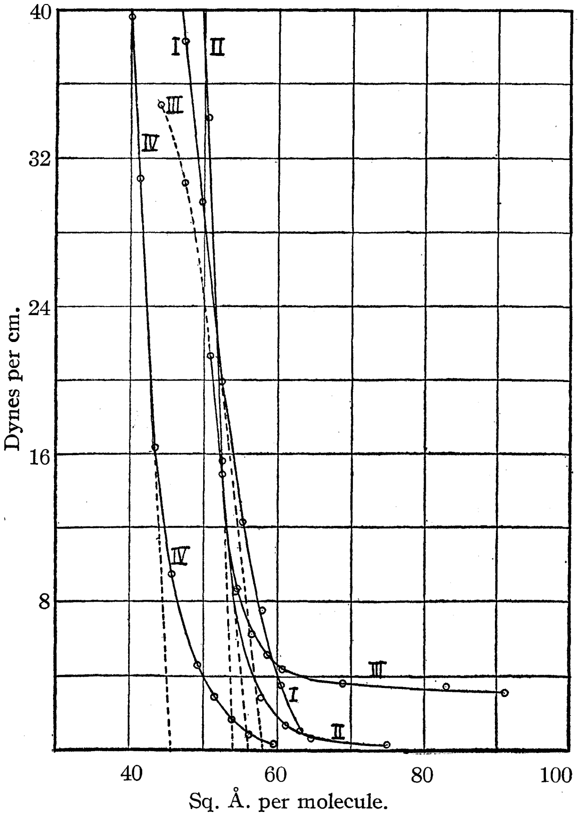

Fig. 1.—Pressure-area curves for surface films of: I, echinocystic acid; II, methyl echinocystate; III, echinocystic acid diacetate; IV, echinocystadienol.

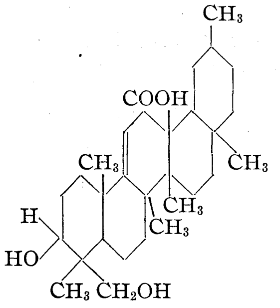
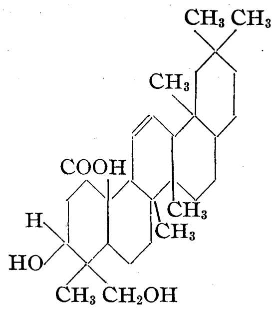
In view of the extensive investigation of Askew[2] on surface films of a large number of triterpenoids, it was thought that similar measurements on echinocystic acid and its derivatives might give valuable information concerning its structure. Echinocystic acid gives a solid incompressible film occupying an area of about 58 sq. Å. per molecule (Curve I) as compared with an area of 54 sq. Å. for hederagenin. Methyl echinocystate (Curve II) and echinocystic acid diacetate (Curve III) give films very similar to that of echinocystic acid with areas of 56 and 54 sq. Å., respectively. All films show the phenomenon of contraction even at low pressures but it is much more pronounced with the methyl ester and the diacetate than with echinocystic acid.

Curve IV represents the data on films of echinocystadienol obtained by decarboxylating and dehydrating echinocystic acid. The area occupied is only 45 sq. Å. per molecule or about 20% less than that for the other three compounds. Examination of Askew's curves shows that hederabetulin, which is obtained by the decarboxylation of hederagenin,[3] occupies an area of about 46 sq. Å., in close agreement with that for decarboxylated and dehydrated echinocystic acid.



I



II

It is difficult to see how formula I proposed by Ruzicka[4] for hederagenin could account for this decrease in area. With the carboxyl group near the middle of the molecule the free acid should lie flat at low pressures and occupy a large area. Askew assumes that the molecules in the films of hederagenin have been forced to stand on end with

---

[3] Winterstein and Meyer, *Z. physiol. Chem.*, **199**, 43 (1931); Winterstein and Stein, *ibid.*, **199**, 76 (1931). The formulas given by Askew for hederabetulin and dihydrohederabetulin diacetate are incorrect. Group B should be CH_2OH and CH_2OAc, respectively, while group C should be hydrogen in both cases.

[4] Ruzicka and Giacomello, *Helv. Chim. Acta*, **20**, 301 (1937).

the carboxyl group out of the water but if this were the case, hederabetulin and echinocystadienol should occupy the same area as hederagenin and echinocystic acid. If, however, the carboxyl group in these compounds occupies the position of that in formula II proposed by Kitasato,[5] one could assume that in the acids the molecules are tilted so that the carboxyl group also may touch the water but that in the decarboxylated compounds the molecules are permitted to stand on end and occupy a smaller area.

The chief difficulty with this explanation is the behavior of films of oleanolic acid which has a methyl group in place of the hydroxymethyl group. According to Askew's measurements this acid occupies an area of 48.5 sq. Å. However, Askew's dotted curve XIIIa, which presumably is for the initial film of oleanolic acid, approaches the curve for hederagenin indicating that the initial film, if it were stable, would occupy an area near that for hederagenin. It is conceivable that a second hydroxyl group nearer the B ring is necessary to help the carboxyl group to remain in the water.[6] The fact that oleanolic acid formed gaseous films on sodium hydroxide solutions does not appear to us to be significant since the methyl ester behaved likewise.

It seems to us that assigning the carboxyl group to the position indicated in formula II also provides a better explanation for the behavior of the methyl ester of hederagenin and echinocystic acid and of the diacetate of the latter. If formula I is correct, the free acids should lie flat and esterification should decrease the attraction of the carboxyl group for water and permit the molecules to stand on end and occupy a smaller area; or if it is assumed that the carboxyl group is out of the water in the case of the free acids, acetylation of the alcoholic hydroxyl groups should decrease their attraction for water and permit the molecule to lie flat and occupy a larger area. Actually esterification and acetylation have little effect on the areas occupied which is what one would expect if the groups are all close together near the end of the molecule.

The procedure used in making the measurements of surface pressure was identical with that previously described[7] except that the solvent consisted of 80 parts by volume of cyclohexane and 20 parts of isopropyl alcohol. The preparation of echinocystic acid and of its methyl ester and diacetate has been reported[1] and that of echinocystadienol will be described in a later publication.

Summary

Measurements of the area occupied by surface films of echinocystic acid and its derivatives indicate a close relationship in structure to hederagenin. It is postulated that the smaller areas occupied by hederabetulin and echinocystadienol have a bearing on the position of the carboxyl group in hederagenin and echinocystic acid and support the formula of Kitasato in which the carboxyl group is placed at the fusion of the A and B rings.

STANFORD UNIVERSITY, CALIF. RECEIVED MAY 24, 1938

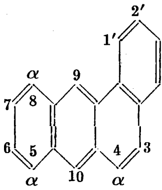
Synthesis of 4,9- and 4,10-Dimethyl-1,2-benzanthracenes[1]

BY LOUIS F. FIESER AND R. NORMAN JONES[2]

Of the ten known dimethylbenzanthracenes those which have shown the most interesting behavior in tests for carcinogenic activity carry substituents in either a meso- or an α-position of the anthracene nucleus. Such substitution is lacking in the 2′,6-, 2′,7-, 3′6-, 3′,7-, and 6,7-dimethyl derivatives,[3] and tests of the hydrocarbons by application to the skin of mice[4] have shown that the first four compounds are inactive and that the 6,7-dimethyl derivative is but weakly carcinogenic. On the other hand, the 5,6-dimethyl isomer[5] is a moderately rapidly acting carcinogen[4] comparable with 1,2,5,6-dibenzanthracene, the 5,9-isomer[6] and the 5,10-derivative[7] are about equal in potency to methylcholanthrene as sarcoma-producing agents, and the 9,10-dimethyl compound[8] is a highly active carcinogen.[9] 1′,10-Dimethyl-1,2-benzanthracene[10] has a substituent in the favorable meso position 10, but the presence of the 1′-methyl group seems to result in decreased activity, for the hydrocarbon has given no subcutaneous tumors in six months.[9] Although it is too early to formulate any but tentative conclusions, the results on record suggest that there is an interesting reinforcing effect of methyl groups in the *meso*- and α-positions. As a means of determining to what extent this effect may be general, it seemed desirable to add to the list of known dimethyl-1,2-benzanthracenes further compounds meeting the specifications indicated. The 4,9- and 4,10-dimethyl derivatives are of particular interest not only because of these considerations but because of the relationship of the former compound to 4,10-ace-1,2-benzanthracene,[11,12] which has been found to give tumors in rats[13] and in mice[14] (Shear[9]), in the latter case in remarkably small dosage.



The scheme of synthesis employed was selected for investigation partly because it offered the possibility of obtaining not only the aromatic hydrocarbons in question but their 1′,2′,3′,4′-tetrahydro derivatives. These seemed of interest in connection with studies in progress on other hydroaromatic derivatives of carcinogens,[15] and since the work was started Shear[9] has made the interesting observation that 1′,2′,3′,4′-tetrahydro-4,10-ace-1,2-benzanthracene[11] has marked carcinogenic activity, giving added significance to the corresponding tetrahydro-4,10-dimethyl compound.

The plan of synthesis is indicated in the chart and involves the introduction of a methyl group at the 4-position by the use of 6-methyltetralin (I) as a component in a phthalic anhydride synthesis. By applying to the intermediate keto acid II the synthetic operations introduced by Fieser and Newman[7] in one series (a) and those of Fieser and Hershberg[16] in another (b), it was possible to introduce methyl groups at positions 10 and 9, respectively. 6-Methyltetralin was synthesized by Krollpfeiffer and Schäfer[17] from toluene and succinic anhydride, and a hydrocarbon of similar boiling point was obtained by Schroeter[18] by the high-pressure hydrogenation of β-methylnaphthalene. As an indication of the structure of the hydrocarbon, Schroeter observed that the keto acid (II) resulting from the condensation of the substance with phthalic acid yielded a single anthraquinone on cyclization, whereas the corresponding acid from tetralin affords two isomers. The difference was attributed to the blocking action of the methyl group, and hence it was inferred that the substituent is contained

in the aromatic ring. In the present work this keto acid (II) was prepared from hydrocarbon obtained by hydrogenation and put through the steps of series (b) and (c) and thus converted into a product identical with a sample of the known 4-methyl-1,2,benzanthraquinone,[19] and the hydrocarbon XII and its picrate corresponded in properties with the descriptions given by Cook.[20] This evidence confirms the conclusion reached by Schroeter but does not distinguish between positions 7 and 8 as possible points of attachment of the phthalic acid residue in 6-methyltetralin. In order to settle the matter the keto acid was oxidized exhaustively with dilute nitric acid, and the sublimed product was found to be identical with pyromellitic anhydride. This proves that the structure II is correct and that 6-methyltetralin undergoes substitution at the 7-position. Since the yield of pure keto acid in the Friedel and Crafts reaction was low (42%) and the crude material contaminated with a considerable amount of other acidic products, it is possible that the material obtained by the hydrogenation of β-methylnaphthalene does not consist entirely of pure 6-methyltetralin but contains other hydro derivatives.

No difficulties were encountered in carrying the two series of syntheses to the stage of the isomeric dimethyltetrahydrobenzanthracenes, V and IX. The anthrone IV was obtained by cyclizing the reduction product of the lactone III with sulfuric acid and was isolated easily in a pure condition in the stable ketonic form. Acetylative cyclization[16] of the acid VII with zinc chloride catalyst gave an anthranyl acetate, and when this was cleaved with a Grignard reagent the enol liberated isomerized to the more stable keto form VIII in the process of recovery and purification. With respect to the relative stability of the keto and enol forms, 4-methyl- and 4,10-dimethyl-1′,2′,3′,4′-tetrahydro-1,2-benz-10-anthrone, like the unmethylated compound,[21] con-

[21] Fieser and Hershberg, THIS JOURNAL, **59**, 2331 (1937).

form to the behavior noted for anthrone[21] rather than for 1,2-benz-10-anthrone.[16] In series (b) this was of advantage in facilitating the introduction of the 9-methyl group by a Grignard reaction.

The dehydrogenation of the tetrahydrides V and IX presented considerable difficulty, apparently because of the ready elimination of an alkyl group from a meso position of the 1,2-benzanthracene molecule. The dehydrogenation of the 4,9-dimethyl compound (IX) was tried first and when selenium was used the only reaction product which could be isolated in a satisfactory condition proved to be identical with the sample of 4-methyl-1,2-benzanthracene (XII) prepared from its tetrahydride with the use of selenium. It may be recalled that a similar loss of a *meso* (10)-isopropyl group has been noted in this Laboratory[16,21] in a dehydrogenation with selenium but that with sulfur the group was retained. It is also of interest that in a selenium dehydrogenation investigated by Cook[20] an isopropyl group was lost from the α-position 5. A methyl group in the α-position 4 seems to withstand treatment with selenium, at least in part, although the yield of the pure 4-methyl compound was never good. Since selenium was found unsatisfactory for the dehydrogenation of the dimethyl compounds, and as trial experiments with palladium charcoal seemed unpromising, sulfur eventually was employed. In each case the product was a hydrocarbon mixture, but on careful purification through the picrate or trinitrobenzene derivative it was possible to isolate an apparently homogeneous hydrocarbon having the composition required for a dimethyl-1,2-benzanthracene. The two hydrocarbons differ considerably in melting point and in the melting points of their derivatives and they are easily distinguishable, by analysis and properties, from the 4-methyl compound. Although the yields in the last step were quite low, the desired end was achieved and samples of 4,9- and 4,10-dimethyl-1,2-benzanthracene sufficient for tests of possible carcinogenic activity were obtained.

Experimental Part[22]

6-Methyltetralin (I).—Commercial β-methylnaphthalene was freed from sulfur by distillation from sodium at atmospheric pressure, and 100 g. of the purified hydrocarbon, mixed with 20 cc. of absolute alcohol, was hydrogenated in the presence of Raney nickel catalyst (5 cc. of the suspension) at an initial pressure of 1800 lb. (120 atm.) and a temperature of 130–135°. The reaction was stopped after the absorption of two moles of gas and the product was combined with that from a second batch and fractionated at atmospheric pressure through a 1-meter column. The chief fraction (96 g.) distilled at 222–226° (n^{20}D 1.5328), and a second fraction (44 g.) boiled at 226–227° (n^{20}D 1.5350); total yield, 68%.

***o*-(6-Methyl-7-tetraloyl)-benzoic Acid (II).**—Schroeter[18] prepared this acid in unspecified yield using benzene as the solvent. In our procedure a solution of 63 g. of 6-methyltetralin and 63 g. of phthalic anhydride in 500 cc. of tetrachloroethane was cooled to 0° and 120 g. of aluminum chloride was added with stirring in two and one-half hours while cooling in an ice-bath. After decomposition with ice and acid and removal of the solvent with steam, the solidified product in 800 cc. of 10% sodium carbonate solution was submitted to steam distillation, precipitated with acid, coagulated by boiling, collected and washed. The crude product (124 g., m. p. 135–140°) on crystallization from glacial acetic acid afforded 53 g. (42%) of colorless acid melting at 165–167°. A sample recrystallized to constant melting point from carbon tetrachloride formed small needles, m. p. 167.5–168° (Schroeter, 160°, uncorr.). It was evident that the crude reaction product contained considerable amounts of other acids. Schroeter isolated the acid II in the form of the ammonium salt and, while we found this a less satisfactory method of obtaining the acid in a pure condition than that adopted, use was made of partial purification through the ammonium salt to provide material suitable for reduction.

For proof of structure 1 g. of the keto acid was heated with 2 cc. of nitric acid (sp. gr. 1.42) and 4 cc. of water at 200–210° for one day; a fresh 2-cc. portion of concentrated acid was introduced and heating was continued for fifteen hours. After concentrating the solution, fuming acid precipitated a solid which was dried and sublimed at 250° and 15 mm. Recrystallized twice from dioxane and dried at 150° to remove solvent of crystallization, the product melted at 282–284° and gave no depression with a sample of authentic pyromellitic anhydride which had been freshly sublimed and crystallized and which melted at 283–285°.[23]

Series (b)

***o*-(6-Methyl-7-tetralylmethyl)-benzoic Acid (VII). (a) From Purified Keto Acid.**—The acid II (2 g., m. p. 164.5–165.5°) was heated with zinc dust (2 g.) and 2 *N* sodium hydroxide solution (50 cc.) for forty-eight hours on the steam-bath and after acidification the reaction product was extracted with ether, taken into soda solution, precipitated, and crystallized from methanol, giving 1.45 g. (76%) of long, white needles, m. p. 168.5–168.9°. After recrystallization the m. p. was 168.9–169.1°.

Anal. Calcd. for $C_{19}H_{20}O_2$: C, 81.04; H, 7.19. Found: C, 81.48; H, 7.12.

(b) From the Crude Ammonium Salt.—The crude product (59 g.) of the Friedel and Crafts reaction from 32 g. of 6-methyltetralin was dissolved in 500 cc. of hot 1 *N* ammonia solution, and after clarification with Norite the

[22] All melting points are corrected. Analyses by Mrs. Verna R. Keevil, Dr. C. Fitz, and the Arlington Laboratories.

[23] Observation of Dr. E. B. Hershberg; this value is believed to be more reliable than that reported previously by Fieser and Hershberg, THIS JOURNAL, **57**, 2196 (1935).

filtrate was treated with ammonium chloride and cooled to 0°. The ammonium salt of II separated in a crystalline condition and weighed 52 g. (the acid liberated from this material is impure). A mixture of this salt with 52 g. of zinc dust and 1 liter of 2 *N* sodium hydroxide solution was refluxed gently with mechanical stirring for twenty-four hours and the solution, filtered through sintered glass, was acidified with dilute hydrochloric acid. The crude precipitate (45 g.) on crystallization from methanol gave 22 g. of acid, m. p. 166.5–167.5°, and 4.5 g., m. p. 161.5–163.5°. The yield from 6-methyltetralin was 43%, as compared with an over-all yield of 32% via the purified acid.

1',2',3',4'-Tetrahydro-4-methyl-1,2-benzanthranyl-9-acetate.—The acid VII (3.5 g.) was refluxed for one and one-half hours with glacial acetic acid (21 cc.), acetic anhydride (14 cc.) and anhydrous zinc chloride (0.28 g.) and sufficient water was added carefully to the pale yellow solution to produce faint cloudiness. On cooling there separated 3.4 g. (89%) of long, pale yellow needles, m. p. 148–149°. Recrystallization from acetic acid raised the melting point to 150.5–151°.

Anal. Calcd. for $C_{21}H_{20}O_2$: C, 82.86; H, 6.62. Found: C, 82.40; H, 6.45.

1',2',3',4'-Tetrahydro-4-methyl-1,2-benz-9-anthrone (VIII).—The above acetate (6.5 g.) was refluxed for one hour in ether–benzene with the Grignard reagent from 11 g. of *n*-butyl bromide, and after hydrolysis the extracted product was crystallized from benzene–petroleum ether, giving colorless, non-fluorescent needles; yield, 5.54 g. (97%). Recrystallization raised the melting point slightly (0.5°) to 151.5–151.7°.

Anal. Calcd. for $C_{19}H_{18}O$: C, 86.98; H, 6.91. Found: C, 86.85; H, 6.81.

1',2',3',4'-Tetrahydro-4,9-dimethyl-1,2-benzanthracene (IX).—The anthrone VIII (3.75 g.) dissolved in benzene was added to the Grignard reagent formed by action of excess methyl chloride on 1 g. of magnesium. A deep red color developed and faded to yellow as the mixture was refluxed for one and one-half hours. After the addition of dilute acid to the cooled solution the organic layer (fluorescent) was washed and concentrated. The oily residue crystallized from methanol on seeding with a crystal previously obtained by the decomposition of the purified picrate (see below), giving 3.26 g. (88%) of small, pale yellow plates, m. p. 57–58°.

For the preparation of a pure sample, 2 g. of oily material in alcohol was treated with 2 g. of picric acid, yielding 2.5 g. of dark reddish-black needles of the **picrate**, m. p. 135.8–136.2° (1.65 g.).

Anal. Calcd. for $C_{20}H_{20}{\cdot}C_6H_3O_7N_3$: N, 8.59. Found: N, 8.83.

On decomposition of the picrate by chromatographic adsorption on activated alumina from benzene, the colorless, fluorescent filtrate on evaporation of the solvent and crystallization of the residue from methanol gave 0.65 g. of pale yellow plates of the hydrocarbon, m. p. 62.4–62.8°.

Anal. Calcd. for $C_{20}H_{20}$: C, 92.26; H, 7.74. Found: C, 92.55; H, 7.54.

Dehydrogenation of IX. (a) **With Sulfur: 4,9-Dimethyl-1,2-benzanthracene.**—A mixture of 500 mg. of the tetrahydride and 100 mg. of sulfur was heated slowly in a salt-bath in a stream of nitrogen. Evolution of hydrogen sulfide commenced at 180° and the mixture was maintained at 180–210° until liberation of this gas was complete (about four hours). The product was then distilled at 2 mm. pressure, yielding a ruby-red distillate which failed to crystallize from methyl or ethyl alcohol or to form a crystalline picrate. After passing a benzene solution of the oil through a tower of alumina there was obtained a light yellow oil which likewise failed to crystallize but which when dissolved in methanol with 300 mg. of trinitrobenzene yielded 135 mg. of long, bright red needles melting at 124.2–124.8°. The melting point of the complex remained unchanged on recrystallization, and by careful working of the mother liquors 195 mg. of satisfactory material was collected. This was adsorbed from benzene onto activated alumina, the trinitrobenzene being retained as a crimson zone at the top of the tower and the hydrocarbon forming a colorless zone having a blue fluorescence. After sectioning the tower this zone was eluted with benzene containing 5% methanol, and a solution of the pale yellow, oily residue in methanol slowly deposited small, faintly yellow needles, m. p. 73.3–74.3°; yield, 42 mg. (8.5%). Concentration of the mother liquors gave 13 mg., m. p. 69–71°. Recrystallization of the best material from methanol gave hydrocarbon melting at 75.1–75.5°. The picrate forms deep bronze colored needles, m. p. 116–116.4°, from methanol.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.70; H, 6.30. Found: C, 93.68; H, 6.61.

(b) **With Selenium.**—The tetrahydride IX (800 mg.) was heated with 1.1 g. of selenium in a salt-bath at 300° for twenty-one hours, with the further addition of 1 g. of selenium in the course of the reaction. The product was extracted with boiling benzene and the solution was clarified by refluxing with metallic sodium and by two passages through activated alumina. Removal of the solvent and crystallization from methanol gave 350 mg. (44%) of 4-methyl-1,2-benzanthracene in the form of rosets of needles, m. p. 117.5–118.5°. Repeated crystallization from methanol raised the m. p. to 122.8–123.4°, and the sample gave no depression when mixed with the hydrocarbon prepared as described below. The picrate melts at 148–148.5°.

Series (c)

1',2',3',4'-Tetrahydro-4-methyl-1,2-benzanthracene (XI).—A mixture of 2 g. of the anthrone VIII, 10 cc. of toluene, 5 g. of zinc dust, and 100 cc. of 2 *N* sodium hydroxide was refluxed for forty-eight hours, with the further addition of 5 g. of zinc dust. The progress of the reduction was indicated by the development of blue fluorescence under ultraviolet light. The cooled reaction mixture was extracted repeatedly with benzene, and the solution was washed with acid and water and evaporated. The residue on crystallization from methanol afforded 1.1 g. (58%) of faintly yellow crystal clusters, m. p. 81.3–82.3°, and the mother liquors yielded 0.17 g. of material, m. p. 78–79°. Repeated crystallization from methanol–benzene gave faintly yellow clusters of needles, m. p. 82.3–82.9°. The picrate crystallized from methanol as deep reddish-brown needles, m. p. 158–158.2°.

Anal. Calcd. for $C_{19}H_{18}$: C, 92.63; H, 7.37. Found: C, 92.34; H, 7.61.

4-Methyl-1,2-benzanthracene.—Dehydrogenation of the tetrahydride XI (730 mg.) was accomplished by heating with selenium (2.1 g., added in portions) at 290–300° for twenty hours. The product, obtained by extraction with benzene and clarification with the use of sodium and an adsorption tower, was crystallized from methanol and gave 170 mg. (24%) of small, pale yellow needles, m. p. 119–120°. Repeated crystallization from alcohol–benzene gave material melting constantly at 124.1–124.6°.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.82. Found: C, 94.33; H, 5.61.

Cook[20] found the melting point 124.5–125.5° for the hydrocarbon and 149–150° for its picrate. The picrate prepared from the above sample formed brown-red needles, m. p. 148.5–149°; the trinitrobenzene derivative formed bright red needles, m. p. 163.5–164°. Oxidation of the hydrocarbon (29 mg.) with chromic anhydride in acetic acid at 60° gave, after crystallization from benzene–ligroin, 7 mg. of 4-methyl-1,2-benzanthraquinone, m. p. 167.5–168°, giving no depression when mixed with the sample prepared by Fieser and Peters.[19]

Series (a)

Lactone of 2-(α-Hydroxy-6,α-dimethyl-7-tetralylmethyl)-benzoic Acid (III).—A solution of 15 g. of *o*-(6-methyl-7-tetraloyl)-benzoic acid (II) in benzene was added to the Grignard solution from 4.8 g. of magnesium and excess methyl chloride in 100 cc. of ether. The solution became greenish-yellow and an oil deposited on the walls of the flask. After adding more benzene the mixture was refluxed for one and one-half hours, decomposed, and the product taken into benzene–ether. An amorphous white precipitate often separated at this point at the interface but eventually dissolved on vigorous shaking. In one experiment the solid was collected and found to be a magnesium complex which on being refluxed with methanol gives a flocculent precipitate and a solution containing the pure lactone. After washing the benzene–ether solution with sodium carbonate solution, removing the solvent, and crystallizing the product from methanol, there was obtained 7.85 g. (53%) of crystalline lactone, m. p. 112–113.5°. The recrystallized material formed granular prisms, m. p. 115–115.5°.

Anal. Calcd. for $C_{20}H_{20}O_2$: C, 82.16; H, 6.90. Found: C, 82.43; H, 6.96.

2-(6,α-Dimethyl-7-tetralylmethyl)-benzoic Acid.—The lactone III (8 g.) was refluxed for forty-two hours with amalgamated zinc (400 g.), toluene (150 cc.), glacial acetic acid (40 cc.), concentrated hydrochloric acid (160 cc.), and water (80 cc.), with three further additions of 50-cc. portions of acid. The product was extracted with benzene and the acidic portion taken into 10% sodium carbonate solution, precipitated, and dried in ether. Evaporation left a colorless oil which was obtained crystalline from methanol containing 10% of water; yield, 2.2 g., m. p. 165–165.5°. In a second reduction 5.5 g. of lactone gave 1.75 g. of the acid, and the combined neutral material from the two experiments on further reduction gave 0.9 g. of acid; total yield 13.5 g. (36%).

Recrystallized from aqueous methanol, the acid formed micro-needles, m. p. 165.5–166°; occasionally a second form was obtained melting at 147–148° and remelting after fusion at 165.5–166°.

Anal. Calcd. for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53. Found: C, 81.63; H, 7.68.

1′,2′,3′,4′-Tetrahydro-4,10-dimethyl-1,2-benz-9-anthrone (IV).—The above acid (2.2 g.) was dissolved slowly in 50 cc. of concentrated sulfuric acid at room temperature and after one hour the red solution was poured onto ice and the precipitate extracted with ether. The ether solution, washed with water, soda and water, was dried and evaporated and the residue crystallized from methanol. This gave 1.6 g., m. p. 112–113°, and 0.18 g., m. p. 111–112°; yield, 86%. The recrystallized anthrone formed colorless blades, m. p. 112.8–113.4°.

Anal. Calcd. for $C_{20}H_{20}O$: C, 86.92; H, 7.30. Found: C, 87.41; H, 7.49.

1′,2′,3′,4′-Tetrahydro-4,10-dimethyl-1,2-benzanthracene (V).—For reduction, 3 g. of IV in 10 cc. of toluene was refluxed for thirty hours with 5 g. of zinc dust and 75 cc. of 2 *N* sodium hydroxide, with the further addition of 10 g. of zinc and 100 cc. of alkali. In contrast to the behavior noted in the reduction of the anthrone VIII, no fluorescence developed in the course of the reaction, probably because the intermediate dihydroanthranol persists in the alkaline medium and escapes dehydration. The reaction mixture was extracted thoroughly with benzene, and on washing the extract with dilute hydrochloric acid it acquired a fluorescence which became more pronounced on concentrating the washed solution. After removing the solvent the residual oil was distilled at 2 mm., yielding a yellow, fluorescent distillate which formed crystals, m. p. 77–80° from methanol (2.02 g.). As the melting point was not improved by recrystallization, the product was dissolved in alcohol with 3 g. of picric acid, yielding 2 g. of violet-black picrate, m. p. 145–146°. This was decomposed with sodium carbonate solution–benzene, giving 1.05 g. (37%) of microcrystalline hydrocarbon, m. p. 104–105°. Recrystallized from methanol, the substance formed pale yellow micro-needles, m. p. 105–105.5°. The purified picrate formed slender, violet-black needles, m. p. 146–147°.

Anal. Calcd. for $C_{20}H_{20}$: C, 92.26; H, 7.74. Found: C, 91.87; H, 8.01.

4,10-Dimethyl-1,2-benzanthracene.—For dehydrogenation 540 mg. of the tetrahydride V was heated with 120 mg. of sulfur for four hours at 190–215° in an atmosphere of nitrogen. The material collected after extraction with benzene and purification by chromatographic adsorption proved to be a mixture and the separation of a satisfactory product was a tedious process which need not be described in detail but which involved selective adsorption on alumina (some tetrahydride passed into the filtrate and was treated again with sulfur), elution with benzene–methanol, and fractionation both as the picrate and as the hydrocarbon. The best sample of picrate formed long black needles, m. p. 161.5–162°. After collecting in all 235 mg. of picrate melting at 161.3–161.9°, decomposition with sodium carbonate solution yielded 79 mg. of hydrocarbon, m. p. 108.5–111.5°, and further recrystallizations from methanol gave 17.5 mg. (3%) of opaque, pale yellow needles melting at 114–114.4° (softening at 113°).

Anal. Calcd. for $C_{20}H_{16}$: C, 93.70; H, 6.30. Found: C, 93.64; H, 6.61.

Summary

6-Methyltetralin, prepared by the catalytic hydrogenation of β-methylnaphthalene, is substituted in the 7-position in the Friedel and Crafts reaction with phthalic anhydride. The resulting keto acid has been used as the starting material for the synthesis of the 4-methyl and the 4,9- and 4,10-dimethyl derivatives of 1,2-benzanthracene, as well as their 1′,2′,3′,4′-tetrahydro derivatives, all of which are of interest in investigating the relationship between structure and carcinogenic activity. Although the syntheses were completed successfully, some difficulty was experienced in the dehydrogenations, apparently because of the ease of elimination of meso alkyl groups.

Separation of Sulfuric Acid from Nitric, Alkyl- and Arylsulfonic, and Alkylsulfuric Acids by Means of Liquid Ammonia

BY JOHN H. BILLMAN AND L. F. AUDRIETH

The ammonium salts of many oxy acids such as sulfuric, phosphoric, oxalic and arsenic are insoluble in liquid ammonia. Use has been made of the insolubility of some of these ammonium salts in liquid ammonia to effect the preparation of such nitrogen bases as hydrazine,[1] semicarbazide[2] and hydroxylamine[2] by ammonolysis of the respective sulfates, oxalates, phosphates and arsenates. The nitrogen bases are very soluble in liquid ammonia and are recovered in the anhydrous condition by evaporation of the solvent.

This marked insolubility of ammonium sulfate in liquid ammonia suggested that liquid ammonia might be used for the removal of excess sulfuric acid where the latter is employed either by itself or with other reagents. The experimental results reported in this paper demonstrate that it is possible (1) to separate quantitatively sulfuric and nitric acids by conversion into the ammonium salts and extraction of soluble ammonium nitrate with liquid ammonia; (2) to use liquid ammonia as a solvent for alkyl- and arylsulfonic acids, as well as alkylsulfuric acids; (3) to use liquid ammonia for the removal of excess sulfuric acid from compounds of the types listed under (2), especially where it is desired to produce directly the ammonium salts of the alkyl- and arylsulfonic acids and alkylsulfuric acids.

Experimental

It should be emphasized that no special apparatus is necessary in using liquid ammonia for the reactions outlined below. Filtration is carried out using ordinary Büchner funnels and filter flasks. It is a simple task to cool the funnel and flask quickly by running a small quantity of liquid ammonia through the filter. Filtration is simplified where sintered glass crucibles or filter funnels are used in place of filter paper. Naturally, good ventilation is not only desirable, but necessary.

Separation of Sulfuric Acid from Nitric Acid.—The separation and recovery of nitric and sulfuric acids in the spent acids after use in nitration reactions, by conversion into ammonium salts and extraction with liquid ammonia is practically quantitative. In a typical experiment a solution containing 20.8 g. of 96% sulfuric acid and an approximately equal quantity of concentrated nitric acid was neutralized with concentrated aqueous ammonia. The solution was evaporated and the solid residue treated with 200 cc. of liquid ammonia. The insoluble ammonium sulfate was removed by filtration, washed with liquid ammonia, heated at 60°[3] for several hours and weighed; yield, 26.8 g. of ammonium sulfate corresponding to a 99.3% recovery. No sulfate was found to be present in the ammonium nitrate recovered from the filtrate.

Solubility of Alkyl- and Arylsulfonic Acids and Alkylsulfuric Acids in Liquid Ammonia at −33°.—A representative number of compounds of this type were prepared and their solubility in liquid ammonia tested qualitatively. With the exception of laurylsulfuric acid, all compounds listed below are readily and easily soluble to the extent of at least 10 g. in 100 cc. of ammonia. Solution of these acids in liquid ammonia brings about their conversion into the ammonium salts. In a number of cases the products obtained upon evaporation of the liquid ammonia solution were recrystallized from absolute alcohol and analyzed for their nitrogen content. These compounds are listed in Table I.

In extending this study to other derivatives of these acids, it was found that the sodium salts of benzenesulfonic acid and *n*-butylsulfonic acid are very soluble in liquid ammonia, whereas the sodium salts of laurylsulfuric and benzylsulfonic acids are only slightly soluble.

Laurylsulfuric	$C_{12}H_{29}O_3NS$	4.94	5.07

Ammonium Ethyl Sulfate.—A mixture of 50 g. of sulfuric acid (96%) and 70 g. of ethanol was refluxed for two and one-half hours on the steam-bath. The reaction mixture was then saturated with gaseous ammonia and the excess of alcohol removed by evaporation. The solid residue was treated with 200 cc. of liquid ammonia, allowed to stand for one hour and the ammonia insoluble material removed by filtration, weight of ammonium sulfate recovered 32.2 g., corresponding to 23.9 g. of pure sulfuric acid. Evaporation of the filtrate yielded 28.6 g. of $C_2H_5OSO_3NH_4$, approximately 90% of the theoretical yield based upon the sulfuric acid which had reacted.

Ammonium Lauryl Sulfate.—Nineteen and two-tenths grams of lauryl alcohol in 40 cc. of ether was treated with 19 g. of concentrated sulfuric acid (96%) and allowed to stand at room temperature for forty-eight hours. After removal of the excess ether, the residual liquid was treated directly with gaseous ammonia, resulting in the formation of a solid mass. This mixture was digested for one hour with 400 cc. of liquid ammonia. Filtration and evaporation of the liquid ammonia solution yielded 10 g. of a white crystalline product possessing excellent detergent properties. This material was recrystallized from alcohol and washed with ether. Analysis showed this compound to be the ammonium salt of laurylsulfuric acid. The yield obtained corresponds to a 34% conversion of the alcohol into the ammonium salt. The ammonia-insoluble residue was found to contain unreacted alcohol, ammonium sulfate and some ammonium lauryl sulfate. Qualitative tests indicate that the solubility of ammonium lauryl sulfate is greater than 5 g. but less than 10 g. per 100 cc. of liquid ammonia at −33°. The solubility increases markedly, however, with rise in temperature.

Ammonium Sulfanilate.—Twenty-eight grams of aniline and 80 g. of concd. sulfuric acid were heated at 180–190° for five hours. The solid product was neutralized with aqueous ammonia and the resulting solution evaporated until the total volume of solid and liquid had been reduced to approximately 100 cc. The material was treated directly with 400 cc. of liquid ammonia, allowed to digest for one hour and filtered. Evaporation of the filtrate and subsequent drying of the product in a vacuum desiccator yielded 41.5 g. of the ammonium sulfanilate, $H_2NC_6H_4SO_3$-NH_4, corresponding to a 72% yield based on the aniline used. The product was sulfate free, indicating that removal of ammonium sulfate is possible even in the presence of considerable quantities of water.

Sodium and Ammonium Benzene Sulfonates.—Two 20-g. samples of benzene were converted into benzenesulfonic acid by treatment with 83.3 g. of fuming sulfuric acid (15% SO_3). One sample was neutralized in the cold with aqueous sodium hydroxide, the other with aqueous ammonia. The solutions were concentrated on a steam-bath to a sirupy consistency and each digested with 400 cc. of liquid ammonia. Removal of the ammonium sulfate and evaporation of the liquid ammonia filtrate gave in the first experiment 42.1 g. of sodium benzene sulfonate (91%) and in the other case 41.1 g. of the ammonium salt (91.5%). The above values are those obtained after the removal of diphenyl sulfone, which is soluble to a limited extent in liquid ammonia.

Summary

It has been demonstrated experimentally that liquid ammonia permits the quantitative removal of sulfuric acid as ammonium sulfate from mixtures containing nitric acid, alkyl- and arylsulfonic acids or alkylsulfuric acids.

Potassium Nitrilosulfonate

BY H. SISLER AND L. F. AUDRIETH

A study of the preparation and properties of potassium nitrilosulfonate was undertaken as one phase of an extended investigation of the chemistry of sulfamic acid and its derivatives. The nitrite–bisulfite reaction[1] has been suggested and used for the preparation of sulfamic acid. It is significant, however, that no information concerning the rate of hydrolysis and stability of the primary reaction product, the nitrilosulfonate, or of the intermediate imidodisulfonate, has been recorded. The present paper, therefore, concerns itself with a study of the preparation of potassium nitrilosulfonate and a characterization of its properties, specifically its hydrolysis under carefully controlled conditions. The potassium salts of imidodisulfonic and sulfamic acids were both prepared by hydrolysis of the nitrilosulfonate.

Experimental

Preparation of $N(SO_3K)_3 \cdot 2H_2O$.—The procedure of Claus and Koch[2] was modified as follows: A solution of 25 g. of potassium nitrite (0.294 mole) in 100 ml. of water is added slowly and with constant stirring to a hot solution of potassium bisulfite, prepared by saturating 75 g. (1.34 mole) of potassium hydroxide in 150 ml. of water with sulfur dioxide. Clouding of the solution takes place with formation of a mass of needle-like crystals. After standing for an hour in the mother liquor enough water (about 1500 ml.) is added in order to redissolve the precipitate on heating. The solution is then cooled to effect precipitation of the needle-like crystals which are separated by filtration, washed thoroughly with ice water, alcohol and ether and finally dried in a vacuum desiccator; yield of purified $N(SO_3K)_3 \cdot 2H_2O$, 74 g. (62% based on nitrite employed).

Anal. Calcd. for $N(SO_3K)_3 \cdot 2H_2O$: K, 28.8; S, 23.6. Found: K, 28.8, 28.7; S, 23.4, 23.8.

Care must be taken that the solution remains alkaline during recrystallization. If necessary, a few pellets of potassium hydroxide should be added. If the solution becomes acid the imidodisulfonate, rather than the nitrilosulfonate, will be obtained. It also is necessary that washing be thorough, otherwise some bisulfite may remain behind and bring about rapid decomposition of the nitrilosulfonate. Samples of the potassium salt, prepared as indicated above, have been kept in a vacuum desiccator for several weeks without decomposition.

Theoretically, one would expect a ratio of three moles of bisulfite to one of nitrite to give maximum yields. It is evident, however, from a series of comparable experiments carried out as described above, that excess bisulfite favors the formation of the nitrilosulfonate. With mole ratios of $KHSO_3:KNO_2$ between 6 to 4.5:1 yields of 64–62% were obtained. With smaller relative amounts of bisulfite the yield diminishes, becoming only 15% with a 1.50:1 ratio. Our results may be considered experimental confirmation of Raschig's[3] suggestion that the reaction is best represented by the equation

$$4KHSO_3 + KNO_2 \longrightarrow N(SO_3K)_3 + K_2SO_3 + 2H_2O$$

It is evident, furthermore, that at higher temperatures some nitrilosulfonate is always obtained whenever bisulfite and nitrite are brought together.

Properties of Potassium Nitrilosulfonate.—The compound is only slightly soluble in water and in liquid ammonia. A saturated aqueous solution gives no precipitate on the addition of solutions containing Mn^{++}, Mg^{++}, Ag^+, Cd^{++}, Co^{++}, Cu^{++}, and Fe^{++} ions, but, as stated in the literature,[2] gives a white flocculent precipitate with lead acetate. While no precipitate is formed immediately on the addition of Ba^{++}, the solution rapidly clouds on standing due to hydrolytic decomposition. Prior addition of acid to the solution causes immediate precipitation of barium sulfate. Contrary to reports in the literature,[4] a precipitate is obtained on the addition of barium hydroxide. This precipitate is momentarily dissolved by nitric acid, but a cloudiness appears almost immediately thereafter due to formation of sulfate ion by hydrolysis.

Hydrolysis of Potassium Nitrilosulfonate.—The study of the hydrolysis of potassium nitrilosulfonate was restricted to the range of dilute solutions due to the limited solubility of the compound. Duplicate experimental runs were carried out at 25, 40, 67 and 100°. In each case, a 1-g. sample (0.00246 mole) of potassium nitrilosulfonate dihydrate was dissolved in 400 ml. of water preheated to the temperature at which hydrolysis was to be studied. At regular time intervals 25-ml. portions of the solution were removed and titrated with standard sodium hydroxide solution using methylene blue–methyl red indicator. The course of the reaction thus could be followed readily by measuring the increase in the acidity of the solutions, as is evident from the following equations

$$N(SO_3)_3^{\equiv} + H_2O \longrightarrow HN(SO_3)_2^{=} + H^+ + SO_4^{=} \quad (1)$$

$$HN(SO_3)_2^{=} + H_2O \longrightarrow H_2NSO_3^- + H^+ + SO_4^{=} \quad (2)$$

$$N(SO_3)_3^{\equiv} + 2H_2O \longrightarrow H_2NSO_3^- + 2H^+ + 2SO_4^{=} \quad (3)$$

Complete hydrolysis, as represented by Equation 3, results in the formation of two moles of hydrogen ion per mole of nitrilosulfonate employed. The experimental results are represented graphically in Fig. 1 in which moles of hydrogen ion formed are plotted against time.

It is quite evident from Fig. 1 that hydrolysis with

(4) Mellor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry," Longmans, Green and Company, New York, N. Y., 1928, Vol. VIII, p. 668.

formation of one mole of hydrogen ion is quite rapid, even at 25°. This corresponds to the intermediate formation of the imidodisulfonate, as represented by Equation 1. The formation of the second mole of hydrogen ion is considerably slower, leading to the conclusion that the rate determining reaction in the complete hydrolysis of the nitrilosulfonate is that represented by Equation 2.

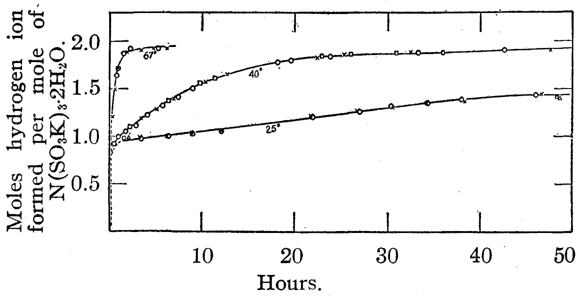

Fig. 1.—Hydrolysis of potassium nitrosulfonate.

In checking this assumption experimentally, it was found that neutral solutions of the intermediate product, potassium imidodisulfonate, did not become acid, that is, undergo hydrolysis, even over a period of eighteen hours at 67°. However, addition of an equimolar quantity of potassium acid sulfate, thus approximating the composition and concentration of the solution after the nitrilosulfonate had hydrolyzed in accordance with Equation 1, was found to bring about hydrolysis. In following the increase of acidity with time, results were obtained which checked satisfactorily with those plotted in Fig. 1.

It is significant that alkaline solutions of potassium nitrilosulfonate are resistant to hydrolysis, whereas neutral solutions undergo rapid decomposition. Solutions of the imidodisulfonate[5] seem to be quite stable, but in the presence of hydrogen ion undergo hydrolysis, thus leading to the conclusion that the reaction is acid catalyzed. Since the acid concentration approaches a constant value of two moles per mole of nitrilosulfonate hydrolyzed, it is apparent that the end-product, potassium sulfamate, H_2NSO_3K, is quite stable, even in presence of acid.

As is evident from Fig. 1 rise in temperature quite naturally increases rate of hydrolysis. Experiments carried out at 100°, using solutions of the same concentration, demonstrated that hydrolysis to the sulfamate is complete within one-half hour.

Potassium Imidodisulfonate.—In preparing this intermediate product the following procedure was adopted: 38 g. of $N(KSO_3)_3 \cdot 2H_2O$ was moistened with 16 ml. of 2% sulfuric acid and allowed to stand for twenty-four hours. The pasty mass was then filtered and the solid residue washed with 60 ml. of ice water. This product was recrystallized from a solution containing 10 ml. of concentrated aqueous ammonia in 60 ml. of water. The crystals obtained on cooling were washed with ice water, alcohol and ether and dried in a vacuum desiccator over sulfuric acid; yield, 12 g. (51%).

Anal. Calcd. for $HN(SO_3K)_2$: N, 5.53; K, 30.9. Found: N, 5.75; K, 30.4.

Potassium imidodisulfonate is much more soluble in water than the nitrilosulfonate. The addition of $BaCl_2$–HCl solution gives no immediate precipitate. Upon warming, or after standing for a short time, barium sulfate begins to form. This shows qualitatively that the imidodisulfonate is much more stable to hydrolysis than the nitrilosulfonate.

Preparation of Potassium Sulfamate by Hydrolysis of Potassium Nitrilosulfonate.—Sixty grams of potassium nitrilosulfonate (0.147 mole) was suspended in 300 ml. of water and boiled for seventy-five minutes. The solution was then neutralized with 20 g. of potassium carbonate (0.145 mole) and evaporated to dryness. The residue was placed in a Soxhlet apparatus and extracted with 80% ethanol for forty-six hours. Potassium sulfamate crystallized from the alcoholic extract on cooling; yield, 13.5 g. (67%).

Summary

1. Maximum yields of potassium nitrilosulfonate are obtained when the ratio of $KHSO_3$: KNO_2 is 4:1, or greater, and when the reaction is carried out at higher temperatures.

2. The hydrolysis of potassium nitrilosulfonate has been studied at 25, 40, 67 and 100°. The nitrilosulfonate is rapidly converted into the imidodisulfonate, which in turn hydrolyzes more slowly to give the sulfamate as the final product.

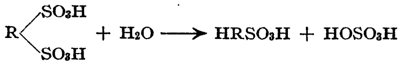
[5] It is of interest to point out the relationship between imidodisulfonic, pyrosulfuric, trithionic and hydroxylaminodisulfonic acids. In each of these compounds the SO_3H radicals are linked together by one of the following isosteric atoms or groups: O, S, NH, NOH. If these isosteres are represented by R the hydrolysis of any one of these four acids may be represented by the general equation:



$$R\begin{cases}SO_3H\\SO_3H\end{cases} + H_2O \longrightarrow HRSO_3H + HOSO_3H$$

Partial Molal Volumes of Lithium Chloride and of Sodium Nitrate in Liquid Monomethylamine

BY E. A. KELSO WITH W. A. FELSING

Introduction

The purpose of this investigation was to determine the densities and the partial and apparent molal volumes of salts at different temperatures in liquid monomethylamine. This investigation is one of a series[1] dealing with the thermodynamic properties of the methylamines and their solutions, with special reference to their use in the absorption type of refrigerating units.

It was found by Anderson[2] that the conductance of lithium chloride in liquid monomethylamine seemed to be abnormal over certain concentration ranges, possibly indicating compound formation. Bonnefoi[3] has shown the existence of compounds of the formula $LiCl{\cdot}CH_3NH_2$, $LiCl{\cdot}2CH_3NH_2$, $LiCl{\cdot}3CH_3NH_2$, and $LiCl{\cdot}4CH_3NH_2$. Since in the electrical conductivity of this salt in the liquid amine it was desirable to know how much of the solvent, in the more concentrated region, was tied up with the salt (*i. e.*, the ions), it was decided to determine the partial molal volumes of this salt (and of sodium nitrate) from density measurements.

Experimental

The experimental method consisted of determining at different temperatures the densities of methylamine solutions of these salts in a specially designed pycnometer, the volume of which was accurately known over a range of calibrations.

The Pycnometer.—The Pyrex pycnometer consisted of a bulb (approx. 9 cc.) sealed to a 1-mm. uniform bore capillary approximately 25 cm. long. To the other end of this capillary was sealed a no. 7 ground joint, to which was sealed a 6 cm. small diameter and small bore tube ending in another no. 7 ground joint. The pycnometer is shown in Fig. 1. The calibration was carried out by filling with mercury at 0°; the volume at any other temperature was calculated from the volume at 0° and the volume coefficient of expansion of Pyrex glass as calculated by Felsing and Thomas[1a] from the determinations of Buffington and Latimer.[4]

The Thermostat.—A Dewar flask 12 cm. in diameter and 20 cm. deep (inside measurements) served as a thermostat. A stirrer, heater, and cooling coil (supplied from a reservoir of cooling liquid by means of a circulating pump) together with a mercury-in-iron thermoregulator actuating a high-sensitivity relay system assured a temperature constancy of better than ±0.02° at any desired temperature. Thermometers calibrated by the U. S. Bureau of Standards were used throughout.

The Loading Apparatus.—The loading apparatus is shown in Fig. 1. The entire system was connected to a high-vacuum line.

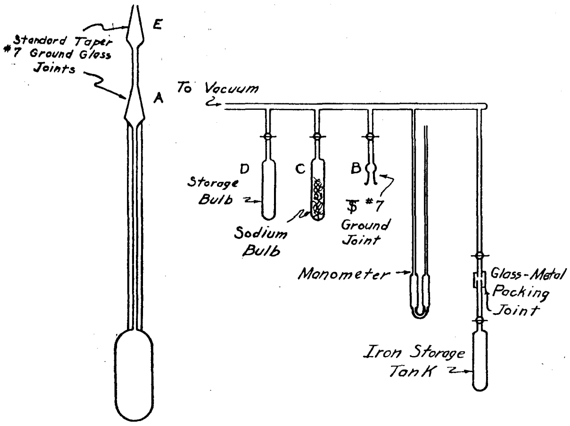

Fig. 1.—Density tube and methylamine loading apparatus.

Purification of Materials. (a) **The Solvent.**—The monomethylamine was prepared from Eastman C. P. hydrochloride. The salt as received was dried in an oven at 110° and over sulfuric acid in a desiccator. The *dry* salt was purified by the method of Bertheaume,[5] using purified and dry chloroform to remove the di- and trimethylamine hydrochlorides, and by the method of François,[6] using yellow mercuric oxide to remove any trace of ammonia. The gaseous amine was liberated by treatment of the purified hydrochloride with 50% potassium hydroxide, using the apparatus of Felsing and Wohlford.[1b] It was dried by passage over potassium hydroxide pellets followed by contact, as a liquid at 0°, with sodium wire. It was stored in a steel cylinder. (b) **The Salts.**—The lithium chloride was C. P. salt, recrystallized three times from conductivity water. It was dried at 110° in a stream of dry hydrogen chloride. The sodium nitrate was C. P. material recrystallized four times from conductivity water and was dried at 150°.

Method of Obtaining Data.—Solutions were prepared as follows. A definite volume of an aqueous stock solution of the salt was introduced into the bottom of the weighed pycnometer by means of a long thin capillary. The water

was then removed by evacuation at slowly increasing temperatures, finishing at 100°. After admitting dry air, the pycnometer was weighed. The pycnometer was then connected to the loading system, the whole evacuated, and liquid methylamine condensed into the pycnometer by surrounding it with a dry ice–acetone mixture. The amount condensed was adjusted by experience to be sufficient to fill the pycnometer to the lower graduations of the capillary when at 0°. The small glass tube between the two ground joints was then sealed off, and the two portions weighed to ascertain the true weight of amine introduced. By means of the ground joint on the capillary, the pycnometer could be emptied back into the system without loss of amine.

Readings on the capillary were made after allowing at least one-half hour for temperature equilibrium to be attained. The weight of the liquid amine was corrected for the amount of gaseous amine above the liquid. The vapor was assumed ideal and the vapor pressure values were those of Felsing and Thomas.[1a]

All weights were corrected to vacuum.

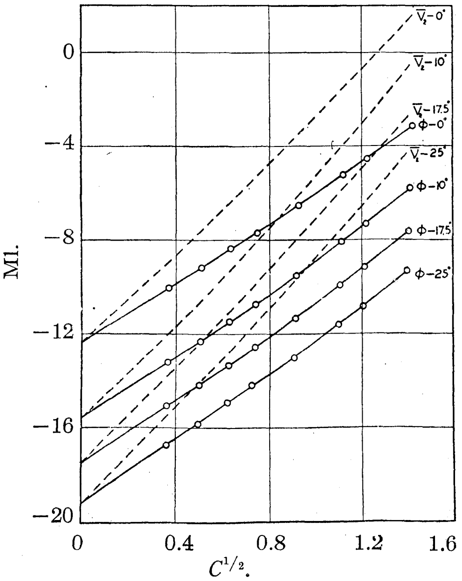

Fig. 2.—Partial and apparent molal volumes of lithium chloride in methylamine.

Experimental Data and Calculated Quantities

For lithium chloride, densities were determined at 0, 10, 17.5, and 25°; for sodium nitrate, at 0, 10, 18 and 25°. These densities are represented by the following relations, which reproduce the observed data to within ±0.01%.

Lithium Chloride *d* (g./ml.)

at 0° $= 0.68667 + 0.05088C - 0.00441C^{3/2}$
at 10° $= .67464 + .05289C - .00452C^{3/2}$
at 17.5° $= .66550 + .05413C - .00458C^{3/2}$
at 25° $= .65623 + .05511C - .00465C^{3/2}$

Sodium Nitrate, *d* (g./ml.)

at 0° $= 0.68667 + 0.07429C - 0.00495C^{3/2}$
at 10° $= .67464 + .07636C - .00559C^{3/2}$
at 18° $= 0.66490 + 0.07752C - 0.00569C^{3/2}$
at 25° $= .65623 + .07778C - .00520C^{3/2}$

The apparent molal volumes were calculated from the *observed* densities by the method of Gucker,[7] using the relation

$$\Phi = \frac{1000}{C} - \frac{1}{d_1}\left[\frac{1000d}{C} - M_2\right]$$

where C is the concentration of the solute in moles/liter of solution, d_1 the density of the solvent, d the density of the solution, and M_2 the molecular weight of the solute. These values are given by the following relations, which reproduce the calculated values to within ±0.1%.

Lithium Chloride

Φ at 0° $= -12.36 + 6.0469C^{1/2} + 0.27971C$
10° $= -15.59 + 6.1411C^{1/2} + .53926C$
17.5° $= -17.51 + 6.3741C^{1/2} + .42964C$
25° $= -19.21 + 6.6034C^{1/2} + .28775C$

Sodium Nitrate

Φ at 0° $= 17.45 + 3.2508C^{1/2} + 2.0660C$
10° $= 14.80 + 3.8672C^{1/2} + 2.3715C$
18° $= 13.42 + 4.2635C^{1/2} + 2.0986C$
25° $= 12.32 + 4.9056C^{1/2} + 1.6339C$

The partial molal volumes were then calculated by the expression given by Gucker[7]

$$\overline{V}_2 = \Phi + C^{1/2}\left[\frac{1000 - C\Phi}{2000 + C^{3/2}\partial\Phi/\partial C^{1/2}}\right]\frac{\partial\Phi}{\partial C^{1/2}}$$

The calculated values for $\overline{V}_2$ and for Φ are presented in Figs. 2 and 3. They represent an over-all accuracy of at least 0.1%.

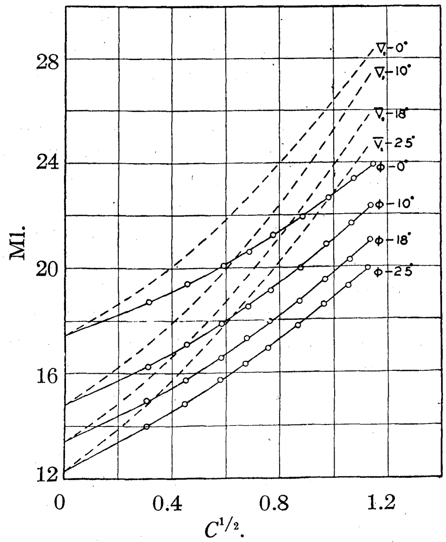

Fig. 3.—Apparent and partial molal volumes of sodium nitrate in methylamine.

---

[7] Gucker, *J. Phys. Chem.*, **38**, 307 (1934).

Fitzgerald[8] cites some density data for lithium chloride and for sodium nitrate solutions in methylamine at 0°. However, a smooth curve cannot be drawn through his determined points; his values are mostly higher than those of this investigation and were only incidental to some conductivity and viscosity determinations.

The results for the apparent molal volumes of lithium chloride are very interesting when compared with the values obtained in other solvents.

APPARENT MOLAL VOLUME OF LiCl AT 25°

Solvent	Dielectric constant	Φ	Observer
Water	78	17.06	Geffcken[9]
Methyl alcohol	31.2	− 3.8	Vosburgh[10]
Ethyl alcohol	26.5	− 4.4	Vosburgh
Methylamine	<10.5	−19.21	K. & F.

As the dielectric constant decreases, the apparent molal volume also decreases. The value of <10.5 for the dielectric constant for methylamine was determined by Schlundt[11] on an impure sample. The correct value for pure methylamine is probably much lower than 10.5.

Negative values of the apparent and partial molal volumes have been obtained by other investigators for lithium and sodium hydroxides and for magnesium and copper sulfates in water. The negative values for lithium chloride obtained in this investigation seem to point definitely to a solvation of the lithium ions in the methylamine solution. Such solvation would explain, in part, the trends in electrical conductance observed by Anderson,[2] especially in the more concentrated region. The positive values for sodium nitrate would indicate a probable lack of extensive solvation.

Summary

1. The densities of solutions of lithium chloride and of sodium nitrate in liquid monomethylamine have been determined at different temperatures and have been recorded as functions of the concentration.

2. The apparent and partial molal volumes have been calculated and presented.

3. An approximate correlation between the apparent molal volume of lithium chloride and the dielectric constant of the solvent has been presented.

AUSTIN, TEXAS
