The calorimetric measurements of some of the more dilute solutions depended upon precision in temperature measurement of a few ten-millionths of a degree. Some of the curves required extrapolations over wide concentration intervals by means of an arbitrary type of equation, the quadratic power series. The remaining discrepancies between theory and the extrapolated limits, therefore, may be without significance. That they do not, in general, indicate failures of theory becomes more probable when a few of the typical cases are examined further. The two series of chords tabulated for potassium nitrate have been discussed already: one or the other must be wrong. Since the general agreement observed for all the salts suggests that the five short chords are in error, an equation was derived from the long chords only. It is in very close agreement with theory.

$$S = 449 - 4{,}578\sqrt{c} + 4{,}708c \qquad (25)$$

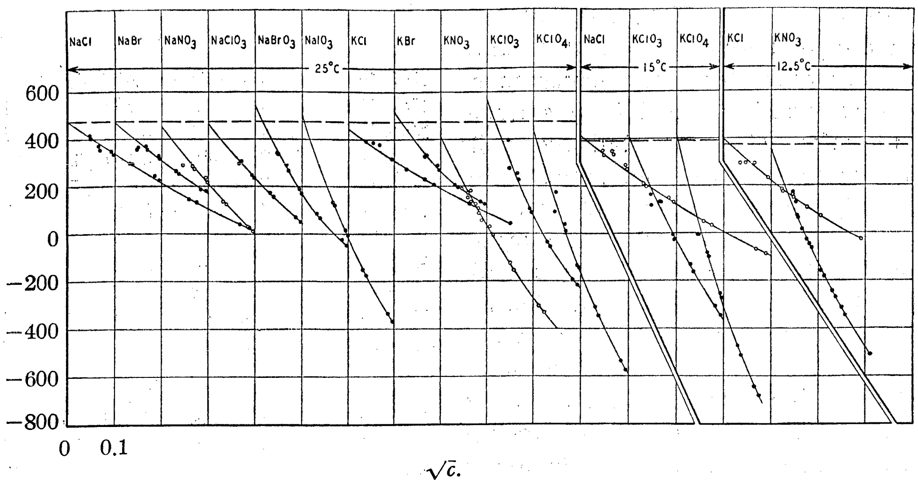

Fig. 1.—The derivative, S, *versus* $\sqrt{c}$. The curves represent the equations of Table I; the symbols ○ and ● are used to distinguish values of P associated with intersecting or adjacent curves. The origin of each successive curve lies one division to the right of the origin of its predecessor. Each horizontal interval represents an increment of 0.1 in $\sqrt{c}$. The respective theoretical limits are shown by the broken horizontal lines.

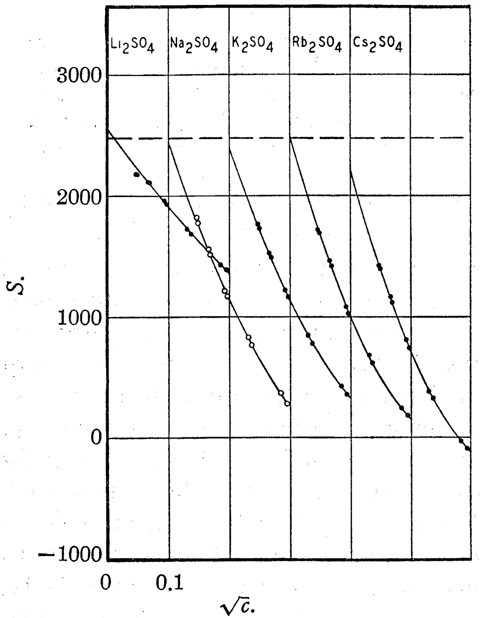

Fig. 2.—The derivative, S, versus $\sqrt{c}$. The curves represent the equations of Table II; the symbols represent values of P.

Though the potassium chloride limit is in satisfactory agreement with theory, the wide range of data available permits a further study of equation types. A cubic was determined from all ten chords

$$S = 460 - 1{,}718\sqrt{c} + 2{,}106c - 1{,}583c^{3/2} \qquad (26)$$

The somewhat better agreement of the extrapolated limit with theory suggests that the quadratic may have been applied to too wide a concentration range. One developed for values of X less than 0.2 actually reverses the algebraic sign of the discrepancy.

$$S = 482 - 1{,}967\sqrt{c} + 2{,}368c \qquad (27)$$

The changes in S^0 produced by these arbitrary variations of method confirm the view that differences of such magnitude are not significant. Moreover, the curves exhibiting the largest discrepancies are, in general, those which are most highly curved, and which are therefore least likely to be well fitted by an equation of arbitrarily chosen type.

The empirical equations, 4 to 24, may be used for calculations of accurate values of the partial molal and apparent molal heat contents. If, however, they are accepted (in addition to other known facts) as evidence that the theory agrees with experiment within the limits of error of the latter, a more precise set of equations may be derived with the aid of theory. Table III contains equations all having the theoretical limit, S^0. The B and C terms were computed by least square methods similar to those described above. Since fewer data are necessary for the determination of two constants the chord centers, X, were restricted to 0.2. Since the five short chords for potassium nitrate at 25° are definitely inconsistent with the theory, as well as with the other measurements, and since theory was being used as a guide for the derivation of this set of equations, the five short chords were not used. To emphasize the somewhat arbitrary character of this pro-

cedure the 25° equation is enclosed in parentheses. For certain theoretical calculations based upon the assumption that the limiting law is valid, this second set of equations will be preferable to those in Tables I and II. Ion size studies, for example, are often based upon the assumption that the Debye–Hückel theory is quantitatively correct, which implies that S^0 of all salts of a given valence type must be the same.[15]

For most purposes, values of the relative partial molal and apparent molal heat contents computed from the two sets of equations do not differ appreciably, nor do they differ much from the values listed in the original tables of Lange, Robinson, *et al.* About five calories per mole is the largest difference produced by various methods of extrapolation.

A few other salts of the alkali metals have been studied, though sufficient data for them have not been published to justify the derivation of least square equations. A few dilutions of lithium chloride[16] and potassium fluoride,[17] represented on a chord-area plot indicate that these three salts obey the limiting law. Chords for rubidium fluoride[8] are erratic and badly scattered and are useless for our purpose.

For investigation of heat capacities, more dilution measurements are necessary over a temperature range and wide concentration range. Young and Machin[18] already have utilized such data for sodium chloride to demonstrate that existing specific heats do not prove the existence of a conflict between the limiting law and experiment.

At the present time no existing calorimetric data for salts of the alkali metals are in disagreement with the Debye–Hückel limiting law. Indeed, most measurements of their heats of dilution support the law with striking consistency.[19]

Summary

The method applied by Young and Groenier to the heats of dilution of aqueous sodium chloride solutions has been extended to all other salts of the alkali metals for which sufficient data are available for the application of the least square technique. The average value of the limiting derivative, S^0, for eleven salts of the 1–1 valence type at 25° and $S^0/3^{3/2}$ for five salts of the 1–2 valence type is about 30% larger than the average of the older estimates based upon an assumed linear relation between the apparent molal heat content and the square root of the concentration. The new average agrees with the theoretical value calculated from Wyman's dielectric constant measurements and the Debye–Hückel limiting law.

Since the calculated values of S^0 appear to confirm the Debye–Hückel limiting law and Wyman's measurements a second set of derivative equations have been derived in which S^0 was fixed at the theoretical value.

---

(15) It already has been pointed out by Young and Vogel, THIS JOURNAL, **54**, 3030 (1932), that reasonable values of the parameter "*a*" may be computed from the *B* terms of the empirical equations. Such a calculation implies that the temperature coefficient of "*a*" is negligible and that certain other factors may be neglected. Lange and Robinson (Ref. 2, p. 111) have pointed out that these assumptions lead to the conclusion that the ion size of the alkali metals increases with atomic weight whereas freezing point measurements and other data indicate the reverse order.

(16) Lange and Messner, *Z. Elektrochem.*, **33**, 431 (1927).

(17) Lange and Eichler, *Z. physik. Chem.*, **129**, 285 (1927).

(18) Young and Machin, THIS JOURNAL, **58**, 2254 (1936).

(19) An incomplete investigation of salts of the alkaline earth metals of the 2–1 valence type indicates similar agreement, at least at 25°. The extrapolations seem to be of poorer precision, and afford less definite support to the Debye–Hückel theory, but no data point to failure of the theory. Existing data for salts of the 2–2 valence type *if treated by the methods described above*, certainly do not lead to limiting values in agreement with theory. *Cf.* Young, *Science*, **85**, 48 (1937).

The Catalytic Effect of Anions upon the Rate of Dissolution of Hydrous Alumina by Acids

BY JOHN P. CLAY AND ARTHUR W. THOMAS

The effect of certain acids in aqueous solution—hydrobromic, hydrochloric, nitric, sulfuric, oxalic, hydrofluoric, phosphorous and phosphoric—upon the rate of dissolution of certain hydrous alumina specimens has been found by the writers to vary greatly with the nature of the anions of the acids. The first four acids mentioned above are extraordinarily less active in the dissolution of aged hydrous alumina than the latter four, despite the fact that the former have greater activity and diffusion coefficients.

These effects, reported herein, are not in accord with the classical theory[1] that the rate-determining factor in reactions at a solid–liquid interface is the rate of diffusion of the reactants into a film of a saturated solution of the solid at the interface and of the product away from this film.

Neither are the observations reported herein in accord with the hypothesis[2] that anions of high valence will increase the velocity of dissolution of hydrous alumina in acid solutions, owing to adsorption of these anions at the solid–liquid interface and to concomitant lowering of the potential difference at this interface.

The present results indicate that the rate-determining factor is chemical in nature, and the writers submit an explanation involving the formation of a complex at the solid–liquid interface.[3]

Materials

Amalgamated Aluminum.—Aluminum ingots[4] were amalgamated by placing them in contact with redistilled mercury in a 5% aqueous solution of mercuric chloride. When the surface of the aluminum was covered with mercury the ingots were washed free of electrolyte with hot distilled water and were kept under distilled water at room temperature until needed.

Hydrous Alumina.—The specimens of hydrous alumina used in this investigation were prepared in the following manner.

Specimen "A."—Twelve pieces of amalgamated aluminum weighing approximately 200 g. each were placed in two liters of distilled water at 25 ± 2° and allowed to react for twenty-four hours. The suspension was filtered and dried in air at room temperature, pulverized to a fine powder, and allowed to remain in contact with the atmosphere until it showed no change in water content on three successive days. This procedure was continued until 1000 g. of oxide was obtained. The oxide was then thoroughly mixed and screened through a 100-mesh sieve. This specimen showed upon analysis the composition $Al_2O_3 \cdot 2.89 H_2O$.

Specimen "B."—The procedure was the same as for Specimen "A" except that the amalgamated aluminum was placed in boiling water and allowed to react at this temperature for six hours. This specimen showed upon analysis the composition $Al_2O_3 \cdot 2.70 H_2O$.

Acids.—The acids used were reagent grade and the acid solutions were prepared by quantitative dilution of solutions which had been standardized by means of carbonate-free sodium hydroxide solution. The latter was standardized against acid potassium phthalate.

Measurement of the Rate of Solution.—A weighed quantity of the hydrous oxide was transferred through a funnel into a 300-ml. flint glass bottle by means of 200 ml. of the acid solution of the desired concentration. The bottle was placed in a motor-driven rotator which revolved at the rate of seven r. p. m., in a water-bath at 25 ± 0.05°. At the expiration of the desired time of rotation the contents of the bottles were poured into centrifuge tubes. One drop of a saturated solution of ammonium sulfate was added to solutions of Specimen "A" and five drops to solutions of Specimen "B" in order to precipitate colloidally dispersed alumina. The bottles were then centrifuged for ten minutes at 1500 r. p. m. (rotating radius to middle of tube was 42 cm.). After centrifuging, the supernatant liquor was siphoned off and appropriate quantities taken for analysis.

Waxed bottles were used whenever hydrofluoric acid was present.

Methods of Analysis

Three methods of analysis for aluminum were used in this investigation: (I) in the presence of phosphate and phosphite, (II) in the presence of oxalate and (III) in the presence of fluoride, sulfate, chloride, bromide and nitrate.

For (I) aluminum in the presence of phosphate, phosphite and pyrophosphate the method of Hillebrand and Lundell was used.[5a] The pyrophosphate was hydrated[6] to the phosphate by addition of hydrochloric acid to 2 *M* strength and by boiling for three hours.

In the presence of sulfate, chloride, fluoride, bromide, and nitrate (II) the aluminum was precipitated as the hydroxide, according to the method of Blum,[7] and ignited

and weighed as Al_2O_3. Since the maximum concentration of fluoride in any determination was 0.008 molar, its presence did not cause an appreciable incomplete precipitation of aluminum. In all cases, treatment of the aluminum oxide residue with hydrofluoric acid, followed by evaporation and re-ignition,[5b] caused no loss in weight, indicating the absence of an appreciable quantity of silica.

In the presence of oxalic acid (II) the solution was evaporated almost to dryness, cooled and treated with 5 ml. of concentrated sulfuric plus 5 to 10 ml. of concentrated nitric acids. After heating for two hours on a steam-plate to oxidize completely the oxalic acid, the aluminum content was determined as in method III.

Analyses for aluminum in the presence of chloride, bromide, sulfate, nitrate and oxalate were also made by precipitation, as the phosphate. Such analyses showed that when aluminum is precipitated as the phosphate the results are consistently 2–3% higher than when the aluminum is precipitated as the hydroxide. Therefore the results of all analyses for aluminum precipitated as the phosphate were lowered by 3%.

It was also found to be necessary to oxidize the oxalate with nitric acid before precipitating the aluminum phosphate.

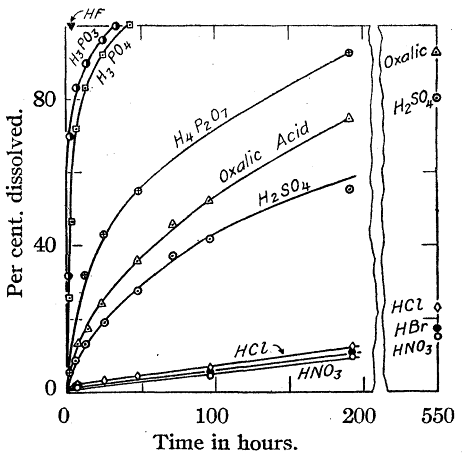

Fig. 1.—The dissolution of $Al_2O_3 \cdot 2.89H_2O$ in diverse acids. This graph contrasts the rates of dissolution of 260 mg. of 100-mesh $Al_2O_3 \cdot 2.89H_2O$ at 25° in 200 ml. of 0.2 *N* solution (H_3PO_3 and H_3PO_4 were 0.1 *M*) of the acids indicated on the curves.

Experimental Results

The curves for the dissolution of Specimen "A" in 0.2 *N* solutions of hydrofluoric, phosphorous, phosphoric, oxalic, sulfuric, hydrochloric, hydrobromic and nitric acids and in a mixture of hydrochloric acid and potassium pyrophosphate, 0.2 *N* to both, are plotted in Fig. 1. In each case there were present 260 mg. of the hydrous alumina (equal to 172 mg. of Al_2O_3) and 200 ml. of the aqueous acid solution. The striking differences in rates of solution are obviously neither a function of hydrogen ion activity nor of diffusibility or valence of the ions. The rate of dissolution in the hydrofluoric acid solution was too great to

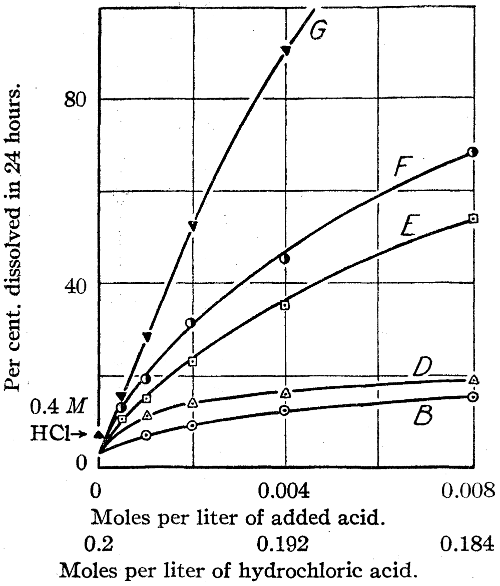

Fig. 2A.—The influence of the concentration of certain acids on the amount of the hydrous oxide (Specimen "A") dissolved in one day, 260 mg. of $Al_2O_3 \cdot 2.89H_2O$ was added to 200 ml. of solutions of HCl containing an added acid (B) H_2SO_4, (D) Oxalic, (E) H_3PO_4, (F) H_3PO_3, (G) H_2F_2. These suspensions were rotated at 25° for 24 hours, centrifuged, and the supernatant solutions analyzed for dissolved aluminum ion. The arrow indicates per cent. dissolved in 0.4 *M* HCl in 24 hours.

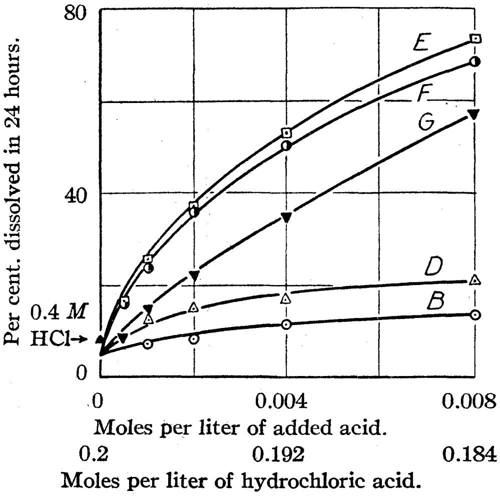

Fig. 2B.—The influence of the concentration of certain acids on the amount of hydrous oxide (Specimen "B") dissolved in one day. 260 mg. of $Al_2O_3 \cdot 2.70H_2O$ was added to 200 ml. of solutions of HCl containing an added acid (B) H_2SO_4, (D) oxalic, (E) H_3PO_4, (F) H_3PO_3, (G) H_2F_2. These suspensions were rotated at 25° for 24 hours, centrifuged, and the supernatant solutions analyzed for dissolved aluminum ion. The arrow indicates per cent. dissolved in 0.4 *M* HCl in 24 hours.

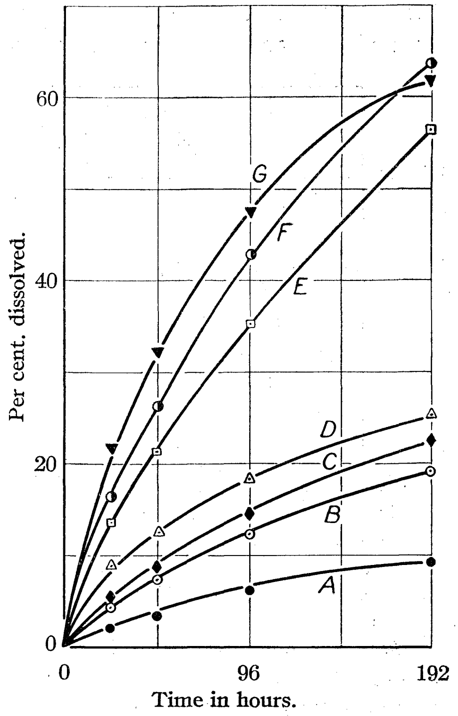

Fig. 3A.—The catalytic effect of anions on the rate of dissolution of the hydrous oxide (Specimen "A") in hydrochloric acid. 520 mg. of $Al_2O_3 \cdot 2.89H_2O$ was added to 200 ml. of 0.198 *M* HCl which was also 0.001 *M* (B) H_2SO_4, (D) Oxalic, (E) H_3PO_4, (F) H_3PO_3, (G) H_2F_2. Curve (A) represents the rate in 0.2 *M* HCl, and (C) the rate in 0.4 *M* HCl.

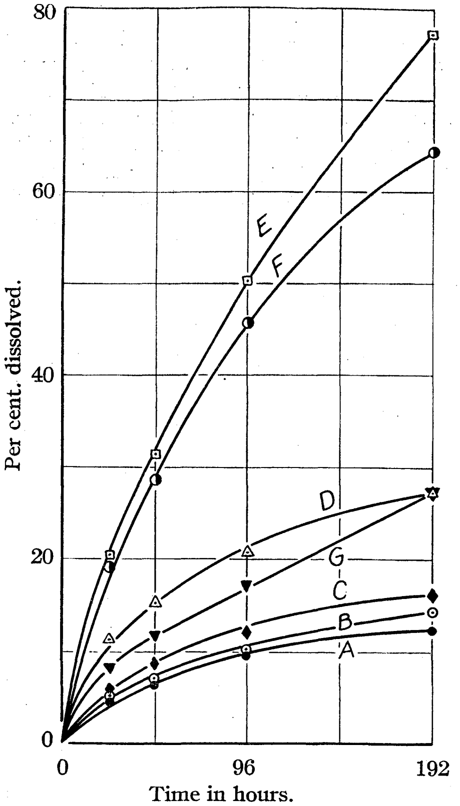

Fig. 3B.—The catalytic effect of anions on the rate of dissolution of hydrous oxide (Specimen "B") in hydrochloric acid. 520 mg. of $Al_2O_3 \cdot 2.70H_2O$ was added to 200 ml. of 0.198 *M* HCl which was also 0.001 *M* (B) H_2SO_4, (D) oxalic, (E) H_3PO_4, (F) H_3PO_3, (G) H_2F_2. Curve (A) represents rate in 0.2 *M* HCl, and (C) the rate in 0.4 *M* HCl.

plot in this figure, the oxide having completely dissolved to a clear crystalloidal solution in about six minutes. In 0.2 *N* hydrofluosilicic acid the solution was complete in about two hours. The measurements were always made in duplicate and sometimes in triplicate, showing a reproducibility to 3%.

In the next series of measurements, the results of which are given in Figs. 2A and 2B, the acid solutions, 200 cc. in each case, consisted of mixtures of hydrochloric acid, 0.2 to 0.184 *M* plus one of the other acids, 0.0 to 0.008 *M*. (For consistency we are using the molecular formula H_2F_2 to represent a mole of hydrofluoric acid.) In the case of Specimen "A," 260 mg. was taken, as in the first instance; the amount of Specimen "B" was also 260 mg. (equal to 176 mg. of Al_2O_3). The time of reaction was twenty-four hours. It is seen that small amounts of the added acids influence greatly the rate of dissolution. In the experiments with both oxide specimens, the effect of 0.4 *M* hydrochloric acid was measured also, the result shown by the arrow on the ordinate axis demonstrating that doubling the concentration of hydrochloric acid was less effective than substituting very small amounts of the diverse acids for part of the 0.2 *M* hydrochloric.

The data in Figs. 2A and 2B show clearly that the amount of oxide dissolved in twenty-four hours in an acid solution is dependent upon the nature and concentration of the anions present and upon the temperatures at which the oxides were prepared.

It is observed that while hydrofluoric, phosphorous, and phosphoric acids greatly accelerate the rate of solution of both oxide specimens, their order of effectiveness differs in the two cases. This change in order will be considered under "Discussion of Results." In passing it might be mentioned that the rates of dissolution of the natural modifications of calcium sulfate—alabaster, fibrous gypsum and selenite—in water have been shown to be different in each of the three cases.[8]

---

[8] Wildermann, *Z. physik. Chem.*, **66**, 445 (1909).

A series of measurements upon the time of dissolution of the oxide specimens (520 mg.) in 200-cc. portions of solution mixtures, 0.198 *M* with respect to hydrochloric and 0.001 *M* with respect to other acids, again showed the striking influence of traces of certain anions. These results are plotted in Figs. 3A and 3B. With the exception of the added sulfuric acid, it is noted that the added anions increased the rate in 0.2 *N* solution more than was effected by doubling the concentration of hydrochloric acid.

In order to determine the influence of extent of surface of the oxide, experiments were performed in which 200-ml. portions of acid solutions, 0.198 *M* with respect to hydrochloric and 0.001 *M* with respect to other acids, were allowed to act for twenty-four hours upon various weights of the oxide specimens. Figures 4A and 4B summarize the results. The weight of oxide dissolved in unit time is a function of the weight of solid (surface exposed) present, and of the temperature at which the oxide was prepared. The effect of the anions in accelerating the rate of dissolution tends to reach a maximum. This is the usual type of phenomena encountered in heterogeneous reactions when the catalyst is exerting its maximum influence; a further increase in the surface has relatively no influence on the rate of the reaction. It will be noticed that the small concentration of hydrofluoric acid used is much less effective in catalyzing the dissolution of Specimen "B" than Specimen "A." This is a significant point which will be discussed later in connection with a consideration of the difference in the two types of hydrous oxides.

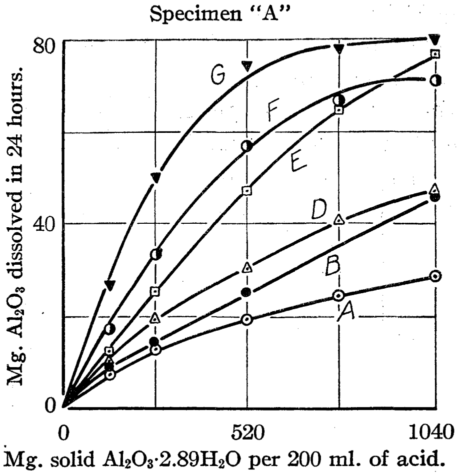

Fig. 4A.—The influence of surface area of hydrous alumina on amount dissolved. Different weights of $Al_2O_3 \cdot 2.89H_2O$ were added to 200 ml. of 0.198 *M* HCl which was also 0.001 *M* (A) H_2SO_4, (D) oxalic, (E) H_3PO_4, (F) H_3PO_3, (G) H_2F_2. Curve (B) represents the amount dissolved in 0.8 *M* HNO_3. The suspension was rotated for 24 hours at 25°, centrifuged, and the supernatant solutions analyzed for aluminum ion.

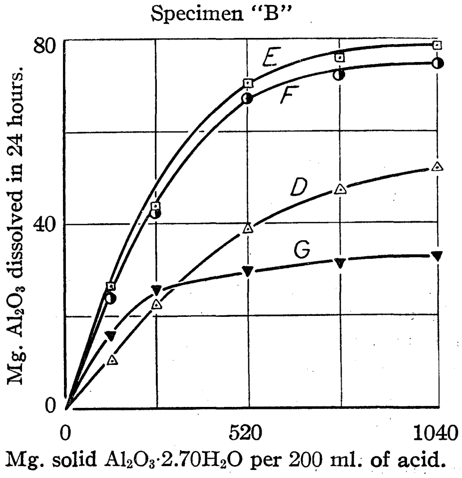

Fig. 4B.—The influence of surface area of hydrous alumina on amount dissolved. Different weights of $Al_2O_3 \cdot 2.70H_2O$ were added to 200 ml. of 0.198 *M* HCl which was also 0.001 *M* (D) oxalic, (E) H_3PO_4, (F) H_3PO_3, (G) H_2F_2. The suspensions were rotated at 25° for 24 hours, centrifuged, and the supernatant solutions analyzed for aluminum ion.

Discussion of Results

The explanation of these facts lies in the structural arrangement of the oxide and the specific nature of the anions, the formula $Al_2O_3 \cdot x(H_2O)$ not adequately representing the structure of the hydrous oxide.

Previous publications from this Laboratory have described the processes of olation and oxolation which take place when hydrous oxide hydrosols are aged at room temperature, which processes are accelerated upon heating.[9] These concepts are based on the Werner–Pfeiffer[10] ideas of hydrolysis and olation, together with Stiasny's[11] concept of oxolation. It is also agreed that oxolation may take place through a reaction of the type suggested originally by Küntzel, Riess and

[11] (a) Stiasny and Balanyi, *Collegium*, 86 (1927); (b) Stiasny, "Gerbereichemie," Verlag von Theodor Steinkopff, Dresden-Blasewitz, Germany, 1931, p. 351.

Königsfeld.[12] The hydrous alumina specimens are polyolated, polyoxolated structures in which there are also hydroxo and aquo groups sufficient with the ol and oxo bridges to satisfy the coördination number of aluminum.

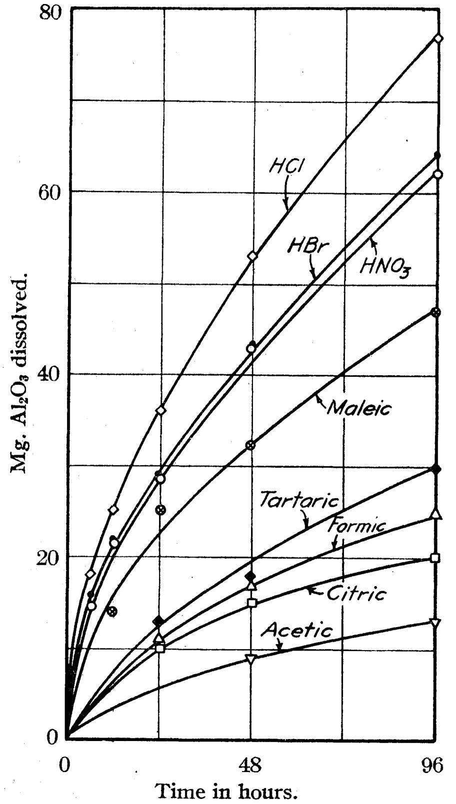

Fig. 5.—The dissolution of the hydrous oxide (Specimen "A") in diverse acids. 2.000 g. of $Al_2O_3 \cdot 2.89H_2O$ was added to 200 ml. of the 0.2 *N* acid solution, rotated at 25° for the desired time, a drop of $(NH_4)_2SO_4$ was added the solutions were then centrifuged and the supernatant solutions analyzed for dissolved aluminum ion.

For an acid to dissolve hydrous alumina and produce crystalloidal solutions of aluminum ions, it is necessary then that (1) the hydroxo groups be converted to aquo groups, (2) the ol bridges be broken and the hydroxo groups thus produced converted to aquo groups and (3) oxo bridges, if present, also be converted to hydroxo groups, etc. The first reaction is accomplished readily by oxonium ion, while (2) ol bridges are well known to be quite stable in the presence of oxonium ion and (3) oxo bridges are extremely resistant to attack by oxonium ion.

Since elevation in temperature favors the conversion of ol bridges to oxo bridges—*i. e.*, favors oxolation—one would expect Specimen "B," the hydrous oxide prepared by the action of boiling water upon aluminum amalgam, to be more oxolated than Specimen "A" which was prepared by the action of water at room temperature. Specimen "A" is perhaps predominantly an ol complex containing some oxo bridges and probably similar in structure to hydrargillite. Megaw[13] has submitted evidence for an olated structure for this mineral. Specimen "B" seems to be predominantly an oxo complex resulting from the partial oxolation of an olated structure possessing, to be sure, hydroxo groups as well as oxo bridges. This latter type, predominating in "B" and present to a minor extent in "A," may be the diaspore or chain-type structure referred to in recent literature.[14]

Considering now the dissolution of these hydrous oxides in aqueous acid solutions, it is apparent, since one of the products of the reaction is water, that the energy of formation of water furnishes the driving force for the reaction. But the potential energy of the ol $(\mathrm{Al\overset{H}{O}Al})$ link in the solid phase, or the oxo $(\mathrm{Al\overset{Al}{O}Al})$ link, is not readily available, as is evident from the slowness of the reaction of the solid hydrous oxide with the strong acids, hydrochloric, hydrobromic and nitric. Before an oxonium ion can react with an ol or oxo link it is necessary to form an intermediate link, the formation of which contributes toward the work required to break an ol or oxo link. Essentially this idea was suggested by London[15] for organic substitution reactions, and has been investigated by Polanyi,[16] Olsen[17] and Hammett.[18]

In other words, an intermediate complex must be formed, the formation of which renders the ol and oxo group reactive toward oxonium ion; and it is obvious that this intermediate complex involves anions, indeed, specific anions.

It is postulated in this paper that the formation of this complex is the rate-determining factor of the dissolution process.

Hydrargillite has been described[19] as an aluminum ion surrounded by six hydroxyl groups at the

corners of a distorted octahedron, the oxygen atoms being polarized in such a manner as to have directed bonds at the corners of an irregular tetrahedron. Two of the bonds of a hydroxyl group go to aluminum ions, at a third the hydrogen is found, and the fourth represents a concentration of negative electricity which has directed toward it the hydrogen belonging to another hydroxyl group. In this manner the coördination numbers of six for aluminum, four for oxygen and two for hydrogen are satisfied. It is this kind of hydroxyl group that is postulated to be present in our hydrous oxide, Specimen "A," and which is referred to here as an ol group.

It is easy to understand then why an ol group should not react readily with a proton, the oxygen of the ol group being already attached to three positive ions.

When an anion which forms complexes with an aluminum ion in acid solution, such as fluoride, phosphate, phosphite, oxalate or sulfate, approaches the aluminum ion in an ol $(\mathrm{Al}\overset{\mathrm{H}}{\mathrm{O}}\mathrm{Al})$ link at the surface, the bond between the aluminum approached and the oxygen will be broken. For convenience, we picture this in the following manner: $\mathrm{F}^- \longrightarrow \mathrm{Al}\ldots\overset{\mathrm{H}}{\mathrm{O}}\mathrm{Al}$. The ol group has now been converted into an hydroxo group which readily reacts[20] with a proton from an oxonium ion in the solution.

A similar mechanism would apply to the other anions, such as the $H_2PO_4^-$, $H_2PO_3^-$, $HC_2O_4^-$ and HSO_4^- ions or to their divalent anions.

It has been stated above that Specimen "B" is a more highly oxolated type of oxide than Specimen "A." By oxolation we mean that the proton of an ol group has migrated into a neighboring ol group, the result being an aquo group and an oxo group, with the simultaneous rearrangement of the structure to satisfy the coördination numbers of the atoms concerned. Such oxo groups exist in diaspore, according to Bernal and Megaw[19] and Ewing,[14a] the oxygen atom lying practically in the same plane with three coördinating aluminum ions[21] while the fourth coördination position is that of a weak hydroxyl bond of a neighboring hydroxyl group. Diaspore has the formula AlOHO.

If such oxo groups occur in Specimen "B" one might reasonably expect that an anion such as the $H_2PO_4^-$ ion would be a more effective catalyst than a F^- ion in dissolving Specimen "B." This idea follows from the fact that the $H_2PO_4^-$ ion is a proton donor as well as a coördinative binder, whereas the F^- ion is only a coördinative binder. Perhaps the (FHF^-) ion is the catalyst in breaking up oxo links. Palmer[22] reported that the rate of solution of quartz in hydrofluoric acid was proportional to the concentration of (FHF^-) ion rather than to the concentration of the hydrofluoric acid.

Davies[23] has shown that the (FHF^-) ion is present in aqueous hydrofluoric acid in much smaller amounts than is the F^- ion. If it is assumed that the (FHF^-) ion is the catalyst in breaking up an oxo group, one can account for the difference in the action of hydrofluoric acid on Specimens "A" and "B," this difference being due to the more limited chances of collision between the (FHF^-) ion than the F^- ion with the surface of the oxide.

Both Specimens "A" and "B" dissolve in maleic, tartaric, formic, citric and acetic acids at rates which are less than the rate of dissolution in nitric acid of the same equivalent concentration (Fig. 5). Therefore, since there is no correlation between the strength of the acid and the rate at which the hydrous oxides dissolve, the catalytic effect of certain anions cannot be explained on the basis of general acid–base catalysis. For example, the dissociation constants of phosphoric and maleic acids are very nearly the same, whereas the rates of dissolution of the hydrous oxides in these two acids are markedly different. Furthermore, while tartaric, hydrofluoric and formic acids are all approximately of the same strength, there is a great difference between hydrofluoric on the one hand and tartaric and formic on the other hand in their action upon the oxides.

The dissociation constants of oxalic and phosphorous acids are approximately the same. Figure 1 shows the great difference in the rapidity of dissolution of Specimen "A" in these two acids.

---

(20) Hydroxo groups also can be displayed by coördinative binding anions, as shown in this Laboratory by the unpublished results of Mr. P. D. Baker. *E. g.*, the *p*H of 200 cc. of an aqueous suspension containing 260 mg. of hydrous oxide specimens increased from *p*H 7 to 10.5 (Specimen "B") and to *p*H 9.6 (Specimen "A") when sufficient potassium fluoride was added to make the solution 0.1 *M* KF (the *p*H of pure aqueous 0.1 *M* KF was 7.2). The same weight of Specimen "A" also raised the *p*H of 200 cc. of 0.1 *M* solutions of the following salts: (a) $K_2C_2O_4$ from 7.1 to 8.4, (b) K_2SO_4 from 5 to 7.1, (c) KCl from 5.5 to 6.8, (d) KBr from 5.7 to 6.4, (e) KNO_3 from 5.7 to 6.3. Natural specimens of hydrargillite and of diaspore also react with a potassium fluoride solution in a similar manner.

(21) Previously the expression "oxo group" has been used in papers from this Laboratory to designate an oxygen ion coördinated between two metallic ions.[12,14] In this paper the idea of "oxo group" is modified to conform to the recent picture[14a] referred to.

(22) Palmer, *J. Chem. Soc.*, 1656 (1930).

(23) Davies and Huddleston, *ibid.*, **125**, 260 (1924).

While the equivalent conductivities of hydrofluosilicic acid and sulfuric acid are practically the same,[24] only two hours were required to dissolve completely 260 mg. of Specimen "A" in 200 ml. of 0.1 *M* hydrofluosilicic acid, whereas five hundred and fifty hours were required to dissolve 80% of the same weight of Specimen "A" in the same volume and concentration of sulfuric acid.

Neither can the catalytic effect of certain of these anions be ascribed to a "salt effect," since the ionic strength of all the aqueous acid solutions would be less than the ionic strength of sulfuric acid of the same equivalent concentration. Rates of dissolution of both Specimens "A" and "B" were investigated in sulfuric and hydrochloric acid solutions of the same calculated ionic strength, and it was found that the sulfuric acid dissolved the hydrous oxides more rapidly under these conditions than did the hydrochloric acid.

It is concluded that the effect of an anion on the rate of dissolution of hydrous aluminum oxide is a specific property of that anion and is not applicable to any generalization, other than that if the anion is a coördinative binder with the aluminum ion even small amounts of it will catalyze the dissolution of the oxide when added to other acids whose anions are not such strong coördinative binders or complex formers.

The mechanism offered above might be useful in explaining why phosphates and fluorides reduce the passivity of aluminum metal in nitric acid.[25]

Turning back to a further discussion of the relatively slow rate of dissolution of the hydrous oxides in citric and tartaric acids, it should be recalled that the anions of these acids form complexes with the aluminum ion in neutral or alkaline solutions. However, the complexes are supposedly of the chelate type, involving the α-hydroxy group of the anion. The dissociation of the proton of this α-hydroxy group would be exceedingly slight in acid solution. Therefore, one would not expect these acids to catalyze the dissolution of the hydrous oxide in acid solutions, since there could be very little complex formation at the solid–liquid interface.

There is another essential difference in the nature of the two hydrous oxide Specimens "A" and "B" which we have not discussed. This difference is as follows. When a gram of Specimen "B" is shaken for a moment with 200 ml. of 0.2 *M* nitric, hydrochloric or hydrobromic acid, about 90% of the oxide is dispersed to the colloidal state, *i. e.*, (1) it remains in suspension when centrifuged at 3000 r. p. m. for thirty minutes; (2) it passes readily through the pores of filter paper but does not pass through the pores of a nitrocellulose membrane; (3) it shows a pronounced Tyndall effect; and (4) it is readily precipitated by ammonium sulfate. Only about 5% of the same weight of Specimen "A" will be colloidally dispersed by the same acids under the same conditions.

To explain the facts just stated it is assumed that there are more hydroxo groups on the surface[26] of particles of Specimen "B" than of Specimen "A." The hydroxo groups react readily with oxonium ions, rendering the particles positively charged and dispersing these particles as colloidal micelles, which ultimately will be broken to the crystalloidal state.

Summary

Certain anions, *viz.*, fluoride, phosphate, phosphite, oxalate and sulfate, or their acids, greatly accelerate the rate of dissolution of hydrous aluminum oxide in 0.2 molar hydrochloric acid solution even when present at a concentration of 0.001 molar.

This phenomenon cannot be explained on the basis of increased acid strength, increased diffusibility of the acid, valence of the anion or general acid–base catalysis.

An explanation based on the coördination structure of the hydrous oxide and the formation of a complex at the solid–liquid interface has been offered.

[26] The presence of hydroxo groups on the surface of the hydrous oxide (Specimen "B") can be demonstrated readily: Dissolve 1 mg. of dry phenolphthalein in 3 ml. of 1,4-dioxane and divide the solution equally in three separate test-tubes. To (1) add anhydrous sodium carbonate; if the solution contains no water it remains colorless. To (2) add a pellet of dry potassium hydroxide. A pink color appears immediately at the interface between the liquid and the solid. This color will remain indefinitely at the interface and will not diffuse into the solution. This is because of the insolubility of potassium hydroxide in the dioxane. To (3) add 0.1 g. of hydroxy aluminum oxide prepared as Specimen "B" was, and the interface will immediately become pink. This color can be removed by the introduction of carbon dioxide and does not reappear on standing. The addition of water does not restore the color; however, the addition of more solid oxide does cause the color to reappear.

A Study of the Esterification of Benzoic Acid with Methyl Alcohol Using Isotopic Oxygen

BY IRVING ROBERTS AND HAROLD C. UREY

There has been much discussion as to which linkages are broken in the two reactions: (a) the saponification of an ester, and (b) the esterification of a carboxylic acid. The first of these was studied by Polanyi and Szabo,[1] who demonstrated that the saponification of amyl acetate in heavy oxygen water results in amyl alcohol of ordinary isotopic composition. The solution of the second problem, for which evidence has been inconclusive up to the present, is the subject of this paper.

The formation of water by the acid-catalyzed esterification of benzoic acid with methyl alcohol may be represented by either of the equations

$$C_6H_5CO \,\vdots\, OH + H \,\vdots\, O\,CH_3 \longrightarrow C_6H_5COOCH_3 + H_2O \quad (1)$$

$$C_6H_5CO\,O \,\vdots\, H + HO \,\vdots\, CH_3 \longrightarrow C_6H_5COOCH_3 + H_2O \quad (2)$$

The purpose of this work is to distinguish between (1) and (2) by allowing ordinary benzoic acid to react with methyl alcohol containing an increased concentration of oxygen 18. If mechanism (1) is correct, such an experiment will yield water of ordinary isotopic composition (0.200% oxygen 18), whereas by mechanism (2), heavy oxygen water will be obtained.

Attempts to make the reaction go to completion in a short time resulted in esterification of the large amount of hydrochloric acid catalyst which must be used. Therefore the concentrations of catalyst and reactants were so adjusted as to give a half-time of about two weeks at 25°, and samples were withdrawn at known intervals for determination of the heavy oxygen content of the water. The reaction mixtures had the following composition: methyl alcohol, 68.6% by volume; hydrochloric acid, 0.123 *M*; benzoic acid, 2.70 *M*; water, 2.72 *M* (4.9% by volume). A large concentration of benzoic acid was necessary in order to have appreciable amounts of water formed by the esterification. The initial presence of the water, although it would dilute any heavy oxygen water formed, made it possible in the first stages of the reaction to recover enough water for analysis.

Rate of the Reaction.—In order to calculate the concentration of heavy oxygen in the water at any point, the amount of water formed by the esterification must be known. 20.4 cc. of reaction mixture of the above composition was prepared by dissolving in 14.00 cc. of a freshly prepared methanol–hydrochloric acid solution (0.1803 *M*), 1.00 cc. of water and 6.72 g. of benzoic acid. After putting the solution into the thermostat, 1.00-cc. samples were withdrawn and titrated with standard 0.1121 *N* sodium hydroxide to determine the benzoic acid remaining. The results are given in Table I. A plot of these data was made so that, in the experiments given below, one could readily determine at any time the percentage of reaction and therefore the number of moles of water formed.

TABLE I

RATE OF ESTERIFICATION AT 24.93°

Time, hours	Titer, cc.	% reaction
0.0	25.40	0.00
22.0	23.56	7.58
43.3	21.89	14.46
96.4	19.34	24.97
144.0	17.41	32.92
209.9	15.65	40.17
383.0	12.01	55.17

The amount of the reverse reaction which takes place was determined by allowing a methyl alcohol solution containing 2.50 *M* methyl benzoate, 2.50 *M* water and 0.114 *M* hydrochloric acid to stand in the thermostat. Samples withdrawn for titration of the benzoic acid formed showed that over a period of 196.5 hours, only 1.3% of the possible hydrolysis had taken place. This error is negligible, since in this work the esterification was never continued beyond 55% reaction.

Exchange Experiments.—It is obvious that exchange of oxygen between the water in the system and the methyl alcohol, methyl benzoate or benzoic acid, will give rise to errors whose magnitudes must be determined.

The fact that methyl alcohol does not exchange in the presence of hydrochloric acid already has been reported.[2]

---

[1] Polanyi and Szabo, *Trans. Faraday Soc.*, **30**, 508 (1934).

[2] Roberts, *J. Chem. Phys.*, **6**, 294 (1938).

To determine whether methyl benzoate exchanges, a methyl alcohol solution containing 2.49 *M* methyl benzoate, 0.123 *M* hydrochloric acid and 2.96 *M* heavy oxygen water was allowed to stand in the thermostat. Twenty-five-cc. samples were taken and the water was recovered by fractional distillation and analyzed (see experimental part). Table II shows the results obtained. It can be seen that within experimental error no exchange of the methyl benzoate has taken place.

Table II

Exchange Experiment with Methyl Benzoate

Time, hours	H_2O recovered, cc.	% H_2O^{18}
0	....	0.462
172	0.43	.464
314	.67	.460

The amount of exchange of the benzoic acid was determined as follows: 102 cc. of a reaction mixture, having the composition originally given, was set up, using ordinary benzoic acid, ordinary methyl alcohol and water containing 0.509% oxygen 18. If no exchange of the benzoic acid were taking place, the heavy oxygen content of the water would be lowered by dilution with the ordinary water arising from the esterification. The amount of such lowering could be determined by taking the weighted mean of the composition of the water originally present and the water formed. If, on the other hand, the benzoic acid were exchanging, the heavy oxygen content of the water would be decreased even further than that calculated. Table III shows the results obtained.

Table III

Exchange of Benzoic Acid under Conditions of Esterification

Initial composition: 0.2752 mole benzoic acid, 0.2775 mole of H_2O^{18}, 70 cc. of methanol, HCl 0.123 *M*.

Time, hours	% reaction	Mole H_2O formed	% H_2O^{18} calcd.	H_2O recovered, cc.	% H_2O^{18} found
0	0.0	0.0000	0.509	0.08	0.510
94.0	24.5	.0674	.449	.28	.431
206.4	39.9	.1098	.421	.29	.400
378.8	54.7	.1505	.400	.34	.371

A comparison of the fourth and sixth columns will show that some exchange of the benzoic acid is taking place. This observation is in accord with the fact that benzoic acid has been shown to exchange both its oxygens rather readily.[2] That the exchange occurring in these experiments is small can be seen from the following consideration. If immediate complete exchange of the benzoic acid had taken place, the composition of the water would drop to 0.304% oxygen 18. The differences in Table III are of much smaller magnitude than this decrease. Rough calculations of the amount of exchange were made by separating the two simultaneous processes, *i. e.*, by assuming that first the known amount of esterification takes place and then the remaining benzoic acid exchanges with the water. It must be remembered that both oxygens of the benzoic acid are available for the exchange process. The results of these calculations are given in the second column of Table IV.

Esterification with $CH_3O^{18}H$.—The final experiment, performed at the same concentrations, contained ordinary benzoic acid, ordinary water and methyl alcohol containing 0.372% oxygen 18. In calculating the results to be expected by mechanism (2), a correction must be made for the decrease in heavy oxygen content of the water due to exchange with the benzoic acid. This was done by separating the two reactions as outlined above, and using the data on the benzoic acid exchange from the above experiment. These calculations result in the values given in Table IV. It can be seen that the corrections are comparatively small, and that they have very little effect upon the difference of oxygen content to be expected by the two mechanisms.

Table IV

Corrections for Exchange of Benzoic Acid in Data Calculated for Mechanism (2)

% reaction	Equivalents of benzoic acid exchanged	% H_2O^{18} expected for mechanism (2) Original	Corr.
24.5	0.0269	0.234	0.232
39.9	.0407	.249	.244
54.7	.0726	.260	.251

The results of the heavy oxygen methyl alcohol experiment are given in Table V.

Table V

Esterification Using $CH_3O^{18}H$

Time, hours	Percentage H_2O^{18} calculated Mechanism (1)	Mechanism (2)	H_2O recovered, cc.	H_2O^{18} found, %
0	0.200	0.200	....	.....
94.0	.200	.232	0.28	0.204
212.4	.200	.244	.42	.200
334.0	.200	.250	.78	.200

These experiments demonstrate that in the esterification of benzoic acid with methyl alcohol, the oxygen in the water formed originates entirely from the benzoic acid. It is notable that this is in accord with the conclusions drawn from experiments with mercaptans and thioacids.[3]

Experimental

Materials.—Methyl alcohol was purified by the method of Lund and Bjerrum.[4] Benzoic acid of the Mallinckrodt "Analytical Reagent" grade was found by titration to contain a maximum of 0.2% of impurity, and was therefore used directly. Hydrochloric acid was of the C. P. reagent quality. Hydrochloric acid solutions in methanol were prepared by passing the gas into anhydrous methanol; the solutions were used immediately after preparation. Standard 0.1 *N* sodium hydroxide, made up from a saturated carbonate-free solution, was standardized against Bureau of Standards potassium acid phthalate. Methyl benzoate was shaken three times with sodium carbonate solution, three times with water, dried over calcium chloride, and fractionated.

Heavy oxygen water, prepared by fractional distillation,[5] was refluxed with alkaline permanganate for one hour, fractionated and distilled from chromic acid. Heavy oxygen methyl alcohol, also prepared by fractional distillation,[6] was treated with magnesium and iodine in the same manner as the ordinary material[4] and fractionated. The middle fraction was further fractionated after the addition of two drops of phosphoric acid. The middle fraction, which distilled constantly at 65°, contained traces of volatile amines from which the methanol could not be freed completely. These small amounts of impurity caused the slow formation of a light yellow color in the reaction mixture when the methanol was used for the esterification.

Analyses.—The mass spectrograph was of the type described by Bleakney[7]; the procedure for analysis of the water was that of Cohn and Urey.[8] In the present work, the water recovered from the experiments was shaken with 26 cc. of ordinary carbon dioxide gas at atmospheric pressure for five hours. The precision of analyses was generally 1% or better.[9]

The heavy oxygen methyl alcohol was analyzed for its oxygen content by converting it to water and analyzing the water as above. This was done by passing a mixture of the methanol vapor and hydrogen through a quartz tube which contained a nickel spiral at about 650° and a thoriated nickel catalyst[10] at about 400°. The water was caught in a trap enclosed in solid carbon dioxide–acetone mixture; the yields were practically quantitative. Heavy oxygen water, passed through the apparatus under the same conditions, was recovered with no decrease in heavy oxygen content, demonstrating that exchange with the quartz tube or with any oxide in the catalyst had not taken place. Analysis of ordinary methyl alcohol by this method gave 0.204% oxygen 18.

Esterification Experiments.—All operations were carried out in glass apparatus fitted with interchangeable ground joints. Esterification experiments were carried out in the thermostat kept at 24.93 ± 0.02°. Twenty-five cc. samples of reaction mixture were pipetted for recovery of the water, and from these the methanol, water and a small amount of the methyl benzoate were distilled *in vacuo* at room temperature. This initial process took thirty minutes at a maximum, thus causing a negligible error in the reaction time recorded. The distillate was then fractionated at atmospheric pressure, the water and methyl benzoate remaining behind. In the final step, the water was distilled off *in vacuo* from the methyl benzoate. The water samples obtained by this method were always contaminated by small amounts of methanol and methyl benzoate; these impurities can have no effect on the results obtained by the method of analysis given above.

Summary

Ordinary benzoic acid has been esterified with heavy oxygen methyl alcohol in the presence of a small amount of hydrochloric acid catalyst. The water resulting from the reaction is of ordinary isotopic composition, demonstrating that the oxygen in the water formed originates entirely from the benzoic acid. Slow exchange of the benzoic acid proceeds simultaneously with the esterification, necessitating a small correction in the calculated results.

Conductance of Mixtures of Lead Abietate and Tributylammonium Chloride in Toluene

BY VICTOR DEITZ WITH RAYMOND M. FUOSS

I. Introduction.—While the properties of a number of 1–1 salts in solvents of low dielectric constant have been determined,[1-4] the properties of higher salt types in such solvents have not been investigated. One difficulty in the way of a study of the problem is the low solubility of most 2–1 salts in the hydrocarbon solvents. Two classes of salts are, however, soluble: the higher quaternary salts of dicarboxylic acids and the salts of heavy metals with the higher carboxylic acids. In this paper will be presented the results of an investigation of the properties of lead abietate in benzene and toluene solution.

II. Materials, Apparatus and Method.—**Benzene** was purified by washing with concentrated sulfuric acid, water, dilute caustic and water. It was then dried with calcium chloride and refluxed with potassium. Samples for use in the conductance experiments or analyses were distilled from potassium just before using. **Toluene** was treated in the same way, except that the potassium was replaced by sodium.

Tributylammonium picrate was prepared by adding a nearly saturated hot alcoholic solution of picric acid to a slight excess of tributylamine in alcohol. The crude product, which separates on cooling, was recrystallized once from alcohol, m. p. 106.9° (corr.).

Tributylammonium chloride was precipitated by *dry* hydrogen chloride from a solution of tributylamine in *dry* petroleum ether. It is advisable to precipitate less than half of the available amine, in order to prevent the coprecipitation of impurities which are difficult to separate. The precipitate was washed with dry petroleum ether, and then pumped dry over phosphorus pentoxide in a desiccator. Samples for use were dried to constant weight at 70–75° in weighing bottles in a miniature vacuum oven.

Several samples were analyzed by titration in 50% acetone solution with sodium hydroxide, using phenolphthalein as indicator. A small blank correction for acid in the acetone was made. Equivalents of $(C_4H_9)_3HNCl$ calculated from weight of salt taken: 0.001384, 0.001725, 0.001896; equivalents sodium hydroxide found by titration: 0.001390, 0.001749, 0.001896.

Lead Abietate.—Considerable difficulty was encountered in preparing pure lead abietate. Precipitation from lead nitrate or lead acetate solutions gives basic or double salts, whose composition depends on concentration, sequence and relative amounts of reagents.[5] It also proved useless to try to purify lead abietate made from impure abietic acid; it is essential that the abietic acid be in the highest state of purity initially. We obtained nearly colorless abietic acid, completely free from tacky impurities, by recrystallizing a good commercial grade (from Hercules Powder Co.) from methyl alcohol and washing the crystals with cold methyl alcohol. The crystallization yield was poor, but the quality of the product was compensation for the loss of raw material. The abietic acid was then dissolved in an equivalent amount of sodium hydroxide in water and this (very slightly yellow) solution was slowly added in turn to a hot dilute aqueous solution of an equivalent amount of lead chloride. The lead abietate formed as a pure white crystalline precipitate. This was recrystallized from ethyl acetate (2 g./100 cc.) which had been purified by shaking with aluminum oxide and distilling just before use. The final product consisted of small twinned needles. It was necessary to store the lead abietate in an evacuated phosphorus pentoxide desiccator, because exposure to air converted it into a product (presumably one of oxidation) insoluble in ethyl acetate and aromatic hydrocarbons. Heating to 100° in air causes the crystals to darken.

Of several new methods of analysis for lead in lead abietate, we found the most reliable to be the precipitation of the lead as lead chloride from a toluene solution of the abietate by means of dry hydrogen chloride. Moisture was excluded by working in a dry box; this precaution is necessary, because any water which condenses into the solution containing hydrogen chloride separates and preferentially wets the lead chloride precipitate, causing it to adhere so firmly to the walls of the vessel that quantitative transfer is very tedious.

The dry box was fed with air passed over activated aluminum oxide. At the start of an analysis, several weighed samples of lead abietate in capped weighing bottles, several weighed Gooch crucibles with fine asbestos mats, toluene wash bottle, toluene supply bottle, suction flask, hydrogen chloride generator and hot plate were placed in the dry box, which was swept out overnight with dry air. The next day, the abietate was dissolved in toluene (*ca.* 1 mg./cc.) in an Erlenmeyer flask which had a tea-kettle spout attached to the bottom. Hydrogen chloride from sulfuric acid and potassium chloride was passed slowly in through the spout, after which the precipitate was digested for about thirty minutes. Then the lead chloride was transferred to the Gooch crucible by sluicing it through the spout. (This procedure entirely eliminated the necessity of policing the precipitate.) After washing, the precipitate was sucked dry. After all the precipitations were complete, the dry box was opened and the crucibles were transferred to an oven at 110° where they were dried to constant weight. In some of the preliminary work, the crucibles were next washed with hot water and again dried to constant weight. The water insoluble resi-

due (of the order of 0.1 mg.) was probably abietic acid adsorbed on the lead chloride. The results of several typical analyses by this method are given below: wt. lead abietate, 0.2165, 0.2471, 0.1420; wt. $PbCl_2$ found, 0.0751, 0.0854, 0.0485; % Pb, 25.84, 25.75, 25.46; calcd. for $Pb(C_{20}H_{30}O_2)_2$, 25.61%.

As a control on the method, a sample of recrystallized silver perchlorate, which is toluene soluble, was analyzed by the same method: wt. $AgClO_4$, 0.1644, 0.3211; wt. AgCl found, 0.1138, 0.2218; wt. AgCl calcd. 0.1137, 0.2221.

Conductance Cells.—For the preliminary conductimetric titrations, several types of cells were used. The simplest and most convenient consisted of a beaker containing two concentric cylindrical platinum gauze electrodes, at the center of which was a motor driven glass stirrer.

For the final work, a three terminal cell was used. Figure 1 is a simplified sketch of the cell. The inner (test) electrode was a platinum cylinder 6.5 cm. long and 2.0 cm. in outside diameter. To each end of this cylinder and on the same axis, by means of platinum wires and lead glass beads, were attached two cylinders of the same diameter, 5 mm. long, and separated from the test electrode by about 1 mm. These end cylinders were the guard electrodes. The guard-test combination was then mounted by more platinum wire supports with lead glass insulators inside a platinum cylinder 7.7 cm. long and 2.3-cm. diameter, which served as the high potential electrode. The seams on the cylinders were soldered with gold. The electrode assembly was then sealed into an electrode capsule of Corning 332 glass by means of platinum tube supports coated with Corning 707 glass.[6] The capsule (40-cc. volume) was in turn sealed to a Pyrex mixing chamber (300-cc. volume), the inlet tube of which was equipped with a ground glass cap carrying a stopcock. The stopcock permitted rapid drying of the cell, by exhausting the cell after washing and heating. The three lead wires (high potential, test and guard) were brought up beside the neck of the cell in small glass tubes. (For simplicity, only one of these is shown in Fig. 1.) These, as well as the electrode capsule, were coated with gold by firing on at 500° a layer of Dupont "Liquid Bright Gold ZW." The gold screening was connected to the guard line. The bridge cable, which consisted of the test lead, sheathed with an insulated copper screen attached to the guard circuit, was plugged into the end of the test lead from the cell, so that the test electrode and its lead to the bridge were unbrokenly shielded.

The cell constant was determined by measuring the capacity of the empty cell on a Schering bridge[7] at 60 cycles; since the cell contains guard electrodes, the cell constant k can be obtained from the capacity by the relationship

$$C = 0.08842 \times 10^{-12}/k$$

(For an ideal cell consisting of parallel plates of area A separated by a distance d, $k = d/A$, if fringing is eliminated.) For the cell of Fig. 1, $k = 0.004423$.

The conductance determinations were made either at 60 cycles on the Schering or resistance bridge[8] which have been used for other work in this Laboratory, or on a d. c. bridge which has also been described previously.[8]

Method.—In the preliminary titrations, a solution of tributylammonium chloride in benzene or toluene was delivered in successive portions from a buret into the gauze electrode cell, which contained the lead abietate solution. The resistance was determined on the d. c. bridge after each portion. It was observed that both moisture and oxygen affected the results; titrations in the dry box gave steadier conductances.

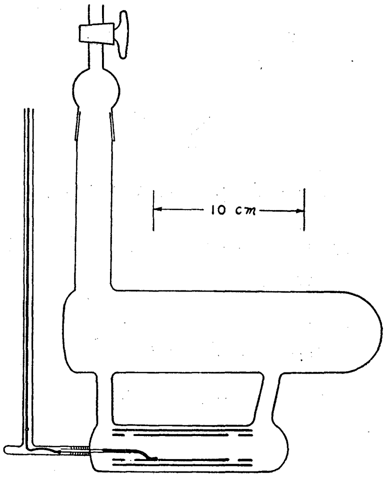

Fig. 1.—Conductance cell.

In the final work, toluene was distilled in a nitrogen stream from sodium directly into the carefully dried three terminal conductance cell. Access of moisture was prevented by a drying tube. After determining the solvent conductance,[9] a sample of lead abietate was weighed into the cell, and the solution was allowed to come to equilibrium in an oil thermostat held at 35.00 ± 0.03°. The conductance was determined and then a small portion of a solution of tributylammonium chloride in toluene was added from a weight buret. A conductance run consisted in adding several stoichiometrical equivalents of chloride to the lead salt in successive portions, and determining the conductance at 60 cycles at each point. The field strength was kept below one kilovolt per centimeter, in order to minimize both heating effects and a possible Wien effect.[10,11]

Polarization.—A very marked dependence of apparent resistance on voltage was noted when solutions were measured on the d. c. bridge. An analysis of the results indicates that a fairly high polarization e. m. f. is responsible. The bridge is shown schematically in Fig. 2, where R_1 is the cell resistance, R_2 and R_3 are Shallcross high resistance coils and R_4 is a variable decade box. Suppose the voltage applied to the bridge is V and

[8] Fuoss, *ibid.*, **60**, 451 (1938).

[9] The solvent conductance was of the order of 10^{-14} and represented a negligible correction.

[10] M. Wien, *Physik. Z.*, **29**, 751 (1928); L. Onsager, *J. Chem. Phys.*, **2**, 599 (1934).

[11] An appreciable dissociation effect in accordance with Onsager's theory appears in solvents of low dielectric constant at fairly low field strengths. (Unpublished observations of D. J. Mead and R. M. Fuoss, made in this Laboratory.)

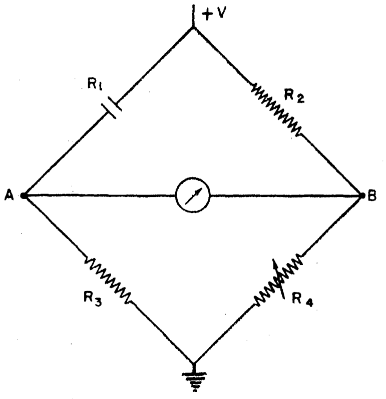

Fig. 2.—Diagram of d. c. bridge.

the back e. m. f. of the cell is E. Then at balance, $V_a = V_b$ and we have

$$V = I_a(R_1 + R_3) - E = I_b(R_2 + R_4) \qquad (1)$$

$$(I_aR_1 - E)/I_aR_3 = R_2/R_4 \qquad (2)$$

Combining (1) and (2), and noting that $R_1 >> R_3$, we find

$$\frac{R_1R_4}{R_2R_3} = 1 + \frac{E}{V} \qquad (3)$$

A typical result for a 5.85×10^{-3} molar solution of lead abietate in benzene at 25° in a cell with chromium plated brass electrodes is shown in Fig. 3. According to (3), if we plot R_4V against V, we should obtain a straight line whose slope determines R_1, and whose intercept determines E. Having determined R_1, a plot of R_1R_4/R_2R_3 against $(1/V)$ should give a straight line with slope E and intercept unity at infinite voltage $(1/V) = 0$. The data satisfy these requirements, and give, for this example, $E = 10$ v. Lack of time unfortunately forced us to postpone a detailed study of this phenomenon. A study of the rates of decay of these polarization voltages should give useful information concerning the diffusion coefficients and mobilities of the ions involved.

Subsequent d. c. titrations were made at a fixed cell voltage (100 v.) and the final titrations were made with alternating current. Since the latter was low frequency (60 cycles), some polarization error undoubtedly is present, but experiments made at several frequencies between 60 and 500 cycles showed that the effects were considerably less than with d. c. and our a. c. results at 60 cycles are no more than several per cent. in error in absolute value due to polarization. Since we were primarily interested in relative values, the study of polarization effects was dropped.

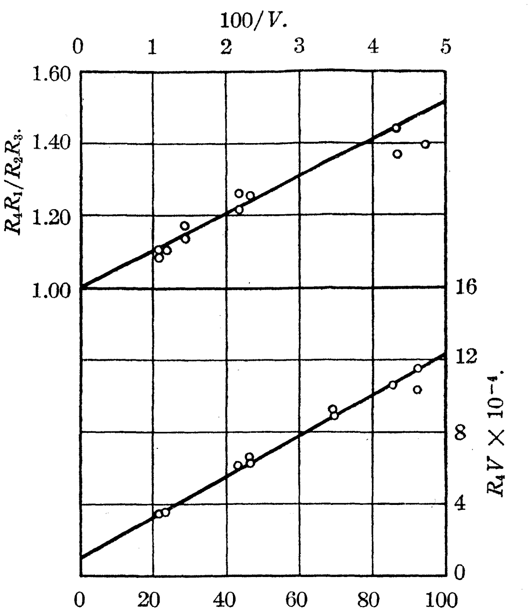

Fig. 3.—Polarization curves.

III. Experimental Results and Discussion.

In order to test the reliability of the conductance methods, the conductance of tributylammonium picrate in toluene at 35° was determined. Three dilution runs were made. The results are given in Table I.

TABLE I

CONDUCTANCE AND DIELECTRIC CONSTANT OF TRIBUTYLAMMONIUM PICRATE IN TOLUENE AT 35°

Series	$C \times 10^3$	$\Lambda \times 10^6$	ϵ'
1	13.04	2.650	...
	8.12	1.500	...
	5.03	0.957	...
	2.82	.603	...
	1.62	.442	...
2	2.65	.597	2.391
	1.21	.370	2.368
3	4.88	.926	2.428
	3.05	.548	2.400
	0.0	..	2.347

For comparison with earlier work, the only available data are those of Kraus and Fuoss[1] on tri-*i*-amylammonium picrate in benzene at 25°. These data, multiplied by the ratio of the viscosity of benzene at 25° to that of toluene at 35° are shown as the dotted curve in Fig. 4, where the present data are given as the circles on curve IV. It will be noted that the behavior of the two systems is, as expected, very similar.

The conductance of tributylammonium chloride as a function of concentration was determined by adding successive portions of an approxi-

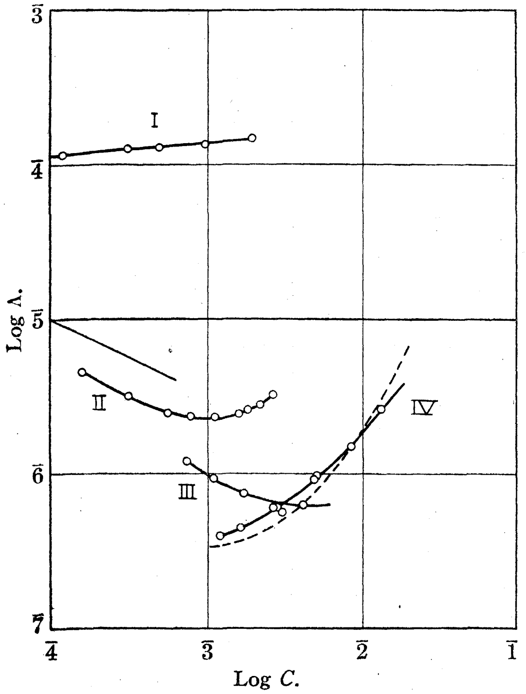

Fig. 4.—Conductance curves: I, PbAbCl in C_6H_6; II, Bu_3HNCl in $C_6H_5CH_3$; III, $PbAb_2$ in $C_6H_5CH_3$; IV, Bu_3HNPi in $C_6H_5CH_3$.

mately 0.01 normal solution of the salt in toluene to 66 g. of pure solvent in the conductance cell. The results are given in Table II, and are shown as curve II in Fig. 4, where the logarithm of the equivalent conductance Λ is plotted against the logarithm of the concentration. The appearance of a characteristic minimum in the equivalent conductance[12] near thousandth normal will be noted.

TABLE II

CONDUCTANCE AND DIELECTRIC CONSTANT OF TRIBUTYLAMMONIUM CHLORIDE IN TOLUENE AT 35°

$C \times 10^3$	$\Lambda \times 10^6$	ϵ'
0.000	..	2.347
.159	4.49	2.348
.290	3.13	2.348
.568	2.45	2.352
.790	2.32	2.352
1.116	2.30	2.356
1.575	2.38	2.359
1.819	2.58	2.362
2.203	2.76	2.365
2.692	3.22	2.368

The conductance and dielectric constants of a series of lead abietate solutions in toluene at 35° are given in Table III. Each solution was made up by weighing a definite amount of salt and solvent.

TABLE III

CONDUCTANCE AND DIELECTRIC CONSTANTS OF LEAD ABIETATE IN TOLUENE AT 35°

$C \times 10^3$	$\Lambda \times 10^6$	ϵ'	ϵ_0'
4.083	0.626	2.349_5	2.348_2
1.686	0.762	2.348_8	2.348_2
1.073	0.936	2.349_0	2.347_8
0.740	1.213	2.348_6	2.348_2

No dilution runs were made for this salt; the solutions of Table III were the initial solutions for the conductimetric titrations to be described later. In the last column, the dielectric constant ϵ_0' of the solvent, as measured before addition of the salt, is given for each solution.

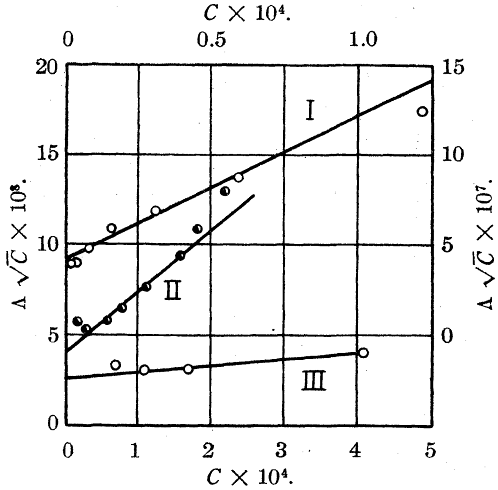

Fig. 5.—Triple ion test plots: I, PbAbCl in C_6H_6 (coördinates, top and right); II, Bu_3HNCl in $C_6H_5CH_3$ (coördinates, bottom and left); III $PbAb_2$ in $C_6H_5CH_3$ (coördinates, bottom and left).

If $\Lambda\sqrt{c}$ is plotted (Fig. 5, curve II) against concentration for the tributylammonium chloride,[11] a straight line is obtained, whose intercept at $c = 0$ gives $K\Lambda_0^2 = 3.8 \times 10^{-8}$ for this salt. If we set Λ_0, the limiting conductance, equal to 100 in order of magnitude (a reasonable value, assuming Walden's rule to apply), we find for the dissociation constant $K \approx 1.5 \times 10^{-19}$. This is of the order expected.[2] For lead abietate, a value about one half as large is obtained. The dissociation constant of lead abietate refers, of course, to the initial dissociation

$$PbAb_2 \rightleftarrows PbAb^+ + Ab^-$$

because it seems impossible that the second abietate ion should be free in any appreciable amount in solvents of low dielectric constant. Confirmation of this opinion is furnished by the numerical

(12) R. M. Fuoss and C. A. Kraus, THIS JOURNAL, **55**, 2387 (1933).

value of the dissociation constant of silver perchlorate in benzene,[4] 8×10^{-20}, which is a 1-1 salt with a metallic cation.

The dependence of the dielectric constants of the solutions on concentration is shown in Fig. 6.

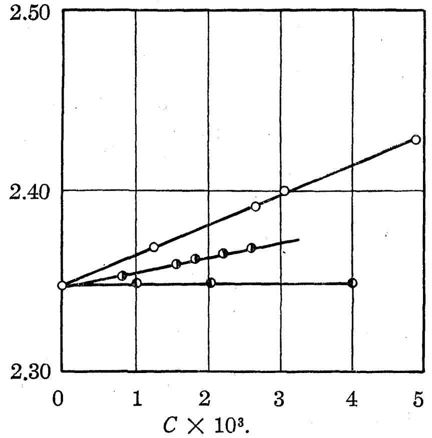

Fig. 6.—Dielectric constant–concentration curves for salts in toluene at 35°: ○, Bu_3HNPi; ◑, Bu_3HNCl; ◐, $PbAb_2$.

It is seen at once that the tributylammonium picrate has a higher dipole moment than the chloride and that the lead abietate has zero moment. Calculation of the moments from the data gives $\mu\,(Bu_3HNP_i) = 11.7 \times 10^{-18}$ and $\mu\,(Bu_3HN{\cdot}Cl) = 7.3 \times 10^{-18}$. These are of the expected order of magnitude and agree very well with Geddes' values,[13] $\mu\,(Bu_3HNP_i) = 13.1 \times 10^{-18}$, $\mu\,(Bu_3HN\text{-}Cl) = 7.2 \times 10^{-18}$. It should be pointed out that our values were determined by bridge measurements at 60 cycles, while Geddes' values were determined by Wyman's resonance method[14] at several megacycles. The value of zero for the moment of lead abietate is entirely in agreement with the theory of ion association[15] because one naturally assumes the abietate ions symmetrically located with respect to the lead ion.

We shall next consider a few of the preliminary conductimetric titrations. The examples chosen are shown in Fig. 7; in order to save space, no tabulation of data will be presented. The vertical scale is specific conductance; as abscissas are chosen the ratio r of equivalents of chloride to the equivalents of lead present in the cell. At $r = 0.5$, the empirical composition is $(Bu_3HNCl + PbAb_2)$; at $r = 1$, it is $(2Bu_3HNCl + PbAb_2)$.

Curve I represents the conductance curve obtained on the d. c. bridge when successive portions of 0.01 normal tributylammonium chloride solution in benzene were added to a 6.84×10^{-4} N solution of lead abietate in benzene. It will be seen that the conductance rises to a very high peak near the point where one mole of chloride has been added to one mole of lead, after which the conductance rapidly drops. Beyond the equivalence point, the conductance slowly rises again. The appearance of the maximum was entirely unexpected and its presence suggested that some hitherto unsuspected reaction was taking place. If the titration is carried out using hydrogen chloride in benzene, curve II, where the initial lead concentration was 7.64×10^{-4}, is obtained. It is similar to curve I in that a maximum appears, but the maximum is not nearly so high. Finally, curve III represents the reverse titration in which lead abietate was added to a solution of the amine hydrochloride. (The initial point of the titration here corresponds to $r = \infty$, of course.) As more and more lead is added (moving from right to left in Fig. 7), the conductance goes through a shallow minimum and then rises, going through

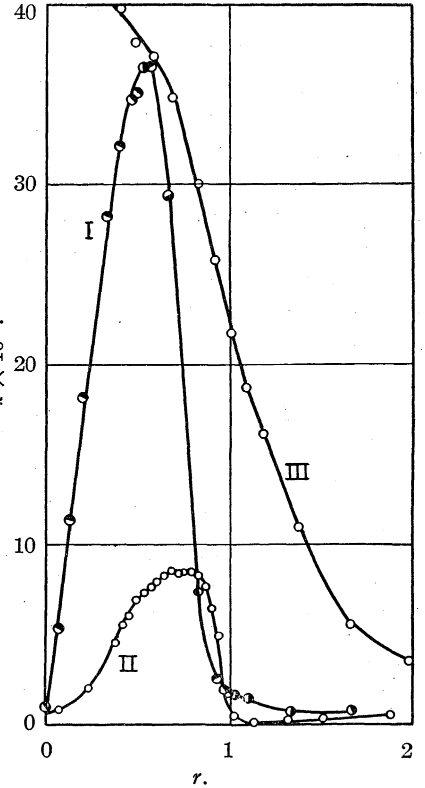

Fig. 7.—D. c. titrations in benzene.

---

[13] J. A. Geddes and C. A. Kraus, *Trans. Faraday Soc.*, **32**, 585 (1936).

[14] J. Wyman, *Phys. Rev.*, **33**, 623 (1930).

[15] Fuoss, *Chem. Rev.*, **17**, 27 (1935).

an inflection point at the equivalence point corresponding to lead chloride. The initial solutions were clear; then an opalescence appeared, and finally a precipitate formed as the amount of lead was increased.

The increase of conductance on adding tributylammonium chloride to lead abietate was certainly not due solely to the formation of tributylammonium abietate by metathesis: a 5×10^{-4} normal solution of abietic acid in benzene had a specific conductance of 0.07×10^{-12} and the addition of an equivalent amount of tributylamine raised this to only 0.15×10^{-12}, showing that the amine abietate is, as expected, an exceedingly weak electrolyte. An estimate from the above conductance gives it a dissociation constant of the order of 10^{-21} in benzene. Incidentally, it would be interesting to study the properties of acids and of their salts with weak bases in non-protonic solvents: this field is practically unexplored. In this particular case, the conductance of the tributylammonium abietate is completely negligible compared to the maximum specific conductance observed near $r = 0.5$ in the titration curves.

In Tables IV and V are given the results of the titrations in the closed cell, where moisture and oxygen were excluded and, as has been mentioned, where the determinations were made at 60 cycles on the Schering bridge.

TABLE IV

CONDUCTIMETRIC TITRATION OF LEAD ABIETATE WITH TRIBUTYLAMMONIUM CHLORIDE IN TOLUENE AT 35°. CONCENTRATION DATA

Series	$10^3 C_{Pb}$	$10^3 C_{Cl}$	w_0	w_{Cl}
1	4.083	13.29	74.85	27.86
2	1.686	9.51	79.27	16.62
3	1.073	9.51	69.50	12.99
4	0.740	9.51	73.89	14.43

In the second column of Table IV is given the initial concentration of lead abietate in equivalents per liter; in the third, the concentration of the tributylammonium chloride; in the fourth, the initial weight of toluene in the cell and in the last, the total weight of chloride solution added by the end of the titration. We used the density of the solvent (0.8538 g./cc. at 35°) as an approximation for the density of the solutions in calculating normalities from weight concentrations.

In Table V are given the conductances for the various solutions, corresponding to successive values of the ratio r of equivalents of chloride added to equivalents of lead initially present. For the most concentrated solution (Series 1), dielectric constants are also given.

Examples of the titration curves are shown in Fig. 8, where the logarithm of the specific conductance is plotted against r. It will be noted that the conductance rises by approximately two decades for the first half equivalent of chloride added. During the addition of the second half equivalent, the conductance drops to a very low value, and then rises again, corresponding to the conductance of the excess tributylammonium chloride now present in the solution.

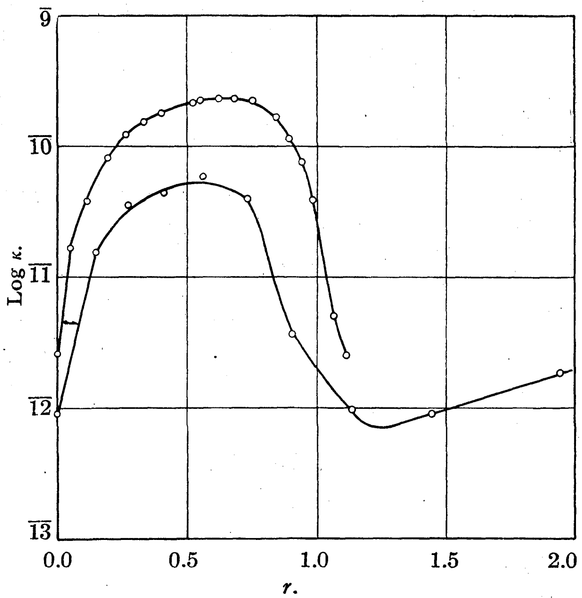

Fig. 8.—A. c. titrations in toluene.

The interesting part of the curve is, of course, the maximum. The following explanation is proposed. We know from the conductance curves of the tributylammonium chloride and lead abietate (Fig. 4, curves II and III) that these salts exist almost completely as ion pairs at the concentrations in question; only a minute fraction is present as free ions (singles or triples). The degree of dissociation involved is of the order of *one millionth* per cent. We also know that tributylammonium abietate is almost completely associated ($K \approx 10^{-21}$). In the first part of the titration, we therefore assume that the few free tributylammonium ions, present in the titrating solution added, combine with the abietate ions from the lead abietate solution in the cell, giving completely associated ion pairs of tributylammonium abietate.[16] This leaves $(PbAb)^+$ and

---

[16] We shall use the abbreviation "Ab" for $(C_{20}H_{29}O_2)^-$, the abietate ion.

Cl^- ions in solution. But the ion pair $(PbAb)^+(Cl^-)$ has a smaller coulomb binding energy than the $(PbAb^+)(Ab^-)$ pair, because the negative oxygens of the carboxyl group in the abietate ion can approach the lead ion closer than the chloride ion, a fact which makes for higher conductance. The practically irreversible reaction

$$Bu_3HN^+ + Ab^- \longrightarrow Bu_3N{\cdot}HAb$$

eventually removes all the free abietate ions from solution, leaving the ion pair equilibrium

$$PbAb^+ + Cl^- \rightleftarrows (PbAb^+)(Cl^-)$$

Then as more chloride is added, we get the reactions

$$(PbAb^+)(Cl^-) + (Cl^-) \rightleftarrows (Cl^-)(PbAb^+)(Cl^-)$$
$$(Cl^-)(PbAb^+)(Cl^-) \rightleftarrows Ab^- + PbCl_2\downarrow$$

In other words, the triple ion[12] formed from the abietate–chloride ion pair and a chloride ion rearranges to give lead chloride, which is insoluble and precipitates out, leaving (Bu_3HN^+) and (Ab^-) ions in solution. But since this ion pair is much more highly associated than the $(Cl^-)(PbAb^+)$ pair, the conductance again drops. The final rise is simply due to increasing $Bu_3HN{\cdot}Cl$ concentration, after the available lead has been precipitated as lead chloride.

The assumption that a soluble mixed salt, lead chloride–abietate (PbAb·Cl), is formed is in accordance with the observation that the initial additions of chloride to the lead solution produce no precipitate, and that the lead chloride only begins to precipitate in quantity as the $r = 0.5$ point is approached. The opalescence before this point corresponds to the formation of some lead chloride, and accounts for the displacement of the maximum to the right of the point where $r = 0.5$.

We also observed that lead chloride could be dissolved in a solution of tributylammonium chloride (evidence: increased conductance; black precipitate with hydrogen sulfide) which indicates that complexes can be formed in which lead is in the negative ion. This is in accord with the fact that the conductance minimum corresponds to a value of r somewhat greater than unity. We are inclined to ascribe the maximum in the preliminary $HCl–PbAb_2$ titration (Fig. 7) to the presence of moisture in the benzene; this experiment was made without exclusion of atmospheric moisture. Here the much weaker $H_3O^+{\cdot}Cl^-$ was probably the actual titrating solution.

The behavior of the solutions on the addition of chloride during titration was particularly interesting. In the first part of the titration, the conductance increased with time, approaching an asymptotic value (the values given in Table V) exponentially. On the down-side of the titration, the conductance decreased exponentially to an asymptotic value. Approach to within a per cent. or so of the limiting value was reached in serveral hours. If reactions of the type postulated above occur, we would expect finite times to be required for their completion, because the dissociation constants of the two reagents are of the order of 10^{-19}. The marked contrast to electrolytic reactions in water, which take place almost instantaneously, is easily understood when we recall that association of ions in aqueous solutions is negligible for salts of low valence type. These observations suggest a study of the rates of electrolytic dissociation in solvents of low dielectric constant through their conductance–time curves. With dissociation constants of the order of 10^{-20}, there should exist a measurable rate of establishment of equilibrium when an electrolytic solution in benzene, for example, is diluted. We hope that further work on this phase of the problem will be done.

The dielectric constant–concentration curve (Fig. 9) for series 1 of Table V gives further evidence for the existence of a stable mixed salt $(PbAb^+)(Cl^-)$. The dielectric constant goes through a maximum at the same point as the conductance curve, and, after a following minimum, rises at a rate corresponding to the presence of free $Bu_3HN{\cdot}Cl$ ion pairs. From the dielectric constant at the maximum point for Series 1, we have the data $\epsilon' = 2.378$ at $C = 3.52 \times 10^{-3}$. From these, we calculate $\mu(PbAb{\cdot}Cl) = 8.6 \times 10^{-18}$. This value is of the same order as that of the ion pair $Bu_3HN{\cdot}Cl$, and since it is due to the vectorially opposed (Pb^+Ab^-) and (Pb^+Cl^-) moments, we conclude that either the $(Cl^-)(PbAb^+)$ ion pair is not linear, or that the Pb–Cl bond is much more polar than the lead–carboxyl bond. The latter view is more probable, if we compare the dissociation constants of the two ion-pairs $(PbAb^+)(Ab^-)$ and $(PbAb^+)(Cl^-)$.

Finally, we consider the conductance curve of the mixed salt $(PbAb^+)(Cl^-)$. To a solution of 1.314×10^{-4} equivalent (0.1063 g.) of lead abietate in benzene was added an equivalent amount of tributylammonium chloride in benzene, giving a solution 1.943×10^{-3} normal in PbAbCl. No precipitate appeared, although the solution became opalescent. A regular dilution run was made on this solution, giving the conductance curve I of Fig. 4, where the equivalent conductance was calculated as that of PbAbCl. A typical conductance curve for a 1–1 salt appears. In Fig. 4 is given a $\Lambda\sqrt{c} - c$ plot for these data. From the intercept at $c = 0$, we obtain for the reaction

$$PbAb^+ + Cl^- \rightleftarrows PbAbCl$$

$K = 1.5 \times 10^{-17}$, assuming $\Lambda_0 = 100$. This result confirms the assumption made above that a chloride ion is less firmly bound to a lead ion than an abietate ion. The value 1.5×10^{-17} is of the order as that of the strongest electrolytes previously studied in benzene: for example, K for tetra-*i*-amylammonium picrate in benzene at 25° is 1.0×10^{-17}.

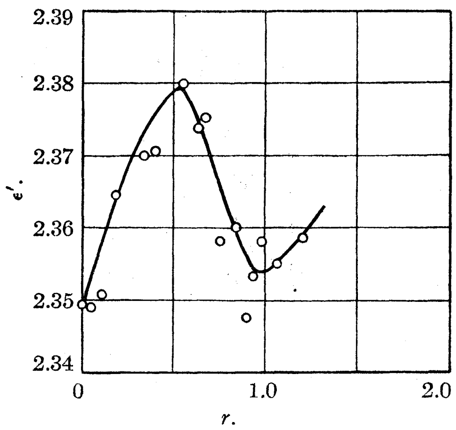

Fig. 9.—Change of dielectric constant during titration.

Summary

1. The conductances of lead abietate and of tributylammonium picrate and chloride in toluene at 35° have been determined at 60 cycles by means of the Schering bridge.

2. The polar moment of lead abietate in toluene is zero. Values for the other two salts check values in the literature.

3. The reaction between lead abietate and tributylammonium chloride in aromatic hydrocarbons has been studied. It is suggested that an intermediate soluble mixed salt, PbAbCl, is formed. The moment of the corresponding ion pair is 8.6×10^{-18} and its dissociation constant is approximately 1.5×10^{-17}.

4. An analytical method for the determination of lead in compounds soluble in aromatic hydrocarbons is described. The method depends on the fact that dry hydrogen chloride precipitates lead chloride quantitatively from benzene or toluene solutions of lead salts.

5. The preparation of pure lead abietate is described.

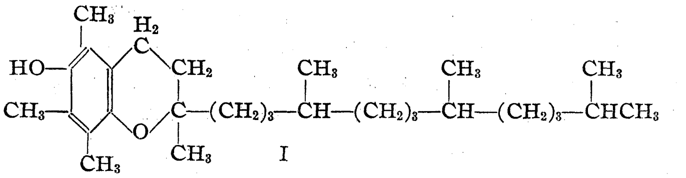
Studies on Vitamin E. Ethers of Durohydroquinone

BY E. FERNHOLZ[1] AND JACOB FINKELSTEIN

Ethers of durohydroquinone have attained significance to those conducting research on vitamin E since the discovery[2] that α-tocopherol gives this phenol in a high yield on thermal decomposition. In a recent publication[3] the reasons which led to the abandonment of the original idea that α-tocopherol might be a monoether of durohydroquinone were summarized. Experimental evidence was cited to prove that α-tocopherol is a derivative of 6-hydroxychromane of the probable structure I.



I

Our interest in the preparation of monoethers of durohydroquinone did not cease, at the end of last year, after we had convincing evidence that α-tocopherol was a chromane derivative of durene. This was due to the discovery by H. M. Evans and G. A. Emerson of the University of California that certain of these ethers showed definite vitamin E-like activity.[4]

The absorption spectra and reducing properties of the primary and secondary ethers, the preparations of which are described below, previously have been reported briefly.[3] With the exception of the monocetyl ether, all mono- and diethers were formed simultaneously by adding an equivalent amount of alcoholic potassium hydroxide to a gently refluxing alcoholic solution of durohydroquinone and the halide. The two ethers were separated by distillation or by taking advantage of their difference in solubility in alcohol. To prepare the monocetyl ether, the diether was refluxed with one mole of aluminum chloride in benzene. When two moles of aluminum chloride were used with the diether the cleavage was complete. The properties of our mono- and dicetyl ethers are in good agreement with the properties of those prepared by John,[5] who used a method similar to that first mentioned. These ethers were also prepared by Bergel, *et. al.*,[6] by a slightly different method, but the melting points and analyses indicated that they were not quite pure.

In order to synthesize 2-methyl-*n*-octadecyl alcohol, an intermediate for one of the ethers, we first prepared ethylmethylcetyl malonate. Partial hydrolysis and decarboxylation of this gave ethyl α-methylstearate. This ester was reduced to the corresponding alcohol by hydrogen under high pressure in the presence of copper chromite catalyst.[7]

Although the preparation of the primary and secondary ethers did not prove to be difficult, the preparation of tertiary ethers of durohydroquinone failed completely as might have been expected.

Experimental

Mono-*s*-butyl Ether of Durohydroquinone.—To a gently boiling alcoholic solution of 8.6 g. of durohydroquinone and 20.2 g. of *s*-butyl iodide in an atmosphere of hydrogen, 111 cc. of 0.9 normal alcoholic potassium hydroxide was added in small drops over a period of fifteen minutes. After several hours of refluxing, the solution was cooled, diluted with an equal volume of water and extracted with ether. After it had been dried and concentrated, the oil was distilled.

After a forerun, consisting mainly of duroquinone, the monoether distilled at air-bath temperature of 145 to 150° at 0.05 mm. It was recrystallized from petroleum ether and obtained in the form of small needles; m. p. 85–86°; yield 0.5 g. This compound reduced silver nitrate slowly.

Anal. Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97. Found: C, 75.57; H, 10.20.

The acetyl derivative was prepared by refluxing with excess acetic anhydride for twenty-four hours. The compound was obtained as long needles from alcohol; m. p. 62–63°.

Anal. Calcd. for $C_{16}H_{24}O_3$: C, 72.69; H, 9.15. Found C, 72.88; H, 9.13.

Ethers of Durohydroquinone and Dodecyl Iodide.—As described above, 20 g. of dodecyl iodide, 8.3 g. of durohydroquinone in 50 cc. of alcoholic potassium hydroxide were interacted and worked up.

The monoether distilled at an air-bath temperature of 160° at 0.05 mm., and recrystallized from alcohol; m. p. 96–97°; yield 5 g.

Anal. Calcd. for $C_{22}H_{38}O_2$: C, 78.99; H, 11.45. Found: C, 79.30; H, 11.25.

The residue from the above distillation, which contained the diether, was dissolved in chloroform and filtered through charcoal. Upon evaporation of the solvent a white crystalline substance was obtained which was further purified by recrystallization from alcohol; m. p. 79–80°; yield 3.5 g.

Anal. Calcd. for $C_{34}H_{62}O_2$: C, 81.21; H, 12.43. Found: C, 81.13; H, 12.39.

Ethers of Durohydroquinone and Cetyl Iodide.[5,6]—As described above, 6.6 g. of durohydroquinone, 14 g. of cetyl iodide in 100 cc. of amyl alcohol and 200 cc. of 2 normal solution of potassium hydroxide in amyl alcohol were interacted. After refluxing several hours and as a crystalline substance formed, the mixture was diluted with water and ether and filtered. The undissolved crystals were purified by first crystallizing from chloroform-alcohol mixture and then from butanol and obtained as white leaflets. The crystals do not reduce silver nitrate, as the product is the diether; m. p. 88–89°.

Anal. Calcd. for $C_{42}H_{78}O_2$: C, 82.02; H, 12.78. Found: C, 82.06; H, 12.76.

The mono-ether was obtained from the diether, as follows.

To 3.6 g. of dicetyl ether of durohydroquinone in 50 cc. of benzene, 0.9 g. of aluminum chloride (1.1 mol) was added and the mixture refluxed for eight hours. It was washed successively with dilute hydrochloric acid, dilute sodium hydroxide, water and then concentrated until crystals appeared. It was now diluted with alcohol and filtered. After dissolving the precipitate in ether, the solution was washed with Claisen solution (equal parts of 50% potassium hydroxide solution in water and methanol), dried and distilled. After a forerun of duroquinone and some halide, the monoether distilled at air-bath temperature at about 190° at 0.05 mm. After recrystallizing from alcohol, it melted at 99–100.5° and reduced silver nitrate; yield 0.4 g.

Anal. Calcd. for $C_{26}H_{46}O_2$: C, 79.94; H, 11.87. Found: C, 79.98; H, 11.74.

When the above procedure was repeated using 2.7 g. of dicetyl ether and 1.35 g. of aluminum chloride in 50 cc. of benzene, the cleavage was so complete that no monoether was isolated.

Ethers of Durohydroquinone and Octadecyl Iodide.—In the usual way, 8.3 g. of durohydroquinone, 24 g. of octadecyl iodide in 50 cc. of alcohol and 50 cc. of normal alcoholic potassium hydroxide were interacted. After three hours, the mixture was cooled and the crystals which separated were filtered. The product was recrystallized from a hot mixture of alcohol and benzene to give the pure diether; m. p. 95–97°.

Anal. Calcd. for $C_{46}H_{86}O_2$: C, 82.32; H, 12.91. Found: C, 82.49, 82.25; H, 12.92, 12.84.

The mother liquor was concentrated to dryness and the residue dissolved in ether. This solution was washed with Claisen solution, dried and concentrated. The monoether distilled at 0.05 mm. with air-bath temperature at 170–190°. It was then recrystallized from alcohol and obtained as white leaflets. It reduces silver nitrate; m. p. 105.5°.

Anal. Calcd. for $C_{28}H_{50}O_2$: C, 80.32; H, 12.04. Found: C, 80.43, 80.16; H, 11.92, 12.18.

Methyl *n*-Heptadecyl Ketone.—This compound was prepared from barium stearate and barium acetate by the method of Morgan and Holmes.[8]

Methyl-*n*-heptadecylcarbinol.—A solution of 29 g. of the above ketone in 500 cc. of glacial acetic acid was hydrogenated at room temperature and atmospheric pressure using Adams platinum catalyst. The required amount of hydrogen was absorbed in twenty-five minutes and the solution was filtered. Upon the addition of water to the filtrate, a precipitate was obtained which was dissolved in ether and washed with dilute caustic and water. After drying, the ether was distilled and the remaining liquid was treated with excess alcoholic potash to saponify any ester that might have formed. The product was extracted with ether, dried and the oil obtained on concentration was treated with 21 g. of *p*-nitrobenzoyl chloride in pyridine. After recrystallization from petroleum ether, the derivative melted at 95.5°; yield 40 g.

Anal. Calcd. for $C_{26}H_{43}O_4N$: C, 72.02; H, 10.00. Found: C, 72.22, 72.14; H, 9.87, 9.64.

A solution of 38 g. of the above *p*-nitrobenzoate in 90 cc. of alcohol containing 4.5 g. of potassium hydroxide was refluxed for one hour. After diluting with water, extracting with ether and concentrating, a crystalline compound was obtained. After recrystallizing it from petroleum ether the m. p. was 48–49°; yield 17 g.

Anal. Calcd. for $C_{19}H_{41}O$: C, 79.93; H, 14.47. Found: C, 80.11; H, 14.30.

***n*-Nonadecyl Bromide-2.**—A stream of hydrogen bromide was passed into 15 g. of the above alcohol, heated in an oil-bath at 110–120° until the reaction was completed. The product was cooled, dissolved in chloroform, washed with concentrated sulfuric acid, water and then dried over calcium chloride. The chloroform was evaporated under reduced pressure and the oil which remained distilled at an air-bath temperature of 170° at 0.05 mm. The distillate was slightly yellow and turned darker on standing; yield 13 g.

Anal. Calcd. for $C_{19}H_{39}Br$: Br, 23.00. Found: Br, 23.65.

Ethers of Durohydroquinone and *n*-Nonadecyl Bromide-2.—In the usual way, 5.7 g. of durohydroquinone, 11 g. of *n*-nonadecyl bromide-2 in 50 cc. of alcohol and 37 cc. of 0.9 normal alcoholic potassium hydroxide were interacted. When the reaction mixture was neutral, it was diluted with water and extracted with a large volume of ether. After drying and concentrating, a crystalline product was obtained. Upon distillation at 0.05 mm. and air-bath temperature of 180–200°, the monoether was obtained. It was recrystallized from alcohol; m. p. 94–95°; yield 5 g. This compound reduced silver nitrate solution.

Anal. Calcd. for $C_{29}H_{42}O_2$: C, 80.49; H, 12.12. Found: C, 80.21; H, 11.93.

To obtain the diether, the residue in the flask was dissolved in chloroform and treated with charcoal. The

---

solvent was evaporated and the product recrystallized from alcohol–benzene mixture; yield 3.5 g., m. p. 75–76°.

Anal. Calcd. for $C_{48}H_{90}O_2$: C, 82.45; H, 12.97. Found: C, 82.20; H, 13.00.

Ethyl Methyl Cetyl Malonate.—To a solution of 5.2 g. of sodium in 100 cc. of absolute alcohol, 40 g. of ethyl methylmalonate was added. Then, 77 g. of cetyl iodide was added and the mixture refluxed until neutral. The alcohol was distilled *in vacuo* and the residue extracted with ether. The oil obtained after concentration was fractionated at reduced pressure: at 1 mm., b. p. 185–190°; yield 63 g.

Anal. Calcd. for $C_{24}H_{48}O_4$: C, 71.95; H, 12.07. Found: C, 72.47; H, 11.82.

Ethyl α-Methylstearate.—A mixture of 30 g. of the above malonate and 4.6 g. of potassium hydroxide in 52 cc. of alcohol was refluxed for sixteen hours. The solution was diluted with water and alcoholic potassium hydroxide and extracted with ether. The aqueous solution was acidified to congo with concentrated hydrochloric acid and the oil separated. After drying, the oil was heated at 180° until no more carbon dioxide was evolved. After cooling, it was taken up with ether and washed with dilute sodium carbonate and water and distilled, after drying: at 1 mm., b. p. 161–163°; yield 20 g.

Anal. Calcd. for $C_{21}H_{42}O_2$: C, 77.24; H, 12.96. Found: C, 77.56; H, 12.70.

2-Methyl-*n*-octadecyl Alcohol.—An alcoholic solution of 14 g. of the above ester, in the presence of 1 g. of copper chromite, was heated at 250° under 2000 lb. (133 atm.) pressure of hydrogen for eight hours. After cooling and filtering, the product was distilled. At air-bath temperature of 125–130° and 0.05 mm., the alcohol was obtained and upon cooling it solidified; m. p. 32–33°; yield 12 g.

Anal. Calcd. for $C_{19}H_{40}O$: C, 80.21; H, 14.17. Found: C, 80.25; H, 14.00.

2-Methyl-*n*-Octadecyl Iodide.—A mixture of 12 g. of the above alcohol, 6 g. of iodine and 1 g. of red phosphorus was heated at 170–180° for one hour. The product was dissolved in ether and washed with water, thiosulfate, water and then dried. On distilling at 0.05 mm. and air-bath temperature of 185°, a colorless liquid is obtained which soon turns pink; yield 14 g.

Anal. Calcd. for $C_{19}H_{39}I$: C, 57.86; H, 9.96. Found: C, 57.74; H, 10.04.

Ethers of Durohydroquinone and 2-Methyl-*n*-octadecyl Iodide.—In the usual way, 5.5 g. of durohydroquinone, 13 g. of the above iodide in alcohol and 28 cc. of 1.15 *n* alcoholic potassium hydroxide interacted. After several hours of refluxing, water was added and the precipitate dissolved in ether. The extract was washed with Claisen solution, water and then dried. On distillation at 0.05 mm., a fore-run of a hydrocarbon and duroquinone was obtained and then at an air-bath temperature of 210–220°, the mono-ether distilled. After recrystallization from alcohol, it was obtained pure, m. p. 94–95°; yield 2 g. The reducing power of this ether was rather strong but not like that of α-tocopherol.

Anal. Calcd. for $C_{29}H_{52}O_2$: C, 80.49; H, 12.12. Found: C, 80.44; H, 11.91.

The residue was dissolved in chloroform and filtered through charcoal several times. The solvent was evaporated and the diether recrystallized from alcohol, m. p. 76–78°; yield 1 g.

Anal. Calcd. for $C_{48}H_{90}O_2$: C, 82.45; H, 12.97. Found: C, 82.34; H, 12.99.

We gratefully acknowledge our indebtedness to Messrs. D. F. Hayman and W. Reiss for the microanalyses.

Summary

Several mono- and diethers of durohydroquinone have been prepared.

RAHWAY, NEW JERSEY RECEIVED JULY 22, 1938

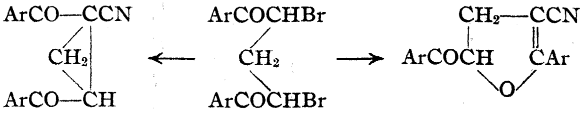
The Action of Sodium Cyanide on 1,3-Dibromo-1,3-dibenzoylpropane

BY REYNOLD C. FUSON, J. R. LITTLE AND GAIL MILLER

The successful closure of the cyclobutane ring by treatment of α,α′-dibromoadipic esters with sodium cyanide[1] could not be extended to 1,4-dibromo-1,4-diaroylbutanes. The latter underwent closure to cyanodihydro-1,4-pyrans, *i. e.*, to six-membered rings.[2] The present work grew out of an attempt to extend the method to the closure of a 1,3-dibromo-1,3-diaroylpropane (I). It was thought that this compound might yield a cyclopropane derivative (II) or a cyanodihydrofuran derivative (III) depending on whether the reaction resembled the cyclobutane or the dihydro-1,4-pyran closure.



II I III

In an effort to determine which of these two courses the reaction would follow, we have treated 1,3-dibromo-1,3-dibenzoylpropane (IV) with sodium cyanide. A rapid reaction took

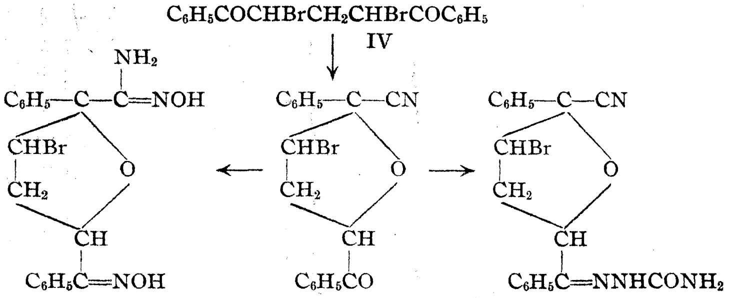
[2] Fuson, Kuykendall and Wilhelm, THIS JOURNAL, **53**, 4187 (1931).

place, but there were no cyclopropane or dihydrofuran derivatives among the products. A mixture of four isomeric compounds was obtained. The molecular formula was $C_{18}H_{14}O_2NBr$. The net change in the molecule, therefore, consisted in the loss of one bromine atom and the gain of one carbon atom and one nitrogen atom.

The observation that there are four isomers and that they do not give a precipitate with alcoholic silver nitrate greatly restricts the number of possible structures. Of these only that of 2-cyano-2-phenyl-3-bromo-5-benzoyltetrahydrofurans (V) satisfies all of the requirements. In particular, the fact that it is a β-bromo ether would account for the inertness of the bromine atom toward silver nitrate.[3]

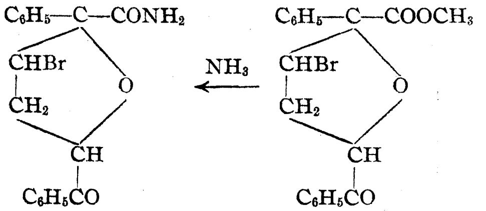
The products correspond to the four pairs of optical isomers theoretically possible on the basis of formula V, and for convenience have been called A, B, C and D. A few reactions have been run on all four compounds to show their similarity, but many of the reactions have been carried out only with A, the most plentiful isomer.



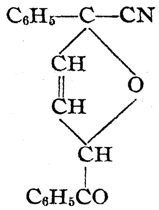
VI V VII

Treatment with hydroxylamine converted the four compounds into similar derivatives having the formula $C_{18}H_{18}O_3N_3Br$. These have been assigned formula VI—that of 2-phenyl-3-bromo-5-oximinobenzoyltetrahydrofuramidoxime. The change in composition indicates that the ketone group has been converted to an oximino group and the cyano group to an amidoxime group as reported by Tiemann.[4]

Isomers A, B and D yielded different monosemicarbazones (VII) which confirm the presence of one carbonyl group. Treatment of A and B with acids gave amides (VIII) which resisted attempts to bring about hydrolysis to the corresponding acids. Isomer A was transformed into a mixture of the amide (VIII) and the methyl ester (IX) by treatment with a solution of hydrogen chloride in methanol. Ammonia converted the ester to the amide.



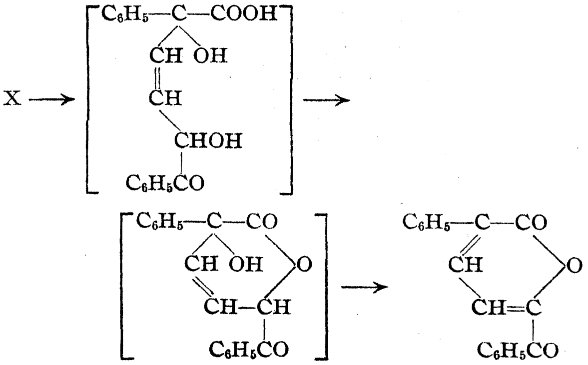
VIII IX



X

The most interesting reaction of A, B, C and D occurred when they were treated with aqueous alkali. All lost a molecule of hydrogen bromide and gave the same product. This result may be explained by reference to formula X which has two asymmetric carbon atoms one of which—that attached to the benzoyl group—might be expected to undergo inversion due to enolization. The latter process would be favored by the alkalinity of the reaction medium. In this connection it is interesting to note that isomer C was found to change spontaneously into isomer B—a result which can be explained in a similar manner.

Further evidence for the structure of the dihydrofuran (X) was obtained by treating it with strong acid. By this process a nitrogen-free product was obtained which had the formula $C_{18}H_{12}O_3$, and was shown to be 3-phenyl-6-benzoyl-1,2-pyrone (XI). The following sequence of reactions appears probable



XI

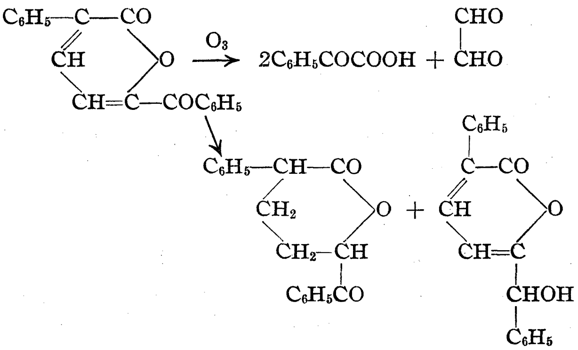
In an attempt to benzoylate the 1,2-pyrone (XI) it was dissolved in hot alkali and treated with benzoyl chloride. From the alkaline solution it was possible to isolate an acid whose com-

---

(3) See Kirner, THIS JOURNAL, **48**, 2745 (1926).

(4) Tiemann, *Ber.*, **17**, 126 (1884).

position corresponded to that of the monohydrate of the diketo acid, $C_6H_5COCOCH_2CH{=}C(C_6H_5)COOH$. The presence of a ketone group in the 1,2-pyrone (XI) was established by oximation; two forms of the oxime were isolated. Degradation of the 1,2-pyrone into known compounds was accomplished by ozonization followed by catalytic reduction of the ozonide. Phenylglyoxylic acid and glyoxal were isolated in the form of their phenylhydrazine derivatives

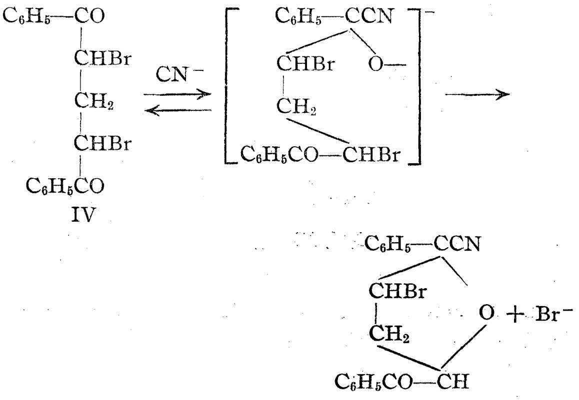


XII XIII

When the pyrone was reduced catalytically α-phenyl-δ-benzoyl-δ-valerolactone (XII) was isolated. It was accompanied by a dihydro derivative of the pyrone which formed an acetate, and may be the carbinol (XIII) resulting from reduction of the carbonyl group.

Discussion of Results

The transformation of 1,3-dibromo-1,3-dibenzoylpropane (IV) into the 2-cyano-2-phenyl-3-bromo-5-benzoyltetrahydrofurans (V) is complete in a minute or two and no appreciable amount of heat is liberated. It does not take place at all unless water is present. Apparently the first step in the reaction is the addition of cyanide ion to one of the carbonyl groups.[5] Ring closure is then effected by the elimination of a bromide ion.

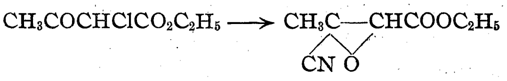


IV

V

This suggests that the addition of the cyanide ion is a rapid reversible reaction which goes to completion because the ring closure is irreversible.

The process is similar to that involved in the formation of α-epoxy nitriles from α-halo ketones. Favrel and Provost,[6] for example, showed that potassium cyanide converted ethyl α-chloroacetoacetate into the corresponding epoxy nitrile



$$CH_3COCHClCO_2C_2H_5 \longrightarrow \underset{CN\ O}{CH_3C}{-}CHCOOC_2H_5$$

Similar results were obtained by Kohler and Brown[7] and by Richard[8] with desyl chloride. Richard[9] also converted α-chloro-α-phenylacetone into α-epoxy-α-methyl-β-phenylpropionitrile by this method.

These examples might lead one to think that this type of reaction would be general for ketones which have a halogen atom in the α-, γ- or perhaps δ-position. Yet Wohlgemuth[10] reported that it could not be carried out with γ-chloropropyl ethyl ketone. Allen and Boyer[11] found that γ-chlorobutyrophenone when treated with potassium cyanide in absolute alcohol gave cyclopropyl phenyl ketone and none of the cyanotetrahydrofuran which might have been expected. Since the closure under consideration occurs only in the presence of water, we repeated the experiment of Allen and Boyer using, however, aqueous alcohol as the solvent; there was no reaction after two hours at room temperature.

Another and perhaps more striking example of this sort is afforded by the work on 1,4-dibromo-1,4-diaroylbutanes which, as has been indicated earlier, react in a manner entirely different from that observed with the next lower homolog.

In conclusion it may, therefore, be said that the action of sodium cyanide on 1,3-dibromo-1,3-dibenzoylbutane to give 2-cyano-2-phenyl-3-bromo-5-benzoyltetrahydrofurans is an extension of a new type of reaction hitherto limited to the formation of epoxy nitriles. The conditions which have obtained in all of the examples cited are the following:

1. Water is present in the solvent. 2. The halogen atom directly involved is in the α-position relative to an activating group such as a carbonyl or phenyl group. 3. The carbonyl group which enters into the reaction has a halogen atom in the α-position with respect to it. 4. The reactive groups involved are conveniently spaced for ring formation.

That the foregoing conditions are necessary remains to be shown. That they are not always sufficient is indicated by the results with 1,4-dibromo-1,4-dibenzoylbutane. This and other types of halo ketones are being examined in an effort to determine more precisely the generality of the reaction.

Experimental Part

The Preparation of the Isomeric 1,3-Dibromo-1,3-dibenzoylpropanes.—1,3-Dibenzoylpropane made by the method of Auger[12] was brominated according to the procedure of Conant and Lutz.[13] The latter authors reported two isomeric dibromides melting at 115–115.5 and 89°. In the present work the crude bromination product was fractionally crystallized from carbon tetrachloride. From 74 g. of crude product there was obtained 40 g. of a dibromide melting at 117–118° and 21 g. of a mixture which melted at 90–94°.

In an effort to separate the mixture absolute alcohol was used as a solvent. A chance seeding gave crystals which melted at 112–113°. A mixture of these with those melting at 117–118° melted at 92–95°. It appears probable that the low-melting isomer reported by Conant and Lutz is really a mixture of the two forms.

Anal. Calcd. for $C_{17}H_{14}O_2Br_2$: C, 49.8; H, 3.4. Found for the compound melting at 117–118°: C, 49.8; H, 3.7. Found for the compound melting at 112–113°: C, 50.2; H, 4.2.

Conversion of 1,3-Dibromo-1,3-dibenzoylpropane into the Isomeric 2-Cyano-2-phenyl-3-bromo-5-benzoyltetrahydrofurans.—Sixty grams of 1,3-dibromo-1,3-dibenzoylpropane was suspended in 800 cc. of 95% ethyl alcohol in a flask equipped with a mechanical stirrer. A solution of 10 g. of sodium cyanide in 40 cc. of water was added gradually, with stirring, over a period of about three minutes. A slight coloration occurred and the dibromide went partially—sometimes wholly—into solution. A few minutes after the addition of the cyanide was complete a heavy precipitate formed suddenly. The stirring was discontinued after about fifteen minutes, the solid collected on a filter, dried and crystallized from carbon tetrachloride. In this way isomer A was obtained in white cotton-like needles melting at 166–167°.

The alcoholic mother liquors from the reaction were poured into water and the semi-solid material which separated was extracted with benzene. Acidification of the water–alcohol solution with hydrochloric acid seemed to hasten the extraction. The benzene layer was dried over sodium sulfate and concentrated under diminished pressure. Absolute alcohol was added to the viscous concentrate; cooling and triturating induced the formation of a finely divided crystalline precipitate. Alternate concentration of alcohol solutions and trituration with absolute alcohol gave several more crops of a mixture which proved to consist of A and its isomers.

No successful method was found for separating the isomers by fractional crystallization. This was finally accomplished by dissolving the mixture in hot methyl alcohol (about 200 cc. for each 10 g. of crystals), allowing the solution to cool so that the crystals formed slowly. The crystallization was carried out by pouring the hot methyl alcohol solution into a large crystallizing dish such that the depth of the solution was from 1 to 2 cm. The dish was then covered with a watch glass and allowed to stand for several days without disturbance.

When the crystals had grown to a sufficient size for handling, the mother liquor was carefully decanted and the different types of crystals were separated by picking them out mechanically. Compound A was found in clusters of very fine needles. Long oblong crystals occurring singly or in rosets melted at 101–102° and were designated Compound B. Compact clusters of opaque needles usually having a slight color melted at 120–123° and were called Compound D. Thick square plates softening at 101–102° and melting at 120° were found to contain both B and a third isomer, D. These square crystals formed only occasionally with methyl alcohol as the solvent, more frequently with a mixture of benzene and petroleum ether as solvent. The crystals of isomer D were tough and hard to grind whereas those of the other isomers were brittle. Isomer D was also found to exist in long slender needles melting at 108–109°. By rapid cooling and stirring the lower-melting form usually could be isolated; slower crystallization gave the higher-melting form.

Diamond-shaped crystals melting at 86–88°—obtained in only two of the several runs—were called isomer C. On being allowed to stand for long periods of time this isomer underwent isomerization to Compound B. The fact that C was not found in all preparations was probably due to its tendency to rearrange to B during the process of recrystallization.

The yields of the isomers were: A, 52–68%; B, 12–16%; C, 0–2%; D, about 6%. Approximately the same ratio of isomers was obtained from either the high-melting or the low-melting dibromide. Similarly, sodium cyanide and potassium cyanide gave about the same results.

Anal. Calcd. for $C_{18}H_{14}O_2NBr$: C, 60.7; H, 4.0; Br, 22.5; mol. wt., 356. Found for A (m. p. 166–167°): C, 60.4, 60.3; H, 4.0, 4.1; Br, 22.3; mol. wt., 346. Found for B (m. p. 101–102°): C, 60.3, 60.3; H, 4.1, 4.1. Found for C (m. p. 86–88°): C, 60.4, 60.4; H, 4.0, 4.1. Found for D (m. p. 120–123°): C, 60.5; H, 4.2.

Each of the four isomers was shown to contain bromine and nitrogen. None, however, gave even a turbidity when treated with boiling alcoholic solutions of silver nitrate.

Treatment of 1,3-Dibromo-1,3-dibenzoylpropane with Potassium Cyanide in Absolute Alcohol.—To a suspension of 1 g. of the dibromide (m. p. 116–118°) in 300 cc. of carefully prepared absolute ethyl alcohol was added 0.4 g. of

[13] Conant and Lutz, THIS JOURNAL, **49**, 1083 (1927).

potassium cyanide. After three days the mixture was found to contain none of isomers A, B, C and D but a new compound melting at 127–128.5°. It contained halogen, but was not further investigated.

The Isomeric 2-Phenyl-3-bromo-5-oximinobenzoyltetrahydrofuramidoximes.—The usual procedure for oxime formation was employed. The following table shows solvents used for recrystallization, the melting points and the analytical data. Mixed melting point determinations showed the four derivatives to be different.

Furamidoxime from	M. p., °C.	Recrystallization solvent	Analyses, % C	H	N	Br
A	171–173	Methyl alcohol	53.4	4.2	10.5	19.6
			53.5	4.5		
			53.7	4.5		
B	179–181	Methyl alcohol	53.6	4.7		
C	182–183	Ethyl alcohol			10.5	
D	180–182	Chloroform	53.4	4.5		
Calcd. for $C_{18}H_{18}O_3N_3Br$			53.5	4.5	10.4	19.8

The Semicarbazones of Isomers A, B and D.—These derivatives were prepared in the customary manner. Their melting points and analytical data are listed in the table.

Semicarbazone from	M. p., °C.	Analyses, % C	H	N	Br
A	202	55.2	4.3	13.4	19.4[a]
B	178–179	55.4	4.0	13.9	
D	202	55.5	4.1	13.2	
Calcd. for $C_{19}H_{17}O_2N_4Br$		55.2	4.1	13.5	19.4

[a] This compound was prepared and analyzed by Sister M. Faith Hand.

2-Phenyl-3-bromo-5-benzoyltetrahydrofuramide.—Three grams of isomer A was dissolved in a solution of 50 cc. of concentrated hydrochloric acid and 50 cc. of glacial acetic acid and the mixture was heated on a steam-bath for three hours. The resulting dark green solution was poured into water and the mixture neutralized with sodium bicarbonate and extracted with benzene. In addition to some unchanged A there was obtained colorless crystals of the amide which after recrystallization twice from ethyl alcohol and then once from methyl alcohol melted at 200–201°. The compound was insoluble in alkali. It contained nitrogen and halogen but gave no precipitate with hot alcoholic silver nitrate.

Anal. Calcd. for $C_{18}H_{16}O_3NBr$: C, 57.8; H, 4.3; N, 3.8. Found: C, 57.5; H, 4.4; N, 3.8.

Methyl 2-Phenyl-3-bromo-5-benzoyltetrahydrofuroate.—An ice-cold suspension of 6 g. of isomer A in 400 cc. of absolute methyl alcohol was saturated with dry hydrogen chloride gas. After the mixture had stood at room temperature for fifteen hours it was poured into 2 liters of water. The ester was extracted with benzene, the benzene evaporated and the residue crystallized from methyl alcohol. The compound formed compact crystals melting at 101–102°. It contained nitrogen and halogen but was not soluble in alkali and gave no precipitate with hot alcoholic silver nitrate.

Anal. Calcd. for $C_{18}H_{17}O_3Br$: C, 58.6; H, 4.4. Found: C, 58.4, 58.6; H, 4.6, 4.4.

A small amount of the corresponding amide (m. p. 200–201°) was also obtained.

A similar treatment of isomer B (later found to contain some of isomer D) gave no ester but an amide probably derived from isomer B but possibly from isomer D. It melted (from alcohol) at 207°, with decomposition.

Anal. Calcd. for $C_{18}H_{16}O_3NBr$: C, 57.8; H, 4.3; N, 3.8. Found: C, 58.0; H, 3.4; N, 3.9.

2-Cyano-2-phenyl-5-benzoyl-2,5-dihydrofuran (X).—To a solution of 50 g. of isomer A in 400 cc. of hot methyl alcohol was added a solution of 9 g. of sodium hydroxide in 250 cc. of water. After being refluxed for one hour on the steam-bath the hot solution was poured into 2 liters of water. Acidification with dilute hydrochloric acid changed the dark red color of the solution to a bright yellow. By extraction of this acidified solution with benzene the dihydrofuran was obtained which crystallized from benzene in bright yellow, cotton-like needles, melting at 136–137°, with darkening at 130°. These crystals turn brown in the light. The yield was 28 g.

Anal. Calcd. for $C_{18}H_{13}O_2N$: C, 78.6; H, 4.7; N, 5.1. Found: C, 78.5; H, 4.5; N, 5.2.

The same product was obtained from isomers B, C and D by similar treatment with sodium hydroxide. Potassium cyanide or sodium acetate could be used in place of sodium hydroxide but with those reagents conversion was incomplete.

3-Phenyl-6-benzoyl-1,2-pyrone (XI).—A mixture of 20.5 g. of dihydrofuran, 400 cc. of glacial acetic acid and 180 cc. of concentrated hydrochloric acid was heated on a steam-bath for fifteen hours and poured into 2500 cc. of water. The brown crystals which formed were treated with decolorizing charcoal and recrystallized from alcohol. In this way 16.5 g. of the pyrone was obtained as slightly colored crystals melting at 126–127°. The compound was insoluble in alkali, contained neither halogen nor nitrogen and readily decolorized an acetone solution of potassium permanganate.

Anal. Calcd. for $C_{18}H_{12}O_3$: C, 78.3; H, 4.4. Found: C, 78.2; H, 4.4.

The oxime crystallized from alcohol in large needles melting at 193–194°.

Anal. Calcd. for $C_{18}H_{13}O_3N$: N, 4.8. Found: N, 4.8.

From the mother liquors was obtained **an isomeric oxime** which crystallized from alcohol in large squares melting at 159–161°.

Anal. Calcd. for $C_{18}H_{13}O_3N$: N, 4.8. Found: N, 4.9.

The Ozonolysis of the 1,2-Pyrone.—In a large test-tube were placed 1.0 g. of the pyrone and 30 cc. of glacial acetic acid. The mixture was cooled in an ice-bath and ozonized oxygen was bubbled through it for five hours at 0° and then continued overnight, during which time the bath came to room temperature. About 0.1 g. of palladium catalyst on charcoal was added to the mixture and the test-tube was placed in the shaker of a catalytic reduction machine equipped with an open mercury manometer. The apparatus was evacuated until bubbles formed in the solution, and then hydrogen was admitted up to 800 mm. pressure. After the mixture had been shaken for four hours the pressure was 680 mm. The catalyst was removed by filtration and 5 cc. of water and 2 cc. of phenylhydrazine were added to the filtrate. The precipitate which formed almost immediately was collected on a filter and recrystallized several times from alcohol and from benzene. The **phenylosazone of glyoxal** was obtained in almost colorless crystals melting at 162–166°. The melting point of a mixture of this sample with an authentic one (m. p. 166–169°) was 163–167°.

The filtrate was poured into water and the solution extracted with benzene. The benzene was extracted with sodium carbonate solution. The resulting solution when acidified gave **the phenylhydrazone of phenylglyoxylic acid** which crystallized from benzene in bright yellow crystals melting at 159–160°. A mixture of this compound with an authentic specimen (m. p. 159–160°) melted at 159–160°.

α-Phenyl-δ-benzoyl-δ-valerolactone.—The 1,2-pyrone in methyl cellosolve was reduced catalytically in the presence of a platinum oxide catalyst. In addition to a small amount of unchanged 1,2-pyrone there were formed two hydrogenation products. These were separated by crystallization from carbon tetrachloride. The less soluble was purified by crystallization from benzene or aqueous alcohol. It melted at 137–138°. It was very soluble in alcohol, did not decolorize bromine in chloroform solution and was not attacked by chromic acid in acetic acid solution.

Anal. Calcd. for $C_{18}H_{14}O_3$: C, 77.7; H, 5.1. Found: C, 77.8; H, 5.1.

The acetate was formed by treatment with acetic anhydride and sodium acetate. It melted at 102–103°.

Anal. Calcd. for $C_{20}H_{16}O_4$: C, 75.1; H, 5.0. Found: C, 75.7; H, 5.0.

The oily residue left after the carbon tetrachloride mother liquor had evaporated was solidified when triturated with ethyl alcohol. Recrystallization from ethyl alcohol gave the valerolactone in diamond-shaped crystals mixed with crystals of the original 1,2-pyrone. The two types of crystals were separated mechanically. The new compound when pure melted at 142–143°. It was very soluble in carbon tetrachloride and did not decolorize a solution of bromine in carbon tetrachloride.

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.1; H, 5.8. Found: C, 77.3; H, 5.8.

In a second run in which fresh catalyst was introduced twice during the course of the hydrogenation the lactone was the only product which could be isolated.

Summary

1,3-Dibromo-1,3-dibenzoylpropane (IV) reacts with sodium cyanide to give a mixture of the four theoretically possible 2-cyano-2-phenyl-3-bromo-5-benzoyltetrahydrofurans (V).

Treatment with alkali converts the four isomeric tetrahydrofurans into 2-cyano-2-phenyl-5-benzoyl-2,5-dihydrofuran (X).

The dihydrofuran is transformed into 3-phenyl-6-benzoyl-1,2-pyrone (XI).

Ozonolysis of the 1,2-pyrone gave glyoxal and phenylglyoxylic acid. Reduction converted the 1,2-pyrone into α-phenyl-δ-benzoyl-δ-valerolactone (XII).

Studies in the Phenanthrene Series. XVIII. Synthesis of Acyl Compounds Derived from 1- and 4-Phenanthrol

By Harry M. Duvall[1] and Erich Mosettig

In the search for substances with oestrogenic activity, the plan has been developed to synthesize more or less simple phenanthrene derivatives containing a phenolic hydroxyl group and a carbonyl group, the latter being located either in a side chain attached to, or in a five- or six-membered hydroaromatic ring condensed with, the phenanthrene nucleus.

This communication describes the preparation by means of the Fries rearrangement and the Friedel–Crafts reaction of methyl and ethyl ketones derived from 1- and 4-phenanthrol. It was found that in the "1-series" the Fries rearrangement was much superior to the Friedel–Crafts reaction. 1-Hydroxy-2-acetylphenanthrene (I) and 1-hydroxy-2-propionylphenanthrene (II) were obtained in yields of 60 and 72%, respectively, in the Fries rearrangement, and in yields of only 30 and 26% by the Friedel–Crafts reaction.

In the "4-series," 4-hydroxy-*y*-acetylphenanthrene was formed in a poor yield only (30%) in the rearrangement of 4-acetoxyphenanthrene together with a small amount (6%) of another compound that is probably 4-hydroxydiacetylphenanthrene. In the Friedel–Crafts reaction, employing acetyl and propionyl chloride, diketones could be isolated in satisfactory yield (60–70%), but no monoketones were found.

While 4-methoxyphenanthrene reacted smoothly with acetyl and propionyl chlorides in the pres-

---

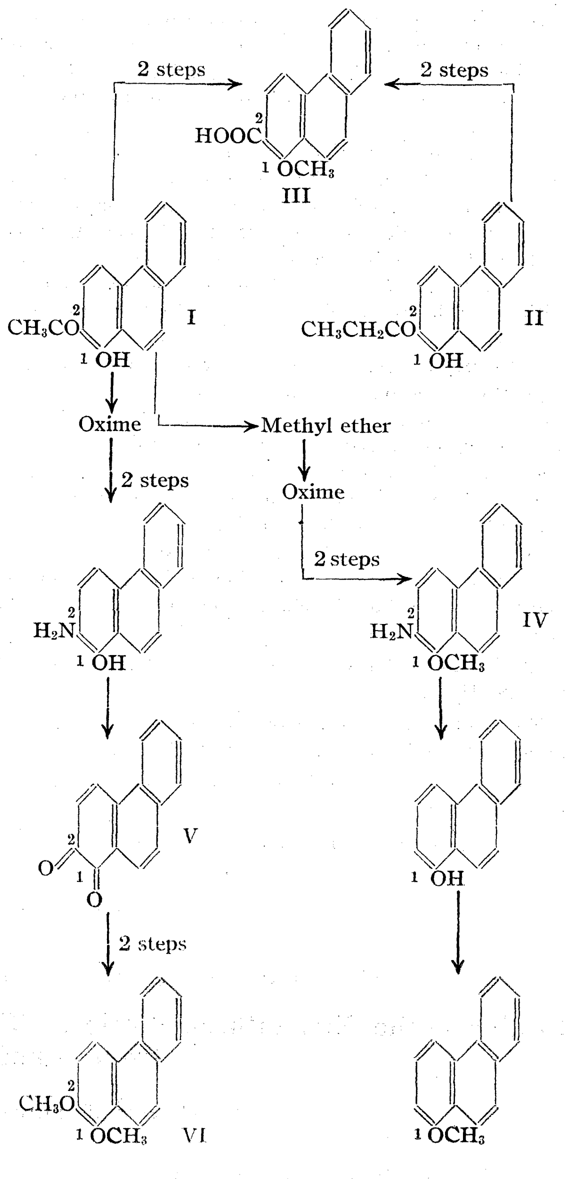
(1) E. R. Squibb and Sons Research Fellow.

ence of aluminum chloride to give 4-methoxy-*x*-acetylphenanthrene and 4-methoxy-*x*-propionylphenanthrene in yields of 70%, the analogous reactions with 1-methoxyphenanthrene, employing the solvents nitrobenzene, *sym*-tetrachloroethane, or a mixture of both, were entirely unsuccessful, resulting only in tarry products from which no individual compounds could be isolated.

That the acyl groups in both 1-hydroxy-2-acetylphenanthrene (I) and 1-hydroxy-2-propionylphenanthrene (II) occupy the same relative position was shown by the identity of the acids resulting from the oxidation of the methylated ketones with sodium hypochlorite.

The first attempt to determine the position of the acetyl group in the ketone I, though not successful, appears to be worthy of mention. The hydroxy ketone was methylated and its oxime subjected to the Beckmann rearrangement. The resulting methoxyacetylamino derivative was hydrolyzed and the methoxyaminophenanthrene (IV) was diazotized, with the expectation of arriving at a methoxyhydroxyphenanthrene that might be converted to a known dimethoxyphenanthrene. In the diazotization, however, elimination of the amino group, with simultaneous demethylation of the methoxyl group, took place and 1-phenanthrol was formed (identified through its methyl ether). The yield was about 10% and speculation concerning the mechanism of the formation of 1-phenanthrol seems to be, therefore, unimportant.

The structure of 1-hydroxy-2-acetylphenanthrene was established by transforming the oxime of ketone I to a hydroxyamino compound, which was oxidized with chromic acid to a quinone (V), the properties of which corresponded closely to those of 1,2-phenanthrenequinone described by Fieser.[2] We converted the quinone (V), via the hydroquinone, to a dimethoxy compound (VI), according to the directions of Fieser.[2] The latter compound (VI) was identified with an authentic sample of 1,2-dimethoxyphenanthrene, which was prepared in this Laboratory from 2-phenanthrol, according to Fieser.[2]



The acyl groups in 4-methoxy-*x*-acetylphenanthrene and 4-methoxy-*x*-propionylphenanthrene were shown to occupy the same relative position, by oxidation of the methoxy ketones with sodium hypochlorite to identical methoxycarboxylic acids. 4-Methoxy-*x*-acetylphenanthrene proved to be different from the methyl ether of 4-hydroxy-*y*-acetylphenanthrene (obtained by Fries rearrangement). Thereby the difference of the location of the acetyl group in both compounds became evident.

Attempts to locate the positions *x* and *y* by various methods have been without success so far. In a series of efforts to demethylate 4-methoxy-*x*-acetylphenanthrene (30% hydrogen bromide in glacial acetic acid, concentrated hydrochloric acid in a sealed tube, aluminum chloride in benzene, phosphoric acid), the methoxy ketone either was not attacked at all, or was destroyed. With a mixture of 48% aqueous hydrobromic acid and glacial acetic acid, demethylation

[a] A solution of 9.00 g. of 1-acetoxyphenanthrene in 110 ml. of nitrobenzene and a solution of 11.3 g. of aluminum chloride in 45 ml. of nitrobenzene were mixed and allowed to stand for forty-eight hours. [b] A solution of 3.30 g. of 1-propionoxyphenanthrene (prepared from 1-phenanthrol by the action of propionyl chloride in pyridine; m. p. 94–96°) in 15 ml. of nitrobenzene and a solution of 3.87 g. of aluminum chloride in 15 ml. of nitrobenzene were mixed and allowed to stand for seventy-two hours. [c] A solution of 8.00 g. of 4-acetoxyphenanthrene in 60 ml. of nitrobenzene and a solution of 10.0 g. of aluminum chloride in 40 ml. of nitrobenzene were mixed and allowed to stand for forty-eight hours. A small amount of a by-product, m. p. 193–194°, was obtained. This compound was probably 4-hydroxydiacetylphenanthrene. [d] Prepared from 4-hydroxy-*y*-acetylphenanthrene by methylation in the usual manner. [e] A solution of 7.10 g. of 4-methoxyphenanthrene and 2.70 g. of acetyl chloride in 36 ml. of nitrobenzene and a solution of 10.0 g. of aluminum chloride in 35 ml. of nitrobenzene were mixed and allowed to stand for forty-eight hours. [f] A solution of 4.00 g. of 4-methoxyphenanthrene and 1.84 ml. of propionyl chloride in 20 ml. of nitrobenzene and a solution of 5.64 g. of aluminum chloride in 20 ml. of nitrobenzene were mixed and allowed to stand for forty-eight hours. [g] A solution of 9.00 g. of 4-acetoxyphenanthrene and 3.96 ml. of acetic anhydride in 45 ml. of nitrobenzene and a solution of 11.3 g. of aluminum chloride in 45 ml. of nitrobenzene were mixed and allowed to stand for forty-eight hours. [h] Prepared from 4-hydroxydiacetylphenanthrene in the usual manner. [i] A solution of 6.40 g. of 4-phenanthrol and 6.31 ml. of propionyl chloride in 32 ml. of nitrobenzene and a solution of 9.70 g. of aluminum chloride in 32 ml. of nitrobenzene were mixed and allowed to stand for seventy-two hours.

was effected, but only with simultaneous elimination of the acetyl group.[3]

Furthermore, 4-methoxy-*y*-acetylphenanthrene was converted, through the oxime, and the rearrangement of the latter, to 4-methoxy-*x*-aminophenanthrene. It was planned to demethylate this compound and oxidize the expected hydroxy amine to a quinone. Unfortunately, we were unable to effect demethylation under varied experimental conditions.

It is not unlikely that one of the two positions, *x* and *y*, is position 1, and the other is position 3. Further, we believe it probable that in the diacetyl compound, at least one of the acetyl groups is located in position *x* or *y*.

Attempts to elucidate the structures of the compounds in the 4-series are being continued.

Experimental

1- and 4-acetoxyphenanthrene were prepared by boiling under reflux for five hours a solution of five parts of the respective phenanthrol and one part of anhydrous sodium acetate in fifty parts of acetic anhydride. The reaction mixture, after cooling to room temperature, was poured into water, whereupon the acetoxyphenanthrene separated in a practically pure state; m. p. 131–134, and 58–60°, respectively; yields, nearly quantitative.

1- and 4-methoxyphenanthrene were prepared, according to the method of Stevens and Tucker,[4] by adding dimethyl sulfate dropwise, with vigorous stirring, to a suspension of the acetoxyphenanthrene in a mixture of 66% potassium hydroxide solution and acetone (by weight, 1 part of acetoxyphenanthrene and 2.80 parts of potassium hydroxide; by volume, 1.45 parts of water, 10 parts of acetone and 1.60 parts of dimethyl sulfate). The reaction mixture was then poured into a large excess of water. The methyl ethers were obtained in a practically pure state (m. p. 101–103, and 65–67°, respectively), and were crystallized once from ethyl and methyl alcohol, respectively. The yields were nearly quantitative.

All other methylations cited in this communication were carried out by the procedure described above.

Friedel–Crafts Reaction.—Hydroxy-, acetoxy- or methoxyphenanthrene was dissolved in nitrobenzene and to the solution was added one or two moles, plus 10% excess, of acid chloride or acid anhydride. A solution of two moles, plus 10% excess, of aluminum chloride in nitrobenzene was poured slowly into the first solution, both solutions having been cooled previously in an ice-bath. The reaction mixture was kept at 0–5° for forty-eight or seventy-two hours and then decomposed by pouring onto ice and concentrated hydrochloric acid. The nitrobenzene was removed by steam distillation.

The reaction product from methoxyphenanthrene was

---

(3) An analogous elimination has been observed recently by Robinson and Walker, *J. Chem. Soc.*, 185 (1938). 1-Acetyl-2-hydroxynaphthalene, by boiling with hydriodic acid, readily gave 2-hydroxynaphthalene. See also Hill, Short and Stromberg, *ibid.*, 1619 (1937).

(4) Stevens and Tucker, *J. Chem. Soc.*, **123**, 2140 (1923).

purified by crystallization from alcohol, with use of Norite.

The reaction product from hydroxy- and acetoxyphenanthrenes was dissolved in an excess of 5% potassium hydroxide solution and alcohol, heated to boiling, to ensure complete saponification of any ester present. The hot solution was filtered and, after cooling to room temperature, acidified with concentrated hydrochloric acid. The hydroxyacylphenanthrene thus precipitated was collected and purified by crystallization from alcohol, with the use of Norite.

Fries Rearrangement.—The experimental procedure for the Fries rearrangement differed from that described for the Friedel–Crafts reaction only in that no acid chloride or acid anhydride was used.

Proof of Structure

1-Methoxyphenanthrene-2-carboxylic Acid (III).—A suspension of 0.20 g. of the methyl ether of ketone I (m. p. 80–81°) in 38 ml. of a 1% aqueous hypochlorite solution was boiled under reflux until a practically clear solution resulted. (The hypochlorite solution was prepared from calcium hypochlorite "HTH" and sodium carbonate.) The hot reaction mixture was filtered and cooled, and two grams of sodium thiosulfate was added. The acid (III), along with some sulfur, was liberated by acidification with concentrated hydrochloric acid. The sulfur was removed by digesting the precipitate with saturated sodium bicarbonate solution and filtering the solution while hot. The acid was regenerated by acidifying the filtrate at room temperature. Crystallized from alcohol, the acid was obtained as colorless needles; m. p. 224–225° (dec.).

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.79. Found: C, 76.17; H, 5.12.

The same acid was obtained by hypochlorite oxidation of the methyl ether of ketone II (m. p. 74–76°). The identity of these two acids was established by their melting points (224.5 and 223–224°, respectively) and a mixture melting point determination (224–225°) and by the melting points (109–110 and 109°) and mixture melting point (109–110°) of their respective methyl esters.

1-Methoxy-2-acetylphenanthrene.—The methyl ether of ketone I was prepared in quantitative yield by the methylation procedure described above. Crystallized from methyl alcohol, it was obtained as colorless plates; m. p. 81–82°.

Anal. Calcd. for $C_{17}H_{14}O_2$: OCH_3, 12.40. Found: OCH_3, 12.12.

Oxime.—A solution of one molecular equivalent of the above ketone, two moles of hydroxylamine hydrochloride and two and one-half moles of anhydrous sodium acetate in alcohol was boiled under reflux for four hours. The solution was then concentrated, cooled to room temperature and diluted with water until the oxime had separated completely. The yield was quantitative. Crystallized from methyl alcohol, the oxime was obtained as colorless needles; m. p. 166–167° (dec.).

Anal. Calcd. for $C_{17}H_{15}O_2$: N, 5.28. Found: N, 5.47.

1-Methoxy-2-acetylaminophenanthrene.—A solution of 1.00 g. of the above oxime in a mixture of 5 ml. of glacial acetic acid and 5 ml. of acetic anhydride was saturated with dry hydrogen chloride. The reaction mixture, now a solid paste, was allowed to stand for twenty hours, and was then poured onto ice and water. The acetylamino compound was collected, washed with water and dried; m. p. 220–222° (dec.). The yield was quantitative. After crystallization from methyl alcohol, 1-methoxy-2-acetylaminophenanthrene was obtained as colorless plates; m. p. 222–223° (dec.).

Anal. Calcd. for $C_{17}H_{15}O_2$: N, 5.28. Found: N, 5.12.

1-Methoxy-2-aminophenanthrene (IV).—A solution of 0.90 g. of the above N-acetylamine in a mixture of 10 ml. of 6 *N* hydrochloric acid and 10 ml. of glacial acetic acid was boiled under reflux for one hour. The amine hydrochloride, which separated on cooling the reaction mixture, was filtered off and converted to the free base by treatment with ammonium hydroxide. The amine (IV), obtained in a yield of 87%, was crystallized from alcohol: colorless needles, m. p. 139.5–141°.

Anal. Calcd. for $C_{15}H_{13}ON$: C, 80.70; H, 5.87; N, 6.27; OCH_3, 13.90. Found: C, 80.63; H, 5.93; N, 6.41; OCH_3, 13.34.

The amine was diazotized according to the method of De Milt and van Zandt.[5] A solution of 0.50 g. of the amine in 2.3 ml. of pyridine was added slowly (one hour) to a solution of nitrosyl sulfuric acid cooled to 0° with ice and salt. (The nitrosyl sulfuric acid solution was prepared by first adding 0.34 g. of sodium nitrite to a cold mixture of 3.4 ml. of concentrated sulfuric acid and 1.7 ml. of water, and then carefully warming the mixture to 40° until a clear solution resulted.) The mixture was stirred for an hour at 0° and then was diluted with ice and water to a volume of about 100 ml. An aqueous solution of 0.22 g. of urea was added and stirring was continued for another hour at 0°. The solution of the diazonium sulfate was filtered and added, in small portions, to 300 ml. of boiling water. Boiling was continued for about fifteen minutes. After standing overnight, the precipitate which had separated was filtered off and dissolved in 5% potassium hydroxide solution. The filtered alkaline solution was acidified with concentrated hydrochloric acid and the phenolic product (0.06 g.) thus obtained was methylated in the usual manner. The methylated product was purified by sublimation and crystallization and melted at 102–103°. It was shown to be 1-methoxyphenanthrene; a mixture melting point determination with an authentic sample (m. p. 103–104°) showed no depression (m. p. 103°).

Oxime of I.—The oxime of ketone I was prepared in the usual manner, yield quantitative. When first isolated, the oxime was nearly colorless, but it turned yellow on short standing. It crystallized from alcohol in yellow needles, m. p. 224–225° (dec.).

Anal. Calcd. for $C_{16}H_{13}O_2N$: C, 76.48; H, 5.21; N, 5.58. Found: C, 76.57; H, 5.42; N, 5.40.

1,2-Dimethoxyphenanthrene (VI).—A solution of 3.84 g. of the above oxime and 4 g. of phosphorus pentachloride in 500 ml. of dry benzene was boiled under reflux for thirty minutes, according to the method of Bachmann and Boatner.[6] The solution, after cooling to room temperature, was extracted with water, sodium bicarbonate solu-

[6] Bachmann and Boatner, *ibid.*, **58**, 2097 (1936).

tion and water again to remove phosphorus compounds. The dried benzene solution yielded 3.12 g. of crude 1-hydroxy-2-acetylaminophenanthrene.

The crude hydroxyacetylaminophenanthrene was hydrolyzed to the corresponding amine hydrochloride by boiling under reflux for one hour with 28 ml. of 6 *N* hydrochloric acid and 28 ml. of glacial acetic acid. The reaction mixture, after cooling in an ice-bath, was diluted with several volumes of water, and the amine hydrochloride which had separated was collected; yield 2.31 g.

The amine hydrochloride was converted, through the quinone (V) and the hydroquinone, to 1,2-dimethoxyphenanthrene (VI), according to the directions of Fieser,[2] as given for the analogous conversion of 1-amino-2-hydroxyphenanthrene hydrochloride to 1,2-dimethoxyphenanthrene. The dimethoxyphenanthrene thus obtained, after purification by sublimation and crystallization, melted at 103–104° (corr.). A mixture melting point determination with an authentic sample (m. p. 103–104°) showed no depression (m. p. 103–104°).

Anal. Calcd. for $C_{16}H_{14}O_2$: OCH_3, 26.05. Found: OCH_3, 25.91.

Samples of 1,2-phenanthrenequinone (V) from the above hydroxyamine hydrochloride and from 1-amino-2-hydroxyphenanthrene hydrochloride were purified by sublimation and crystallization. Both samples were brilliant red in color and gave in concentrated sulfuric acid the characteristic color change from blue to green. We found the melting point of both samples of the quinone to be indefinite and unsatisfactory for the purpose of identification (the quinone did not soften, but decomposed over a variable range of about ten to twenty degrees, starting at 190–195°).

4-Methoxyphenanthrene-*x*-carboxylic Acid.—4-Methoxy-*x*-acetylphenanthrene was oxidized to the corresponding carboxylic acid by the hypochlorite method described above. The acid, crystallized from toluene as colorless needles, melted at 238–239°.

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.79. Found: C, 76.92; H, 5.32.

The same acid was obtained by hypochlorite oxidation of 4-methoxy-*x*-propionylphenanthrene. The identity of these two acids was established by their melting points (238–239°) and a mixture melting point (238–239°).

Methyl Ester.—Both acids described above, from 4-methoxy-*x*-acetylphenanthrene and from 4-methoxy-*x*-propionylphenanthrene, were methylated in the usual manner. Both esters, crystallized from methyl alcohol and obtained as colorless needles, melted at 93–94°. A mixture melting point determination showed no depression (m. p. 93–94°).

Anal. Calcd. for $C_{17}H_{14}O_3$: C, 76.68; H, 5.30. Found: C, 76.63; H, 5.36.

Oxime of 4-Methoxy-*x*-acetylphenanthrene.—This oxime was prepared in the usual manner from 4-methoxy-*x*-acetylphenanthrene, yield quantitative. It crystallized from ethyl alcohol as colorless needles of m. p. 190–191° (dec.).

Anal. Calcd. for $C_{17}H_{15}O_2N$: N, 5.28. Found: N, 5.11.

4-Methoxy-*x*-acetylaminophenanthrene.—The above oxime rearranged to 4-methoxy-*x*-acetylaminophenanthrene in quantitative yield by the glacial acetic acid–acetic anhydride–hydrogen chloride method already described. Crystallized from methyl alcohol, the N-acetylamino compound appeared as colorless needles of m. p. 201°.

Anal. Calcd. for $C_{17}H_{15}O_2N$: N, 5.28. Found: N, 5.44.

Summary

1. A series of acyl compounds derived from 1- and 4-phenanthrol has been synthesized by means of the Fries rearrangement and the Friedel–Crafts reaction.

2. 1-Hydroxy-2-acetylphenanthrene and 1-hydroxy-2-propionylphenanthrene have been described and their structures have been established.

3. 4-Hydroxy-*y*-acetylphenanthrene, 4-hydroxydiacetylphenanthrene, 4-hydroxydipropionylphenanthrene, 4-methoxy-*x*-acetylphenanthrene and 4-methoxy-*x*-propionylphenanthrene have been described.

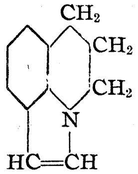
Synthesis of Polycyclic Indoles

BY GEORGE BARGER AND ELIZABETH DYER[1]

This research originated in an attempt to synthesize an indole, which had been obtained[2] by the degradation of the alkaloid calycanthine, and for which the following possible structure had been proposed



The synthesis of this indole was accomplished by condensing N-aminotetrahydroquinoline[3] with pyruvic acid, and converting the hydrazone thus obtained into 2-carboxy-1,8-trimethyleneindole by an application of the Fischer method.[4] Decarboxylation yielded the above 1,8-trimethyleneindole.

The structure of this indole was established by its conversion on reduction to 2,3-dihydro-1,8-trimethyleneindole or lilolidine, previously obtained by von Braun and co-workers through an independent synthesis.[5] The synthetic 1,8-trimethyleneindole was found to be not identical with the indole previously obtained from calycanthine. The properties of the calycanthine fragment differ also from those of the 3,4-trimethyleneindole described by Jacobs and Gould.[6]

The chemistry of polycyclic indoles of the type of 1,8-trimethyleneindole, a type which comprises both the tetrahydroquinoline and indole systems, was extended by the study of other members of the series. The 2-phenyl derivative of 1,8-trimethyleneindole was obtained from the hydrazone of acetophenone and N-aminotetrahydroquinoline. All attempts to prepare the corresponding 2-methyl derivative from the acetone hydrazone of N-aminotetrahydroquinoline were unsuccessful. A similar difficulty in preparing an indole from acetone-2-quinolyl hydrazone was experienced by Perkin and Robinson.[7]

With a view to applying the same type of reaction in the tetrahydrobenzoquinoline series, N-amino-1,2,3,4-tetrahydro-5,6-benzoquinoline was prepared. Although this readily formed a hydrazone with pyruvic acid, the corresponding indole could not be obtained. A similar resistance to indole formation was observed with the pyruvic acid hydrazone of N-amino-carbazole.

Grateful acknowledgment is made to the American Association of University Women for the Sarah Berliner Research Fellowship held by one of us (E. D.); and to the Moray Fund of Edinburgh University for a grant in support of the research.

Experimental Part

N-Amino-1,2,3,4-tetrahydroquinoline.—This substance was prepared from N-nitrosotetrahydroquinoline[8] by the method of Hoffmann and Königs.[3] To obtain 50% yields, care must be taken to keep the temperature of the reduction mixture between 60 and 75°. The product, purified by recrystallizing the sulfate, yielded a picrate (not previously described) which crystallized from alcohol as long, brownish-yellow needles, m. p. 140–141° with decomposition.

Anal. Calcd. for $C_{15}H_{12}O_7N_5$: N, 18.58. Found: N, 18.50.

Hydrazones.—The following table summarizes the successful methods of preparing the new hydrazones needed for indole syntheses. The hydrazones I and II were convertible to indoles, but all attempts to cyclize III, IV and V failed. The methods investigated included: heating with (a) zinc chloride at 100–130, 180–190° at 760 mm. or 110–120° at 12 mm.; (b) 10% aqueous hydrochloric acid at 50–60 or 80–100°; (c) dry hydrogen chloride gas in ethanol or *n*-butanol solution.

2-Carboxy-1,8-trimethyleneindole.—When a mixture of 2 g. of the pyruvic acid hydrazone of N-aminotetrahydroquinoline and 25 cc. of 10% hydrochloric acid was heated at 55° for one hour, the hydrazone gradually dissolved with the precipitation of the indole together with a dark impurity. The precipitate was filtered, dried, dissolved in ether and filtered from the small quantity of amorphous impurity. The ether solution was extracted with sodium carbonate, and 0.95 g. of the acid obtained on acidification of the basic extract (50% yield). For analysis the substance was recrystallized from benzene, from which it separated as needles, melting with decomposition at 210–212° when pure.

[a] A = N-amino-1,2,3,4-tetrahydroquinoline; B = N-amino-1,2,3,4-tetrahydro-5,6-benzoquinoline; C = N-aminocarbazole.

Anal. Calcd. for $C_{12}H_{11}O_2N$: C, 71.61; H, 5.51; N, 6.97. Found: C, 71.49; H, 5.54; N, 7.02.

The substance was easily soluble in cold methanol and ethanol, and in acetone, moderately soluble in ether and practically insoluble in water. It gave a violet Ehrlich reaction on boiling.

1,8-Trimethyleneindole.—This indole was obtained in 68% yield from the corresponding acid by an adaptation of Reichstein's procedure for decarboxylation.[9] A mixture of 1.5 g. of 2-carboxy-1,8-trimethyleneindole, 0.4 g. of copper chromite[10] and 4 cc. of quinoline was heated at 180–190° in a stream of hydrogen. After one hour the absence of a further precipitate in a barium hydroxide trap indicated completion of the reaction. The mixture was diluted with ether, filtered from the copper chromite and extracted with 2 *N* hydrochloric acid until no more quinoline was removed. A further extraction with dilute sodium carbonate removed traces of the carboxy acid. The ether solution was dried, the solvent evaporated and the residue distilled with steam. The indole, obtained from the distillate by filtration, was recrystallized from a small volume of petroleum ether (b. p. 40–60°). The product separated as large, colorless plates, m. p. 86.5–88° when pure.

Anal. Calcd. for $C_{11}H_{11}N$: C, 84.01; H, 7.06; N, 8.92. Found: C, 84.11; H, 7.02; N, 9.31.

The indole is very soluble in alcohol, acetone, benzene, moderately soluble in petroleum ether and insoluble in water. It is a neutral substance, insoluble in acids and bases. It gives a purple coloration with the Ehrlich reagent in the cold.

An unstable picrate of the indole was obtained by treating a concentrated benzene solution of the substance with a benzene solution containing slightly less than one equivalent of picric acid. The resulting red solution, when diluted with cold petroleum ether to faint turbidity, deposited red needles, melting at 138–139°.

Anal. Calcd. for $C_{17}H_{14}O_7N_4$: N, 14.51. Found: N, 14.67.

The picrate is decomposed by boiling water, by hot alcohol and even by hot benzene and petroleum ether.

2,3-Dihydro-1,8-trimethyleneindole.—When 0.2 g. of 1,8-trimethyleneindole in alcohol solution was reduced with zinc dust and hydrochloric acid, according to the procedure of Schlieper[11] for α-naphthindole, an oil was obtained which boiled at about 140° at 12 mm., and which yielded a yellow picrate that precipitated from ether solution. When recrystallized from alcohol, it separated in two forms, plates and needles, which, however, were identical in mixed melting point. The twice recrystallized picrate sintered at 165°, and liquefied at 168–170° to a red oil, which soon effervesced. The same substance was obtained by reduction of the indole with tin and hydrochloric acid.

Anal. Calcd. for $C_{17}H_{16}O_7N_4$: C, 52.56; H, 4.16; N, 14.43. Found: C, 52.80; H, 4.14; N, 14.47.

This picrate was identical in analysis and properties with the picrate of lilolidine, which was prepared according to von Braun[5] by condensation of trimethylene chlorobromide with dihydroindole.[12] The product was carefully fractionated to separate any unchanged dihydroindole from the lilolidine. The picrate of the highest fraction, after two recrystallizations from alcohol, did not lower the melting point of the picrate from dihydro-1,8-trimethyleneindole. It is to be noted, however, that although the melting point of the picrate was unchanged by this recrystallization, it is higher than that reported by von Braun.[5] The substance gave no evidence of melting at 138°, although held at that temperature for fifteen minutes, but sintered at 165°, and melted to a red oil at 168–170°. A duplicate preparation of lilolidine gave the same results. We have communicated with Professor von Braun, who admits the identity of our reduction product with lilolidine, and states that his original preparation was done under very adverse circumstances.

2-Phenyl-1,8-trimethyleneindole.—One gram of the hydrazone of N-aminotetrahydroquinoline and acetophenone was ground in a mortar with 5 g. of powdered anhydrous zinc chloride and the mixture was heated at 120° for one hour. The mass was then warmed with several small quantities of dilute hydrochloric acid to dissolve the zinc chloride. The residual gummy brown precipitate was filtered, dried, powdered and extracted with ether to separate the indole from brown ether-insoluble by-products. The residue obtained on evaporation of the extracts, when recrystallized from 10 cc. of alcohol, yielded 0.2 g. of the indole, m. p. 130–132° (22% yield). After two recrystallizations from alcohol, from which the substance separated as glittering, colorless leaves, it melted at 133–134°.

Anal. Calcd. for $C_{17}H_{15}N$: C, 87.50; H, 6.49; N, 6.01. Found: C, 87.32; H, 6.41; N, 5.91.

The substance gave with Ehrlich's reagent in the cold a violet color which turned blue on standing.

N - Amino-1,2,3,4-tetrahydro-5,6-benzoquinoline.—The necessary N-nitrosotetrahydrobenzoquinoline was prepared by the procedure of Bamberger and Müller.[13] Yields of 60–70% were obtainable if an adequate quantity of water was used to keep dissolved at 0° the rather insoluble salt of the tetrahydrobenzoquinoline.

The N-aminotetrahydrobenzoquinoline was prepared in yields of 35–40% by mild reduction of the nitroso compound with zinc dust and acetic acid in aqueous alcoholic solution, according to the procedure for N-aminotetrahydroquinoline. The product was isolated as the sulfate, which, after recrystallization from 0.6 N sulfuric acid, separated as glistening brown needles and leaves, m. p. 182° with decomposition.

Anal. Calcd. for $C_{26}H_{30}O_4N_4S \cdot 4H_2O$: N, 9.90. Found: N, 10.15.

Anal. of salt after drying at 120°. Calcd. for $C_{26}H_{30}O_4N_4S$: N, 11.34. Found: N, 11.30, 11.35.

The free base, formed by decomposition of the sulfate in hot aqueous–alcoholic solution with dilute alkali, consisted of tan crystals which melted at 107–108° after two recrystallizations from ligroin.

Anal. Calcd. for $C_{13}H_{14}N_2$: N, 14.18. Found: N, 13.94.

This hydrazine was moderately soluble in alcohol, nearly insoluble in water. It reduced Tollens' solution rapidly in the cold, and Fehling's solution slowly on boiling.

Summary

1. The chemistry of a new tricyclic indole, 1,8-trimethyleneindole, has been studied. The 2-carboxy and 2-phenyl derivatives are also reported, but the 2-methyl derivative could not be obtained. The preparation of the intermediate hydrazones, the pyruvic acid, acetophenone and acetone hydrazones of N-amino-1,2,3,4-tetrahydroquinoline is reported.

2. N-Amino-1,2,3,4-tetrahydro-5,6-benzoquinoline and its pyruvic acid hydrazone have been prepared. The latter is inactive toward indolizing agents.

3. The pyruvic acid hydrazone of N-aminocarbazole is likewise not convertible to an indole.

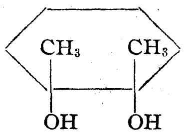
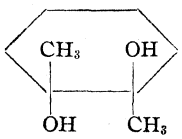
Inversion in the Pinacol Rearrangement of 1,2-Dimethylcyclopentanediol-1,2*

BY PAUL D. BARTLETT AND ABRAHAM BAVLEY

It has been pointed out[1] that in the pinacol rearrangement of the geometrical isomers of 1,2-dimethylcyclohexanediol-1,2 (I and II)



I



II

the methyl group migrates in preference to the ring carbon atom only in the *cis*-pinacol, in which the methyl group is, on a time average, remote from the hydroxyl which it displaces. Because the cyclohexane ring is non-planar and allows many different orientations of adjacent substituents with respect to each other, this example leaves something to be desired in exactness of interpretation. For this reason we have investigated the case of *cis*- and *trans*-1,2-dimethylcyclopentanediol-1,2, in which the planar nature of the five-membered ring makes the relative positions of the groups in space much more certain.

The assignment of configurations to the *cis*- and *trans*-isomers is made on the same basis as in the case of the analogous pinacols with six-membered rings. The *cis* isomer, a liquid boiling at 142–146° (20 mm.), is prepared by the action of potassium permanganate in cold aqueous acetone solution on 1,2-dimethylcyclopentene-1. The *trans* isomer, m. p. 99.5–101° (corr.), results

---

(*) Presented at the Milwaukee meeting of the American Chemical Society, September 6, 1938.

(1) Bartlett and Pöckel, THIS JOURNAL, **59**, 820 (1937).

from the hydrolysis of the oxide of the same hydrocarbon. The assignment of configurations is confirmed by the fact that lead tetraacetate reacts more than a thousand times as fast with the "*cis*" as with the "*trans*" isomer, in accordance with the findings of Criegee, Kraft and Rank[2] for cases where the configuration is in no doubt.

When the *cis* isomer is refluxed with 30% aqueous sulfuric acid, a ketone can be isolated in 87% yield (as semicarbazone) whose physical constants and whose oxime and semicarbazone show it to be identical with the 2,2-dimethylcyclopentanone-1 prepared in different ways by Blanc[3] and by Haller and Cornubert.[4] Thus the methyl group has migrated in that pinacol in which it is in a position to displace the adjacent hydroxyl group by attacking the opposite side of the carbon atom holding it, as in the Walden inversion.

Identical treatment of the *trans* pinacol gives only involatile brown tars, which on standing become progressively more viscous. All our efforts to isolate an unpolymerized product from this reaction have been without avail. Experiments with gentler acid conditions have led to the same type of product, when there was any reaction at all. It seems probable that the pinacol is being dehydrated without rearrangement to yield a dimethylcyclopentadiene which is polymerized irreversibly by any acid strong enough to bring about dehydration. We tried to prove this by carrying out the dehydration in the presence of maleic anhydride and of benzoquinone, but, as might have been anticipated, the diene addition to these reagents was unable to compete with the polymerization reaction under these acid conditions, and again only tar was obtained. An attempt to catch the diene by bromination also failed.

For the interpretation of these reactions it becomes important to know whether this resinification process occurs because the structure and configuration of this pinacol are especially favorable to it, or especially unfavorable to rearrangement, which must be regarded as the normal reaction. To answer this question we carried out some semiquantitative experiments on the reaction rates of the two pinacols when treated under identical conditions with sulfuric acid in aqueous solution at 52°. Under these conditions, with 0.2 *N* acid, the *cis* pinacol was 53.9% converted in two and one-half hours, while only 24% of the *trans* isomer had disappeared in the same length of time. The actual difference in rate between the two isomers is somewhat greater than appears from these figures; for the *cis* pinacol reacts fast enough with lead tetraacetate to be titrated by this reagent, whereas actual isolation of the *trans* pinacol, with attendant manipulative losses, was the only way we found to follow its reaction. The results are consistent with the view that the constitution of the *trans* pinacol is so unfavorable to rearrangement that here alone the slow simple dehydration takes precedence over the pinacol rearrangement.

The results with the five- and six-membered rings support the generalization that a group cannot migrate in the pinacol rearrangement unless by a simple movement it can reach the adjacent carbon atom on the face opposite to the hydroxyl group which it is replacing. Thus in these pinacols the methyl group can migrate only in the *cis* modifications. In the *trans* form of the six-ring pinacol, ring contraction occurs with much greater ease than in its five-ring analog which by this same reaction would have to yield the strained four-membered ring. Here, therefore, rearrangement is no longer a faster process than dehydration to the allylic alcohol and diene. It seems that under comparable conditions these three modes of reaction of the cyclic pinacols do not differ enormously in the ease with which they occur.

Experimental

Ethyl cyclopentanone-2-carboxylate was prepared by the method of Haller and Cornubert.[5] Yields from 65 to 70% were obtained, using 200-g. quantities. The product boiled at 114–116° at 20 mm.

Ethyl 2-methylcyclopentanone-2-carboxylate was made according to the directions of the same authors. The yield was 80%, of material boiling at 108.5–112° at 16 mm. pressure, and having $n^{20}D$ 1.4461.

2-Methylcyclopentanone was prepared by Van Rysselberge's method[6] which consists of refluxing the keto ester with 4 *N* hydrochloric acid. Yields of 82–86% were obtained. The product boiled at 139–142°, and yielded a semicarbazone melting at 174–174.8°.

1,2-Dimethylcyclopentanol-1 was prepared in 70–73% yield by the action of the methyl Grignard reagent upon 2-methylcyclopentanone. The product boils from 56 to 62.5° under 16 mm. pressure, showing an inhomogeneity which is attributed by Van Rysselberge to the presence of

geometrical isomers. No attempt was made to separate these.

1,2-Dimethylcyclopentene-1 was obtained in 83–87% yield by refluxing 1,2-dimethylcyclopentanol-1 with iodine for ten hours with a water trap in the return, and distilling. The fraction boiling at 102.5–105.8° was collected, $d^{20}{}_4$ 0.7950.

1,2-Dimethyl-1,2-epoxycyclopentane.—A solution of 38.5 g. of perbenzoic acid in 700 cc. of chloroform was stirred vigorously and cooled to 0°; 23.5 g. of 1,2-dimethylcyclopentene-1 was added over a period of two and one-half hours, the temperature being held at 0°. Stirring was continued for ten hours, the temperature being held at $-5°$. After standing at $+5°$ for two days, the solution was extracted with 10% sodium hydroxide to remove benzoic acid, washed, dried with sodium sulfate, and distilled; 23 g. of a liquid boiling at 120–122.5° at 20 mm. was obtained, yield 85%.

Anal. Calcd. for $C_7H_{12}O$: C, 75.0; H, 10.7. Found: C, 74.7, 74.9; H, 10.5, 10.7.

trans **Pinacol by Hydrolysis of the Epoxide.**—Twenty-one grams of the oxide was allowed to drop slowly into 20 cc. of water acidified with 6–8 drops of concentrated sulfuric acid, to which ice was added. On gentle shaking the oxide went into solution. By saturation with potassium carbonate the glycol was salted out of solution as a powdery precipitate. It was taken up in ether, from which it crystallized in long needles melting at 99.5–101° (corr.). The yield was 74% of the theoretical.

Anal. Calcd. for $C_7H_{14}O_2$: C, 65.1; H, 11.6. Found: C, 64.7, 64.9; H, 11.3, 11.6.

cis-**1,2-Dimethylcyclopentanediol-1,2** was prepared following a general procedure of Harries.[7] To a solution of 25 g. of 1,2-dimethylcyclopentene-1 in 50 cc. of acetone, cooled to $-5°$, a solution of 47 g. of potassium permanganate in 100 cc. of water and 1 liter of acetone was added slowly. After standing for one hour, the manganese dioxide slime was filtered off. Carbon dioxide was passed into the solution until potassium bicarbonate precipitated. From the filtrate, the acetone was removed on the water-bath and by distillation the fraction boiling at 142–146° at 20 mm. was collected. This amounted to 14 g. (45.2% of the theoretical yield) of a colorless liquid.

Anal. Calcd. for $C_7H_{14}O_2$: C, 65.1; H, 11.6. Found: C, 64.8, 64.7; H, 11.5, 11.5.

We were not successful in preparing any esters of this pinacol, but it could be condensed with benzaldehyde in the presence of ammonium sulfate to a solid crystallizing in plates, m. p. 120–122.5° (corr.).

Anal. Calcd. for the acetal, $C_{14}H_{18}O_2$: C, 77.5; H, 8.2. Found: C, 77.0, 77.1; H, 7.9, 8.1.

Rearrangement of the ***cis*** **Pinacol.**—Five grams of the liquid "*cis*" pinacol was dissolved in 20 cc. of water containing 5 cc. of concentrated sulfuric acid. The solution turned green immediately. After refluxing for three hours a brown oil had appeared, while the aqueous solution was practically colorless. To the steam distillate, semicarbazide hydrochloride and sodium acetate were added, yielding 5.2 g. (87.1%) of crude semicarbazone. In another run the ketone was isolated directly, distilled through a Widmer column, and the fraction boiling at 142–143.8° was collected. Its semicarbazone, recrystallized from methyl alcohol, melted at 191.5–191.8° (corr.). The oxime melted at 68.7° (corr.). Blanc[3] reports 142° as the boiling point of 2,2-dimethylcyclopentanone-1, and 69° as the melting point of the oxime. Haller and Cornubert[4] report the melting point of the semicarbazone as 191°.

Dehydration of the ***trans*** **Pinacol.**—On treatment identical with that applied to the *cis* pinacol, the *trans* isomer yielded no volatile product but, after showing similar color changes, gave a brown tar which rapidly became more viscous on standing and set to an almost black glass. No product which could be characterized was had from attempts to use less dilute acid, to carry out the experiment in acetic anhydride, glacial acetic acid, acetyl chloride, or in the presence of bromine, maleic anhydride, or benzoquinone.

Rates of Reaction with Lead Tetraacetate.—This reagent was prepared by the method of Dimroth[8] and the titrations with it were carried out according to the directions of Criegee and his co-workers.[2b] In a thermostat at 25°, the following results were obtained: 0.0595 g. of the *cis* pinacol was put into solution in 9.92 cc. of acetic acid (f. p. 16.2°) which had been refluxed with lead tetraacetate for ten hours and distilled. To this was added 9.92 cc. of a standard solution containing 0.02266 g. of lead tetraacetate per cc. of acetic acid. By iodometric titration the reaction was found to be 98.6% complete after five hours. Thus this reaction can be made the basis of a satisfactory titration method for the *cis* pinacol.

0.0573 g. of the *trans* pinacol was dissolved in 9.92 cc. of acetic acid and added to the same volume of standard lead tetraacetate solution. After seven hours and seven minutes, only 69.7% of the pinacol had reacted. A rough calculation based upon several such runs shows a 1600-fold difference between the rates of reaction of the isomeric pinacols with lead tetraacetate. Evidently the reaction in the case of the *trans* pinacol is too slow to serve as the basis of a titration method for the pinacol.

Rate of Rearrangement of the ***cis*** **Pinacol.**—0.209 g. of *cis* pinacol was dissolved in 10 cc. of water, and 10 cc. of 0.2 *N* sulfuric acid was added. The whole was kept at 52° in the thermostat. After two and one-half hours excess sodium acetate was added and 20.1 cc. of standard lead tetraacetate. This was allowed to stand at 35° for eight hours and the lead tetraacetate was then titrated iodometrically. The rearrangement was 53.9% complete.

Rate of Dehydration of ***trans*** **Pinacol.**—In order to gain an idea of the rate of reaction of the *trans* pinacol with sulfuric acid, it was necessary to resort to isolation of the unchanged *trans* pinacol, since a suitable titration method was not found. 0.210 g. of *trans* pinacol was dissolved in 10 cc. of water and 10 cc. of 0.2 *N* sulfuric acid was added. The reaction was allowed to proceed at 52° for two and a half hours, at the end of which time barium oxide was added, the barium sulfate precipitate digested on the steam-bath overnight, and filtered off. The pinacol was recovered by ether extraction of the filtrate, after concentrating *in vacuo*, and recrystallization from ether of the crude product. 1.6 g. of the pinacol was recovered (76%

[7] Harries, *Ber.*, **34**, 2979 (1901).

[8] Dimroth, *ibid.*, **63**, 483 (1930).

of the starting material) melting at 100.5–100.7° alone and when mixed with the original material.

Summary

1. *cis*-1,2-Dimethylcyclopentanediol-1,2 undergoes the pinacol rearrangement with migration of a methyl group and production of 2,2-dimethylcyclopentanone.

2. *trans* - 1,2 - Dimethylcyclopentanediol - 1,2 when boiled with dilute aqueous acid undergoes resinification. It has not been possible to characterize any product from this reaction. It is suggested that dehydration without rearrangement is here occurring, yielding a product which is rapidly polymerized by the acid.

3. These observations confirm the conclusion previously reached that in the pinacol rearrangement elimination of a hydroxyl group and the arrival of a migrating radical occur on opposite sides of the same carbon atom.

The Pyrolysis of Esters

BY CHARLES D. HURD AND FORD H. BLUNCK

Although much is known about the pyrolysis of esters, most of the evidence is fragmentary. To supply additional information of a critical nature seven esters were selected for detailed study. These were ethyl, phenyl, *i*-propyl, *i*-butyl, and *t*-butyl acetates and methyl and ethyl phenylacetates.

The known facts concerning simple esters may be summarized briefly. If a β-H is present in the alkyl portion of the ester, $RCOOCR_2CHR_2$, the decomposition into acid (RCOOH) and olefin ($R_2C{=}CR_2$) is general. This was established by Oppenheim and Precht[1] for ethyl acetate and was confirmed recently by Bilger and Hibbert.[2] The latter investigators also extended the reaction (470–500°, 1.2 sec. contact time) to several other esters which included not only the propyl, *i*-propyl, *n*-butyl, *i*-butyl, *s*-butyl and β-chloroethyl acetates but also the ethyl esters of benzoic, formic, butyric and chloroacetic acids. In their work an unsuccessful search was made for aldehydes among the reaction products, the reagent being a solution of *p*-nitrophenylhydrazine in acetic acid. Bilger and Hibbert noted that methyl and benzyl esters (of acetic and benzoic acids) did not decompose under conditions which caused breakdown of the other esters.

The decomposition products of methyl phenylacetate (sealed tube at 360°) have been reported[3] to be toluene, methane, methanol and oxides of carbon. Methyl acetate,[4] at 1100°, has been found to change into acetic acid, formaldehyde and acetaldehyde (or their decomposition products) and ethylene.

Five of the esters studied in the present investigation possessed a β-H on the alkyl group. Greatest instability was noticed when this alkyl was tertiary as in *t*-butyl acetate. It decomposed even at 360°. Secondary alkyl (*i*-propyl acetate) exhibited intermediate stability. Greatest stability was noticed when the alkyl was primary (ethyl or *i*-butyl acetates, ethyl phenylacetate).

Nearly equivalent amounts of acetic acid and isobutylene were observed from *t*-butyl acetate at 360–430° and no other products were found. Also, no products other than ethylene and phenylacetic acid (formed in equivalent amounts) were obtained from ethyl phenylacetate at 435–545°. At 625°, however, the latter gave rise to small amounts of toluene and carbon dioxide which were formed obviously from phenylacetic acid by secondary decomposition. The percentage yields of products based on the ester decomposed were found to be as follows: phenylacetic acid 58, toluene 22, carbon dioxide 21, ethylene 78.

The acetic acid and propylene from *i*-propyl acetate were formed in nearly equimolar amounts, but small amounts of acetaldehyde (4%), acetone (3%) and carbon monoxide (12%) were also observed in an experiment at 460°.

Ethyl acetate yielded acetic acid and ethylene in approximately equivalent amounts as expected, but the presence of other products was established

definitely. These substances were identified in an experiment at 550° (% yields): acetic acid 82, ethylene 83, acetaldehyde 9, formaldehyde 6, acetic anhydride 0.5, methane 8, hydrogen 4, carbon monoxide 1, and a trace of ketene. Similarly, isobutyraldehyde (but not acetaldehyde or formaldehyde), carbon monoxide and methane were found in the products from *i*-butyl acetate, but of course the chief products were acetic acid and isobutylene.

It was established that the olefin from both *t*- and *i*-butyl acetates was isobutylene, unadmixed with isomers. This was determined carefully because *i*-butyl acetate, $Me_2CH—CH_2—OAc$, bears a structural resemblance to 1,1-diphenyl-2-chloroethane, $Ph_2CH—CH_2—Cl$, which is known to pyrolyze[5] into hydrogen chloride and stilbene, PhCH=CHPh. Were isobutyl acetate to behave analogously, one would anticipate 2-butene as the olefin of the reaction, but only 2-methylpropene (isobutylene) was found.

Phenyl acetate and methyl phenylacetate were much more stable than the other esters. At either 435 or 535° practically no change occurred, but at 625° there was decomposition. Evidently, therefore, an interval of about 200° separates the decomposition temperatures of the two groups. Phenyl acetate pyrolyzed smoothly into ketene and phenol. The yield of ketene at 625° was 84%.

$$CH_3COOC_6H_5 \longrightarrow CH_2{=}C{=}O + C_6H_5OH$$

The decomposition of methyl phenylacetate was much more complex. The products formed in greatest amounts were carbon monoxide, benzaldehyde and toluene, but other products included hydrogen, ethylene, methane, formaldehyde, carbon dioxide, water and an organic acid. Formaldehyde, which is known to decompose rapidly above 500°, may have been the precursor of much of the carbon monoxide and hydrogen, and probably much of the hydrogen was consumed at the high temperature. The striking product of the reaction was benzaldehyde. The carbonyl group in it is attached to the aromatic nucleus, whereas the carbonyl group in the ester is separated from the nucleus by a methylene group. Evidently, therefore, something more complex than a simple splitting must have occurred to have caused the formation of benzaldehyde.

These average percentage yields of products were formed, based on the ester which was decomposed. The experiments were performed at 625° and about five seconds contact time: benzaldehyde 71, toluene 49, carbon monoxide 92, formaldehyde 25, ethylene 29, hydrogen 27, methane 15, carbon dioxide 12 and an organic acid 4. The benzaldehyde and toluene were isolated directly and, therefore, represent minimum values.

Mechanisms.—No single mechanism accounts for the facts adequately, and three processes seem to be involved. One of them is the chain mechanism, with univalent radicals as intermediates, but it cannot apply, except in small measure, to the esters which possess a β-hydrogen. A few considerations will make this evident.

If the chain mechanism is applied to *t*-butyl acetate, the predicted products include not only isobutylene and acetic acid but also ketene (or acetic anhydride, from ketene and acetic acid), acetone and methane. Since this mechanism calls for five products instead of two, it is obviously inadequate.

Similar reasoning shows that the chain mechanism cannot serve in the pyrolysis of ethyl phenylacetate since, besides ethylene and phenylacetic acid, it would require the production of formaldehyde, methane, phenylketene, toluene, carbon monoxide and acetaldehyde. None of the last six compounds was formed in experiments at 435–545°.

The steps with ethyl acetate will be taken up in detail. With the chain mechanism, interaction of a radical R with $CH_3COOCH_2CH_3$ would yield RH and residues I, II or III.

$\underset{|}{C}H_2—CO—O—CH_2—CH_3$

I

$CH_3—CO—O—\underset{|}{C}H—CH_3$

II

$CH_3—CO—O—CH_2—\underset{|}{C}H_2$

III

Breakdown of I should lead to formaldehyde, ketene (or acetic anhydride), and methane: I $\longrightarrow$ $CH_2{=}C{=}O$ + $—O—CH_2—CH_3 \longrightarrow O{=}CH_2$ + $CH_3—$. In previous work with ethyl acetate, the presence of formaldehyde and methane among the pyrolytic products has escaped detection, but the "odor of ketene" has been noticed.[6] Breakdown of II should yield acetaldehyde, carbon monoxide and methane: II $\longrightarrow CH_3— + CO + O{=}CH—CH_3$. III should give rise to ethylene and acetic acid: III $\longrightarrow CH_3—CO—O— + CH_2{=}CH_2$.

[5] Hepp, *Ber.*, **6**, 1439 (1873).

[6] Stewart and Wilsmore, *Nature*, **75**, 510 (1907); Wilsmore, *J. Chem. Soc.*, **91**, 1939 (1907).

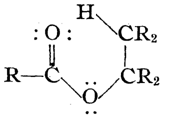
Possibly the aldehydes which were produced did come via I and II but, if so, it seems obvious that no more than a small fraction of the observed acetic acid should come via III because the yields of I, II and III should be comparable. The bulk of the acetic acid, therefore, requires another mechanism to account for it.

As was mentioned earlier, ethyl acetate is more stable than *t*-butyl acetate. The temperature required for pyrolysis of the latter was so low that scission into radicals appeared to be completely inhibited. With the higher temperature required for the decomposition of ethyl acetate the breakdown into radicals was starting to be a factor, although not yet one of importance.

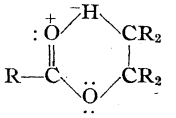
A similar situation exists with *i*-propyl and *i*-butyl acetates. Compounds predicted by the chain mechanism are observed but they comprise only a small portion of the products.

Cyclic Hydrogen Bridge.—The concept of hydrogen bonds or hydrogen bridges[7] has been developed in recent years to explain such facts as the association of water or hydrogen fluoride, the weakness of carboxylic acids, the weakness of ammonium hydroxide and many other facts, all of which, however, have been low temperature phenomena. The concept seems applicable also to some high temperature processes and it is proposed that the esters which require only moderately high temperatures for their pyrolysis break down by a mechanism involving hydrogen bridges.

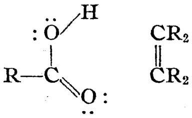
Esters which possess a β-H in the alkyl group (IV) may undergo a chelate type of 6-atom ring closure by way of a hydrogen bridge (V). Readjustment of the electrons would give rise to acid and olefin (VI).



IV



V



VI

Methyl esters cannot change into 6-atom rings comparable to V, which may account for their greater stability.

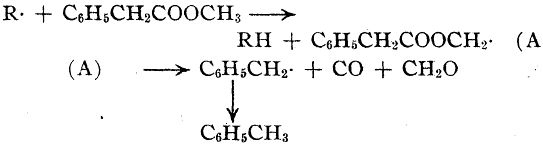
When hydrogen bridges occur in stable structures, negative atoms are involved on both sides of the bridge (such as O–H–O, or O–H–N or F–H–F). The O–H–C bridge has not been observed at ordinary temperatures, but it is reasonable to assume for it a transient existence at elevated temperatures. Also, because oxygen is more negative than carbon, hydrogen should remain with the oxygen when this bridge is broken.

This mechanism calls for only moderately high temperatures. Ethyl phenylacetate, which yielded only ethylene and phenylacetic acid at 435°, was studied at 545 and 625° to see if the mechanism was changed at higher temperatures. No such change was found for no aldehydes were produced. The temperature of 625° is sufficient in some cases to initiate C–C scission with the formation of radicals, but apparently the only effect of the increased temperature in this reaction was to increase the velocity of the original process.

Radicals as Intermediates.—The chain reaction mechanism may account for the pyrolysis of phenylacetate, since the products obtained, namely, ketene and phenol, are those predicted by the theory.

$$R\cdot + CH_3—CO—OC_6H_5 \longrightarrow RH + \cdot CH_2—CO—OC_6H_5$$
$$\cdot CH_2—CO—OC_6H_5 \longrightarrow CH_2{=}C{=}O + \cdot OC_6H_5$$

When a similar mechanism is applied in its simplest form to methyl phenylacetate the products predicted include toluene, carbon monoxide, formaldehyde and hydrogen, all of which were found. Phenylketene was indicated also but was not found. This is not surprising in view of its instability. The steps are as follows



$$R\cdot + C_6H_5CH_2COOCH_3 \longrightarrow RH + C_6H_5CH_2COOCH_2\cdot \quad (A)$$
$$(A) \longrightarrow \underset{\displaystyle \downarrow \atop \displaystyle C_6H_5CH_3}{C_6H_5CH_2\cdot} + CO + CH_2O$$

$$R\cdot + C_6H_5CH_2COOCH_3 \longrightarrow RH + C_6H_5\dot{C}H—CO—OCH_3 \quad (B)$$
$$(B) \longrightarrow C_6H_5CH{=}C{=}O + \cdot OCH_3$$

The $\cdot OCH_3$ radical may change to methanol (RH, in the equation), or to hydrogen and formaldehyde. With methanol, phenylketene would regenerate methyl phenylacetate.

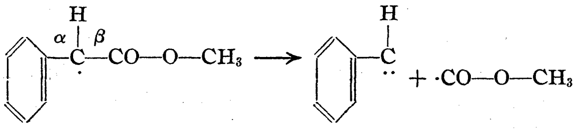
Methylene Radicals as Intermediates.—The above mechanism for methyl phenylacetate is not self-sufficient because it fails to account for the most important product of the reaction, namely, benzaldehyde. Its production may be explained satisfactorily by assuming that phenylmethylene is an intermediate radical. In the pyrolysis of methane, which calls for severe thermal conditions, the methylene radical is

---

(7) For a review of the material, see Huggins, *J. Org. Chem.*, **1**, 407 (1937).

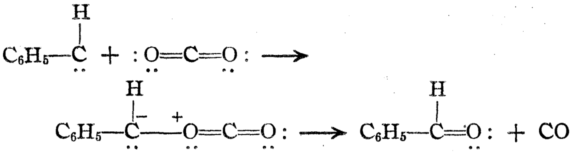
thought by Kassel[8] to be a fundamental intermediate. Storch and Kassel[9] also favor it as an intermediate in the pyrolysis of ethane, but they point out that a chain reaction which involves univalent radicals proceeds concurrently.

With methyl phenylacetate, it is proposed that radical B, because of high temperature and structural weakness, breaks as follows



The C–C bond which undergoes scission is beta to the unsaturation of the phenyl nucleus and, therefore, possesses an instability[10] not found in the acetic esters. The resulting carbomethoxyl radical may break into CO + $\cdot OCH_3$ or into $CO_2 + \cdot CH_3$.

The phenylmethylene radical, possessing as it does only six electrons on the carbon atom, must attach itself to neighboring unshared electrons to create the necessary octet. Most probably, these unshared electrons would come from some oxygen-containing substance, as the original ester, or carbon dioxide, etc. The oxygen atom which is attracted to the carbon atom in this way is the one which appears as benzaldehyde. This may be illustrated most simply with carbon dioxide as the source of the oxygen, but a similar plan would follow for other compounds.



$$C_6H_5-\overset{H}{\underset{\cdot\cdot}{C}} + :\underset{\cdot\cdot}{O}=C=\underset{\cdot\cdot}{O}: \longrightarrow$$

$$C_6H_5-\overset{H}{\underset{\cdot\cdot}{C}}{}^{-}-{}^{+}\underset{\cdot\cdot}{O}=C=\underset{\cdot\cdot}{O}: \longrightarrow C_6H_5-\overset{H}{C}=\underset{\cdot\cdot}{O}: + CO$$

The fact that a much higher decomposition temperature was required for the breakdown of methyl phenylacetate than for ethyl phenylacetate explains why benzaldehyde was not formed in the latter case. Obviously, a formidable energy barrier must be hurdled to bring about this effect.

The fact that several mechanisms are involved in the pyrolysis of esters suggests that several mechanisms may be involved also in the pyrolysis of compounds in other series, particularly if sizeable temperature differences are involved in initiating the breakdown. Most of the earlier thought on this subject has presumed that one type of mechanism alone was adequate for a particular series if not for all series.

Experimental Part

Substances Used.—The following esters were washed, dried and closely refractionated before use: ethyl acetate, b. p. 77.0–77.1°; phenyl acetate, b. p. 96.5–96.6° at 30 mm.; methyl phenylacetate, b. p. 214° (735 mm.), sapon. equiv., 150. Hydrolysis of the last of these yielded phenylacetic acid, m. p. 74–75°, free from benzoic acid.

For some of the runs, methyl phenylacetate and ethyl phenylacetate were synthesized from pure phenylacetic acid, m. p. 75.5–76.0°. The latter was dissolved in anhydrous methanol or ethanol which contained dry hydrogen chloride and the mixture was refluxed for eight hours. The esters were separated and purified in the usual way. After two distillations at 65 mm. the methyl ester was collected at 137.0–137.1° (yield 90%), and the ethyl ester at 141–142°.

Synthetic *i*-propyl acetate was used in all the runs. The *i*-propyl alcohol was thrice distilled through an efficient column. The fraction obtained, b. p. 82.5–82.6°, was shown by oxidation with dichromate to contain less than 0.1% of *n*-propyl alcohol. About 1% of concd. sulfuric acid was added to 9 moles of the alcohol and an equimolar quantity of pure acetic anhydride was added at such a rate as to maintain refluxing. Then the reaction mixture was cooled, the ester salted out and neutralized with sodium bicarbonate, washed with water and dried over calcium chloride. An 80% yield of *i*-propyl acetate, b. p. 89.4–89.5°, was obtained.

The *i*-butyl acetate was made from carefully fractionated *i*-butyl alcohol, b. p. 107.1–107.2°. Esterification of this alcohol with acetic anhydride, or with refluxing glacial acetic acid in the presence of a little hydrogen chloride or *p*-toluenesulfonic acid, yielded *i*-butyl acetate which boiled at 118.1–118.2°.

t-Butyl acetate was prepared from *t*-butyl alcohol (distilled from sodium), acetic anhydride and a little zinc chloride according to the method of Norris and Rigby.[11] The yields were only 48–50%, but the purity was excellent (b. p. 97.4–97.6°).

Apparatus.—The esters were introduced into the top of a vertical Pyrex reaction tube by displacement with mercury. In most runs, a 15-cm. electric furnace was used but in some runs it was replaced by a 30-cm. furnace. The temperature was controlled and recorded by a chromel–alumel thermocouple attached to a Leeds and Northrup recorder-controller. The glass-encased thermocouple was placed in the middle of the reaction tube.

An iced receiver was attached to the bottom of the reaction tube and it in turn was connected to a low-pitched spiral reflux column which was cooled by ice-salt. This served to condense all of the higher boiling products as well as the undecomposed ester. The uncondensed vapors from ethyl acetate were then passed through a second receiver at −80° to collect formaldehyde, acetaldehyde or ketene. The same was used with *i*-propyl, *i*-butyl and *t*-butyl acetates but in these runs no appreciable quantity of liquid was condensed. The remaining gas was passed to a gas-collecting bottle over salt water. With methyl

phenylacetate, the second trap contained water at 3° to collect formaldehyde. In runs with the acetic esters an aniline trap or a trap containing standard alkali was inserted between the second receiver and the bottle, to absorb ketene.

Analytical Methods

Qualitative.—Qualitative tests for formaldehyde, acetaldehyde and ketene were performed to precede the quantitative experiments. Formaldehyde was identified as methylenedi-β-naphthol. For this purpose, one-third of the products (diluted with water) from the second receiver from the ethyl acetate experiments was mixed with 10 cc. of alcohol, 2 cc. of dilute hydrochloric acid and 1 g. of β-naphthol. After heating for fifteen minutes and cooling, 0.5 g. of the derivative, m. p. 204°, was obtained. Formaldehyde was identified similarly in the products of the second receiver from methyl phenylacetate.

To identify acetaldehyde from ethyl acetate, a portion of the solution in the second receiver was neutralized with dilute sodium hydroxide and distilled. The distillate, diluted with water, responded positively to the fuchsin test. It was oxidized with chromic acid and the volatile acid removed by distillation. The latter was neutralized by sodium hydroxide and evaporated to dryness. The sodium acetate in the residue was converted to *p*-bromophenacyl acetate, m. p. 85°, on treatment with *p*-bromophenacyl bromide. Acetaldehyde was detected qualitatively in like manner from the low-boiling products of the first receiver with *i*-propyl acetate.

Direct evidence for ketene was obtained in the run at 525° with ethyl acetate by inserting a trap containing 20 cc. of aniline between the second receiver and the gas-collecting bottle. In working up the products, any acetic acid was extracted by sodium bicarbonate solution.[12] The water solution was ether-extracted and the extract was placed with the aniline. The ether and aniline were distilled off and the residue was extracted with boiling water. About 0.1 g. of acetanilide, m. p. 113°, separated on cooling. A trace of ketene was revealed similarly in runs with *i*-propyl and *i*-butyl acetates. With phenyl acetate it was the chief product.

That the liquid products from the pyrolysis of phenyl acetate contained phenol was established readily by distillation. The fraction which was collected at 179–182° reacted strongly with ferric chloride and gave an α-naphthylurethan, melting at 132°.

The gas from the first receiver and its attached spiral condenser was treated in three different ways. For a time in the first run it was passed into a trap containing 45 cc. of water. Then it was passed into a trap containing 20 cc. of aniline. In the second run, it was passed into an empty trap at −78° which was connected to an aniline trap.

The water in the first trap was free from aldehydes (Schiff reagent). From the aniline traps, acetanilide was isolated in quantity (m. p. 113.5°). No gaseous product was obtained in either run. At the end of the second run, about 1 cc. of ketene had collected in the trap at −78°. When this was vaporized and passed into the aniline, there was no residual acetylketene. The yield of ketene was calculated from the weight of acetanilide isolated.

The liquid products consisted only of phenyl acetate and phenol. The former was determined by acetyl analysis,[13] and the latter by bromate–bromide titration.[14] To analyze for phenol in the presence of phenyl acetate, it was found that phenyl acetate underwent quantitative hydrolysis into phenol on refluxing for thirty minutes with sodium ethoxide solution. Therefore, the mixture of phenyl acetate and phenol was subjected to this hydrolysis prior to the bromate–bromide titration. Since the ester content was known, that portion of the phenol which came from the ester was computed readily.

The qualitative presence of acetone in the liquid products (first receiver) from *i*-propyl acetate was established by neutralizing a portion of it and treating that part which boiled below 80° with semicarbazide hydrochloride and sodium acetate. After standing, 0.5 g. of acetone semicarbazone, m. p. 189–190°, was obtained. No acetone was detected from *t*-butyl acetate.

Acetic acid was identified by boiling point and by its derivative, *p*-bromophenacyl acetate, m. p. 85°. No more than traces of acetic anhydride were present by quantitative determination (below).

No allyl acetate was found by distillation of the products from *i*-butyl acetate. The fraction boiling from 85–116° revealed no ester for no alkali was consumed by saponification test, but it contained much isobutyraldehyde for it gave a strong fuchsin test and yielded a 2,4-dinitrophenylhydrazone, m. p. 182°.

A slight fuchsin test was obtained in the products from the 625°-run of ethyl phenylacetate, but otherwise all tests for aldehydes were negative. Phenylacetic acid and toluene (only from the run at 625°) were identified by direct isolation. The toluene was confirmed as 2,4-dinitrotoluene, m. p. 70°. Water, toluene and benzaldehyde (b. p. 177–183°, semicarbazone m. p. and mixed m. p. 222°) from methyl phenylacetate were isolated directly. No evidence was secured for phenylacetaldehyde, and the trace of acid observed could not be isolated for characterization.

Data summarizing both the qualitative and quantitative data of some representative runs are collected in Table I.

Quantitative.—Quantitative determinations on the various products were carried out volumetrically. The acid content was determined by direct titration on an aliquot portion of the products with standard sodium hydroxide. The ester content was determined on another portion by saponification, using a known amount of standard alkali and back titration with dilute standard sulfuric acid. The acetic anhydride was determined on an aliquot portion by means of the reaction with anhydrous pyridine and oxalic acid,[15] the volume of carbon monoxide and carbon dioxide evolved being indicative of the anhydride content.

The total aldehyde content of both receivers was determined on aliquot portions by oxidation with 0.1 *N* potassium dichromate solution and sulfuric acid. It was necessary to correct this value in the ethyl acetate experi-

[a] Isobutyraldehyde was established qualitatively by its 2,4-dinitrophenylhydrazone.

ments for the dichromate which was consumed in oxidizing the ester concurrently ($CH_3COOC_2H_5 \longrightarrow 2CH_3COOH$). The difference between the total equivalents of dichromate and the equivalents consumed by the ester gave the value for total aldehydes. The procedure was tested on a known mixture of ethyl acetate and acetaldehyde, as follows.

A definite volume of acetaldehyde (capillary pipet) was heated for three hours on the steam-bath with 150.00 cc. of 0.1024 *N* potassium dichromate and sulfuric acid, after which potassium iodide was added. Then, 34.30 cc. of 0.1410 *N* sodium thiosulfate was required. From this 102.77 cc. of 0.1024 *N* dichromate was consumed. Then a mixture of this same quantity of acetaldehyde and 0.050 cc. of ethyl acetate (0.0005 mole) was treated similarly. This time, 122.46 cc. of 0.1024 *N* dichromate was consumed. The difference of 19.69 cc. ($\approx$ 2.01 cc. of 1 *N*) represents 0.002 equivalent, which agrees with the ethyl acetate taken ($0.0005 \times 4 = 0.002$) since four oxidation equivalents are involved in the oxidation of ethyl alcohol to acetic acid.

In a similar manner it was established that the oxidation equivalent for *i*-propyl acetate (*i. e.*, the correction factor) was twice the molecular weight. Thus, there was hydrolysis and oxidation quantitatively to acetone on heating with 0.0789 *N* potassium dichromate and sulfuric acid: $CH_3COOCH(CH_3)_2 \longrightarrow CH_3COOH + (CH_3)_2CO$.

No such corrections were necessary to analyze for isobutyraldehyde from *i*-butyl acetate for it was separated from the ester before oxidation. The benzaldehyde and toluene from methyl phenylacetate were determined by direct distillation analysis.

The acetone content of the products from *i*-propyl acetate was estimated in a manner patterned after the suggestion of Marseo.[16] The aldehyde and ketone both react with a 2% solution of hydroxylamine hydrochloride in water. The aldehyde releases 94.40% of the theoretical amount of hydrochloric acid while 1.00 cc. of 0.1000 *N* sodium hydroxide is required for the hydrochloric acid set free by each 0.0001 mole of acetone. The sample (an aliquot of the liquid products) was neutralized with standard alkali to the methyl orange end-point. Six hundrd cc. of 2% hydroxylamine hydrochloride solution was then added. The solution was titrated to near neutrality and allowed to stand for twenty seconds. This process was repeated several times and the mixture was neutralized after one minute of stirring. By a previous knowledge of the acetaldehyde content the acetone content was determined.

The gaseous products were identified and analyzed by absorption methods in a modified Orsat apparatus.[17] The olefin in the gas from *i*-butyl and *t*-butyl acetates was exclusively isobutylene. In both cases the gas dissolved completely in 63% sulfuric acid. This conclusion was confirmed by distillation analysis in a Podbielniak column. No propylene was found. The C_4-fraction from the distillation was liquefied and distilled analytically from a Frey–Hepp column[18] with ethylene oxide as a "pusher." There was a long distillation plateau for isobutylene at −6° but no plateau at a higher temperature for 2-butene. Methane was the exclusive paraffin in the gas from methyl phenylacetate since n in C_nH_{2n+2} was found to be 1.0.

The acetic acid was determined quantitatively by direct titration. Analysis of the unused ester with some of the esters called for the use of a solution of sodium ethoxide in ethanol, since aqueous solutions of sodium hydroxide were ineffectual. For example, after an eight-hour period of refluxing of 10 cc. of *t*-butyl acetate and 25 cc. of 28% sodium hydroxide an insoluble layer of ester remained. Distillation of this layer yielded 9 cc., b. p. 90–96°. Correct saponification values for the pure ester (1 cc.) were obtained by refluxing for half an hour with 50 cc. of *N* sodium ethoxide solution and back-titrating with *N* sulfuric acid.

Summary

t-Butyl acetate underwent pyrolysis at 360° to yield acetic acid and isobutylene as exclusive products. Ethyl phenylacetate also underwent this simple type of scission into phenylacetic acid and ethylene at 435–545°.

In the case of ethyl acetate, pyrolysis into acetic acid and ethylene also occurred at temperatures of 525–550°, but smaller quantities of aldehydes and other gases were identified. Likewise, *i*-propyl acetate at 430–460° gave rise not only to acetic acid and propylene but also to significant amounts of acetone, acetaldehyde, carbon monoxide and methane. Also, at either 420 or 650°, small amounts of isobutyraldehyde, carbon monoxide and methane were found mixed with the acetic acid and isobutylene produced from isobutyl acetate.

It was demonstrated that no 2-butene was formed during pyrolysis of either *t*- or *i*-butyl acetates.

Phenyl acetate and methyl phenylacetate were much more thermostable than the other five esters. The extent of decomposition was negligible at 530°. At 625–645°, phenyl acetate pyrolyzed smoothly into phenol and ketene. Methyl phenylacetate, at 625°, yielded benzaldehyde, toluene and carbon monoxide in quantity, but formaldehyde, methane, hydrogen, ethylene and carbon dioxide were also formed.

A mechanism involving a cyclic hydrogen bridge is proposed to explain the low-temperature pyrolysis of esters into acid and olefin. The chain reaction mechanism, involving free radicals, cannot account for this process but it becomes important with the thermostable esters. To account for benzaldehyde from methyl phenylacetate, it is suggested that the phenylmethylene radical is an essential intermediate.

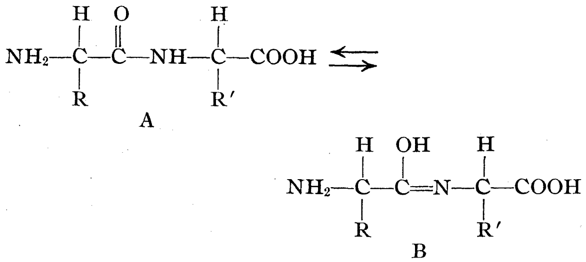
Racemization of Tripeptides and Hydantoins[1]

BY M. BOVARNICK AND H. T. CLARKE

In 1910 Dakin[2] first described the racemization of optically active hydantoins under the influence of mild alkali. At the same time he demonstrated that the presence of a hydrogen atom on the asymmetric carbon atom was a necessary condition for the occurrence of the racemization and further observed that neither the optically active amino acids themselves, their uramino acid derivatives, nor optically active dipeptides, were racemized under the conditions.[2a] He therefore concluded that the mechanism of racemization involved a keto–enol tautomerism and that it was essential that both the α-amino group and the carboxyl group attached to the asymmetric carbon atom be bound up in order for the amino acid to undergo racemization by this method.[3] Extending this work, Dakin and others[4] later identified the terminal amino acids of protein peptide chains by making use of the assumption that, having free amino and carboxyl groups, they would not racemize on alkaline hydrolysis. Levene,[5] working with smaller peptide chains, substantiated the findings of Dakin and reached the conclusion that in a peptide composed of three optically active amino acids only the middle amino acid was racemized by alkali.

On comparing the formulas of dipeptides and tripeptides, a theoretical reason presents itself for the observed difference in racemizability of the two. In both there are two types of structures capable of undergoing tautomerization. One is the familiar keto–enol system, and the other is the amide–imide system. In the dipeptide only the non-racemizing tautomeric equilibrium need be considered; the keto–enol tautomerization obviously does not take place to any appreciable extent as the dipeptides do not racemize.



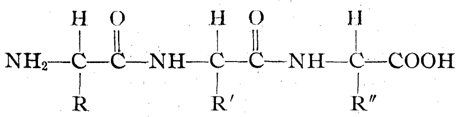
$$\mathrm{NH_2{-}\underset{R}{\overset{H}{C}}{-}\overset{O}{\overset{\|}{C}}{-}NH{-}\underset{R'}{\overset{H}{C}}{-}COOH} \rightleftarrows$$

A

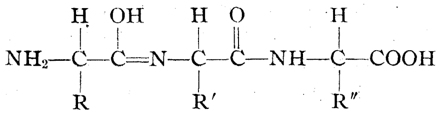
$$\mathrm{NH_2{-}\underset{R}{\overset{H}{C}}{-}\overset{OH}{C}{=}N{-}\underset{R'}{\overset{H}{C}}{-}COOH}$$

B

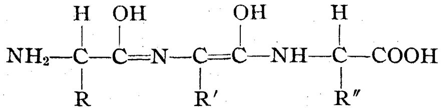
In a tripeptide a wide variety of tautomeric forms is possible, of which only those represented below need be considered here. It is a well-recognized fact that the presence of a double bond in a molecule tends to favor the production (when this is at all possible) of other double bonds in conjugation with it. It was therefore thought that an explanation of the racemizability of the tripeptides might reside in the possibility that in these peptide chains a previous or simultaneous occurrence of an enolized peptide linkage (D), analogous to that outlined above (B) for a dipeptide, might be necessary to induce the formation of a second enolic double bond (E) whereby the asymmetry of the central constituent amino acid is destroyed.



$$\mathrm{NH_2{-}\underset{R}{\overset{H}{C}}{-}\overset{O}{\overset{\|}{C}}{-}NH{-}\underset{R'}{\overset{H}{C}}{-}\overset{O}{\overset{\|}{C}}{-}NH{-}\underset{R''}{\overset{H}{C}}{-}COOH} \quad C$$

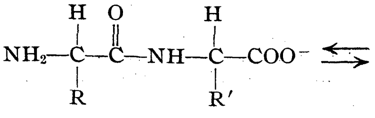


$$\mathrm{NH_2{-}\underset{R}{\overset{H}{C}}{-}\overset{OH}{C}{=}N{-}\underset{R'}{\overset{H}{C}}{-}\overset{O}{\overset{\|}{C}}{-}NH{-}\underset{R''}{\overset{H}{C}}{-}COOH} \quad D$$



$$\mathrm{NH_2{-}\underset{R}{\overset{H}{C}}{-}\overset{OH}{C}{=}N{-}\underset{R'}{C}{=}\overset{OH}{C}{-}NH{-}\underset{R''}{\overset{H}{C}}{-}COOH} \quad E$$

In order for this mechanism to be effective in the case of a dipeptide the following reaction would have to take place



$$\mathrm{NH_2{-}\underset{R}{\overset{H}{C}}{-}\overset{O}{\overset{\|}{C}}{-}NH{-}\underset{R'}{\overset{H}{C}}{-}COO^-} \rightleftarrows$$

---

[2] Dakin, *Am. Chem. J.*, **44**, 48 (1910).

[2a] The optical stability of dipeptides may be further illustrated by the case of alanylglycine, which on treatment with normal sodium hydroxide at room temperature for two days showed no appreciable loss in activity [Levene and Pfaltz, *J. Biol. Chem.*, **70**, 219 (1926)], whereas in half-normal sodium hydroxide under the same conditions it was hydrolyzed to an extent of over 15% [Levene, Bass and Steiger, *J. Biol. Chem.*, **82**, 167 (1929)]. Racemization of the resulting amino acids can be effected by alkali only under very vigorous conditions, such as heating with 15% barium hydroxide at 155–160° for forty-eight hours [E. Fischer, *Z. physiol. Chem.*, **33**, 151, 173 (1901)].

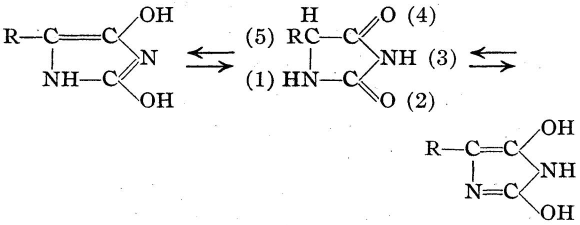
$$\mathrm{NH_2—\underset{R}{\overset{H}{C}}—\overset{OH}{C}{=}N—\underset{R'}{C}{=}C\begin{smallmatrix}OH\\ O^-\end{smallmatrix}}$$

Enolization involving carboxylate ions is not in harmony with the concept of resonance in these ions,[6] and the known non-racemizability of dipeptides conforms with its improbability.

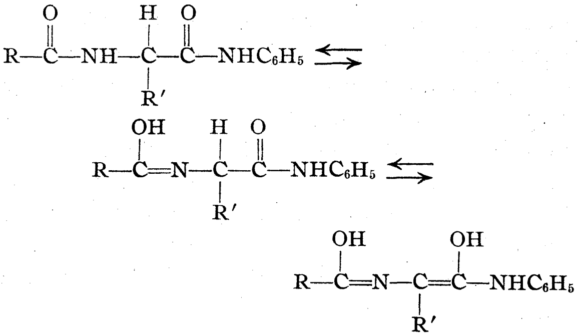
If the above hypothesis, as applied to tripeptides, is to be tenable, then replacement of the hydrogen in the system —CONH— by a methyl group should, by blocking the formation of the modification —C(OH)=N— and thereby preventing conjugation involving the asymmetric carbon atom, prevent racemization in the tripeptide.

In the case of hydantoins there are two possibilities for the occurrence of conjugation involving the asymmetric carbon atom



and if this be a factor controlling racemization, replacement of one of the H atoms in positions 1 or 3 of the ring by an alkyl or aryl group might retard racemization, and replacement of both should prevent it.

Accordingly a series of optically active substituted hydantoins, and a series of α-acylaminoacyl anilides were prepared. For each series the rates of racemization in suitable concentrations of alkali were measured. The latter derivatives contain an amino acid in which both the amino group and carboxyl group are modified. They differ from tripeptides in that they lack the terminal amino and carboxyl groups, but these are not essential for testing the theory as the requisite enolization can take place with equal probability



$$\mathrm{R—\overset{O}{\overset{\|}{C}}—NH—\underset{R'}{\overset{H}{C}}—\overset{O}{\overset{\|}{C}}—NHC_6H_5 \rightleftarrows}$$

$$\mathrm{R—\overset{OH}{C}{=}N—\underset{R'}{\overset{H}{C}}—\overset{O}{\overset{\|}{C}}—NHC_6H_5 \rightleftarrows}$$

$$\mathrm{R—\overset{OH}{C}{=}N—\underset{R'}{C}{=}\overset{OH}{C}—NHC_6H_5}$$

The derivatives studied were chosen because it was thought they might be more accessible than the tripeptides.

The results, given in Table I, have little quantitative significance since practical considerations precluded the use of standard concentrations of the optically active compounds and the precise evaluation of hydroxyl ion activity. Contrary to expectation, the loss of activity did not always follow a monomolecular course, as should have been the case if a single reaction had been involved.[9]

TABLE I

HALF RACEMIZATION TIME OF HYDANTOINS AND ACYL AMINO ANILIDES IN ALKALI

	Compound	Molarity	Medium	Half-time, hours
I	N-Acetyl-tyrosyl anilide	0.0255	0.37 *N* NaOH in 67% EtOH	74

[6] Pauling, *Proc. Nat. Acad. Sci.*, **18**, 293 (1932).

[7] Paal and Zitelmann, *Ber.*, **36**, 3344 (1903).

[8] Behr and Clarke, THIS JOURNAL, **54**, 1630 (1932).

[9] With the acylaminoacyl anilides, the values of *K* drifted upward for compounds I and IV, downward for II and III; with the hydantoins, relatively constant values were observed for VII, VIII, and XI, and those for the 1-methyl hydantoins IX and X showed an upward drift.

and XI with XII, it can be seen that the substitution of H by R groups not only fails to prevent racemization but in some cases even hastens it. These findings completely invalidate the hypothesis that the ease of racemization depends upon the possibility of conjugation.

An alternative explanation is that the racemization, whether or not it is identical with enolization, is similar to enolization in its dependence on the ionization of the hydrogen on the asymmetric carbon atom. That this ionization is the essential step in such processes of racemization or enolization has been demonstrated for various systems including the racemization of *l*-phenyl, *β*-*α*-butyl ketone;[10] mutarotation of an acetoacetic ester derivative;[11] bromination of ketones;[12,13] racemization of alkyl nitromethanes.[14] Even where racemization takes place[15] and enolization is improbable[16] or impossible,[17] there occurs an activation of the hydrogen which is most probably ionization.

This ionization is in turn dependent on two factors: (a) the alkalinity of the medium, and (b) the activating effects of the groups attached to the asymmetric carbon atom. It is obvious that the more alkaline the medium, the greater is the tendency of any hydrogen atom to ionize. The nature of the activating effect is more obscure. If its mechanism involves internal electron displacements,[18–20] then the adjacent activating groups must act by lowering the electron density around the asymmetric carbon atom to the requisite point where those electrons shared as a covalent pair by the hydrogen and carbon are so displaced toward the carbon as to enable the hydrogen to ionize under the influence of the hydroxyl ions. Activation would then depend on electron-attraction, and the problem of racemization of these compounds would resolve itself into a question of the relative electron-attracting effects of the various groups attached to the asymmetric carbon atom. On this basis we can, from our data and the known behavior of di- and tripeptides, uramino acids and hydantoins with respect to racemization of this type, draw certain conclusions about the relative activating effects of different radicals.

Whereas the effect of the carboxyl is not sufficient to induce racemization in either free or N-acylated amino acids under the conditions, the —CO—NHC$_6$H$_5$ group can induce racemization in the N-acetyl and N-benzoyl aminoacyl anilides (I, II, III, IV). Ring closure in the hydantoic acids is essentially substitution of the free carboxyl of a uramino acid by a CONR group, with the result that the non-racemizing uramino acids become racemizable. The greater ease of racemization of the hydantoins as compared with the open-chain compounds indicates that ring closure in itself has a large effect, but this cannot be interpreted from the data here presented.

Amino and methylamino groups are unable to induce racemization when free, as is shown by the failure of dipeptides and aminoacyl anilides to racemize under the conditions. However, acylation of the amino groups in these anilides does not necessarily lead to racemizability, for whereas the —NHCOCH$_3$ and —NHCOC$_6$H$_5$ groups are activating (I, IV), the —NHCOOCH$_2$C$_6$H$_5$ and —NHSO$_2$C$_7$H$_7$ groups have no such effect (V, VI).

In the hydantoins, replacement of the imide hydrogen atoms in position 3 by a phenyl group increases the rate of racemization (compare VII with VIII, IX with X, and XI with XII). This may be due either to an activating effect of the phenyl group or to the possibility that in the simple hydantoins the imide hydrogen atom dissociates sufficiently to decrease the (already low) hydroxyl ion concentration. Suppression of hydroxyl ion activity by ionization of the phenolic hydrogen atoms may be partially responsible for the slower rates of racemization of the tyrosine derivatives as compared with their methyl ethers (compare VII with XI, VIII with XII).

Experimental

The observed optical rotatory powers of the various preparations recorded below do not necessarily represent the maximum possible values. In the racemization experiments carried out at 20–25° the half-times are based on the initial values observed for the alkaline solutions employed.

Carbobenzoxymethoxyphenylalanine.—To 20 g. of *p*-methoxyphenylalanine dissolved in 1 equivalent of 4 *N* sodium hydroxide were added alternately during the course of one-half hour with shaking and cooling 1 equivalent of

carbobenzoxy chloride and 1 equivalent of 4 *N* sodium hydroxide. Shaking was continued until the mixture was homogeneous. On dilution and acidification to congo red an amorphous white solid precipitated out. The crude product weighing 32 g., was recrystallized from ether–petroleum ether, yielding long, flattened needles, m. p. 106–107°; soluble in alkali, ether, acetone, alcohol, benzene; insoluble in water; rotation, $[\alpha]^{25}_D$ +12° in 95% alcohol.

Anal. Calcd. for $C_{18}H_{19}O_5N$: C, 65.7; H, 5.8; N, 4.3. Found: C, 65.6; H, 5.8; N, 4.1.

N-Carbobenzoxy-*p*-methoxyphenylalanyl Anilide (V).—To 4.5 g. of carbobenzoxy-*p*-methoxyphenylalanine suspended in 150 cc. of dry ether was added 3.6 g. of finely powdered phosphorus pentachloride, and the mixture was allowed to stand at room temperature with occasional shaking until homogeneous (four hours). The ether was removed *in vacuo* and the oily residue quickly washed twice with dry petroleum ether. The amorphous residue was redissolved in 150 cc. of dry ether and 15 cc. of freshly distilled aniline in 50 cc. of dry ether was added. After twenty hours at room temperature the mixture was poured into cold dilute hydrochloric acid. The ether-soluble product was recrystallized twice from hot dilute acetone; yield 4.3 g., m. p. 171–173°; soluble in acetone, ether, alcohol; insoluble in water and carbon tetrachloride; rotation, $[\alpha]^{25}_D$ +22.3° in acetone.

Anal. Calcd. for $C_{24}H_{24}O_4N_2$: C, 71.3; H, 5.9; N, 6.9. Found: C, 71.2; H, 6.1; N, 7.0.

***p*-Methoxyphenylalanyl Anilide.**—Hydrogen gas was bubbled through a suspension of 1 g. of carbobenzoxy-*p*-methoxyphenylalanine-anilide in 50 cc. of 70% alcohol in the presence of palladium catalyst until no more carbon dioxide was evolved. The mixture was filtered and the filtrate concentrated at room temperature to 10 cc. A crop of white glistening squares crystallized out. Another crop was obtained from the mother liquor on standing in the ice box overnight; yield 584 mg., m. p. 121–123°; soluble in alcohol, acetone; slightly soluble in water and ether; rotation, $[\alpha]^{25}_D$ +34.3° in 95% alcohol.

Anal. Calcd. for $C_{16}H_{18}O_2N_2$: C, 71.1; H, 6.7; N, 10.4. Found: C, 71.1; H, 6.8; N, 10.4.

N-Acetyl-*p*-methoxyphenylalanyl Anilide (III).—To 0.100 g. of *p*-methoxyphenylalanine anilide in 3 cc. of 50% acetone was added 0.3 cc. of freshly distilled acetic anhydride. After twenty hours another 0.3 cc. of anhydride was added, and the solution was allowed to stand at room temperature for twenty-four hours. On dilution with water and cooling in the ice box overnight clusters of needles separated out; yield 95 mg., m. p. 168–170°; soluble in alcohol and acetone; insoluble in water; rotation, $[\alpha]^{25}_D$ +56.4° in 95% alcohol.

Anal. Calcd. for $C_{18}H_{20}O_3N_2$: C, 69.2; H, 6.4; N, 9.0. Found: C, 69.1; H, 6.7; N, 9.1.

Tyrosyl Anilide.—A mixture of 282 mg. of *p*-methoxyphenylalanine anilide, 10 cc. of concentrated hydriodic acid (sp. gr. 1.7), and a few crystals of phosphonium iodide was allowed to stand in a sealed tube at room temperature for forty-eight hours. The contents were then diluted with water and taken to dryness at room temperature over phosphorus pentoxide. The glassy residue was dissolved in a small amount of water and the solution made alkaline to litmus with ammonia. On cooling overnight in the ice box needles separated out which were recrystallized from hot dilute alcohol; yield 160 mg., m. p. 145–147°; soluble in acetone, alcohol and acid; insoluble in water; rotation, $[\alpha]^{25}_D$ +28.4° in 95% alcohol.

Anal. Calcd. for $C_{15}H_{16}O_2N_2$: C, 70.3; H, 6.3. Found: C, 70.2; H, 6.2.

N-Acetyltyrosyl Anilide (I).—A solution of 0.100 g. of tyrosine anilide in 3 cc. of 50% acetone was treated with acetic anhydride as previously described. On diluting with water and cooling in the ice box 98 mg. of crystalline material was obtained. This was recrystallized from dilute acetone in short rods, m. p. 236–237°; soluble in alcohol and acetone; insoluble in water; rotation, $[\alpha]^{25}_D$ +61.0° in 95% alcohol.

Anal. Calcd. for $C_{17}H_{18}O_3N_2$: C, 68.5; H, 6.0. Found: C, 68.7; H, 6.1.

N-*p*-Toluenesulfonyl-*p*-methoxyphenylalanine.—A mixture of 6 g. of *p*-methoxyphenylalanine dissolved in 1 equivalent of 1 *N* sodium hydroxide and 2 equivalents of toluenesulfonyl chloride in 50 cc. of ether was shaken for one hour. One equivalent of 1 *N* sodium hydroxide was then added and the mixture shaken for another hour. This process was repeated two more times. The aqueous layer was strongly acidified with 5 *N* hydrochloric acid and an oil separated out which solidified on standing overnight. The solid was recrystallized from hot water in long white needles, m. p. 138–140°; soluble in hot water, alcohol, ether, acetone and benzene; yield 8 g.

Anal. Calcd. for $C_{17}H_{19}O_5NS$: N, 4.0. Found: N, 4.0.

N-*p*-Toluenesulfonyl-*p*-methoxyphenylalanyl Methylanilide (VI).—To a solution of 5.5 g. of N-*p*-toluenesulfonyl-*p*-methoxyphenylalanine in 200 cc. of dry ether was added 3.6 g. of finely powdered phosphorus pentachloride and the mixture allowed to stand at room temperature with occasional shaking for four hours. The ether was removed *in vacuo* and the oily residue quickly washed twice with dry petroleum ether. It solidified in clusters of needles. These were redissolved in 150 cc. of dry ether and a solution of 17 cc. of freshly distilled methylaniline in 50 cc. of dry ether was added. The mixture was allowed to stand at room temperature for two days and then poured into cold dilute hydrochloric acid. The ether layer was washed with dilute hydrochloric acid, bicarbonate, water, and dried over sodium sulfate. On concentrating, glistening platelets together with a small amount of needles came out. On recrystallization from ether–petroleum ether 5 g. of platelets was secured; soluble in alcohol, ether, acetone; insoluble in water; m. p. 120°; rotation, $[\alpha]^{25}_D$ +18.8° in 95% alcohol.

Anal. Calcd. for $C_{24}H_{26}O_4N_2S$: C, 65.8; H, 5.9; N, 6.4. Found: C, 65.8; H, 5.9; N, 6.2.

The needles were not investigated.

N-Methyl-N-*p*-toluenesulfonyl-*p*-methoxyphenylalanyl Anilide.—A solution of 5 g. of N-*p*-toluenesulfonyl-O-N-dimethyltyrosine (prepared according to Fischer[21]) in 150 cc. of dry ether was treated with phosphorus pentachloride and aniline and worked up in the manner described above. After finally removing the ether, the glassy

(21) Fischer and Lipschitz, *Ber.*, **48**, 360 (1915).

residue was recrystallized twice from hot dilute alcohol. Clusters of long white prisms were obtained; yield 5.2 g.; m. p. 96–98°; soluble in ether, acetone, alcohol, benzene; insoluble in petroleum ether and water; rotation, $[\alpha]^{25}\text{D}$ +15.3° in 95% alcohol.

Anal. Calcd. for $C_{24}H_{26}O_4N_2S$: C, 65.8; H, 5.9; N, 6.4. Found: C, 65.8; H, 5.9; N, 6.3.

N-Methyltyrosyl Anilide.—A mixture of 4 g. of the above compound, 2.5 g. of phosphonium iodide, and 50 g. of concentrated hydriodic acid (sp. gr. 1.7) was shaken in a sealed tube at room temperature for six hours. The mixture was mixed with ice and allowed to stand for one hour. The thiocresol was filtered off; the filtrate was concentrated *in vacuo*, made alkaline with ammonia and allowed to stand in the ice box overnight. A semi-solid mass came out which was crystallized twice from hot dilute alcohol; yield 1.4 g., m. p. 139–140°; soluble in alcohol, acetone, and acid; slightly soluble in water; rotation, $[\alpha]^{25}\text{D}$ +46.8° in 95% alcohol.

Anal. Calcd. for $C_{16}H_{18}O_2N_2$: C, 71.1; H, 6.7. Found: C, 71.0; H, 6.3.

N-Acetyl-N-methyltyrosyl Anilide (II).—A solution of 200 mg. of N-methyltyrosyl anilide in 6 cc. of 50% acetone was treated with 0.6 cc. of freshly distilled acetic anhydride, allowed to stand overnight at room temperature, and again treated with 0.6 cc. of acetic anhydride and allowed to stand another twenty-four hours at room temperature. On diluting with water and cooling in the ice box for a few days, clusters of rods separated out; yield 190 mg., m. p. 185–186°; soluble in acetone and alcohol; insoluble in water; rotation, $[\alpha]^{25}\text{D}$ −32.1° in 95% alcohol.

Anal. Calcd. for $C_{18}H_{20}O_3N_2$: C, 69.2; H, 6.4; N, 9.0. Found: C, 69.1; H, 6.3; N, 8.9.

N-Benzoyl-*p*-methoxyphenylalanyl Anilide (IV).—To a solution of 74 mg. of *p*-methoxyphenylalanyl anilide in 5 cc. of benzene was added 44 mg. of freshly distilled benzoyl chloride. After standing at room temperature overnight, 0.15 cc. of 1.1 *N* sodium hydroxide was added and the mixture allowed to stand at room temperature for ten hours with occasional shaking. The solid which separated out was centrifuged down, washed with benzene and water, and then recrystallized from dilute acetone; yield 95 mg., m. p. 224–225°; long, white needles; soluble in acetone; very slightly soluble in alcohol and butyl alcohol; insoluble in water and benzene; rotation, $[\alpha]^{25}\text{D}$ +14.7° in acetone.

Anal. Calcd. for $C_{23}H_{22}O_3N_2$: C, 73.8; H, 5.9; N, 7.5. Found: C, 74.0; H, 6.1; N, 7.8.

1-Methyl-5-*p*-hydroxybenzylhydantoin (IX).—To a suspension of 1 g. of N-methyltyrosine[21] in 40 cc. of boiling water was added solid potassium cyanate until everything went into solution. The cooled solution was treated with 20% sulfuric acid until approximately one normal, and then refluxed for three hours. On cooling a white solid separated out. This was recrystallized twice from hot water, yielding 1.1 g. of flat platelets, m. p. 123–124°; soluble in hot water and alcohol; insoluble in cold water; rotation, $[\alpha]^{25}\text{D}$ −12.0° in 95% alcohol.

Anal. Calcd. for $C_{11}H_{12}O_3N_2$: C, 60.0; H, 5.5. Found: C, 59.7; H, 5.3.

1-Methyl-3-phenyl-5-*p*-hydroxybenzylhydantoin (X).—To a solution of 1 g. of N-methyltyrosine in 2 equivalents of half-normal sodium hydroxide was added 1 equivalent of phenyl isocyanate. The mixture was shaken for two hours, filtered, and the filtrate made acid to congo red. A white amorphous mass separated out which was recrystallized from hot dilute alcohol; yield 1.5 g., m. p. 153–155°; short thick rods; soluble in acetone, alcohol, and alkali; insoluble in water; rotation, $[\alpha]^{25}\text{D}$ −15.5° in 95% alcohol.

Anal. Calcd. for $C_{17}H_{16}O_3N_2$: C, 68.9; H, 5.4. Found: C, 68.8; H, 5.5.

5-*p*-Methoxybenzylhydantoin (XI).—To a solution of 0.5 g. of *p*-methoxyphenylalanine in 25 cc. of boiling water was added 2 equivalents of solid potassium cyanate. The solution was cooled and made approximately normal with 20% sulfuric acid, and then refluxed for three hours. On cooling, white leaflets came out which were recrystallized from hot water; yield 0.47 g., m. p. 171–173°; soluble in hot water, acetone and alcohol; slightly soluble in cold water; rotation, $[\alpha]^{25}\text{D}$ −89.0° in 95% alcohol.

Anal. Calcd. for $C_{11}H_{12}O_3N_2$: C, 60.0; H, 5.5. Found: C, 59.8; H, 5.4.

The authors are deeply indebted to Dr. Louis P. Hammett for advice and criticism of the theoretical portions of this paper. They also express their thanks to Mr. W. Saschek, who performed the analyses here reported.

Summary

Racemization of acylaminoacyl anilides and of hydantoins by alkali is not prevented by the introduction of groups which would restrain the formation of conjugated enolic double bonds. It is suggested that such racemization is a reflection of the electronic condition of the various groups attached to the asymmetric carbon atom.

Spinastanol and its Identity with Fucostanol and Stigmastanol

BY C. DONALD LARSEN

α-Spinasterol, first isolated from the unsaponifiable fraction of spinach fat by Clenshaw and Smedley-MacLean,[1] by Heyl, Wise and Speer,[2] and later by Simpson,[3] on the basis of the latest experimental evidence, is an isomer of stigmasterol and fucosterol. α-Spinasterol, like stigmasterol[4] and fucosterol,[5] was formerly shown,[6] by quantitative hydrogenation and perbenzoic acid titration experiments, to be doubly unsaturated. Whereas stigmasterol has been proved to be unsaturated in the 22,23-position[7] and, like fucosterol,[8] unsaturated in the 5,6-position,[9] α-spinasterol, although its points of unsaturation are unknown, apparently exhibits saturation in the more common sites of sterol unsaturation, the 5,6- and 22,23-positions. Exclusion of the 22,23-position as a site of one of the ethylenic linkages in α-spinasterol was demonstrated by the negative results of attempted ozonization.[6] Simpson[3] has drawn attention to the anomalous reactions of α-spinasterol, as compared to sterols with known 5,6-unsaturation, from which he has concluded that "this sterol differs from other sterols in that it does not contain the 5:6-double bond characteristic of the latter."

α-Spinasterol further differs from stigmasterol and fucosterol in that the former possesses a double bond that is unresponsive to hydrogenation[6] or has been caused to migrate, as has been postulated for the 7,8 double bond of ergosterol,[10] to a non-reducible position. In contrast to the nuclear double bond conjugation in ergosterol, Simpson has excluded, by the absence of a maleic anhydride reaction, the existence of conjugated unsaturations in the α-spinasterol nucleus.

Recent investigation of a series of derivatives of the completely saturated spinastanol and comparison of them with the constants of those similarly prepared from fucostanol by Heilbron and co-workers[8] and from stigmastanol[11–13] has established the identity of these three saturated sterols, and corroborates the isomerity of the unsaturated sterols from which they were derived.

Originally[2,14,15] $C_{27}H_{46}O$ was thought to be the correct formula for α-spinasterol. Later,[6,16] quantitative hydrolysis of numerous esters of α- and γ-spinasterol, and of the α- and β-spinastenols, gave molecular weight values for a C_{28} or C_{29} sterol, but preponderantly in favor of the former. Hydrolysis of the acetyl and benzoyl esters of entirely pure spinastanol and titrational determination of the equivalent weight of spinastanedicarboxylic acid now indicate for spinastanol the formula $C_{29}H_{52}O$, identical with the accepted formula for stigmastanol and fucostanol.

Critical examination of the data in Table II on the derivatives of spinastanol and comparison of their physical constants with those of the more carefully investigated C_{29} saturated sterols in Table I establishes the identity of spinastanol, fucostanol and stigmastanol. On the other hand, the melting points and specific rotations of spinastanol, spinastanyl acetate and hydrocarbon, spinastane, are significantly lower than the corresponding values of Bengtsson's sitostanol and sitostane and Bergmann's sitostanyl (ostreastanyl) acetate (Table I). Therefore, it is concluded that spinastanol, fucostanol and stigmastanol are one and the same compound, and that they are different from sitostanol and ostreastanol, in accordance with the views previously set forth by Coffey, Heilbron and Spring[8] and Bergmann.[17] Comparative and mixed melting points of fucostanyl acetate and fucostanyl 3,5-dinitrobenzoate, for samples of which the writer is indebted to Dr. Heilbron, with the respective spinastanyl esters bear out the above conclusion of identity. Likewise, samples of ostreastanol and its phenylurethan, kindly furnished by Dr. Bergmann,

[a] Deviation from theory due to unremovable solvent of crystallization. [b] Rotation in benzene; all others in chloroform.

when compared with spinastanol and its phenylurethan, corroborate the non-identity of these saturated sterols.

It will be noted that spinastanedicarboxylic acid melts at 236–237° (corr.), 7–8° higher than the reported values for the acid from fucostanol and stigmastanol. Thanks to Dr. Heilbron, a sample of fucostanedicarboxylic acid has been available for comparison, for which the reported m. p. of 227–229° (corr.) was verified; when mixed with the acid from spinastanol a m. p. of 234–235° (corr.) was obtained. Due to the very close agreement in m. p. of the several derivatives of spinastanol with available data for derivatives of fucostanol and stigmastanol, such variation in m. p. of the respective acids must be not without reason. The sample of fucostanyl acetate furnished by Dr. Heilbron melted, as reported in the literature,[8] at 129–130°, and when mixed with spinastanyl acetate did not cause any m. p. depression. Nevertheless, subjection of fucostanyl acetate to the Liebermann–Burchard reaction was met with a comparatively faint but distinct development of green color. This fact seems to indicate that fucostanyl acetate contains a small amount of unsaturated, difficultly removable sterol. Analogously, it has been found that spinastanyl acetate is obtained pure only with difficulty; unless one recrystallizes the hydrogenation product of β-spinastenyl acetate from one of the better sterol solvents, such as ether or ethyl acetate, a pure, non-chromogenic spinastanyl acetate is not obtained. The pure, saturated ester is best obtained by treatment of the recrystallized hydrogenation product in chloroform with acetic anhydride and sulfuric acid according to the technique of Anderson and Nabenhauer.[18] Therefore, it seems possible that fucostanol, from which fucostanedicarboxylic acid was obtained by oxidation with chromic acid, might very well have contained a small amount of unsaturated sterol, oxidation of which may have led to a fucostanedicarboxylic acid contaminated with very small amounts of other, difficultly removable, acidic products. Similarly, the melting

---

(18) Anderson and Nabenhauer, THIS JOURNAL, **46**, 1957 (1924).

point[12] of stigmastanedicarboxylic acid, reported as 229–230°, may be due to a small amount of contaminating oxidation product. It should be noted that the only recorded stigmastanedicarboxylic acid was prepared by Windaus and Brunken from a stigmastanol which melted at 134°; this alcohol, when pure, has since been found to melt at 136–7°.[11] It is possible that the low-melting stigmastanol of Windaus and Brunken contained a small quantity of contaminant which, through oxidation, led to a slightly contaminated dicarboxylic acid product of stigmastanol. A study of the dicarboxylic acids from fucostanol and stigmastanol of unquestioned homogeneity appears to be warranted.

Experimental

Spinastanyl Acetate.—The preparation of spinastanyl acetate was accomplished by hydrogenation of β-spinastenyl acetate in the manner previously described.[6] The product was recrystallized repeatedly from ethyl acetate and from ethyl ether. Ten grams of the acetate, m. p. 130–131°, was dissolved in 50 cc. of chloroform, to which was added slowly 10 cc. of acetic anhydride and 1 cc. of sulfuric acid. The mixture was shaken and allowed to stand for a half hour, the small amount of colored material removed by washing with water, and the solution dried and evaporated to dryness. The residue, after crystallization from ethyl acetate or acetone, melted at 131.5–132°; $[\alpha]^{20}\text{D}$ +14.9°.

Spinastanol.—The above acetyl ester was hydrolyzed by boiling for one hour in 3% alcoholic potassium hydroxide. The recovered sterol, after crystallization from alcohol and from acetone, melted at 136.5–137.0°; $[\alpha]^{20}\text{D}$ +24.4°.

Spinastanyl 3,5-Dinitrobenzoate.—This ester was prepared in the usual manner from the sterol and the acid chloride in pyridine. The ester was crystallized from acetone and from ether; m. p. 214–215°; $[\alpha]^{20}\text{D}$ +13.1° (benzene).

Spinastanyl Benzoate.—The preparation of this ester was analogous to that of the 3,5-dinitrobenzoate. It was crystallized from acetone and ethyl acetate; m. p. 135–136°; $[\alpha]^{20}\text{D}$ +19.6°.

Spinastanone.—One gram of spinastanol was dissolved in 360 cc. of 96% acetic acid, to which was added 250 mg. of chromic anhydride in 60 cc. of acetic acid and 2 cc. of water with constant stirring during one-half hour. After standing for twenty hours the acetic acid was removed under reduced pressure, the residue digested with 100 cc. of 6 *N* sulfuric acid, and the oxidation products dissolved in ether. The acidic fraction was removed by extraction with 7% aqueous potassium hydroxide, the ether was evaporated from the neutral fraction, and the residue recrystallized from methyl and ethyl alcohol; m. p. 156.5–157°; $[\alpha]^{20}\text{D}$ +40.5°; yield, 50%.

Spinastanone Oxime.—The oxime of spinastanone was prepared in the usual manner with hydroxylamine hydrochloride and sodium acetate in alcoholic solution. The recovered oxime was crystallized from methyl alcohol and from acetone; m. p. 218–219°; $[\alpha]^{20}\text{D}$ +29.2°.

Spinastanedicarboxylic Acid.—Two grams of spinastanol was dissolved in 100 cc. of warm 96% acetic acid, to which was added 2.6 g. of chromic anhydride dissolved in a few drops of water. The mixture was heated on the steam-bath for two hours with occasional stirring. The solution was cooled, after which the oxidation products were precipitated with excess water and extracted with ether. Separation of the acidic fraction was made with 7% aqueous potassium hydroxide; about 0.2 g. of spinastanone was isolated from the neutral fraction. The acidic fraction was precipitated from the alkaline extract by acidification, extracted with ether, the ether evaporated and the residue recrystallized from methyl alcohol and from acetone. The nearly pure dicarboxylic acid, m. p. 234–235°, was dissolved in ether, again extracted as the potassium salt, precipitated with dilute hydrochloric acid and extracted with fresh ether. The residue from the evaporated ether solution was recrystallized from an alcohol–chloroform mixture (3:1); m. p. 236–237; $[\alpha]^{20}\text{D}$ +33.1°; yield 30%.

Dimethyl Ester.—The methylation of spinastanedicarboxylic acid was carried out in the cold with diazomethane. The recovered dimethyl ester was crystallized from methyl and ethyl alcohol; m. p. 89.5–90°; $[\alpha]^{20}\text{D}$ +23.4°.

Spinastane.—The reduction of 0.5 g. of spinastanone to the hydrocarbon was accomplished according to the directions of Windaus and Brunken.[12] The recovered hydrocarbon was crystallized from alcohol and acetone; m. p. 84.0–84.5°; $[\alpha]^{20}\text{D}$ +25.5°.

Spinastanyl Phenylurethan.—Preparation of the phenylurethan of spinastanol was carried out in benzene with phenyl isocyanate, in the usual manner. The derivative was crystallized from methyl and ethyl alcohol; m. p. 172.0–172.5°; $[\alpha]^{20}\text{D}$ +14.3.

Molecular Weight Determinations.—Samples of spinastanyl acetate were boiled for one hour in 0.1 *N* alcoholic potassium hydroxide, and the excess alkali titrated with accurately standardized 0.1 *N* hydrochloric acid. Blank samples of alkali were boiled and titrated simultaneously. Hydrolysis of 0.3141, 0.2770, 0.2919, 0.1980, 0.1657, 0.3222 and 0.2054 g. of spinastanyl acetate consumed 6.91, 6.02, 6.43, 4.32, 3.56, 7.31 and 4.47 cc. of 0.1000 *N* alkali, respectively, corresponding to molecular weights of 455.7, 460.1, 452.7, 458.3, 464.8, 454.4 and 459.4; average molecular weight found, 457.9; calculated on the basis of $C_{31}H_{54}O_2$, 458.4.

Samples of spinastanyl benzoate were hydrolyzed in a manner analogous to that for the acetyl ester. Hydrolysis of 0.2810 and 0.1413 g. of spinastanyl benzoate consumed 5.45 and 2.73 cc. of 0.1000 *N* alkali, respectively, corresponding to molecular weights of 515.6 and 517.6; average, 516.6; calculated on the basis of $C_{36}H_{56}O_2$, 520.4.

Samples of spinastanedicarboxylic acid were titrated with dilute potassium hydroxide for equivalent weight determination. Samples of 0.1020 and 0.0761 g. of the acid were dissolved in neutral alcohol, to which was added 7.49 and 6.50 cc. 0.1000 *N* hydrochloric acid, respectively. Total 0.1000 *N* alkali required for neutralization was 11.95 and 9.81 cc., respectively; net, 4.46 and 3.31 cc. Equivalent weights found, 228.7 and 229.9; average, 229.3; calculated on the basis of $C_{29}H_{50}O_4$, 231.2.

Summary

1. A series of derivatives of spinastanol have been prepared, the physical constants of which warrant the conclusion that this saturated sterol is identical with fucostanol and stigmastanol.

2. The identity of spinastanol, fucostanol and stigmastanol points out the isomerity of the naturally occurring sterols from which these saturated derivatives are obtained.

3. Spinastanol appears to differ from ostreastanol and sitostanol, probably in the arrangement of the side chain rather than in the carbon skeleton of the nucleus.

4. Hydrolysis of the acetyl and benzoyl esters of spinastanol, and titration of the equivalent weight of spinastanedicarboxylic acid, establish for the spinach sterols a skeleton of twenty-nine carbon atoms, in common with other well investigated phytosterols.

Studies in Organic Peroxides. V. *t*-Butyl Hydroperoxide[1]

BY NICHOLAS A. MILAS AND S. ARTHUR HARRIS[2]

The extraordinary stability of *t*-butyl hydrogen peroxide solution[3] and its therapeutic efficacy in the treatment of various fungus diseases[4] have stimulated our interest in the investigation of its chemical nature. In view of the lability of the hydroxyl group in tertiary alcohols, it was early suspected that pure hydrogen peroxide in non-aqueous solution would react with *t*-butyl alcohol reversibly to form *t*-butyl hydroperoxide. Although such a reaction between alcohols and hydrogen peroxide is unknown, an analogous reaction between organic acids and hydrogen peroxide in non-aqueous solvents has been known for some time.[5]

$$(CH_3)_3COH + HOOH \rightleftarrows (CH_3)_3COOH + H_2O$$

All of the alkyl hydroperoxides known, methyl,[6] ethyl,[6] isopropyl,[7] are much less stable than *t*-butyl hydroperoxide, which, besides being stable at room temperature, decomposes very slowly in alkalies or in the presence of pure liver catalase or horse-radish peroxidase. A distinct advantage, however, lies in the simplicity of its preparation. While the other hydroperoxides have been made by the alkylation of hydrogen peroxide with the corresponding dialkyl sulfates, *t*-butyl hydroperoxide can be prepared very easily from the anhydrous *t*-butyl alcoholic solution of hydrogen peroxide[3] by subjecting the latter to fractionation under reduced pressure in the presence of dehydrating agents such as anhydrous magnesium sulfate or preferably glacial metaphosphoric acid.

Experimental Part

Preparation of *t*-Butyl Hydroperoxide.—To 600 cc. of 30% aqueous hydrogen peroxide "Albone C" was added with frequent shaking 2340 cc. of *t*-butyl alcohol (b. p. 81.7–81.8°) and the solution allowed to stand for fifteen minutes, when 225 g. of anhydrous sodium sulfate was added slowly with vigorous shaking. The mixture separated into two layers and the non-aqueous layer containing most of the peroxide was removed and shaken first with 225 g. more of anhydrous sodium sulfate, then with two 225-g. portions of anhydrous magnesium sulfate. The final mixture which was essentially free from water was filtered and the filtrate allowed to stand several days over 400 g. of glacial metaphosphoric acid. This treatment produced a peroxide solution having an active oxygen content equivalent to about 17% *t*-butyl hydroperoxide.

To obtain the pure hydroperoxide, samples of the above were fractionated several times under diminished pressure over glacial metaphosphoric acid or anhydrous magnesium sulfate using an all-glass apparatus and the fraction boiling at 38–38.5° (18 mm.) collected and analyzed. Both the metaphosphoric acid and the magnesium sulfate, when used as dehydrating agents, brought about the production of the same peroxide. That this peroxide is not a constant boiling mixture between hydrogen peroxide and *t*-butyl alcohol, is shown by its physical and chemical properties.

Anal. Calcd. for $C_4H_{10}O_2$: C, 53.33; H, 11.11; active (O), 17.78. Found: C, 53.68, 53.63; H, 11.10, 11.17; active (O), 17.84, 18.10, 18.21.

The peroxide is a colorless ethereal liquid with a sharp irritating odor having a density at 25° of 0.91063 and a freezing point of −13.5°. It is soluble in most of the ordinary organic solvents and unlike hydrogen peroxide is completely soluble in saturated hydrocarbons such as petroleum ether; in water it goes into solution slowly. It explodes violently when heated in the open flame although it has been refluxed for several hours in *t*-butyl alcohol without any appreciable decomposition. It liberates iodine slowly from an acidified solution of potassium iodide; it decomposes rapidly when heated with dilute alkalies, but retains its peroxide strength for several months when mixed at room temperature with a 10% solution of sodium hydroxide.

t-Butyl hydroperoxide is not easily converted into *t*-butyl chloride unless a reducing agent is used together with concentrated hydrochloric acid. Thus, when an ice-cold solution of concentrated hydrochloric acid containing 20 g. of ferrous chloride was mixed with about 4 g. of pure *t*-butyl hydroperoxide, an immediate reaction occurred with the separation of *t*-butyl chloride, which was separated, shaken with sodium bicarbonate solution, dried over calcium chloride and distilled; a yield of 2.5 g. of *t*-butyl chloride, b. p. 51°, was obtained.

The Effect of Catalase on the Decomposition of *t*-Butyl Hydroperoxide.—It has been known for some time that catalase has a specific action on the decomposition of hydrogen peroxide but has no effect on alkyl hydroperoxides.[8] Contrary to these early observations Stern[9] recently has reported that ethyl hydroperoxide is slowly attacked by catalase although Keilin and Hartree[10] are not in agreement with this observation and attributed the decomposition of this peroxide to a secondary reaction.

Catalase has very little or no effect on the decomposition of *t*-butyl hydroperoxide as can be seen readily by the results given in Table I. The catalase used in these experiments was a crystalline preparation[11] suspended in ammonium sulfate solution and kindly supplied to us by Professor Sumner of Cornell University. The *p*H of the catalase was adjusted just before use with disodium phosphate to 8.2[12] and 1 cc. of this solution was added to each of several glass-stoppered tubes. By means of a calibrated 0.1-cc. special pipet, 0.1 cc. of *t*-butyl hydroperoxide was added to each tube except one which was reserved for a blank with 0.1 cc. of 30% aqueous hydrogen peroxide solution. All tubes were shaken during the experiments at about 26.5°. At the end of a definite time the entire contents of each tube was treated with an acidified solution of sodium iodide and the iodine liberated titrated against standard thiosulfate solution. The hydrogen peroxide in the blank was destroyed completely by the catalase preparation in less than two minutes. With *t*-butyl hydroperoxide, on the other hand, the catalase turned red from a straw color and back again to its original color after fifteen hours of shaking with no evolution of gas. This color change may indicate the formation of an intermediate complex between the peroxide and catalase. An analogous observation was made by Stern[9b] with ethyl hydroperoxide. The results of seven experiments are shown in Table I.

TABLE I

EFFECT OF CATALASE ON THE DECOMPOSITION OF *t*-BUTYL HYDROPEROXIDE

Effect of Peroxidase on the Decomposition of *t*-Butyl Hydroperoxide.—Peroxidase, unlike catalase, has been found to activate the decomposition of alkyl hydroperoxides in the presence of acceptors such as pyrogallol which is simultaneously oxidized to purpurogallin.[13] Although the decomposition of *t*-butyl hydroperoxide is activated slowly by peroxidase, we failed to observe any precipitate of purpurogallin. The peroxidase preparation used in our experiments was an extract of horse-radish kindly supplied to us by Professor Gould of our Biology Department. The *p*H of the preparation was adjusted to 6.21 and all of the experiments were carried out at 28°.

The experimental procedure was as follows: 2 g. of pure pyrogallol was dissolved in 800 cc. of distilled water and to each of several 250-cc. glass-stoppered Erlenmeyer flasks was added 80 cc. of this solution, 5 cc. of the peroxidase preparation and 0.1 cc. of *t*-butyl hydroperoxide; one sample was retained as a blank to which was added 0.1 cc. of 30% hydrogen peroxide instead of *t*-butyl hydroperoxide. At the end of a definite time each sample was titrated as before for the presence of peroxide. Hydrogen peroxide was destroyed completely in about four minutes with considerable evolution of heat and abundant precipitation of purpurogallin. In the experiments with *t*-butyl hydroperoxide, the solution turned orange in color but no precipitate appeared even after one hour of standing. The peroxide was used up very slowly, as the results indicate in Table II.

TABLE II

EFFECT OF PEROXIDASE ON THE DECOMPOSITION OF *t*-BUTYL HYDROPEROXIDE

Effect of Palladium Black on the Decomposition of *t*-Butyl Hydroperoxide.—The palladium black used in these experiments was prepared in accordance with the method of Wieland.[14] Ten mg. of this catalyst was mixed in each of several experiments with 1 cc. of disodium phosphate solution (*p*H 8.2) containing 0.1 cc. of *t*-butyl hydroperoxide and the mixture shaken at room temperature in glass-stoppered tubes similar to those used with the catalase experiments. The results of four experiments are shown in Table III. Hydrogen peroxide under the same conditions was destroyed completely by our palladium catalyst in less than one minute.

TABLE III

EFFECT OF PALLADIUM ON THE DECOMPOSITION OF *t*-BUTYL HYDROPEROXIDE

Time, min.	0	10	23	52
0.01982 *N* thio, cc.	66.0	38.0	22.0	21.7

The results in Table III seem to indicate that palladium black slowly accelerates the decomposition of *t*-butyl hydroperoxide in a dilute solution of disodium phosphate. However, pure *t*-butyl hydroperoxide is only slowly attacked by palladium black and a pure sample of it stirred over this catalyst for several months was still strongly peroxidic.

Summary

1. *t*-Butyl hydroperoxide has been prepared by the fractionation of an anhydrous solution of hydrogen peroxide in *t*-butyl alcohol in the presence of dehydrating agents.

2. This peroxide has been found to be very stable under ordinary conditions.

3. Pure liver catalase and horse-radish peroxidase have very little or no effect on the decomposition of *t*-butyl hydroperoxide.

4. Palladium black catalyzes slowly the decomposition of *t*-butyl hydroperoxide in dilute solution of disodium phosphate, although the decomposition of the peroxide is only slightly affected by this catalyst.

Lengthening Carbon Chains by Three Units: Assay of Primary Bromides from the Addition of Hydrogen Bromide

BY A. P. KOZACIK AND E. EMMET REID

It is well known that an alkyl bromide may be converted into a primary alcohol with either one or two additional carbon atoms in the chain. The object of this investigation was to provide a method of lengthening a carbon chain by three —CH_2— units: $RBr \longrightarrow RMgBr \longrightarrow RCH_2CH{=}CH_2 \longrightarrow RCH_2CH_2CH_2Br$. This combines an old reaction with one[1] that has been studied only recently. In addition to lengthening the chain this gives odd-numbered bromides from the readily obtainable even. It was particularly interesting to extend these reactions to the higher alkyls and to aromatics. Another object was to identify the primary bromides by crystalline derivatives and to get a rough estimate of their purity. The abnormal addition of hydrogen bromide is of great theoretical interest; the availability of the primary bromides so produced for syntheses is a practical question of importance. The alkenes are given in Table I.

The addition of the hydrogen bromide was carried out by Professor Kharasch.[2] Our results show conclusively that the primary bromides are obtained. The melting points of these are in Table II. It was too much to expect that the technique which he has developed for the lower alkenes would apply to the higher without some modification. Unfortunately the whole amounts of the alkenes that were available were run through with the standard technique before any of the products were tested. The results were good with nonene-1 but very poor for heptadecene-1 and nonadecene-1. The identity of the synthetic bromides was shown and their approximate purity estimated by their reaction with para substituted phenols. For compari-

son the authentic bromides previously prepared[3] were treated with the same phenols, under the same conditions and usually at the same time. The products were crystallized two or more times. The phenyl derivatives were treated with β-naphthol. Only in the case of 3-phenylpropyl bromide was an authentic sample available for comparison.

TABLE II

MELTING POINTS OF AUTHENTIC (A) AND SYNTHETIC (S) BROMIDES AS RECEIVED

Carbons	A	S	Diff.	Minimum estimated purity
9				82
11	−13.15	−25	12	65
13	5.94	−15	21	41
15	18.63	7.4–8.4	10	60
17	28.40	1–2	26	12
19	38	13–15	23	3

From the results in Table III it will be seen that the products from the synthetic bromides are somewhat less in amount and melt lower than those from the authentic. The losses on the first crystallization are even more significant. Taking the data for the nonyl bromides, we find this loss to average 11% for the authentic and 28 for the synthetic. In the second crystallization the losses were nearly the same. For practical purposes the primary bromide present may be estimated by comparing the final yields of the twice crystallized derivatives with those from the authentic bromides. These estimates may be regarded as minimum values. Thus we can say that there was at least 82% of the primary bromide, and probably somewhat more, present in the synthetic nonyl bromide. The other syn-

[3] Meyer and Reid, THIS JOURNAL, **55**, 1577 (1933).

thetic bromides do not show up so well: the undecyl may be estimated to contain at least 65% of the primary, the tridecyl, 41, the pentadecyl 60, the heptadecyl 12 and the nonadecyl only 3. The melting points of the bromides put them in the same order as to purity.

Experimental

The procedure of Gilman[4] for the preparation of the Grignard reagents was followed. These reagents were used according to the method of Wilkinson,[5] for making the alkenes, which were separated from the disproportionation by-products of the Grignard reaction, heated with sodium and distilled. The properties of the new alkenes are to be found in Table I. The bromine numbers were determined by the method of Francis[6] as modified by Cortese.[7]

Preparation of Derivatives.—To prepare a derivative, 0.3 to 0.5 cc. of the alkyl halide was measured into a test-tube with 3 cc. of alcohol and about 10% excess of the phenol. As $C_{19}H_{39}Br$ is a solid, it was weighed. This mixture was heated to effect solution and a slight excess of 1 *N* alcoholic potash added. The test-tube was stoppered loosely and placed with others in a beaker of water kept at about 70° for about twelve hours. At the end of the heating any alcohol that had evaporated was replaced and 2 cc. of hot water added. The mixture was boiled for a moment and then cooled quickly with violent shaking. This caused the derivative to separate as a granular solid which was collected on a filter and washed twice with water. The product was crystallized twice or thrice from alcohol. For better comparison the derivatives of the authentic and synthetic bromides were prepared at the same time with the same reagents and the crystallizations were carried on side by side. The final melting points were kindly taken by Mrs. Carrie Gutman Moses with a standardized thermometer.

For preparing derivatives para substituted phenols were used. Experience in another investigation had shown that these give derivatives that are readily purified and melt at convenient temperatures. The monoalkyl hydroquinone ethers will be described later along with other derivatives made from them.

Summary

1. A method has been devised for transforming an alkyl bromide into another alkyl bromide having a carbon chain longer by three units.

2. A method has been worked out for assaying the mixture of bromides obtained by the addition of hydrobromic acid to unsaturates.

3. By the preparation of known crystalline derivatives the formation of primary bromides by the addition of hydrobromic acid to alpha alkenes in the presence of peroxides has been confirmed.

Sterols. XLIV. Pregnanone-3 and Related Compounds[*]

BY RUSSELL E. MARKER AND ELMER J. LAWSON

Although all the pregnanediols, pregnanolones, and pregnanediones isomeric about C_3, C_5 and C_{20} have been described,[1] none of the corresponding pregnanols and pregnanones are known. Since we now have indications of the occurrence in urines of pregnane derivatives having only one oxygen atom,[2] we have begun the synthesis of compounds of this type for purposes of comparison and physiological testing. The present paper describes the preparation of pregnanone-3 and the isomeric 3-pregnanols.

Pregnanol-3(α)-one-20 was reduced by the Clemmensen method with amalgamated zinc and a mixture of acetic and concentrated hydrochloric acids. The reaction mixture, carried through the acid succinate separation, yielded only 19 mg. of pregnanol-3(α), but about 250 mg. (m. p. 102°) of what proved to be pregnanol-3 acetate could be crystallized from the non-hydroxylated fraction, and a further crop of pregnanol-3(α) was obtained from the mother liquor after alkaline hydrolysis and acid succinate separation. The non-hydroxylated fraction, amounting to about 20% of the reaction mixture, did not yield any crystalline products.

Since it was thought at first that the crystalline product might be a pregnene, which could be identified by ozonolysis to give $3\|4$ pregnane-3,4-diacid,[3] or an isomer, this acid was prepared by the Clemmensen reduction of 20-keto-$3\|4$-pregnane-3,4-diacid.[4] The latter forms a 2,4

(4) Butenandt, *Ber.*, **63**, 659 (1930); **64**, 2529 (1931).

dinitrophenylhydrazone, but, after the reaction with zinc and hydrochloric acid, the product no longer forms such a derivative. The same 3||4-pregnane-3,4-diacid was formed in small amounts when pregnanol-3(α) was oxidized with chromic acid. The major reaction product, pregnanone-3, was hydrogenated in acid solution to give pregnanol-3(β).

Since most of the pregnanol-3(α) formed in the Clemmensen reduction of pregnanol-3(α)-one-20 was converted by the acetic acid present into its acetate, model experiments were tried with *epi*- and β-cholestanol. When these were refluxed with amalgamated zinc and acetic acid–hydrochloric acid the chief reaction products were unreacted *epi*-cholestanol, and β-cholestyl acetate, respectively. Evidently, when a Clemmensen reaction is run on a hydroxy ketone, the reaction mixture should be subjected to alkaline hydrolysis to isolate the product. In this connection it also should be noted that the Clemmensen reduction of hydroxylated steroids frequently removes the hydroxyl groups. For example, the diacetate of 4-hydroxystigmasterol is reduced to stigmastane[5] and the hydroxyketocholanic acids give some cholanic acid.

Experimental Part

The pregnanol-3(α)-one-2 used in these experiments was isolated from human pregnancy urine[6] and melted at 134°. Apparently it can exist in two polymorphic forms, for sometimes crystals, m. p. 148°, are obtained. It forms a 2,4-dinitrophenylhydrazone which melts at 229° after recrystallization from alcohol.

Anal. Calcd. for $C_{27}H_{38}O_5N_4$: C, 64.9; H, 7.7. Found: C, 64.8; H, 8.0.

Pregnanol-3(α).—A mixture of 40 g. of amalgamated zinc, 100 cc. of concentrated hydrochloric acid, and 1 g. of pregnanol-3(α)-one-20 in 100 cc. of acetic acid was refluxed gently. The initial pink color of the solution was discharged in ten minutes, and after another ten minutes an oil had separated. After two hours of heating the solution was cooled, diluted with water, and extracted with ether. The ethereal extract was washed with sodium carbonate solution and water, and the ether removed. The sirupy residue was treated with Girard's reagent to remove traces of ketonic material, and then separated into hydroxylated and non-hydroxylated fractions in the usual manner.

The non-hydroxylated sirup, consisting almost all of the product, crystallized on standing a week; so it was triturated with 5 cc. of alcohol, collected on a funnel, and washed with small amounts of alcohol to give 370 mg. of crystals, m. p. 87–93°. One recrystallization from methanol gave 190 mg. of plates, m. p. 101–102°. This was recrystallized to a constant m. p., 106°. It was saturated to bromine and catalytic hydrogenation and did not give a Beilstein test for halogens. Analysis showed it to be the acetate of pregnanol-3(α).

Anal. Calcd. for $C_{23}H_{38}O_2$: C, 79.7; H, 11.1. Found: C, 79.3; H, 11.1.

One hundred and ninety milligrams of the acetate was hydrolyzed by heating with 0.2 g. of sodium hydroxide in 5 cc. of alcohol for one-half hour. The product, isolated by extraction of the diluted solution with ether, was recrystallized from slightly diluted alcohol and methanol to give pure pregnanol-3(α), m. p. 148°, as needle-rosets.

Anal. Calcd. for $C_{21}H_{36}O$: C, 83.2; H, 11.4. Found: C, 83.4; H, 11.4.

The total mother liquor from the crystallization of the acetate was hydrolyzed and carried through the acid-succinate separation, to give an additional quantity of pregnanol-3(α). The yield of pregnanol-3(α) from pregnanol-3(α)-one-20 was about 50%, of which only 19 mg. was obtained from the original hydroxylated fraction.

Pregnanone-3.—To a solution of 200 mg. of pregnanol-3(α) in 10 cc. of acetic acid was added 80 mg. of chromic anhydride in 5 cc. of 90% acetic acid. After standing for one and one-half hours at room temperature, a little methanol was added to destroy any excess chromic acid, and the solution was concentrated *in vacuo*. The residue was diluted and extracted with ether, and the ether extract washed free of chromium salts with dilute hydrochloric acid and water. The ether solution was extracted with 5% sodium carbonate and washed with water.

Acidification of the alkaline extract gave a flocculent acid which coagulated on standing. It was collected and washed with water and small amounts of hot alcohol to give 7 mg. of 3||4-pregnane-3,4-diacid, m. p. 297°, as proved by mixed melting point determination with an authentic sample (*vide infra*).

The neutral ethereal extract was evaporated and the residue crystallized several times from diluted alcohol to give 140 mg. of pregnanone-3, as needles, m. p. 115°. It gave a red coloration with alcoholic *m*-dinitrobenzene and aqueous potassium hydroxide, showing the presence of a 3-carbonyl group.

Anal. Calcd. for $C_{21}H_{34}O$: C, 83.4; H, 11.3. Found: C, 83.6; H, 11.3.

Fifteen milligrams of pregnanone-3 was treated in the usual manner with alcoholic semicarbazide acetate solution. The resulting semicarbazone, m. p. 133°, proved to be difficult to purify because of its great solubility in all ordinary solvents except ether. The 2,4-dinitrophenylhydrazone, however, proved to be a satisfactory derivative. After crystallization from alcohol, it melted at 163°.

Anal. Calcd. for $C_{27}H_{38}O_4N_4$: C, 67.0; H, 8.0. Found: C, 66.7; H, 8.2.

Pregnanol-3(β).—A solution of 100 mg. of pregnanone-3 in 20 cc. of acetic acid and five drops of 48% aqueous hydrobromic acid was added to 50 mg. of previously reduced platinum oxide in 20 cc. of acetic acid, and the mixture was shaken in a hydrogen atmosphere at 35 lb. (2.3 atm.) pressure for two hours. The catalyst was removed by filtration, and the acetic acid removed *in vacuo*. The residue was heated for twenty minutes with 0.3 g. of sodium

(6) Marker and Kamm, *ibid.*, **59**, 1373 (1937).

hydroxide in 8 cc. of alcohol, diluted and extracted with ether. The washed ethereal extract was evaporated, and the crystalline residue dissolved in 10 cc. of hot alcohol. To this solution was added a hot solution of 0.4 g. of digitonin in 20 cc. of alcohol. The next day the digitonide was filtered, dried and decomposed in the usual manner to give the carbinol. After recrystallization from slightly diluted alcohol, the pregnanol-3(β) was obtained as needles, m. p. 144°, which depressed with pregnanol-3(α) to 115–120°.

Anal. Calcd. for $C_{21}H_{36}O$: C, 82.8; H, 11.8. Found: C, 82.9; H, 11.8.

Twenty milligrams of pregnanol-3(β) was converted into its acetate by refluxing for a half hour with 2 cc. of acetic anhydride. After recrystallization from dilute alcohol, it melted at 87°.

Anal. Calcd. for $C_{23}H_{38}O_2$: C, 80.1; H, 11.3. Found: C, 80.4; H, 11.5.

3||4-Pregnane-3,4-diacid.—The 20-keto-3||4-pregnane-3,4-diacid used in these experiments was obtained by D. M. Jones of this Laboratory as a by-product in the preparation of pregnanedione, and it had a melting point of 270°. It formed a 2,4-dinitrophenylhydrazone which was crystallized from alcohol to a constant m. p. 210°.

Anal. Calcd. for $C_{27}H_{36}O_8N_4$: C, 59.6; H, 6.7. Found: C, 59.5; H, 7.0.

A mixture of 40 g. of amalgamated zinc, 1 g. of 20-keto-3||4-pregnane-3,4-diacid, 100 cc. of concentrated hydrochloric acid, and 100 cc. of acetic acid was refluxed for five hours, small portions of acetic acid and hydrochloric acid being added from time to time. The suspended acid was collected and washed with ether to give 0.53 g., m. p. 260–270°. This product was purified by leaching with boiling alcohol, in which, in contrast to 20-keto-3||4-pregnane-3,4-diacid, it is very insoluble. Extraction of the acetic acid–hydrochloric acid filtrate with ether, and concentration of the latter gave an additional quantity of the product, 3||4-pregnane-3,4-diacid, m. p. 297°. This acid is extremely insoluble in all ordinary solvents.

Anal. Calcd. for $C_{21}H_{34}O_4$: C, 71.4; H, 9.7. Found: C, 71.3; H, 9.5.

A solution of 30 mg. of 3||4-pregnane-3,4-diacid in 20 cc. of methanol and 10 drops of concentrated sulfuric acid was concentrated to one-third volume by heating for two hours on a steam-bath. The solution was diluted with water, extracted with ether, and the ethereal extract washed with sodium carbonate solution and water. After evaporation of the ether, the residue was crystallized from methanol to give the dimethyl ester of 3||4-pregnane-3,4-diacid, m. p. 147°.

Anal. Calcd. for $C_{23}H_{38}O_4$: C, 72.5; H, 10.1. Found: C, 72.2; H, 9.9.

We wish to thank Dr. Oliver Kamm and Parke, Davis and Company for their generous support of this work. We also wish to thank Dr. A. H. Popkin for the microanalyses reported in this paper.

Summary

The preparations of pregnanone-3 and the isomeric 3-pregnanols are described. The Clemmensen reduction, in the presence of acetic acid, of hydroxylated compounds may give rise to acetylated products.

Sterols. XLV. The Neutral Reduction Products of Equilenin*

BY RUSSELL E. MARKER, EWALD ROHRMANN, EUGENE L. WITTLE AND FRANK H. TENDICK

While the phenolic reduction products of equilenin have been studied rather extensively[1–3] no such study has been reported on the neutral reduction products which often accompany the phenolic reduction products. Marker *et al.*[2] carried out the catalytic hydrogenation of equilenin in acidic solution and found that the main product of the reaction was $\Delta^{5,7,9}$-oestratrienol-17. All searches for completely saturated compounds in the reaction were unsuccessful, indicating the extreme stability of the $\Delta^{5,7,9}$-oestratrienol-17 to further reduction.

Marker[3] made an extensive study of the phenolic reduction products of equilenin, α-dihydroequilenin, and β-dihydroequilenin, using sodium and amyl alcohol. In every case it was found that the reaction gave approximately 20% of phenolic reduction products, the remainder consisting largely of neutral reduction products. The phenolic reduction products were shown to be the α- and β-oestradiols. We have now extended these studies to the neutral reduction products of these reactions. The neutral fraction from the reduction of equilenin gave a diol (I) $C_{18}H_{24}O_2$, melting at 172°. This same compound was produced by the analogous reduction of α-dihydroequilenin, thus establishing the configuration of the hydroxyl group at C_{17}. The

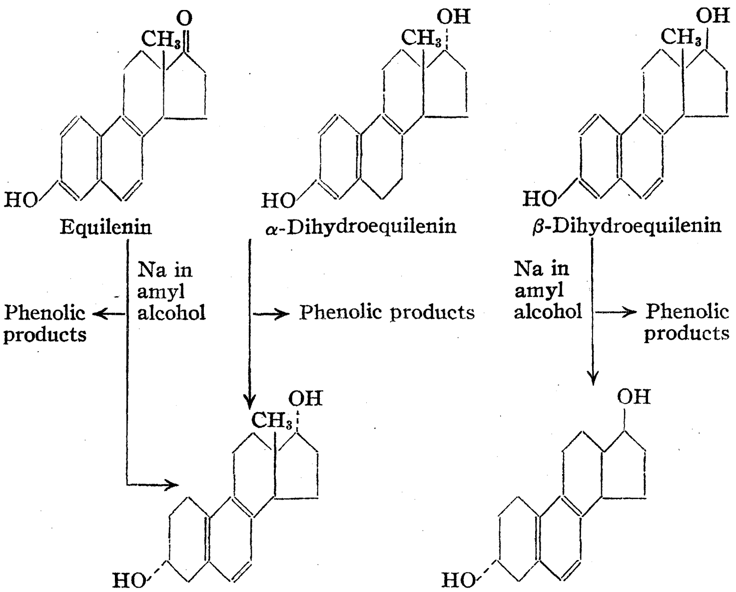
[3] Marker, *ibid.*, **60**, 1897 (1938).

reduction of β-dihydroequilenin gave a diol (II) melting at 179° and possessing the β-configuration at C_{17}. Attempts to oxidize these diols to diketones resulted in the formation of uncrystallizable oils. The fact that the only diol isolated from the equilenin reduction possessed the α-configuration at C_{17} indicates that the sodium and amyl alcohol reduction gives largely the α-form at C_{17} as in the case of oestrone reduction.

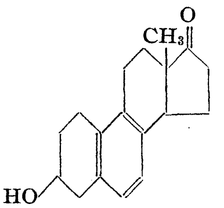
It is not possible to assign a definite configuration to the hydroxyl group at C_3, although it is most probable that the same configuration at C_3 is obtained in both of the diols.

A compound apparently related to the two reduction products which we have prepared is that obtained by Remesov[4] by the degradative oxidation of the side chain of neoergosterol. This compound, being derived from neoergosterol, must possess the β-configuration at C_3. Aside from the differences at C_{17}, this compound may differ from the present diols in the configuration of the hydroxyl group at C_3. Inasmuch as Remesov's compound possessed oestrogenic activity comparable to that of oestrone, one might expect the corresponding dihydro compounds to be high in oestrogenic activity. The fact that Windaus and Deppe[5] obtained *epi*-neoergosterol by the reduction of dehydroneoergosterol with sodium and amyl alcohol suggests that our reduction products of equilenin probably possess the α-configuration at C_3 in contrast to the β-configuration which Remesov's compound possesses.



I, 5,7,9-Oestratrienediol-3(α), 17(α)

II, 5,7,9-Oestratrienediol-3(α), 17(β)



III, 5,7,9-Oestratrieneol-3(β)-one-17 (Remesov)

We wish to thank Dr. Oliver Kamm and Parke, Davis and Company for their generous help and assistance in various phases of this work.

Experimental Part

5,7,9-Oestratrienediol-3(α),17(α) from Equilenin.—The neutral fraction obtained by the reduction of equilenin with sodium and amyl alcohol was used.[3] The crude fraction was sublimed in high vacuum at 160–200°. The sublimed material was crystallized from acetone to give white crystals melting at 172°.

Anal. Calcd. for $C_{18}H_{24}O_2$: C, 79.3; H, 8.9. Found: C, 79.2; H, 8.9.

A monobenzoate was prepared by allowing a solution of the diol in pyridine and a slight excess of benzoyl chloride to stand for two days at room temperature. The solution was diluted with water and after standing for several hours the product was extracted with ether. The ether solution was washed well with a saturated sodium carbonate solution and then with water, and evaporated to dryness. The benzoate thus obtained, after crystallization from ethyl acetate, melted at 195°.

Anal. Calcd. for $C_{25}H_{28}O_3$: C, 79.7; H, 7.5. Found: C, 79.7; H, 7.7.

5,7,9-Oestratrienediol-3(α),17(α).—The neutral fraction obtained by the reduction of α-dihydroequilenin with sodium and amyl alcohol was used.[3] The material was distilled in high vacuum, most of it distilling at 160–200°. The sublimed material was crystallized from acetone to give white crystals melting at 172°, uncorr. This gave no depression in melting point when mixed with a sample obtained by the reduction of equilenin with sodium and amyl alcohol.

5,7,9-Oestratrienediol-3(α),17(β) from β-Dihydroequilenin.—The neutral fraction from the reduction of β-dihydroequilenin with sodium and amyl alcohol[3] was purified by leaching with cold ether, followed by crystallization from dilute acetone. It gave a product crystallizing in thick needles, m. p. 179°. It gave a large depression in melting point when mixed with the 17(α)-diol.

Sterols. XLVI. The Steroid Content of Cows' Pregnancy Urine*

BY RUSSELL E. MARKER

Although numerous investigations of the steroid content of human and mare urines have been described,[1] relatively little work has been done with other urines. In order to supply this deficiency we have undertaken to investigate the steroids present in the urines of other *mammalia*. A preliminary study[2] has revealed the presence in stallions' urine of β-equistanol, an *allo*-triol, $C_{21}H_{36}O_3$, an *allo*-tetrol, $C_{21}H_{36}O_4$, and a uranetriol-3,11,20. A similar preliminary study of cows' pregnancy urine is presented in this paper.

The butanol extract of 200 gallons (760 liters) of cows' pregnancy urine was extracted with alkali to remove phenols, and then hydrolyzed by steam distillation in the presence of an excess of strong alkali. From a concentrated ethereal solution of the resulting non-volatile tar, a crude pregnanediol mixture was obtained. Fractional crystallization of the acetate mixture from this crude crop yielded the diacetate of pregnanediol-3(α),20(α), m. p. 179°, and from this the diol was obtained. The soluble acetate mother liquor after hydrolysis yielded *allo*-pregnanediol-3(α),20(α). The mother liquor from the crude pregnanediol mixture was freed of traces of ketones by the use of Girard's reagent, and treated with digitonin. The insoluble digitonide was decomposed, and after treatment with bromine this 3(β)-OH sterol mixture was again treated with digitonin. The insoluble digitonide gave, after decomposition, *allo*-pregnanediol-3(β),20(α), and the mother liquor from this digitonide gave cholesterol. The mother liquor from the original digitonin treatment yielded the soluble digitonide of β-equistanol, from which the latter was obtained on decomposition, and an ethereal solution free of 3(β)-OH sterols. After the latter was separated into hydroxylated and non-hydroxylated fractions by means of the acid succinates, the non-hydroxylated fraction was distilled in a high vacuum, and yielded a hydrocarbon, $C_{28}H_{58}$, m. p. 63°. The carbinol fraction was epimerized with sodium in boiling xylene, and then treated with digitonin. The insoluble digitonide yielded *allo*-pregnanediol-3(β),20(α), which had been formed from some *allo*-pregnanediol-3(α),20(α) not removed in the original separation of the crude pregnanediol mixture. The soluble digitonide yielded β-equistanol, which must have been produced by the epimerization of α-equistanol originally present. The mother liquor from the digitonides, containing no 3(β)-OH sterols, was distilled in a high vacuum, and sirupy fractions collected at 115–150° and 150–200°. Since these fractions could not be crystallized readily, they were oxidized with chromic acid. The higher boiling fraction gave no definite products, while the lower boiling fraction gave an aliphatic acid, $C_{18}H_{36}O_2$, m. p. 55°, suggesting the presence of an aliphatic primary alcohol in the original urine extract.

The isolation from cows' pregnancy urine of the three pregnanediols, in about half the amounts present in human pregnancy urine, lends further support to the theory of the interrelationships of the sex hormones advanced in a paper of this series.[1] The occurrence of both the β- and α-equistanols in cows' pregnancy as well as in stallions, urine[2] and in mares' pregnancy urine[3] but not in human pregnancy urine seems to indicate, as suggested earlier,[2] that their presence may be traced to the herbivorous diet of these animals. The hydrocarbon $C_{28}H_{58}$, m. p. 63°, has been found to occur in human pregnancy urine,[4] in stallions' urine,[4] and in mares' pregnancy urine[4] as well as

(3) Marker, Rohrmann and Wittle, *ibid.*, **60**, 1561 (1938).

(4) Unpublished results from this Laboratory.

in cows' pregnancy urine. Apparently other hydrocarbons are also present in some of these sources, for Hart and Northrup[5] found heptacosane, $C_{27}H_{56}$, m. p. 59°, and a hydrocarbon, $C_{25}H_{52}$, m. p. 52–54°, in large amounts in human pregnancy urine. Likewise, we find that the hydrocarbons in human and mares' pregnancy urine are rather complex mixtures. The acid, $C_{18}H_{36}O_2$, m. p. 55°, has been obtained by the oxidation of carbinol fractions from human[4] and mares' pregnancy urine[4] as well as from cows' urine. Besides the compounds discussed above, evidence has also been obtained for the presence in cows' pregnancy urine of polyhydroxysteroids, but in quantities too minute for investigation. A more exhaustive study on a much larger quantity of urine is in progress, and the results of this investigation will be reported later.

We wish to thank Dr. Oliver Kamm and Parke, Davis and Company for their generous support of this work.

Experimental Part

The butanol extract of 200 gallons (760 liters) of cows' pregnancy urine after removal of the phenolic fraction was hydrolyzed by steam distilling for three hours with an excess of aqueous 20% sodium hydroxide solution. The tarry product was filtered and washed with water. The residue was dissolved in a minimal amount of hot methanol and one liter of ether was added. The methanol was removed by several washings with water, and the ether was evaporated to 50 cc. The solution was cooled in ice–salt and the crystals collected and washed with a small amount of cold acetone. The resulting product, wt. 6.2 g., was treated in methanol with Norite and then crystallized from methanol and acetone to give a product melting unsharply at 215–228°.

Pregnanediol-3(α),20(α) and *allo*-Pregnanediol-3(α), 20(α).—The crystalline product above was refluxed for thirty minutes with 35 cc. of acetic anhydride. The solution was cooled to 0°, and filtered. The product thus obtained was crystallized from methanol and melted at 179°. A mixture with pregnanediol diacetate gave no depression in melting point. Upon hydrolysis with alcoholic potassium hydroxide it gave pregnanediol-3(α),20-(α), m. p. and mixed m. p. 242°.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.8; H, 11.4.

The mother liquors from the crystallization of pregnanediol-3(α),20(α) diacetate were evaporated to dryness, and the residue hydrolyzed with alcoholic potassium hydroxide. The product was then crystallized from methanol, ethyl alcohol and acetone. It melted at 240° and gave no depression in melting point when mixed with *allo*-pregnanediol-3(α),20(α), but depressed the melting point of pregnanediol-3(α),20(α) to 215–220°.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.6; H, 11.3.

The filtrate from the original pregnanediol(α),(α) mixture was treated in ethanol with Norite and filtered. The ketones were removed by the use of Girard's reagent. The non-ketonic fraction in alcohol was mixed with a solution of 20 g. of digitonin in 500 cc. of 95% alcohol, and the solution diluted to one liter. After standing overnight, the digitonide was filtered. When dry, it weighed 10 g. This digitonide was dissolved in 75 cc. of pyridine by heating on a steam-bath for fifteen minutes, and the solution poured into 500 cc. of ether and filtered. The pyridine was removed from the filtrate by shaking with dilute hydrochloric acid, the ether evaporated, and the residue, 2.2 g., sublimed in a high vacuum, taking the fraction distilling at 110–200°. This sublimate was dissolved in ethanol and enough bromine added at 0° to give a faint yellow color. Then an excess of 1% digitonin solution was added. The solution was filtered the next day. From the filtrate was obtained, after debromination in the usual manner, 320 mg. of cholesterol, m. p. 146°, which gave no depression in melting point when mixed with an authentic sample.

The digitonide was dried and then decomposed by heating for thirty minutes on a steam-bath with 30 cc. of dry pyridine. Ether was added and the digitonin filtered. The pyridine was removed from the ether solution, and the solvent was evaporated. The residue, after crystallization from dilute acetone, melted at 215°. Mixed with pregnanediol-3(α),20(α) and *allo*-pregnanediol-3(α),20(α) it gave a depression in melting point. When mixed with *allo*-pregnanediol-3(β),20(α) it gave no depression in melting point.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.7; H, 11.3.

β-Equistanol.—The mother liquor from the original digitonin precipitation of the β-sterols was concentrated to 50 cc. and one liter of ether added. The digitonin–digitonide mixture was filtered and the dried product treated in the usual way with pyridine. The product thus obtained was sublimed in a high vacuum at 120–150°. After crystallization from a mixture of acetone and methanol, the sublimate gave a product melting at 132–134°. When mixed with equistanol obtained from mares' pregnancy urine or from stallions' urine it gave no depression in melting point; yield 1.2 g. of crude product.

The α-Sterol Fraction.—The filtrate from the digitonide from which the equistanol was obtained was evaporated to dryness and then dried by distilling benzene from it. The residual sirup was heated for thirty minutes with 10 g. of succinic anhydride and 15 cc. of pyridine. Ether was added and the pyridine was removed by shaking with hydrochloric acid. The acid-succinates were removed by shaking with sodium carbonate solution. The ether layer was reserved for investigation of the non-hydroxylated material. The alkaline solution was acidified and the succinate then hydrolyzed with alcoholic potassium hydroxide. The carbinol mixture was extracted with ether and the ether removed to give sirupy carbinols. Five and three-tenths grams of this sirup was refluxed with 10 g. of sodium and 150 cc. of xylene for eight hours, the excess product extracted with ether and washed well with water. The solvent was removed and the residue dissolved in 95%

---

[5] Hart and Northrup, THIS JOURNAL, **57**, 2726 (1935).

alcohol and 5 g. of digitonin dissolved in 200 cc. of hot ethanol was added. After standing overnight, the digitonide was filtered, dried, and decomposed by warming with pyridine in the usual manner. The product thus obtained was distilled in a high vacuum, collecting the portion distilling below 200°. This fraction was crystallized from methanol to give *allo*-pregnanediol-3(β),20(α); m. p. and mixed m. p., 214°.

The digitonin mother liquors were evaporated to about 30 cc. and 500 cc. of ether added. The digitonide was filtered, dried and then decomposed with pyridine. The crude product was distilled and crystallized from methanol. It proved to be β-equistanol, m. p. 133°. This was formed by the epimerization of α-equistanol, as the β-form had been removed previously.

The filtrate from the equistanol digitonide was evaporated to dryness and sublimed *in vacuo*. Two fractions were taken, one at 115–150° and the other at 150–200°. The lower boiling fraction after separation of some crystalline pregnanediol-3(α),20(α) was oxidized in acetic acid with an equal weight of chromic acid for thirty minutes. The oxidation mixture yielded mostly acidic material, and only a very small neutral fraction. The acidic fraction was extracted with ether and removed from the ethereal solution with sodium carbonate solution. Acidification of the alkaline solution yielded a crystalline acid which was recrystallized from ethanol to a constant m. p., 55°. Calcd. for $C_{18}H_{36}O_2$: neut. equiv., 284; found, 277.

Anal. Calcd. for $C_{18}H_{36}O_2$: C, 75.9; H, 12.7. Found: C, 76.2; H, 12.9.

Although polyhydroxy sterols probably belonging to the cortical series were present, the quantities were too minute for separation from the small amount of urine processed.

Hydrocarbon Fraction.—The ether soluble material from the preparation of the succinates of the sterols was distilled *in vacuo*. The portion distilling at 80–110° was dissolved in acetone and methanol was added. It was allowed to stand for two days at room temperature in an unstoppered flask. The crystalline material was recrystallized from acetone to give a product of m. p. 63°. Molecular weight calcd. for $C_{28}H_{58}$, 394; found (Rast), 393. It gave no depression in melting point with a hydrocarbon isolated from human pregnancy urine.

Anal. Calcd. for $C_{28}H_{58}$: C, 85.3; H, 14.8. Found: C, 85.2; H, 14.6.

Summary

An investigation of the sterols present in cows' pregnancy urine gave pregnanediol-3(α),20(α), *allo*-pregnanediol-3(α),20(α), and *allo*-pregnanediol-3(β),20(α), in approximately one-half the quantities present in human pregnancy urine. β-Equistanol was also isolated, and the presence of α-equistanol was demonstrated. The carbinol fraction upon oxidation gave an acid of the aliphatic series with a molecular formula of $C_{18}H_{36}O_2$. There was also isolated a hydrocarbon of the aliphatic series melting at 63° and having the molecular formula $C_{28}H_{58}$.

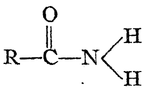
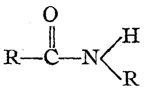
Infrared Absorption Studies. VI. Association in the Acid Amides and Oximes[1]

BY A. M. BUSWELL, W. H. RODEBUSH AND M. F. ROY

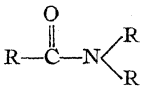
Structure of Acid Amides.—The classical structures assigned to amides and N-substituted amides are



$R{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}N\begin{smallmatrix}H\\H\end{smallmatrix}$

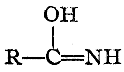


$R{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}N\begin{smallmatrix}H\\R\end{smallmatrix}$



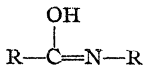
$R{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}N\begin{smallmatrix}R\\R\end{smallmatrix}$

However, certain reactions of the amides, *e. g.*, alkylation, indicate that compounds of the first two types above may have the alternative tautomeric structures



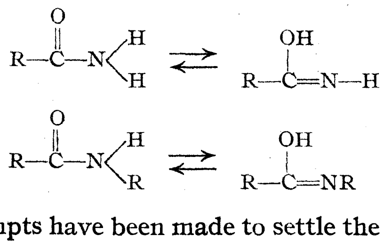
$R{-}\overset{\overset{\displaystyle OH}{|}}{C}{=}NH$

and



$R{-}\overset{\overset{\displaystyle OH}{|}}{C}{=}N{-}R$

in that two isomeric reaction products are obtained in each case. Reactions of this type led to the belief that the amides probably existed in tautomeric equilibria of the two forms.



$R{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}N\begin{smallmatrix}H\\H\end{smallmatrix} \rightleftarrows R{-}\overset{\overset{\displaystyle OH}{|}}{C}{=}N{-}H$

$R{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}N\begin{smallmatrix}H\\R\end{smallmatrix} \rightleftarrows R{-}\overset{\overset{\displaystyle OH}{|}}{C}{=}NR$

Attempts have been made to settle the question as to which of the two forms prevails by a study of the physical properties. Various authors[2] have found that the ultraviolet absorption spectrum indicates either tautomerism or the enolic form. Most of this work was in alcoholic solution but

---

[1] These studies are carried out with the aid of a grant from the Rockefeller Foundation. The main problem is the mechanism of hydration of biological substances ("bound water"). The present paper (VI) presents data on the absorption spectra of relatively simple organic nitrogen compounds whose functional groups resemble those found in proteins. Previous publications from this Laboratory dealing with association are II, *J. Chem. Phys.*, **5**, 501 (1937), and V, THIS JOURNAL, **60**, 2239 (1938).

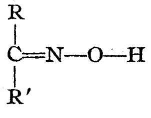
[a] (s) indicates a nearly saturated solution.

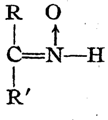
[b] μ is the wave length of the absorption. K is the molal absorption coefficient.

Herzberg and Kölsch[3] have reported that the vapor of formamide shows no absorption characteristic of N—H or C═O. Data upon dipole moments and the Raman spectrum do not appear to offer any conclusive evidence upon this point. It is always possible, of course, to account for the reaction products assuming either formula to be correct. The only chance for a final decision upon the question would appear to be the determination of the characteristic infrared absorption due to hydrogen in the region from 2.6 to 3.6 μ. No report of any work in this region has appeared in the literature. Some results have been obtained in the region of the first overtone, which are however necessarily difficult to interpret.

The situation in regard to the oximes is somewhat similar to that of the amides. There are two structures which are compatible with the chemical evidence.



$$RR'C{=}N{-}O{-}H$$



$$RR'C{=}N(\rightarrow O){-}H$$

There is of course a possibility of tautomerism and the final decision as to structure must be made from a study of physical properties. Here again Freymann and Freymann[4] have studied the infrared absorption in the region of the harmonics with results which indicated the presence of the hydroxyl group.

Experimental

The infrared spectrograph used for this work has been described in previous publications in this series. The compounds used in this work were prepared and carefully purified in this Laboratory by Mr. J. R. Downing. The data in every case represent the ratio of the absorption of a solution in carbon tetrachloride to the absorption of the pure solvent. The molal absorption is calculated as given by the formula

$$\frac{1}{cd}\log\frac{I_0}{I}$$

and the product $c \times d$ is maintained constant for each compound in order to avoid deviations from Lambert's law. The chief difficulty was the low solubility of amides and oximes in carbon tetrachloride. The higher homologs were found to be somewhat more soluble. For those amides for which no curve is shown the data for the principal absorption peaks are included in a table. Curves are given for all of the oximes which were studied.

The Amides.—The high melting and boiling points of the amides have long been recognized as evidence for a high degree of association. Kumler[5] has pointed out that this evidence as well as that of cryoscopic data point to a marked differ-

[5] W. D. Kumler, THIS JOURNAL, **57**, 600 (1935).

ence in the behavior of the amides when the hydrogens attached to the nitrogen are replaced by alkyl groups. This evidence points to hydrogen bonding as the mechanism by which association takes place. Recently Zellhoefer, Copley and Marvel[6] have found that the solubility of chloroform varies in the different amides in such a way as to agree closely with the degree of association to be expected.

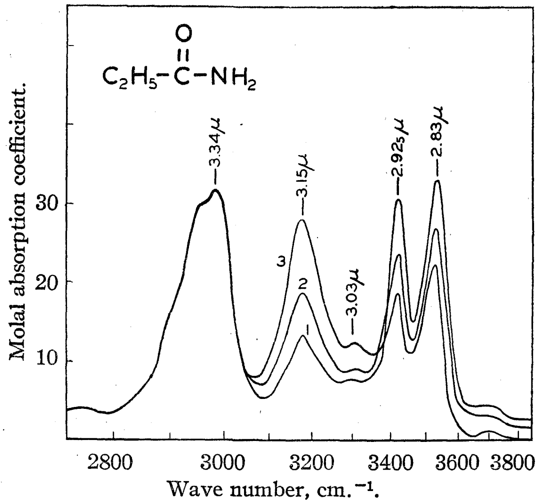

Fig. 1.—Propionamide: (1) 0.002 *M* in 10.18-cm. cell. (2) 0.004 *M* in 5.07-cm. cell. (3) 0.008 *M* in 2.53-cm. cell.

The first curve shown, Fig. 1, is that for propionamide which because of somewhat greater solubility permits a greater range of concentration than acetamide. The C–H absorption at 3.34 μ remains constant over the concentration range while a marked variation with concentration is shown in the region of N–H absorption and there is no indication of any O–H absorption. One may say, therefore, that in the ordinary amides in carbon tetrachloride solution there is no tendency toward enolization. The NH_2 group may be expected to show modes of vibration similar to that of the water molecule.[7] There are two modes involving the stretching of the N–H bonds which are infrared active. One of these is symmetric with respect to the hydrogens and one anti-symmetric. In water these frequencies are at 2.67 and 2.76 μ, respectively. Here we find the N–H frequencies at 2.83 and 2.92 μ. As the concentration is increased the association through hydrogen bonding increases and the absorption at 3.15 μ characteristic of hydrogen bonded N–H increases. The unbonded N–H peaks are reduced in intensity but otherwise unmodified. The solubility is limited so that the association is not complete at the highest concentration obtainable but one cannot doubt that at higher concentrations in another solvent for example, the absorption characteristic of the unbonded N–H would disappear completely.

This behavior is perhaps best accounted for by assuming that when the molecule enters a polymer both hydrogens are involved in the bond formation. Benzamide does not show any particular difference except that the relative intensity of the two peaks in the N–H absorption is altered. The intensities depend indirectly upon the dipole moments associated with the N–H bonds and also the angle between them, and these are evidently slightly altered by the introduction of the phenyl group. The C–H absorption at 3.25 μ which is characteristic of aromatic molecules appears to vary somewhat, but this may be due to the overlapping N–H bond peak. The absorption curves for N-ethyl acetamide in Fig. 3 show interesting variations from those for the unsubstituted amides. The C–H peak is the same as before and only a single peak is to be expected for the N–H absorption and this appears as might be expected intermediate in position between the two peaks of Fig. 1. The peak at 3.22 μ may be assumed to correspond to the peaks at 3.15 μ in the other cases and hence to represent the hydrogen bonded N–H but the peak at 3.03 μ corresponds exactly to that of a hydrogen bonded hydroxyl. Furthermore, the great increase in intensity is strongly suggestive of a hydroxyl which absorbs more strongly than does an N–H group. We believe therefore that this absorption indicates the presence of the enolic form  $\overset{\text{OH}}{\overset{|}{\text{CH}_3\text{C}}}{=}\text{NC}_2\text{H}_5$. This form only exists in the polymer at higher concentrations since there is no absorption in the region 2.8 μ which would be characteristic of unbonded hydroxyl. It may be said therefore that at higher concentrations N-ethylacetamide is largely associated and that a considerable fraction (one-half or more) of the molecules so associated exist in the enolic form. It should be noted of course that N,N-dimethylacetamide shows no absorption except that due to C–H and no physical behavior indicating association.

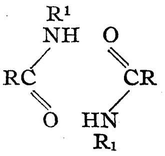
---

[6] G. F. Zellhoefer, M. J. Copley and C. S. Marvel, This Journal, **60**, 1337 (1938); also an article to appear soon.

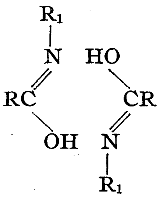
[7] E. F. Barker and W. W. Sleator, *J. Chem. Phys.*, **3**, 660 (1935).

To summarize we may say that while the ordinary amides show a strong tendency toward association (much greater than the alcohols at low concentration) the monosubstituted amides show a smaller tendency, and the disubstituted amides do not associate at all. This conclusion is confirmed by the various physical properties, cryoscopic behavior, behavior as a solvent, etc. In the case of the unsubstituted amides the dielectric constant and other properties suggest the formation of polymers of indefinite molecular weight, similar to those which occur in the alcohols. In the monosubstituted amides the tendency toward association is less strong and one may assume that a considerable fraction of the molecules are associated to form dimers. Dr. M. J. Copley of this Laboratory informs us that the solubility of chloroform in N-ethylacetamide could be accounted for by assuming the pure liquid to consist largely of dimers.

While there are certain well-recognized conditions necessary for enolization to take place in a molecule, we believe that one which has not been sufficiently emphasized is that *the shift of the mobile hydrogen usually involves the formation of a hydrogen bond.* An isolated amide molecule in carbon tetrachloride has no opportunity for forming a hydrogen bond. (The case would of course be different if the solvent were alcohol.) Dr. M. J. Copley has suggested to us that if a dimer is formed with bonds N–H–O similar to the carboxylic acids



then by a shift of hydrogens the structure



is easily obtained and the second structure may easily be the more stable. It must be remembered that our evidence shows that enolization takes place only in the associated molecules and it is only in the dimers with N–H → O bonds that a simple mechanism has been suggested. In a chain polymer, for example, enolization would involve a molecular rearrangement equivalent to ionization of the hydrogen, which is hardly to be expected to take place in a carbon tetrachloride solution. In the absence of other suggestions as to the mechanism of enolization one is forced to assume the existence of dimers in the monosubstituted amides and, as has been said above, this assumption is favored by the other known properties of these substances in the liquid state. Any attempt to explain why the unsubstituted amides do not form dimers or if they do form these, why these dimers do not enolize, would of course be highly speculative. One of course may reason by analogy with formic acid where in the pure liquid the dimers give way to polymers, presumably because of the bonding action of the hydrogen attached to carbon. In an unsubstituted amide the R_1 groups shown above would be replaced by hydrogens and it is easy to suggest ways in which these additional hydrogens might interfere with the formation of stable dimers. It should be noted of course that there is a slight absorption at 3.03 μ in Figs. 1 and 2 suggestive of a slight tendency toward enolization. One may predict that the reactions of the acid amides will under comparable conditions confirm the hypothesis of enolization that has been proposed above.

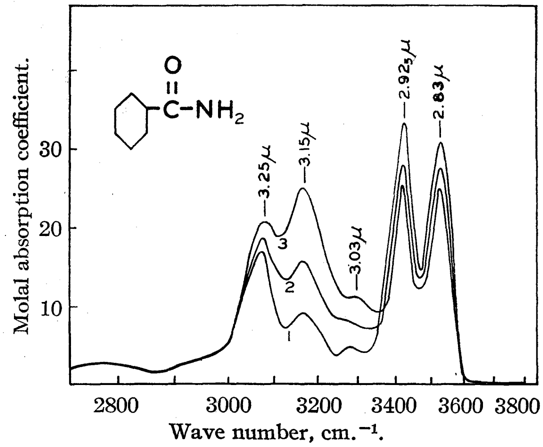


Fig. 2.—Benzamide: (1) 0.0005 *M* in 10.18-cm. cell. (2) 0.001 *M* in 10.18-cm. cell. (3) 0.002 *M* in 5.07-cm. cell.

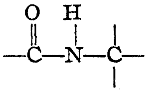
It should be noted that the essential group in the N-substituted amides is the same as that of the peptide linkage in the proteins, *viz.*



$$\begin{array}{ccccc} & \mathrm{O} & & \mathrm{H} & \\ & \| & & | & | \\ — & \mathrm{C} & — & \mathrm{N} & —\mathrm{C}— \\ & & & & | \end{array}$$

The absorption curve of gelatin[8] shows such

---

(8) A. M. Buswell, Karl Krebs and W. H. Rodebush, THIS

striking similarities that one can scarcely doubt that precisely the same type of hydrogen bonding is present in both cases. One would assume, of course, that the hydrogen bonding occurs as a cross linkage between two polymeric chains or perhaps between parts of the same chain.

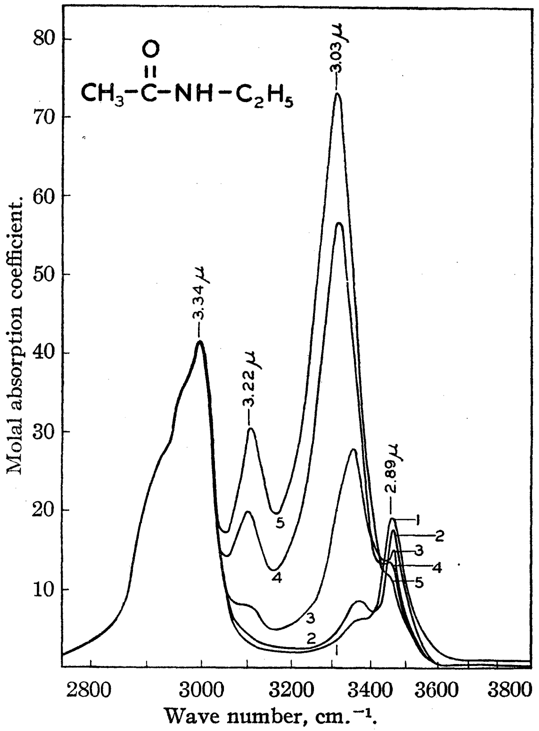


Fig. 3.—N-Ethylacetamide: (1) 0.002 *M* in 10.18-cm. cell. (2) 0.008 *M* in 5.07-cm. cell. (3) 0.032 *M* in 0.640-cm. cell. (4) 0.128 *M* in 0.1582-cm. cell. (5) 0.512 *M* in 0.0374-cm. cell.

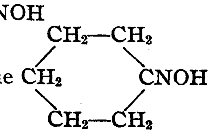
The Oximes.—In order to avoid complications which might arise from possible geometrical isomerism, only symmetrical ketoximes were studied. In Figs. 4, 5, 6 and 7 the absorption curves are given at various concentrations for the following compounds.

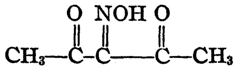
Acetoxime $(CH_3)_2CNOH$

Cyclohexanone oxime



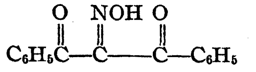
Benzophenone oxime $(C_6H_5)_2CNOH$

The oxime of dimethyl triketone



$$CH_3-\overset{\overset{\displaystyle O}{\|}}{C}-\overset{\overset{\displaystyle NOH}{\|}}{C}-\overset{\overset{\displaystyle O}{\|}}{C}-CH_3$$

The oxime of diphenyl triketone



$$C_6H_5\overset{\overset{\displaystyle O}{\|}}{C}-\overset{\overset{\displaystyle NOH}{\|}}{C}-\overset{\overset{\displaystyle O}{\|}}{C}-C_6H_5$$

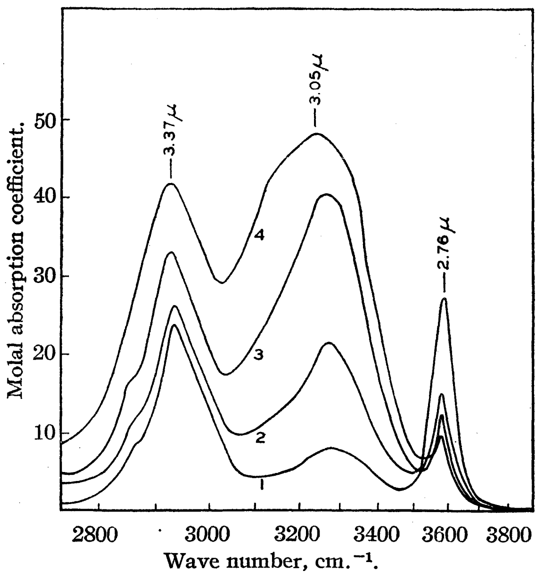


Fig. 4.—Acetoxime: (1) 0.001 *M* in 10.18-cm. cell. (2) 0.004 *M* in 10.18-cm. cell. (3) 0.016 *M* in 2.53-cm. cell. (4) 0.064 *M* in 0.640-cm. cell.

The absorption peak at 2.76 μ in Figs. 4, 5 and 6 is clearly indicative of the hydroxyl group which is to be expected in the usually accepted formula for oximes. There is no indication whatever of an N–H absorption. As the concentration is in-

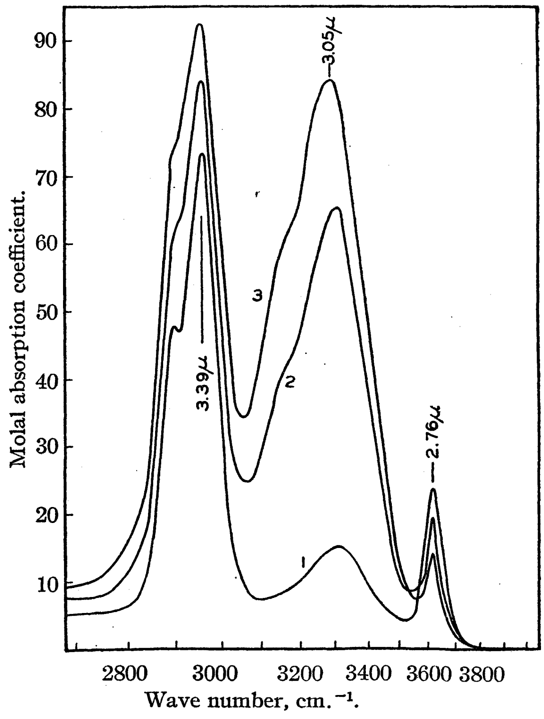

Fig. 5.—Cyclohexanone oxime: (1) 0.0178 *M* in 10.18-cm. cell. (2) 0.0285 *M* in 0.640-cm. cell. (3) 0.1139 *M* in 0.1582-cm. cell.

JOURNAL, **59**, 2603 (1937). One of us (M. F. R.) has called attention to the fact that the enolized dimer should dissociate into enolized monomers. This does not happen and the hypothesis of enolization cannot be considered as fully substantiated until the absence of the enolic form in the monomers is accounted for.

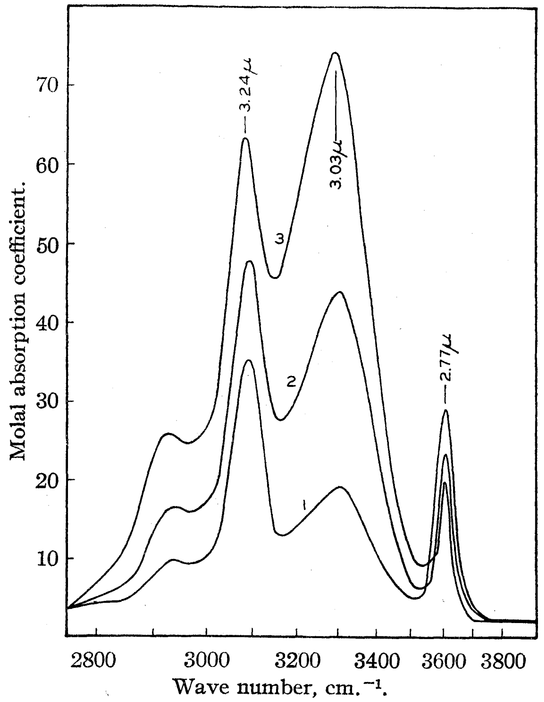

Fig. 6.—Benzophenone oxime: (1) 0.002 *M* in 10.18-cm. cell. (2) 0.008 *M* in 2.53-cm. cell. (3) 0.032 *M* in 0.640-cm. cell.

creased the "association peak" characteristic of hydrogen bonding appears at about 3.0 just as in the alcohols.[9] All this is quite to be expected. The startling thing about these curves is that the molal absorption due to C–H increases with increasing concentration in spite of the fact that the product of concentration times cell length was maintained constant. This behavior has been noted already in the case of benzamide which shows C–H absorption and we are by no means certain how to account for it. There is of course the possibility that the oximes form unsymmetrical dimers so that all C–H vibrations remain active. (In a symmetrical dimer as acetic acid only the anti-symmetric C–H vibrations are active.) Under these conditions because of the augmented dipole moment, the change in moment associated with transition might be increased sufficiently to account for the increased absorption. A simpler explanation of course of the increasing C–H absorption is that the absorption due to the hydrogen bonding overlaps the C–H region. In view of the acidic character of the oximes, this is a reasonable assumption. In the carboxylic acids the absorption extends over a very broad interval. The unbonded hydroxyl frequency of the oximes is at 2.77 μ which is very near the unbonded hydroxyl wave length of acetic acid.

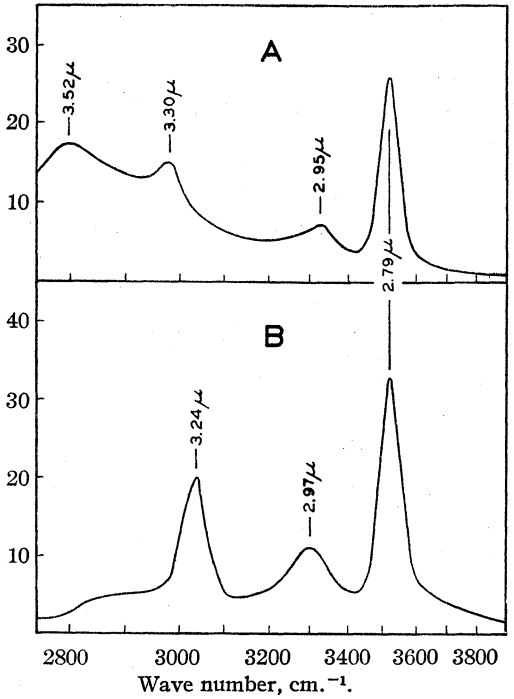

Fig. 7.—A. Oxime of dimethyl triketone: 0.002 *M* in 10.18-cm. cell. B. Oxime of diphenyl triketone: 0.002 *M* in 10.18-cm. cell.

In all of the results so far we have no direct evidence as to whether the bonding is to oxygen or nitrogen (N–H → O or N–H → N) since either is generally possible. In an attempt to distinguish between these possibilities the absorption for the two triketone oximes was measured, Fig. 7. Here while the solubility is too low to permit of much association, there is reason to believe that the absorption at 2.95–2.97 μ is indicative of intermolecular hydrogen bonding which is presumably OH → O. The absorption at 2.79 is of course the unbonded hydroxyl and there is no evidence of chelation.

Summary

Infrared absorption has been studied for a number of acid amides and oximes. Association due to hydrogen bonding is observed and in the case of monosubstituted amides association is accompanied by a considerable amount of enolization. Attention is called to the striking similarity of the absorption due to association in the substituted amides and that due to the peptide group in gelatin.

Photo-voltaic Effects in Grignard Solutions

BY ANNA JANE HARRISON,[1] DOROTHY NIGHTINGALE AND R. T. DUFFORD

It has previously been reported that metallic electrodes in ether solutions of Grignard compounds form a voltaic cell and that the potential difference between the electrodes changes when one or both electrodes are illuminated.[2] Both electrodes may be made from the same metal or from different metals. An extensive list of metals and a number of both aliphatic and aromatic Grignard compounds have been investigated.[3] In all cases both the dark voltage and the photovoltaic response were only roughly reproducible or completely non-reproducible. Several cases, however, indicated that the magnitude and direction of the response might be dependent upon the Grignard compound.

This investigation was undertaken in an attempt to obtain reproducible results so that this effect might be used in the study of homologous series of organic groups. Magnesium amalgam electrodes were studied first since these would have a liquid surface which could be changed by shaking and since magnesium would be present to establish equilibrium with the ions of the Grignard compound.

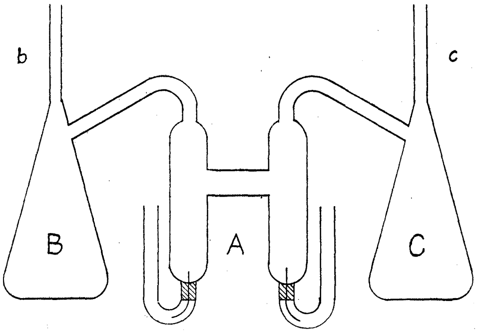

Fig. 1.

Experimental.—Each cell was kept in a separate compartment of a black light-proof box and was illuminated through a small window by a thousand-watt lamp. The temperature was controlled by a water-bath and the voltage was measured by a potentiometer which was sensitive to a few tenths of a millivolt. Ordinary laboratory reagents were used. All organic compounds were dried over calcium chloride and all liquids were distilled. The ether was dried over and distilled from sodium. Freshly sanded magnesium ribbon was used both in the reactions and as electrodes.

The apparatus shown in Fig. 1 was filled with nitrogen and kept closed as much as possible while 15 mg. of fluorenone, 25 cc. of ether and 5 cc. of saturated sodium amalgam were placed in B and 5 cc. of 1% magnesium amalgam and 25 cc. of the Grignard solution in C. The Grignard compound had been synthesized previously in a nitrogen atmosphere. Concentrations ranged from one-half to two molar. The magnesium amalgam had been made in a partial vacuum and the sodium amalgam under dry kerosene. The cell was again filled with nitrogen, evacuated, and openings b and c sealed. After shaking for several hours, the sodium fluorenone produced in B was decanted into the cell, A, and after standing for at least two hours to allow complete drying,[4] was returned to B. After rinsing A several times with ether distilled from B, this side bulb was sealed off. The Grignard solution and the electrode material were transferred to the cell and C sealed off. Electrical connections were made to the magnesium amalgam through very fine platinum ribbon which had been worked into a section of glass tubing at the bottom of each arm of the cell. Mercury contacts were made on the outside. With the exception of the lower part of one arm, the cell was well covered with black friction tape so that only one electrode could be exposed to light.

Similar cells were constructed with metallic magnesium electrodes. These electrodes were suspended by a platinum wire from the platinum connection through the glass at the top of the cell. The platinum–magnesium connection was high enough to be above the solution in the cell. In these cells, the Grignard compound was synthesized in the side bulb after the apparatus had been sealed. In order to avoid any possible reaction between the sodium fluorenone and the magnesium electrodes, the cell was dried with ether distilled from the sodium fluorenone solution rather than by transferring sodium fluorenone into the cell. After the sodium fluorenone side bulb, B, had been removed, a mixture of the Grignard reagent and excess alkyl halide was transferred into the cell to allow the alkyl halide to react with the magnesium electrodes for a short time to ensure a clean electrode surface. The Grignard solution was then returned to its side bulb and ether distilled into the cell to rinse it. The cell was filled with Grignard reagent and the reaction bulb removed. Both types of cells were prepared with phenylmagnesium bromide and with ethylmagnesium bromide.

Results.—Typical results obtained are given in Fig. 2. In this the potential difference in millivolts is plotted against the time in minutes. The sign is that of the electrode in the untaped arm

with respect to the electrode in the taped arm. An arrow pointed upward indicates the beginning and an arrow pointed downward the end of the exposure to light. All cells containing the magnesium amalgam electrodes gave a zero dark voltage with the exception of occasional temporary variations of the order of a millivolt Curve A shows the effect of light on the untaped arm. The illuminated electrode became positive with respect to the dark electrode to the extent of almost 2 mv. and then decreased slightly. Curve B shows the effect produced in the same cell by focusing the light on the taped arm instead of the untaped arm. The latter was unprotected from the large amount of diffused light. The response was in the opposite direction and somewhat larger. These responses must, therefore, be due to heating effects rather than any direct effect of the light. Similar curves of greater magnitude (12 to 20 mv.) were obtained when no water-bath was used. The curves were reproducible and after illumination ceased the voltage became smaller until zero was reached. Similar responses were obtained by placing the two arms of the cell in two water-baths which were not at the same temperature. Cells containing metallic magnesium electrodes gave the same type of results as is shown by curves C and D. In these the heating effect was slightly greater in the untaped arm than in the taped arm. This might be expected, however, since absorption was taking place on the electrode surface in one case and on the cell wall in the other case. Responses of this type will be referred to as no photo-voltaic effect.

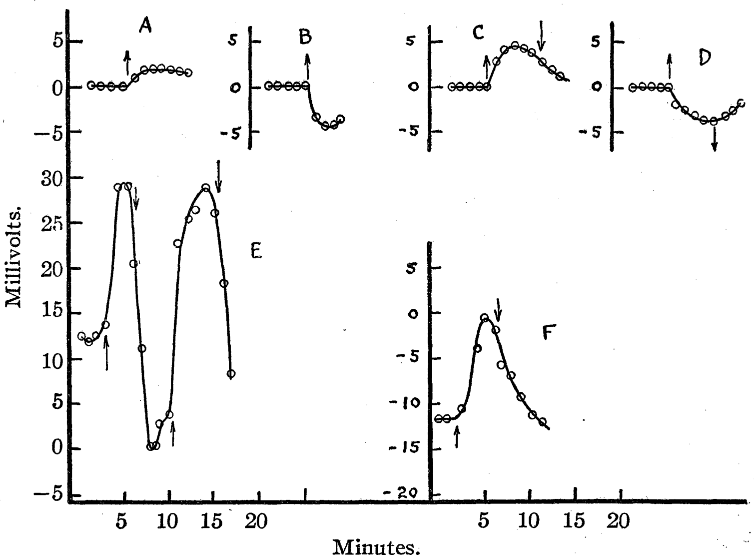

Fig. 2.—Curves A and B show the response of magnesium amalgam electrodes with the light focused on the untaped electrode (A) and on the taped electrode (B). Curves C and D are the same for magnesium electrodes which have been cleaned by the reaction with the organic halide. Curve E shows the response to light obtained with magnesium electrodes which had not been "cleaned." Curve F gives the response to light of cleaned magnesium electrodes which had been exposed to oxygen. An arrow pointed upward indicates the beginning and an arrow pointed downward the end of the exposure to light. In all cells one electrode was protected from light by tape. The sign of the voltage is that of the electrode in the untaped arm with respect to the electrode in the taped arm.

Cells containing magnesium electrodes, which had not been cleaned with the reaction mixture but had been dried with ether distilled from the sodium fluorenone, showed variable dark voltages and variable photo-voltaic responses. For the most part these responses to light were rather large as is shown by curve E. The illuminated electrode always became positive with respect to the dark electrode. Responses of this magnitude could not be produced by temperature changes. Both the dark voltage and the light sensitivity could be destroyed by opening the cell and adding a few drops of the corresponding organic halide or by simply allowing the cell to stand for several days. The phenylmagnesium bromide solutions in two of these cells in which the photo-voltaic sensitivity had been destroyed by adding phenyl bromide were returned to the reaction bulbs. The Grignard solutions were kept cold with dry ice and ether while the cells were filled with oxygen, which had not been dried. After fifteen minutes the apparatus was evacuated and closed. After rinsing with ether distilled from the reaction flasks, the cells were filled. Both cells showed variable dark voltages and photo-voltaic responses. One such response is shown by Curve F. The Grignard solutions were clear and gave no evidence of having been oxidized. The dark voltage and the light sensitivity were destroyed in one cell by the addition of phenyl bromide and in the other by allowing it to stand.

Discussion.—A surface film appears to be necessary for light sensitivity in the case of magnesium electrodes. Presumably, this film is removed by the reaction of the organic halide with the adjacent atoms of magnesium. If the film is magnesium hydroxide its disappearance on standing might be explained by the reaction with the magnesium bromide from the Grignard equilibrium to produce basic magnesium bromide which is soluble in ether.

Summary

(1) Magnesium amalgam electrodes gave zero dark voltage and no light sensitivity with ether solutions of either phenylmagnesium bromide or ethylmagnesium bromide. (2) Magnesium electrodes which had been cleaned by reacting with the organic halide gave the same results. (3) Magnesium electrodes which had not been cleaned in this manner showed variable dark voltages and variable photo-voltaic responses. Both of these could be destroyed by adding the organic halide or by allowing the cell to stand for several days. (4) "Cleaned" magnesium electrodes were made sensitive to light by exposure to oxygen.

The Addition of Sulfur, Hydrogen Sulfide and Mercaptans to Unsaturated Hydrocarbons

BY S. O. JONES[1] AND E. EMMET REID

There have been many investigations of the action of sulfur and hydrogen sulfide on unsaturated hydrocarbons[2] and a few on the addition of mercaptans[3] but so many points have not been cleared up that further study seemed desirable.

Curiously enough the end-products are much the same whether an unsaturated hydrocarbon is treated with sulfur, hydrogen sulfide or a mercaptan. Thus with ethylene, sulfur gives hydrogen sulfide which reacts with more ethylene to form ethyl mercaptan which then adds to more ethylene to form ethyl sulfide.

Our results help to explain the presence of ethyl, *i*-propyl and other mercaptans and the corresponding sulfides in petroleum distillates but do not account for the presence of methyl mercaptan and methyl sulfide.

The Action of Sulfur.—Quite different results are obtained from the reaction with sulfur according to the conditions and whether free sulfur or a compound which readily liberates sulfur is used. When ethylene was passed over pyrites at 350° about 1% of thiophene was isolated along with hydrogen sulfide and ethyl mercaptan, while when it was bubbled through sulfur at 325° much hydrogen sulfide was formed along with 3% of ethyl mercaptan and small amounts of carbon disulfide and ethyl sulfide. We found it advantageous to use ethyl tetrasulfide as a sulfur donor. This is a liquid which mixes well with organic compounds and decomposes on heating, giving off what may be assumed to be atomic sulfur. The proportions were calculated on the basis of the tetrasulfide going down to the disulfide. A noteworthy difference is that with it, appreciable yields of the cyclic sulfides were obtained.

When ethylene was bubbled slowly through ethyl tetrasulfide kept at about 150°, the main product isolated was ethyl mercaptan with some ethyl sulfide and in addition some ethylene sulfide. The results of heating several hydrocarbons in a bomb with ethyl tetrasulfide are given in Table I.

TABLE I

Hydrocarbons with Et_2S_4, 10 hrs. at 180°

Hydrocarbon	Yields of products, % Mercaptan	Sulfide	Cyclic sulfide
Ethylene	5	18	1
Propylene	6	20	15
Heptene-1	20	..	..
Octene-1	19	..	..
Cyclohexene	8	..	8

The mercaptans, except from ethylene, and sulfides were all secondary.

The Addition of Hydrogen Sulfide.—The addition of hydrogen sulfide was effected by heating in the bomb for ten hours at 180°. Sulfur was added as a catalyst for without it there was little if any addition. The results are given in Table II. The sulfur is found on the secondary or tertiary carbon atom in accordance with Markownikow's rule.

TABLE II

Addition of hydrogen sulfide, 10 hrs. at 180°

Hydrocarbon	Yields of products, %	
	Mercaptan	Sulfide
Ethylene	11	80
Propylene	7	90
i-Butylene	23	6
Octene-1	9	35
Cyclohexene	7	5

The addition takes place according to Markownikow's rule. In all cases the mercaptan that is first formed adds to a second molecule of the hydrocarbon to form the sulfide. In the case of the simple unsaturates this second reaction must be rapid as compared to the first addition as little of the mercaptans is left over. *t*-Butyl and cyclohexyl mercaptans evidently do not add so readily to the hydrocarbons.

The Addition of Mercaptans.—The unexpected observation was made in the course of our experiments that peroxides influence the mode of addition of mercaptans to unsaturates just as Kharasch[4] found that they influence the addition of hydrogen bromide. When we heated ethyl mercaptan with propylene we obtained ethyl *i*-propyl sulfide, but with octylene the product was ethyl *n*-octyl sulfide. The propylene had never been exposed to the air while the octylene had been stored for some time in a partly filled bottle and gave a strong test for peroxides. By adding ethyl mercaptan to propylene in the presence of added peroxides, we obtained ethyl *n*-propyl sulfide.

It has been observed by Posner and Nicolet[3] that thiophenol and *p*-thiocresol add to unsaturates contrary to Markownikow's rule. We have verified this in a large number of cases, but by using freshly distilled thiophenol and *p*-thiocresol we were able to reverse the mode of addition. Kharasch[4] observed that *p*-thiocresol was not effective as an anti-oxidant unless it was freshly distilled. It appears that only very small amounts of peroxides such as are usually present in the hydrocarbon or in the *p*-thiocresol itself are sufficient to influence the addition of mercaptans while for hydrogen bromide much larger amounts are required. In the absence of catalysts scarcely any addition takes place even on heating for twenty-four hours at 180°. Sulfur catalyzes the normal addition and peroxides the abnormal. It is difficult to suppress the abnormal addition entirely. Into each of 3 tubes of 2-cc. capacity were placed 0.25 g. of *p*-thiocresol and 0.4 cc. of tridecene. The *p*-thiocresol had been distilled recently *in vacuo* and the tridecene had just been distilled over sodium. To the first tube was added a trace of ascaridole, to the second a trace of sulfur and nothing to the third. After the usual heating the product in the first tube was solid and on recrystallization gave 0.3 g. which melted at 39.9°, the melting point of *p*-thiocresyl *n*-tridecyl sulfide made from *n*-tridecyl bromide in the usual way. From the liquid products in the other two tubes it was possible to isolate 0.01 and 0.08 g., respectively, of the sulfide melting at the same point.

In a number of experiments the products were identified by their boiling points and by oxidation to known solid sulfones but for positive proof of structure unsaturated hydrocarbons[5] and mercaptans were chosen that would give known crystalline sulfides which previously had been prepared from the potassium salt of the mercaptans and the normal alkyl bromides.[6] The tubes were of 2-cc. capacity and the hydrocarbon was in slight excess. The heating was for ten hours and 180°. The results given in Table III show conclusively that the abnormal addition took place with these hydrocarbons which had been exposed to air for some weeks.

In another series tridecylene was added to dimercaptans.[7] The results are given in Table IV.

In one experiment lauryl mercaptan was added to allyl lauryl sulfide $C_{12}H_{25}SCH_2CH{=}CH_2$ and the product was $C_{12}H_{25}S(CH_2)_3SC_{12}H_{25}$, m. p. 47°, proved by melting point and mixed melting point to be identical with that from lauryl bromide and trimethylene mercaptan.

Experimental

Ten moles of ethylene bubbled at the rate of 50 cc. per minute through a 25-cm. layer of sulfur in a vertical tube kept at 325° gave much hydrogen sulfide. The 25 cc. of condensate gave 15 g. of ethyl mercaptan, b. p. 34–37°, $Hg(SEt)_2$, m. p. 76°, 2 g. of carbon disulfide and 3 g. of ethyl sulfide, b. p. 91–92°, $Et_2S{\cdot}HgCl_2$, m. p. 76.5°. Five moles passed at the rate of 20 cc. per minute through a 20-cm. column of ethyl tetrasulfide at 140–150° gave 30 g. of condensate, largely ethyl sulfide but containing 10 g. of ethyl mercaptan $Hg(SEt)_2$, m. p. 76°, and 1.5 g. of ethylene sulfide,[8] b. p. 54–57°, S calcd. 53.36, found 53.09 and 53.12.

This was identical with a preparation by the method of Delépine.

All other experiments unless otherwise stated were made by heating in a steel bomb for ten hours at 180°. From 30 g. of propylene and 45 g. of ethyl tetrasulfide we obtained: 1 g. of carbon disulfide, 3 g. of i-PrSH, Hg(i-PrS)$_2$, m. p. 62°; 21 g. of i-Pr$_2$S, b. p. 118–121°; oxidized to sulfone, m. p. 36.4°; i-Pr$_2$SO$_2$, m. p. 36°,[9] and 10 g. of cyclic propylene sulfide, S calcd. 43.26, found 43.14. Under the same conditions, substituting sulfur for the ethyl tetrasulfide, the same products were found except that there was none of the cyclic sulfide.

Isobutylene, 14 g., and 23 g. of ethyl tetrasulfide in the bomb eight hours at 160° gave 1 g. of carbon disulfide, 5 g. of ethyl disulfide and a mixture of unsaturated hydrocarbons from which no sulfur compounds could be isolated.

From 27 g. of heptene-1 and 15 g. of Et$_2$S$_4$, we obtained 5 g. of carbon disulfide, 2 g. of ethyl disulfide, and 10.5 g., b. p. 140–170°, from which, by extraction with potassium hydroxide solution, heptane-thiol-2, b. p. 163–165°, n^{25}D 1.4459, was obtained, agreeing with the data in the literature. There was much carbonization.

From 56 g. of octene-1 and 45 g. of Et$_2$S$_4$ 10 g. of octylene was recovered along with 8 g. of carbon disulfide, 5 g. of ethyl disulfide and 30 g. of which half was hydrocarbon and half octanethiol-2. This was identified by treating it with octadecyl bromide, the resulting $C_8H_{17}SC_{18}H_{37}$ had m. p. 24° and was identical with that made from authentic octanethiol-2; n-$C_8H_{17}SC_{18}H_{37}$, m. p. 42.6°. There was much carbonization.

Cyclohexene, 82 g., and 32 g. of sulfur gave 6 g. of carbon disulfide and 15 g. of cyclohexyl mercaptan, b. p. 153–155°, S calcd. 27.60, found by I titration 27.45 and 27.49. Five runs were made using in each the same amount of cyclohexene with 93 g. of ethyl tetrasulfide, equivalent to 32 g. of sulfur. The products, united and fractionated, gave 34 g. of carbon disulfide, 105 g., b. p. 80–84°, of chiefly unreacted cyclohexene, 45 g., b. p. 154–155°, of cyclohexyl mercaptan and 50 g., b. p. 180°, of cyclohexene sulfide. This had d^0_4 0.9466, d^{25}_4 0.9274; n^{25}D 1.4881; S calcd. 28.10, found 28.00 and 28.05%. Besides these there were 15 g. of ethyl disulfide, b. p. 151–154°, and 40 g. of ethyl trisulfide, b. p. 85° at 15 mm.

Addition of Hydrogen Sulfide.—From 28 g. of ethylene and 34 g. of hydrogen sulfide liquefied in the bomb, with 5 g. of sulfur, there were obtained 7 cc. of ethanethiol, b. p. 34–7°, and 77 cc. of ethyl sulfide, b. p. 90.5–93°.

From 21 g. of propylene, 17 g. of hydrogen sulfide and 5 g. of sulfur, we obtained 2.5 g., b. p. 57–60°, which gave Hg(i-PrS)$_2$, melting at 62°, and 25 g., b. p. 117–121°, oxidized to sulfone, m. p. 35.5°, i-Pr$_2$SO$_2$ melting at 36°. This was repeated after thoroughly cleaning the bomb and leaving out the sulfur catalyst. The liquid product was only 3 cc., b. p. 60–180°, and contained mercaptan and sulfide.

---

[9] Delépine, *Compt. rend.*, **172**, 158 (1921).

From 14 g. of isobutylene, 8.5 g. of hydrogen sulfide and 3 g. of sulfur we obtained 6 g. of *t*-butyl mercaptan, b. p. 65–67°, S calcd. 35.56, found by I titration 35.48 and 35.44, and 6 g., b. p. 115–160°, of *t*-butyl sulfide. This was refractionated, 1.8 g., b. p. 72° at 71 mm., S calcd. for *t*-Bu_2S 21.92, found 21.63 and 21.76. The remainder was hydrocarbons.

From 46 g. of octene-1, 17 g. of hydrogen sulfide and 3 g. of sulfur were recovered 20 g. of octylene and 5 g., b. p. 89° at 30 mm., identified as octane-thiol-2, $n^{25}D$ 1.4480. Titrated with I, found S, 21.69 and 21.78, calcd. 21.92. With octadecyl bromide it gave a sulfide melting at 24°. The sulfide fraction boiled at 281–283°.

From 82 g. of cyclohexene, 34 g. of hydrogen sulfide and 3 g. of sulfur, 40 g. of cyclohexene was recovered along with 8 g. of the mercaptan, b. p. 153–155°, and 4 g. of the sulfide, b. p. 180° at 50 mm., S calcd. 16.17, found by Br titration 16.08 and 16.01, $n^{25}D$ 1.50473, sulfone m. p. 126°.

Addition of Mercaptans.—All runs were made in a steel bomb for ten hours at 180°. Small samples for Tables III and IV were sealed in glass tubes which were surrounded in the bomb by a liquid of the proper vapor pressure. The solid sulfides from these were recrystallized from alcohol.

From 20 g. of thiophenol, 8 g. of propylene and 1 g. of sulfur were obtained 1 g. of *i*-PrSH, boiling at 57–59°, 2 g. of *i*-Pr_2S boiling at 118–120° and 12 g. of *i*-PrSPh which gave a liquid sulfone, *n*-$PrSO_2Ph$, m. p. 46°.

From 28 g. of ethylene and 62 g. of ethanethiol with 3 g. of sulfur the yield of diethyl sulfide was 93% but without the sulfur catalyst there was no condensation, Propylene and ethyl mercaptan did not combine without the catalyst but from 3 g. of sulfur, 21 g. of propylene and 31 g. of ethanethiol, 44 g. of *i*-PrSEt boiling at 103–104°, 4 g. of PrSEt boiling at 115–117° and 4 g. of *i*-Pr_2S boiling at 120–121° were obtained. From 21 g. of the same propylene mixed with 61 g. of octene-2, 3 g. of ascaridole and 62 g. of ethanethiol the products were: 2 g. of *i*-PrSEt, b. p. 103–110°; 25 g. of *n*-PrSEt, b. p. 115–117°; sulfone, m. p. 25°; and 13 g. of EtSOct, b. p. 102–103° at 11 mm.; sulfone, m. p. 68°.

Starting with 56 g. of octene-1 containing peroxides and 31 g. of ethanethiol we obtained 14 g., b. p. 145–154° at 100 mm., of which 75% was *n*-octyl SEt, and 14 g., b. p. 154–156°, pure *n*-octyl SEt identified as sulfone, m. p. 68°. The same materials with the addition of 4 g. of hydroquinone gave only 4 g. of sulfide which was not increased by twenty-four hours of heating. When the same were heated with 4 g. of sulfur the products were 5 g., b. p. 109° at 70 mm., of octane-thiol-2; 50 g., b. p. 145–147° at 100 mm., of *s*-octyl ethyl sulfide of which the sulfone was a liquid; and 5 g., b. p. 281–283°, 175° at 20 mm. of di-*s*-octyl sulfide; and 5 g., b. p. 281–283°, 175° at 20 mm. of di-*s*-octyl sulfide.

Cyclohexene, 7 cc., and ethanethiol 5 cc. were sealed in a glass tube which was surrounded in the bomb by a like mixture containing hydroquinone. From the sealed tube 5 cc. of cyclohexyl SEt was isolated but there was no reaction in the outside mixture. Two runs were made with half mole each of these reactants. With sulfur as catalyst the yield was 60% and with peroxides 40%.

Ethyl mercaptan, 0.5 mole, and 0.25 mole of *n*-butylacetylene with 2 g. of sulfur were heated. Fractionation of the product gave 4 g., b. p. 133°, and 16 g., b. p. 95–110° at 150 mm. The first of these took up $2Br_2$ and gave 2HBr on hydrolysis, showing the presence of 1 = and 1 S. The other took up $2Br_2$ and gave 4HBr, showing the presence of 2 S. The constitutions of these were not determined.

Summary

1. Sulfur strips hydrogen from unsaturates even to form hydrogen sulfide a part of which adds to the double bond producing a mercaptan which adds to more of the unsaturate to give a sulfide.

2. The addition of hydrogen sulfide takes place readily and follows Markownikow's rule. Sulfur is an effective catalyst.

3. Mercaptans add to double bonds in accordance with Markownikow's rule if peroxides are eliminated or sulfur used as a catalyst. In the presence of peroxides the abnormal addition takes place. The amount of peroxide required is small.

Polyazines. II. The Reaction of Hydrazine Hydrate with Acetylacetone, Acetonylacetone, and Benzil[1,2]

BY BERNHARD G. ZIMMERMAN[3] AND H. L. LOCHTE

The reaction between the two bifunctional types of compounds, diketones and hydrazine hydrate, should generally yield polyazines which are formed by continued condensation of ketone and hydrazine. Cyclic compounds are formed directly only in those special cases which lead to the formation of 5- or 6-membered rings.[4,5] Four- and seven-membered rings apparently are formed in such cases only rarely and then in small yield.

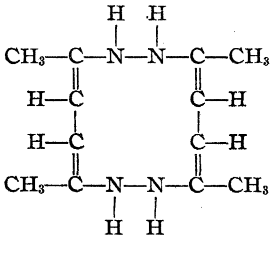
Kinetic theory and probability considerations lead us to predict that in cases in which there is simultaneous formation of both cyclic and open chain compounds, the yield of cyclic products can be increased by working in very dilute solutions.[6]

A previous communication[5] on the reaction between diacetyl and hydrazine hydrate showed that the main product obtained is a polyazine of the type

$$H_2N—N{=}C(CH_3)[C(CH_3){=}N—N{=}C(CH_3)]_nC(CH_3){=}O$$

The present paper presents results obtained with several other diketones.

The reaction between acetonylacetone and hydrazine hydrate was first studied by Gray,[7] who isolated two crystalline products. Equimolecular amounts of the reactants yielded a 12-membered ring compound to which he assigned the formula



while the reaction between two moles of ketone and three of hydrazine hydrate yielded the azine-hydrazone

$$H_2N—N{=}C(CH_3)—CH_2—CH_2—C(CH_3){=}N—N{=}C\text{-}(CH_3)CH_2—CH_2C(CH_3){=}N—NH_2$$

The direct formation of a 12-membered ring in a concentrated solution, as reported by Gray, is unexpected; but Gray gave not only complete analyses which are of no value as a means of differentiating between the cyclic and open chain polymeric structure, but also reported derivatives, solubility in various solvents, and made molecular weight determinations. Gray, however, did not report a melting point for this crystalline 12-membered ring. Molecular weights found agreed closely with those required for the 12-membered ring. Smith and McCoy[8] also obtained the same substances, but gave no additional information.

In view of Gray's results a number of attempts were made to repeat his work, but experiments under conditions reported by Gray, as well as in very dilute solution in which the yield of such a compound should have been better, failed to reveal any crystalline substance that could be identified as Gray's compound.

Gray's directions yielded a viscous oil which remained liquid for months. Analysis of a fraction boiling at 114–115° at 2 mm. agreed with results obtained by Gray, as did cryoscopic molecular weight determinations in benzene. Even after careful fractionation of the liquid, no crystalline 12-membered ring could be isolated.

Dilute solutions yielded in all cases mainly 3,6-dimethylpyridazine which has been prepared in a number of different ways, but Gray,[7] Smith and McCoy,[8] and Paal and Ubber[9] all agreed that it could not be prepared by direct reaction between acetonylacetone and hydrazine hydrate. Apparently, the only essential difference between their experiments and ours lay in the fact that our work was done in very dilute solution. About 3% yield of a crystalline polymer of the type

$$H_2N_2C(CH_3)CH_2[CH_2C(CH_3){=}N—N{=}C\text{-}(CH_3)CH_2]_{n=184}—CH_2C(CH_3)O$$

also could be isolated from the same dilute solution. In benzene solution, the azine-hydrazone

[7] Gray, *J. Chem. Soc.*, **79**, 682–686 (1901).

[8] Smith and McCoy, *Ber.*, **35**, 2169 (1902).

[9] Paal and Ubber, *ibid.*, **36**, 497 (1903).

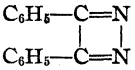
of Gray was obtained in excellent yield. In concentrated solutions, using no solvents and heating on a steam-bath for two weeks, only a black tar, from which no crystalline products could be isolated, was obtained.

The reaction of benzil, diacetyl, and acetylacetone with benzil dihydrazone yielded only mixed polyazine resins. No definite structure could be assigned to these resins.

Two crystalline azines, the mono- and diazine, were isolated from the reaction between benzil monohydrazone and diacetyl.

As expected, acetylacetone and hydrazine hydrate yielded only the 5-membered ring, 3,5-dimethylpyrazole; no polymeric substance could be isolated as a by-product.

According to Curtius,[10] benzil monohydrazone decomposes in an aqueous solution to yield the four-membered ring



All attempts to isolate such a 4-membered ring were unsuccessful.

Experimental

Condensation of Acetonylacetone with Hydrazine Hydrate in Dilute Solution.—Ninety-seven grams of acetonylacetone and 42.5 g. of hydrazine hydrate were dissolved in 5 liters of water, and heated on a steam-bath for six weeks.

The crystals that separated on evaporating most of the water and cooling were filtered off and recrystallized four times from a large volume of 50% alcohol. Except for slight solubility in ethanol, the white crystals were insoluble in all common solvents; m. p., softens at 260° and melts at 276° with decomposition.

Anal. Calcd. for $O{=}C(CH_3){-}CH_2[CH_2{-}C(CH_3){=}N{-}N{=}C(CH_3){-}CH_2]_{184}{-}CH_2C(CH_3){=}N{-}NH_2$: C, 65.41; H, 9.10; N, 25.39; mol. wt., 20,366. Found: C, 65.28; H, 9.08; N, 25.42; mol. wt., micro Rast camphor, 9.314 mg. of product dissolved in 84.40 mg. of camphor showed a depression in the freezing point of 0.200°, mol. wt., 21,836. Check determinations indicated molecular weights from 18,000 to 22,000.

Picrate.—This separated as shiny yellow crystals when a dilute alcoholic solution of picric acid was added to a hot alcoholic solution of the polymer. Recrystallized from much ethanol, it melted at 170–176° with decomposition.

Anal. Calcd. for $n = 184$: N, 20.63. Found: N, 20.62.

Platinic Chloride Salt.—An orange-yellow crystalline salt formed when a 10% solution of platinum chloride was added to a hot alcoholic solution of the polymer. The salt was washed with water, alcohol, ether, and dried; m. p. 260–266° dec.

Anal. Calcd. for $n = 184$: Pt, 31.00. Found: (micro) Pt, 30.89, 30.93.

Hydrochloride.—Five-tenths gram of the polymer was dissolved in hot alcohol and dry hydrogen chloride passed in. The resulting white salt melts at 200–201° with decomposition to a red mass.

Anal. Calcd. for $n = 184$: Cl, 24.10. Found: Cl, 24.07.

The hydrochloride is very soluble in water. Neutralization equivalent (calcd. 146.5, found 146.7) corresponds to the structural unit of the polymer.

Each of these salts has thus resulted from reaction with each structural unit.

3,6-Dimethylpyridazine.—The filtrate from the polymer was fractionated at 40 mm. in a stream of hydrogen. The 40–200° fraction was then fractionated at 37 and 31 mm. The fraction boiling at 119–122° at 31 mm. was then refractionated at 2 mm. The main fraction boiling at 64° at 2 mm. solidified on cooling. After further purification, it melted at 34–35°. Complete analysis of the base as well as the analysis and properties of the picrate, platinic chloride, and hydrochloride agreed with those reported by Paal and Koch.[11] The platinum chloride was found to contain either one or four molecules of water of crystallization.

Gray's Azine-Hydrazone ($C_{12}H_{14}N_6$).—This compound reported by Gray was obtained when 10 cc. of acetonylacetone was dissolved in 300 cc. of benzene and 15 cc. of hydrazine hydrate added with shaking for one hour. After numerous recrystallizations from ethanol it melted at 136–137° (Gray reported 132°).

Benzil Monohydrazone and Diacetyl.—Six and five-tenths grams of benzil and 2.5 g. of diacetyl dissolved in 125 cc. of alcohol were refluxed for eighteen hours. On cooling, the yellow crystals which formed were filtered off and recrystallized from alcohol; m. p., 85.8°.

Anal. Calcd. for $C_{18}H_{16}N_2O_2$: C, 73.94; H, 5.25; N, 9.59; mol. wt., 292. Found: C, 74.01; H, 5.69; N, 9.67; mol. wt. (ebullioscopic in benzene), 285.

On continued refluxing of the filtrate, a second yellow product was isolated. After recrystallization from benzene, the melting point was found to be 238.3° with decomposition.

Anal. Calcd. for $C_{32}H_{26}N_4O_2$: C, 77.07; H, 5.26; N, 11.24; mol. wt., 498. Found: C, 77.29; H, 5.49; N, 11.17; mol. wt. (micro Rast camphor), 505.

3,5-Dimethylpyrazole.—This compound was prepared according to the directions of Rosengarten[12] and Dedichen[13] and the filtrate examined for polymeric by-products, but none could be isolated. This compound was found to be satisfactory as a selective inhibitor for some micro-organisms.[14]

Molecular Weight Determinations.—In the course of attempts to determine the molecular weight of these moderately high molecular weight polyazines, it was observed that the molecular weight appeared to increase with concentration of the polymer in benzene in spite of the fact that the solutions appeared to be perfectly clear up to the

point at which the benzene started to freeze. Figure 1 shows results obtained with three different resins. Meanwhile Staudinger and co-workers[15] reported similar difficulties with polymers, and offer an explanation for this observed increase in molecular weight with an increase in concentration.

Summary

Acetonylacetone and hydrazine hydrate react to yield 3,6-dimethylpyridazine, the azine-hydrazone of Gray, and an insoluble crystalline polyazine.

The 12-membered ring of Gray could not be isolated under any conditions.

Benzil dihydrazone reacts with benzil, diacetyl, and acetylacetone to yield resins.

The 4-membered ring, formed by the decomposition of benzil monohydrazone, of Curtius could not be isolated.

Acetylacetone and hydrazine hydrate yield 3,5-dimethylpyrazole without polymeric by-product.

Cryoscopic molecular weight determinations of polyazines with benzene as solvent yield values that appear to increase with concentration of polymer.

The Reducing Action of Primary Grignard Reagents

By Frank C. Whitmore, A. H. Popkin, J. S. Whitaker, K. F. Mattil and J. D. Zech

The reducing action of *t*-butylmagnesium chloride on trimethylacetyl, isobutyryl, *n*-butyryl[1] and *t*-butylacetyl[2] chlorides has been reported already. Similar studies have now been made to find the effect of branching, in both the Grignard reagent and the carbonyl compound, on the yields of the reduction products.

n-Butylmagnesium bromide and trimethylacetyl chloride produced neopentyl alcohol in 27% yield together with a 69% yield of *n*-butyl-*t*-butylcarbinol representing a total yield of 96% of the reduction products. In the case of *t*-butylmagnesium chloride, the yield of neopentyl alcohol was 95% with a 1% yield of di-*t*-butylcarbinol.

Several other reactions of the Grignard reagent were studied next with emphasis on the by-product obtained. Excess *n*-butylmagnesium bromide gave the usual products with acetyl chloride, ethyl acetate, acetaldehyde and 2-hexanone and, in addition, the by-products indicated

$CH_3COCl \longrightarrow 8\%\ CH_3CH_2OH$

$\searrow 13\%\ CH_3CHOHC_4H_9$

$CH_3CO_2C_2H_5 \longrightarrow 3\%\ CH_3CHOHC_4H_9$

$CH_3CHO \longrightarrow 18\%\ CH_3CH_2OH$

$CH_3COC_4H_9 \longrightarrow 9\%\ CH_3CHOHC_4H_9$

The preparation of a series of tertiary carbinols for subsequent dehydration studies involved the addition of methylneopentyl ketone to some primary Grignard compounds. With ethylmagnesium bromide, evidence of a trace of methylneopentylcarbinol was obtained but its identity was not established positively. This reduction product was identified when higher Grignard reagents were used. The yields of methylneopentylcarbinol were 5.5% using *n*-propylmagnesium bromide, 5.7% using *n*-butylmagnesium bromide

---

[2] Whitmore and Heyd, *ibid.*, **60**, 2030 (1938).

and 3.4% using *n*-amylmagnesium bromide. The conditions of concentration and temperature during the addition of ketone in the preparations of the neopentylcarbinols were approximately identical.

An attempt to isolate neopentyl alcohol from the action of *n*-butylmagnesium bromide on ethyl trimethylacetate was not successful. The only reduction product isolated was *n*-butyl-*t*-butylcarbinol, present in 40% yield. This verified the observation of Leroide.[3] As had been observed previously,[4] the addition of ethyl trimethylacetate to *t*-butylmagnesium chloride in ether produced no reaction, the recovery of the ester being quantitative. There was indication, however, of a reaction at elevated temperatures and studies are now in progress employing di-*n*-butyl ether and benzene as solvents. Because of the unusual stability of ethyl trimethylacetate toward the tertiary Grignard reagent and its reactivity toward *n*-butylmagnesium bromide, an investigation is being made of its behavior toward isopropylmagnesium bromide.

There is the possibility that 2-hexanol might appear as a result of acetaldehyde formation due to peroxidation of the ether.[5,6] Careful studies indicate that this is not the source of the 2-hexanol in the present experiments.

Experimental

Description of Apparatus.—A description of the columns employed is given because of the importance of fractionation in this work. The fractionating columns were of the total condensation, variable take-off type[7] containing single turn, 4-mm. glass helices as packing.[8] The dimensions are reported as length of packing space and internal diameter of the column: Column I, 62 × 0.9 cm.; II, 90 × 1.5 cm.; III, 110 × 1.5 cm.; IV, 68 × 1.5 cm.; V, 58 × 1.1 cm.; VI, 46 × 0.9 cm.; VII, 77 × 1.4 cm.; VIII, 48 × 0.9 cm.; IX, 27 × 0.5 cm.; X, 47 × 0.9 cm.; XI, 64 × 1.2 cm.; XII, indented, 110 × 1.4 cm.

Reaction of *n*-Butylmagnesium Bromide with Trimethylacetyl Chloride.—Trimethylacetyl chloride, b. p. 58° (150 mm.), $n^{20}\text{D}$ 1.4126, was prepared in 87% yield from thionyl chloride (Eastman Kodak "practical") and trimethylacetic acid, b. p. 158° (725 mm.), m. p. 34°. *n*-Butylmagnesium bromide was obtained by treating 97 g. (4 moles) of magnesium with 548 g. (4 moles) of *n*-butyl bromide, b. p. 99–100° (724 mm.), $n^{20}\text{D}$ 1.4400, and 1400 cc. of anhydrous ether. The undiluted acid chloride was added during one hour. The Grignard complex was decomposed with ice, extracted with ether and the ether removed, b. p. 34° (726 mm.), using column IV. The residue was then placed under column VI and fractions 1–5 were collected, 26.2 g., b. p. 42–105° (726 mm.), $n^{20}\text{D}$ 1.3693–1.3718. Fractions 6–12, 24.1 g., b. p. 110–111.5°, were solid at room temperature. Of these, fractions 7 and 12 yielded phenylurethans melting at 112–113° which did not depress the m. p. when mixed with the known phenylurethan of neopentyl alcohol. The yield of neopentyl alcohol based on acid chloride was 27%. Fractions 13 and 14, 2.7 g., 36–71° (16 mm.), $n^{20}\text{D}$ 1.4042–1.4190, were the intermediate fractions between the two reduction products. Fractions 15–25, 99.8 g., b. p. 71° (15 mm.), $n^{20}\text{D}$ 1.4319–1.4321, gave a phenylurethan melting at 64.5–65.5° which gave no depression on mixing with an authentic sample of the same derivative of *n*-butyl-*t*-butylcarbinol. The yield of the secondary carbinol as reduction product was 69%. A residue of 4.5 g., $n^{20}\text{D}$ 1.4329, was pure *n*-butyl-*t*-butylcarbinol, the weight representing the operating hold-up in column VI. A careful search gave no trace of 2-hexanol. It had been suggested that the secondary alcohol might be a product of acetaldehyde formation from peroxide in the ether.

Reaction of *n*-Butylmagnesium Bromide with Acetyl Chloride.—*n*-Butylmagnesium bromide was prepared from 685 g. (5 moles) of *n*-butyl bromide, b. p. 99° (732 mm.), 1450 cc. of dry ether and 122 g. (5 moles) of magnesium. Acetyl chloride ("practical" Eastman Kodak Co. product) was purified by distillation, b. p. 52° (737 mm.), from dry dimethylaniline. The addition of 157 g. (2 moles) of the undiluted acetyl chloride to the above Grignard reagent, concentrated by boiling off one liter of ether, was completed in one hour and twenty minutes. The complex was decomposed with ice, extracted with ether and the ether removed through column IV. The reaction mixture was fractionated through column VI to give: 1, 4.9 g., b. p. 34–64° (736 mm.), $n^{20}\text{D}$ 1.3579; 2–3, 8.9 g., 64–78°, 1.3672–1.3800; 4, 3.2 g., 78–86°, 1.3944; 5, 8.8 g., 79–115° (727 mm.), 1.4011; 6–8, 13.0 g., 115–116.5°, 1.4022–1.4032; 9–10, 10.2 g., 120–134°, 1.4047–1.4118; 11–13, 22.5 g., 134–139.5°, 1.4152–1.4169; 14, 8.6 g., 139.5–145°, 15–20, 53.5 g., 35–74° (14 mm.), 1.4181–1.4278; 21–23, 51.9 g., 85–101° (12 mm.), 1.4351–1.4362; residue 8.2 g.

Fraction 1 was largely ether; 2 and 3 represented an 8% yield of ethyl alcohol as identified through the α-naphthylurethan, m. p. and mixed m. p. with an authentic sample, 78.5–79°. Fractions 4 and 5 contained water layers. Fractions 6–8 were identified as *n*-butyl alcohol by the α-naphthylurethan, m. p. and mixed m. p. with an authentic derivative, 70–71°. Fractions 9 and 10 gave no test for 2-hexanone on treatment with 2,4-dinitrophenylhydrazine. They probably consisted of 2-hexanol and *n*-butyl alcohol. Fractions 11–13 were identified as 2-hexanol by oxidation of a sample to the corresponding ketone with an aqueous acid dichromate solution and the formation of the 2,4-dinitrophenylhydrazone, m. p. and mixed m. p., 106–107°. Fractions 14 and 15 were probably mixtures of 2-hexanol with the decenes formed by the dehydration of some of the methyl-di-*n*-butylcarbinol during the fractionation.

Fractions 16–20 proved to be mainly olefins from the dehydration of methyl-di-*n*-butylcarbinol. They approached the values b. p. 97° (84 mm.) and $n^{20}\text{D}$ 1.4295.

(7) Whitmore and Lux, *ibid.*, **54**, 3451 (1932).

(8) Wilson, Parker and Laughlin, *ibid.*, **55**, 2795 (1933).

Fractions 21–23 were methyl-di-*n*-butylcarbinol, the constants of a known sample of which were b. p. 100° (24 mm.), n^{20}D 1.4349.

Reaction of *n*-Butylmagnesium Bromide with Ethyl Acetate.—Ethyl acetate was purified by treatment of commercial ethyl acetate (Eastman Kodak Co.) with phosphorus pentoxide and fractionation through column V, b. p. 74° (737 mm.), n^{20}D 1.3722. *n*-Butylmagnesium bromide was prepared using 1465 g. (10.6 moles) of *n*-butyl bromide, 258 g. (10.6 moles) of magnesium and 1750 cc. of dry ether. The addition of the ethyl acetate, 440 g. (5 moles), in 700 cc. of dry ether was completed in ten hours. The products were isolated as usual and fractionated through column IV to give: 1, 17.3 g., 35–55° (737 mm.), n^{20}D 1.3592; 2–4, 88.0 g., 75–76°, 1.3731–1.3688; 5, 8.7 g., 37° (24 mm.), 1.4037; 6, 16.3 g., 58° (24 mm.), 1.4160; 7, 32.8 g., 62.5–100° (24 mm.), 1.4304; 8–17, 513.4 g., 100° (24 mm.), 1.4348–1.4351.

Fractions 1–5 contained ether, ethyl alcohol and unreacted ethyl acetate. Fraction 6 was identified as 2-hexanol (3% yield) by oxidation to the ketone and preparation of a 2,4-dinitrophenylhydrazone, m. p. and mixed m. p., 106–107°. Treatment of fraction 6 with 2,4-dinitrophenylhydrazine before oxidation gave no evidence of the presence of 2-hexanone. Fraction 7 contained methyl-di-*n*-butylcarbinol with some 2-hexanol as impurity. Fractions 8–17 represented a 64% yield of the tertiary carbinol which gave a 90% yield of decenes, b. p. 69° (27 mm.), n^{20}D 1.4294, when refluxed with anhydrous copper sulfate.

Reaction of *n*-Butylmagnesium Bromide with Acetaldehyde.—*n*-Butylmagnesium bromide was made from 685 g. (5 moles) of *n*-butyl bromide, 121.5 g. (5 moles) of magnesium and one liter of dry ether. After boiling off 400 cc. of ether, 88 g. (2 moles) of acetaldehyde, b. p. 22–23° at 720 mm. (purified by distillation of 500 g. of a technical grade Eastman Kodak Co. product to which had been added 4 g. of hydroquinone), was added. The addition complex was decomposed with ice and an excess of sulfuric acid. The layers were separated and the aqueous layer extracted again with ether. The final water layer was distilled through column IV. After the dissolved ether had been collected at 34°, a fraction, 15.4 g., b. p. 75–90°, which yielded an α-naphthylurethan, m. p. and mixed m. p., 78.5–79°, corresponding to that for ethyl alcohol, was obtained. A second fraction 90–99°, on drying, also gave an α-naphthylurethan corresponding to ethyl alcohol. The weight of fractions 1 and 2 after drying was 21.4 g., or approximately 18% yield.

The ether was removed from the ethereal extracts of the reaction products through column IV and the products were fractionated through column V to give: 1, 8.4 g., 42–75° (727 mm.), n^{20}D 1.3622; 2–4, 11.9 g., 75–134°, 1.3940–1.4100; 5–6, 66.4 g., 136°, 1.4144–1.4147; residue 28 g. Fraction 1 contained a small amount of ethyl alcohol as identified by its α-naphthylurethan. Fractions 5 and 6 contained the normal product, 2-hexanol.

Reaction of *n*-Butylmagnesium Bromide with 2-Hexanone.—Dehydrogenation of 3 kg. of Eastman "Technical" 2-hexanol yielded crude 2-hexanone which was fractionated through column II into 67 fractions of approximately 40 g. each. The best fractions were combined and refractionated through column V. Addition of 200 g. (2 moles) of purified 2-hexanone, b. p. 125° (732 mm.), n^{20}D 1.4010 to 4.5 moles of filtered *n*-butylmagnesium bromide in 2 liters of ether was completed in one hour with the liberation of 0.15 mole of olefin. The reaction mixture was decomposed with ice, the ether layer decanted, and the aqueous layer steam distilled. The aqueous layer of the distillate was extracted with ether and the total ethereal solutions combined for removal of ether through column XII. The residual products were then fractionated through column I to give: 1–12, 33.1 g., 45° (125 mm.) –80° (98 mm.), n^{20}D 1.4051–1.4079; 13–16, 18.1 g., 80° (87 mm.) –82° (24 mm.), n^{20}D 1.4138–1.4186; 17–33, 343 g., 95° (20 mm.) –78° (3 mm.), 1.4331–1.4358.

Fractions 1–12 were refractionated through column VI to give: 34–36, 10.1 g., 105–111° (739 mm.), n^{20}D 1.4060–1.4008; 37–41, 19.3 g., 116–118°, 1.4017–1.4030; residue, 5 g. Fractions 37–41 were unreacted 2-hexanone, 2,4-dinitrophenylhydrazone, m. p. and mixed m. p., 106–107°.

Fractions 13–16 were refractionated through column IX to give: 42–44, 3.1 g., 131–133.5° (739 mm.), 1.4068–1.4150; 45–50, 7.8 g., 135–136°, 1.4160–1.4162; residue, 0.9 g.

Fractions 42–50 and the residue of that fractionation were identified as 2-hexanol by oxidation with an acid dichromate solution and formation of a 2,4-dinitrophenylhydrazone for 2-hexanone, m. p. and mixed m. p., 106–107°. A portion of fraction 48, 1.7 g., gave no test for 2-hexanone with 2,4-dinitrophenylhydrazine prior to oxidation.

Reaction of *n*-Butylmagnesium Bromide with Ethyl Trimethylacetate.—Ethyl trimethylacetate, b. p. 116.5° (735 mm.), n^{20}D 1.3912 was prepared by the action of ethyl alcohol on trimethylacetyl chloride. *n*-Butylmagnesium bromide was prepared using 97 g. (4 moles) of magnesium, 548 g. (4 moles) of *n*-butyl bromide and 1600 cc. of ether. On completion of Grignard formation, 400 cc. of ether was distilled off and 130 g. (1 mole) of undiluted ethyl trimethylacetate was added to the concentrated Grignard solution during one-half hour. The complex was decomposed with ice, extracted with ether and after removal of the ether through column IV the products were fractionated through column VI to give: 1–2, 4.3 g., 32–110° (741 mm.); 3–4, 4.2 g., 111–116°; 5–6, 7.9 g., 43–63° (11 mm.), n^{20}D 1.4150–1.4208; 7, 7.2 g., 64.5° (11 mm.), 1.4250; 8–13, 57.5 g., 65.5–67° (11 mm.), 1.4295–1.4310; 14–22, 99.6 g., 105.5–107° (11 mm.), 1.4488.

Fractions 3–4 were identified as *n*-butyl alcohol by the α-naphthylurethan, m. p. and mixed m. p., 70–71°. Fractions 8–13 represented a 40% yield of *n*-butyl-*t*-butylcarbinol which gave a phenylurethan melting at 65–66°. Fractions 14–22 were di-*n*-butyl-*t*-butylcarbinol in 50% yield. Based on a density determination of a representative fraction, d^{20}_4 0.8498, the molecular refraction was found to be 63.16; calcd. 63.76.

Fractions 5–6 were investigated for 2-hexanol as a possible product of peroxide and aldehyde formation in the ether but no α-naphthylurethan was obtained, nor did oxidation with acid dichromate solution yield any evidence of 2-hexanone. Fraction 7 was impure di-*n*-butyl-*t*-butylcarbinol.

Addition of Methyl Neopentyl Ketone to Ethylmagnesium Bromide.—The methyl neopentyl ketone[9] used in this and subsequent reactions had a b. p. range of 122–124° (725–730 mm.) and $n^{20}D$ 1.4035–1.4040. The Grignard reagent was prepared from 121 g. (5 moles) of magnesium, 545 g. (5 moles) of ethyl bromide (Eastman Kodak Co. "practical"), and 1 liter of ether. The addition of 353 g. (3.1 moles) of ketone was completed in four hours. The complex was decomposed with ice, the mixture extracted with ether, and the ether removed through column XII. The products were fractionated through column XI at reduced pressure to minimize dehydration of the tertiary carbinol. A salt–ice trap and a solid carbon dioxide–acetone trap were used in series to condense the low boiling material evolved as gases when the pressure was lowered: 1, 5.2 g., 40–48° (176 mm.); 2, 3.8 g., 42° (93 mm.); 3, 2.9 g., 35° (18 mm.), $n^{20}D$ 1.4284; 4, 6.8 g., 66° (18 mm.), 1.4315; 5–18, 359 g., 44° (4 mm.), 1.4335–1.4375. The trap condensed 29.1 g. of liquid which, on fractionation through column X, gave 26.5 g. of ether and a residue, 19, of 1.9 g. The 23.2 g. collected in the salt–ice trap gave a residue, 20, of 2.1 g. after the ether had been removed through column X. Fraction 4, above, on distilling through column X, gave 21, 3 g., 115° (739 mm.), 1.4240 which was combined with fractions 3, 19 and 20 to give on distillation through a semi-micro fractionating column (43.5 × 0.6 cm.): 22, 1.1 g., 90–115° (744 mm.), 1.4160; 23, 1.0 g., 130–145°, 1.4288; residue, 6 drops. Since no derivative could be made for 23 using α-naphthyl isocyanate, no methylneopentylcarbinol was found.

Fraction 22 gave no indication of the presence of *s*-butyl alcohol as a by-product of peroxide and aldehyde formation in the ether. Fractions 5–18 represented methylethylneopentylcarbinol.[10]

Addition of Methyl Neopentyl Ketone to *n*-Propylmagnesium Bromide.—*n*-Propylmagnesium bromide was prepared from 553 g. (4.5 moles) of *n*-propyl bromide, b. p. 70–71° (735 mm.), $n^{20}D$ 1.4344, 109 g. (4.5 moles) of magnesium and one liter of ether. The addition of 342 g. (3 moles) of methyl neopentyl ketone was completed in three hours. The complex was decomposed with ice, extracted with ether which was then removed through column XII, and the products fractionated through column V to give: 1, 27.1 g., 37–87° (728 mm.), $n^{20}D$ 1.3850; 2, 5.2 g., 20.5° (13 mm.). Dehydration of the tertiary carbinol made fractionation difficult. The remainder was dried with anhydrous potassium carbonate, then fractionated through column XI using a salt–ice trap and a solid carbon dioxide–acetone trap in series to give: 3–7, 101.8 g., 35–56° (14 mm.), 1.4232–1.4260; 8–13, 42.6 g., 62–73° (14 mm.), 1.4280–1.4352; 14–20, 74.1 g., 74–75° (14 mm.), 1.4367–1.4371; 21–23, 32.8 g., 85–97° (14 mm.), 1.4528–1.4590; residue, 26 g.; trap, 2.9 g.

Fractions 8–13, fractions 32–39 and the residue of the refractionation (below) represented 106 g. (0.76 mole) of olefin.

Fractions 14–20 contained 77 g. (0.49 mole) of methyl-*n*-propylneopentylcarbinol.

Fractions 1, 2, 3–7 and the contents of the traps were dried over anhydrous sodium sulfate, and fractionated through column X to give at 741 mm. pressure: 24–28, 33.5 g., 35–132°, 1.3630–1.4130; 29–31, 16.6 g., 132–140°, 1.4170–1.4218; 32–39, 39.4 g., 142–150°, 1.4237–1.4260; residue 25 g. Fractions 29–31, gave the 3,5-dinitrobenzoate of methylneopentylcarbinol, m. p. and mixed m. p., 95°. This was confirmed by the α-naphthylurethan, m. p. 86–87°, which likewise did not depress in m. p. when mixed with the α-naphthylurethan of methylneopentylcarbinol.

Fractions 24–29 were refractionated through column X, in an attempt to isolate possible 2-pentanol. Fractions 40–44, 17.2 g., 35–116° (738 mm.), 1.3655–1.3920; 45–47, 1.8 g., 116–126°, 1.4006–1.4050; 48–52, 15.4 g., 126–145°, 1.4090–1.4245; residue 4.1 g. were obtained. Fractions 45–47 gave no 2-pentanol. The rapid absorption of bromine with liberation of hydrogen bromide in fractions 44–52 indicated the presence of unchanged methylneopentyl ketone.

Based on boiling point and refractive index curves, the total yield of methylneopentylcarbinol was 5.5%.

Addition of Methyl Neopentyl Ketone to *n*-Butylmagnesium Bromide.—The addition of methyl neopentyl ketone, 342 g. (3 moles), to 3.17 moles of *n*-butylmagnesium bromide, was completed in two hours. The products were isolated in the usual fashion and fractionated through column XI, using salt–ice and dry ice–acetone traps, to give: 1–7, 44.9 g., 28° (187 mm.) –78° (9 mm.), 1.3900–1.4354; 8–19, 325 g., 78–79° (9 mm.), 1.4400; 20–23, 40.5 g., 125° (6 mm.), 1.4572–1.4590; residue 8.2 g., wt. in traps, 91 g.

Fractions 8–19 represented a 62% yield of methyl-*n*-butylneopentylcarbinol.

The 91 g. collected in the traps left 10.1 g. after removal of ether. This was combined with fractions 1–7 and refractionated at 739 mm. through column X to give: 24–31, 30.6 g., 48–136°, 1.3820–1.4168; 32–33, 7.1 g., 137°, 1.4180–1.4190; 34, 2.4 g., 145°, 1.4225; residue, 3 g.

Fraction 32 gave a quantitative yield of the α-naphthylurethan of methylneopentylcarbinol, m. p. 86–87°, when treated with α-naphthyl isocyanate indicating the presence of methylneopentylcarbinol as reduction product and the absence of 2-hexanol in detectable quantities. The same fraction gave a 3,5-dinitrobenzoate which, on one crystallization, melted at 95–95.5° corresponding to the derivative of methylneopentylcarbinol, again indicating the purity of the fraction. Both derivatives were confirmed by mixed melting points with authentic samples. Boiling point and refractive index curves showed a 5.7% yield of methylneopentylcarbinol as reduction product.

Addition of Methyl Neopentyl Ketone to *n*-Amylmagnesium Bromide.—The addition of 342 g. (3 moles) of the ketone to 3.75 moles of the Grignard reagent was completed in two and one-half hours. The products were isolated in the usual fashion and fractionated through column XI to give: 1–6, 39.4 g., 55° (31 mm.) –48° (16 mm.), 1.4080–1.4150; 7–8, 12.3 g., 48–49° (16 mm.), 1.4215–1.4245; 9–17, 105 g., 79–81° (16 mm.), 1.4340–1.4350; 18–30, 222 g., 92° (8 mm.), 1.4425; 31–32, 16.4 g., 103–109° (6 mm.), 1.4540–1.4587; residue, 43 g. The traps used in this fractionation condensed 41 g. of low boiling material which

---

(9) Methyl neopentyl ketone is one of the products of the chromic acid oxidation of diisobutylene. The experimental details of its preparation will be discussed in a later paper.

(10) Previously prepared by K. C. Laughlin of this Laboratory.

contained 9.6 g. after removal of ether through column X. This was combined with fractions 1–6 to give through column X: 33–36, 14.8 g., 35–122° (750 mm.), 1.3542–1.4040; 37–39, 10.3 g., 122–132°, 1.4040–1.4140; 40–41, 6.6 g., 136°, 1.4158–1.4170; residue, 3.5 g.

The residue above, 37–39, and fractions 7–8 were combined and fractionated through column X to give 5.0 g. of methylneopentylcarbinol, $n^{20}D$ 1.4175–1.4195, which gave an α-naphthylurethan, m. p. and mixed m. p., 86–87°. This was checked with a 3,5-dinitrobenzoate, m. p. and mixed m. p., 95–95.5°. This sample, together with the 6.6 g. of fractions 40–41, represents a 3.4% yield of reduction product. Attempts to find 2-heptanol were unsuccessful. Fractions 9–17 contained dodecenes (0.63 mole) and fractions 18–30 contained methyl-*n*-amylneopentylcarbinol.

Summary

1. The yields of reduction products from the action of *n*-butylmagnesium bromide on acetyl chloride and trimethylacetyl chloride are reported.

2. Reductions involving *n*-butylmagnesium bromide with ethyl acetate, acetaldehyde and 2-hexanone are also described.

3. The reducing actions of ethyl-, *n*-propyl-, *n*-butyl- and *n*-amyl-magnesium bromides with methyl neopentyl ketone are reported.

4. No evidence was found that ether peroxide was the source of the carbinols.

The Action of Primary Grignard Reagents on *t*-Butylacetyl Chloride

BY FRANK C. WHITMORE, A. H. POPKIN, J. S. WHITAKER, K. F. MATTIL AND J. D. ZECH

The reduction of trimethylacetyl chloride to neopentyl alcohol in 95% yield[1] and *t*-butylacetyl chloride to neopentylcarbinol[2] in 1% yield when treated with *t*-butylmagnesium chloride has been reported. The results of the present investigation agreed with these observations, the action of ethyl-, *n*-propyl-, *n*-butyl- and *n*-amylmagnesium bromides on *t*-butylacetyl chloride giving no evidence for the formation of neopentylcarbinol in detectable quantities. In view of the yields of primary alcohol obtained by the reduction of isobutyryl-, *n*-butyryl-[3] and pivalyl chlorides using *t*-butylmagnesium chloride and of acetyl chloride using *n*-butylmagnesium bromide,[4] it is possible that the primary, secondary or tertiary character of the groups attached to the α-carbon of the acid chloride may have a more pronounced influence on the extent of reduction than has the branching of the chain. This possibility is being studied.

No reduction product was isolated when *t*-butylacetyl chloride was added to ethylmagnesium bromide, but similar addition to *n*-propyl, *n*-butyl and *n*-amylmagnesium bromides produced the corresponding secondary carbinols in 24.4, 20.5 and 19.3% yields. The chief products were the expected tertiary alcohols, although the recognized instability of such higher molecular weight tertiary carbinols was again evidenced in the partial dehydration of di-*n*-propylneopentyl-, di-*n*-butylneopentyl- and the complete dehydration of di-*n*-amylneopentylcarbinols during fractionation at reduced pressure.

Pure *n*-propyl-, *n*-butyl- and *n*-amylneopentylcarbinols were required for identification of the reduction products obtained. The action of aluminum isopropylate in isopropyl alcohol on *n*-propyl, *n*-butyl and *n*-amyl neopentyl ketones produced the desired secondary carbinols in 92, 93 and 89% yields, respectively. The ketones had been prepared in excellent yields by the action of the appropriate Grignard compound on *t*-butylacetamide.[5]

Experimental

Addition of *t*-Butylacetyl Chloride to Ethylmagnesium Bromide.—The Grignard solution was prepared from 545 g. (5 moles) of ethyl bromide, b. p. 36° (730 mm.), $n^{20}D$ 1.4240, magnesium and 1.5 liter of dry ether. Addition of 182 g. (1.3 moles) of *t*-butylacetyl chloride, b. p. 68° (100 mm.), $n^{20}D$ 1.4226, prepared in 86% yield from the action of thionyl chloride on the acid, was completed in seventy-five minutes. The complex was decomposed with ice, extracted with ether and the product, on removal of solvent using column XII, was fractionated through column XI,[6] to give: fraction 1, 2.6 g., b. p. 35–78° (740 mm.), $n^{20}D$ 1.3770–1.4010; 2, 7.7 g., 50° (10 mm.), 1.4370;

[4] Whitmore, Popkin, Whitaker, Mattil and Zech, *ibid.*, **60**, 2458 (1938).

[5] A detailed description of the synthesis of branched aliphatic ketones from the acid amide and Grignard reagent is in preparation.

[6] The fractionating columns used have already been described, Whitmore, Popkin, Whitaker, Mattil and Zech, THIS JOURNAL, **60** 2458 (1938).

3–12, 89.4 g., 62–64° (10 mm.), 1.4390–1.4400; 13–14, 29.1 g., 76–93° (9 mm.), 1.4440; residue 7.3 g.

Fraction 1 contained ethyl alcohol; 3,5-dinitrobenzoate, m. p. and mixed m. p. 91–92°.

Fractions 3–14 were diethylneopentylcarbinol, d^{20}_4 0.8352, *MR:* calcd. 50.0, obsd. 49.8. Dehydration of the carbinol took place even on standing.

The constants for ethylneopentylcarbinol[7] are b. p. 150–152° (735 mm.), $n^{20}_{\rm D}$ 1.4250. Attempts to find this carbinol in the reaction mixture were not successful. Similar attempts to identify neopentylcarbinol also were unsuccessful.

Addition of *t*-Butylacetyl Chloride to *n*-Propylmagnesium Bromide.—Addition of 228 g. (1.7 moles) of *t*-butylacetyl chloride, b. p. 79° (150 mm.), $n^{20}_{\rm D}$ 1.4212 to 4.5 moles of *n*-propylmagnesium bromide in 1.5 l. of ether was completed in one hour and forty minutes. The addition complex was decomposed with ice, extracted with ether and the product fractionated through column XI to give (using 2 solid carbon dioxide traps): 1–8, 137.3 g., 20° (120 mm.) –62° (13 mm.), $n^{20}_{\rm D}$ 1.4142–1.4230; 9–13, 104.4 g., 62° (13 mm.) –88° (9 mm.), 1.4330–1.4410; residue, 19 g.; traps, 85 g. The trap condensate gave 7.5 g. of residue after removal of ether and this, together with fractions 1–8, through column X gave: 14, 2.4 g., 40–82° (733 mm.), 1.3780; 15–16, 4.1 g., 86–96°, 1.3825–1.3970; 17–19, 4.9 g., 135–172°, 1.4156–1.4200; 20–23, 22.9 g., 172°, 1.4220–1.4290; 24–25, 10.5 g., 172°, 1.4340–1.4345; 26–34, 46.0 g., 58–60° (10 mm.), 1.4300–1.4315; 35–37, 30.0 g., 58–59° (8 mm.), 1.4320–1.4330; residue, 1 g.

Fractions 9–13, on refractionation through column X, gave: 38, 55 g., 62–64° (10 mm.), 1.4325; 39–43, 44.8 g., 64° (10 mm.), 1.4330–1.4332, d^{20}_4 0.7759; 44–46, 18.3 g., 66–90° (10 mm.), 1.4340–1.4385; 47–48, 8.4 g., 94–96° (10 mm.), 1.4429, d^{20}_4 0.8376; 49–50, 5.1 g., 108–110° (10 mm.), 1.4390–1.4400; residue, 3.2 g.

Fractions 15–16 were identified as *n*-propyl alcohol by the m. p. and mixed m. p. of the 3,5-dinitrobenzoate, 74–74.5°.

Fractions 20–23 and 26–34 represented a 24.4% yield of *n*-propylneopentylcarbinol, phenylurethan, m. p. and mixed m. p. 82°.

Fractions 24, 25 and 35–43 were dodecenes obtained by dehydration of the tertiary carbinol. Fractions 47–48 were di-*n*-propylneopentylcarbinol. *Anal.* Calcd. for $C_{12}H_{26}O$: C, 77.4; H, 14.0. Found: C, 77.2; H, 13.9. All attempts to identify neopentylcarbinol failed.

Addition of *t*-Butylacetyl Chloride to *n*-Butylmagnesium Bromide.—The addition of 228 g. (1.7 moles) of *t*-butylacetyl chloride to 4.5 moles of *n*-butylmagnesium bromide in 1.5 l. of ether was completed in one hour and thirty-five minutes. The product was isolated in the usual manner to give through column XI: 1–14, 83 g., 26–82° (14 mm.), 1.4024–1.4352; 15–21, 43 g., 87–112° (8 mm.), 1.4391–1.4400; 22–24, 132.3 g., 112° (8 mm.), 1.4415–1.4424; residue, 9 g. The solid carbon dioxide trap contents, 95.0 g., were largely ether. Fractions 1–21 contained water, indicating dehydration.

The trap condensates, on removal of ether, yielded 17 g. which on combining with fractions 1–14 gave through column X: 25–28, 11.3 g., 35–75° (733 mm.), 1.3540–1.3680; 29–41, 47.2 g., 102–190°, 1.3840–1.4291; 42–49, 31.2 g., 190–200°; 1.4300–1.4390; residue, 3.4 g.

Fractions 15–24 were refractionated through column X to give: 50, 6.7 g., 90° (8 mm.), 1.4385; 51–53, 23.1 g., 90° (8 mm.), 1.4400–1.4403; 54–61, 84.0 g., 101–110° (8 mm.), 1.4415–1.4458; 62–64, 35.8 g., 112–113° (8 mm.), 1.4460; 65, 10.2 g., 113° (8 mm.), 1.4469; residue, 2 g.

Fractions 29–41, on refractionation through column X, gave: 66–69, 6.5 g., 74–108° (735 mm.), 1.3807–1.3980; 70–74, 10.0 g., 109–113°, 1.4010–1.4050; 75–76, 3.2 g., 113–186°, 1.4170–1.4250; 77–81, 19.0 g., 186–190°, 1.4260–1.4300; residue, 1 g.

Fractions 42–49 and 77–81 represented 54.9 g. (0.35 mole), 20.5% yield of *n*-butylneopentylcarbinol, α-naphthylurethan, m. p. and mixed m. p., 70–70.5°.

Fractions 51–53 were olefins obtained by the dehydration of di-*n*-butylneopentylcarbinol, d^{20}_4 of olefins was 0.7824; *MR*, calcd. 66.38; obsd. 66.12.

Fractions 62–64 contained di-*n*-butylneopentylcarbinol d^{20}_4 0.8320; *MR*, calcd. 68.5; obsd. 68.59. Dehydration followed on standing.

Fractions 70–74 were *n*-butyl alcohol, phenylurethan, m. p. and mixed m. p., 62.5–63°. All attempts to identify neopentylcarbinol failed.

Addition of *t*-Butylacetyl Chloride to *n*-Amylmagnesium Bromide.—The addition of 200 g. (1.5 moles) of *t*-butylacetyl chloride to 4.1 moles of *n*-amylmagnesium bromide, completed in one hour and twenty minutes, yielded a crude product which gave through column XI: 1–4, 43.9 g., 42–87° (15 mm.), 1.4140–1.4280; 5–7, 36.5 g., 90° (15 mm.) –92° (10 mm.), 1.4310–1.4316; 8–11, 36.7 g., 92–107° (10 mm.), 1.4340–1.4348; 12–18, 186.3 g., 118–130° (13 mm.), 1.4442–1.4460; residue, 5 g.; trap contents, 59 g. Fraction 1–7 contained water, indicating dehydration.

The trap condensate yielded 5.1 g. which was combined with fraction 1. Repeated fractionation of all the fractions using column X gave: 19, 1.4 g., 35–113° (733 mm.), 1.3530; 20–24, 19.9 g., 113–136°, 1.4132–1.4170; 25, 3.7 g., 50–90° (13 mm.), 1.4260; 26–32, 54.5 g., 90–93° (10 mm.), 1.4302–1.4350; 33, 8.0 g., 90–112° (10 mm.), 1.4410; 34–39, 147.7 g., 118° (10 mm.), 1.4450, d^{20}_4 0.7856, *MR* for the hexadecenes; calcd. 75.62; obsd. 75.70; residue, 12.7 g., 1.4452.

Fractions 20–24 were *n*-amyl alcohol, phenylurethan, m. p. and mixed m. p., 48°.

Fractions 26–32 were *n*-amylneopentylcarbinol, phenylurethan, m. p. and mixed m. p., 60–61°. The yield, estimated from the boiling point and refractive index curves, was 19.3%.

Fractions 34–39 were 0.71 mole of olefins from the dehydration of di-*n*-amylneopentylcarbinol. No evidence was obtained for the presence of neopentylcarbinol.

Preparation of *n*-Propylneopentylcarbinol.—*n*-Propyl neopentyl ketone, 39 g. (0.27 mole), b. p. 111–112° (150 mm.),[8] was heated for twenty-four hours under column VI with 32.6 g. (0.15 mole), of aluminum isopropylate in 300 cc. of dry isopropyl alcohol, the acetone being removed as formed. The reaction mixture was treated with ice and excess hydrochloric acid, extracted with ether and the product, on removal of the solvent, fractionated through VI to give: 1–2, 1.7 g., 80–84.5° (29 mm.), 1.4193–1.4243;

[7] Prepared by C. I. Noll, this Laboratory.

[8] Prepared by H. C. Crafton, this Laboratory.

3–7, 35.5 g., 85° (29 mm.), 1.4260; residue, 0.8 g. Fractions 3–7 were a 92% yield of *n*-propylneopentylcarbinol. *Anal.* Calcd. for $C_9H_{20}O$: C, 75.0; H, 14.0. Found: C, 74.5; H, 14.5. The phenylurethan had m. p. 82°.

Preparation of *n*-Butylneopentylcarbinol.—*n*-Butyl neopentyl ketone, b. p. 69° (13 mm.), n^{20}_D 1.4204, d^{20}_4 0.8143, was prepared in 77% yield by the action of *n*-butylmagnesium bromide on *t*-butylacetamide, m. p. 132°. Heating of 26.7 g. (0.17 mole) of the ketone with 20.4 g. (0. 1 mole) of aluminum isopropylate in 120 cc. of dry isopropyl alcohol was conducted for twenty-four hours with the removal of acetone, during the course of the reaction, through column VI: 1–2, 3.1 g., 90–99° (30 mm.), 1.4254–1.4300; 3–5, 22.2 g., 95° (24 mm.), 1.4308, d^{20}_4 0.8212; residue, 2.0 g. Fractions 3–5 represented a 93% yield of *n*-butylneopentylcarbinol. *Anal.* Calcd. for $C_{10}H_{22}O$: C, 75.9; H, 13.9. Found: C, 75.7; H, 14.1. The α-naphthylurethan had m. p. 70–70.5°.

Preparation of *n*-Amylneopentylcarbinol.—*n*-Amylneopentyl ketone, b. p. 86° (13 mm.), n^{20}_D 1.4247, d^{20}_4 0.8184, was prepared in 60% yield from *n*-amylmagnesium bromide and *t*-butylacetamide. Heating of 51 g. (0.25 mole) of aluminum isopropylate in 400 cc. of dry isopropyl alcohol with 90 g. (0.53 mole) of the ketone for thirty-three hours gave a crude carbinol which, on fractionation through column VI, gave: 1–2, 3.4 g., 80–94° (12 mm.), 1.4271–1.4326; 3–12, 80.7 g., 96° (13 mm.), 1.4338, d^{20}_4 0.8225. Fractions 3–12 represented an 89% yield of *n*-amylneopentylcarbinol. *Anal.* Calcd. for $C_{11}H_{24}O$: C, 76.7; H, 14.0. Found: C, 76.9; H, 14.0. Phenylurethan, m. p. 60.5–61°; α-naphthylurethan, m. p. 63–63.5°.

Summary

1. The action of *n*-propyl-, *n*-butyl- and *n*-amylmagnesium bromides on *t*-butylacetyl chloride produced, together with the expected tertiary carbinols and olefins, *n*-propylneopentylcarbinol in 24.4% yield, *n*-butylneopentylcarbinol in 20.5% yield, *n*-amylneopentylcarbinol in 19.3% yield, respectively. No reduction product could be isolated when ethylmagnesium bromide was used.

2. The preparation and physical constants of *n*-propylneopentyl-, *n*-butylneopentyl-, and *n*-amylneopentylcarbinols have been reported.

Studies in the Phenanthrene Series. XXI. Morpholino Alcohols Derived from Phenanthrene[1]

BY ERICH MOSETTIG, FORREST W. SHAVER AND ALFRED BURGER

As part of a systematic search for substances with central narcotic action, which, eventually, might replace morphine, we have synthesized in previous years a large variety of amino alcohols derived from phenanthrene.[2] Dr. N. B. Eddy at the University of Michigan has shown[3] that some of these phenanthryl amino alcohols produce in the cat marked analgesia and a physiological picture very like that of morphine. Furthermore, a distinct interdependence of degree of analgesic action and nature of the tertiary amino group became evident when, in the various groups of amino alcohols, individual members differing only in the basic group were compared. Thus, for example, the diethylamino derivatives of types I and II are superior to the dimethylamino derivatives.[4]

Extension of these studies to morpholino alcohols (I–VI) seemed justified, in order that comparison with the corresponding diethyl and piperidino compounds might be made.

The preparation of the various amino alcohols proceeded quite normally except that in the catalytic hydrogenation of 2-morpholino-1-keto-1,2,-3,4-tetrahydrophenanthrene the two diastereoisomeric forms (A and B) of the corresponding amino alcohol (type III) were formed. We have

[a] To a solution of 5 g. of 2-ω-bromoacetylphenanthrene[2a] in 40 ml. of dry benzene was added 3.5 g. of morpholine (n^{20}D 1.4547), and the mixture was allowed to stand overnight. It was diluted with ether, the solution was washed with water, and the solvent was evaporated under reduced pressure; yield 89%.

[b] The hydrochloride was obtained by adding an ethereal solution of hydrogen chloride to an acetone solution of the free base.

[c] Liberated from No. 4 with sodium hydroxide solution and extracted into ether.

[d] A suspension of 4 g. of No. 2 and 0.16 g. of platinum oxide in 160 ml. of ethanol absorbed the required amount of hydrogen in about ten hours. The catalyst was filtered out and the solvent was evaporated under reduced pressure. The residue was dissolved in acetone, the acetone solution was diluted with ether, and allowed to crystallize; yield 75%.

[e] Obtained like No. 1, by employing 8.3 g. of 3-ω-bromoacetylphenanthrene, 40 ml. of benzene, and 5.6 g. of morpholine. The amino ketone was purified through the hydrochloride; yield 85%.

[f] Prepared like No. 4; yield 70%.

[g] A mixture of 3 g. of 2-acetylphenanthrene,[5] 1 g. of paraformaldehyde, 2 g. of morpholine hydrochloride (prepared by neutralizing morpholine with alcoholic hydrogen chloride and precipitating the salt with ether), and 12 ml. of isoamyl alcohol was boiled under reflux for six minutes. The amino ketone hydrochloride precipitated out within this time, and the precipitation was completed by addition of ether to the cooled reaction mixture. The free base was liberated from the salt with ammonium hydroxide, and extracted into ether. The ether solution was washed with water. The base was purified by sublimation in an oil-pump vacuum, and crystallization; yield 73%.

[h] Prepared from No. 12 and purified by sublimation in an oil-pump vacuum.

[i] Prepared like No. 4; yield 63%.

[j] A suspension of 0.3 g. of the amino alcohol in 5 ml. of dry pyridine and 1 ml. of acetic anhydride was allowed to stand for forty-eight hours. The solvent was evaporated under reduced pressure, the residue was washed with acetone and recrystallized.

[k] Prepared from No. 15.

[l] Prepared like No. 9, except that the hydrochloride, as precipitated from the reaction mixture, was purified by crystallization; yield 76%.

[m] Prepared by catalytic hydrogenation of No. 15; yield 82%.

[n] Ten and two-tenths grams of 3-methoxy-9-ω-bromoacetylphenanthrene[2b] was allowed to react with 7.5 g. of morpholine in 50 ml. of benzene for one hour. The mixture was extracted with water, the benzene solution was dried, evaporated in a vacuum, and the oily residue was converted to the hydrochloride in acetone solution; yield 82%.

[o] Prepared by catalytic hydrogenation of No. 19 (methanol, platinum oxide); yield 70%. The free base could not be obtained crystalline.

[p] Nine grams of 1-keto-2-bromo-1,2,3,4-tetrahydrophenanthrene[2d] and 7.5 g. of morpholine were allowed to react in 30 ml. of benzene for forty-eight hours. The red mixture was extracted with water and a crystalline residue was obtained by evaporation of the benzene layer; yield 55%.

[q] Seventeen and five-tenths grams of No. 22 in 400 ml. of methanol and 0.5 g. of platinum oxide absorbed approximately the calculated amount of hydrogen in a week. The mixture of crystalline hydrochlorides was converted to the bases, m. p. 95–127°; yield 16 g. This mixture was dissolved in 100 ml. of hot ethanol and allowed to crystallize. The first crop (A) was filtered when the temperature of the solution had reached 30°. Another crop (B) was obtained by allowing the filtrate to crystallize slowly. The base A was recrystallized from ethanol three times to the constant m. p. 179–180°; yield 1 g. The hydrochloride was formed from the base in acetone suspension with ethereal hydrogen chloride. The acetyl derivative was obtained by the action of acetic anhydride in pyridine solution. The base B was recrystallized from ethanol three times to the constant m. p. 139–140.5°; yield 1 g. In a second experiment, similarly, two bases were obtained. The one was base A of m. p. 179–180°, the other one melted at 153–154° (B_1). A new determination of the melting point of B showed that this compound had changed, in the meantime, to the higher-melting form.

[r] Prepared by the Mannich reaction, by heating to boiling a solution of the reactants (10 g. of 1-ketotetrahydrophenanthrene, 12 g. of paraformaldehyde, and 7 g. of morpholine hydrochloride) in 50 ml. of isoamyl alcohol for four minutes. The crude hydrochloride was washed with acetone; yield 41%.

[s] Prepared by catalytic hydrogenation of No. 31; yield 94%.

[t] Prepared like No. 21 by allowing 3-bromo-4-keto-1,2,3,4-tetrahydrophenanthrene to react with morpholine in benzene solution; yield 63%.

[u] Prepared by catalytic hydrogenation of No. 35; yield 68%.

[v] Six grams of 4-keto-1,2,3,4-tetrahydrophenanthrene was boiled with 4.2 g. of morpholine hydrochloride, 7.2 g. of paraformaldehyde, and 24 ml. of isoamyl alcohol for twenty-five minutes. The reaction mixture was worked up in the usual manner; yield 30%.

never observed in our previous work the simultaneous formation of diastereoisomeric amino alcohols under analogous conditions. When a noble metal catalyst is employed in the reduction of amino ketones, generally only one of the two possible amino alcohols is formed, while in the sodium amalgam reduction both forms may be obtained.[6]

The possibility that one of the two compounds A or B is a hexahydro derivative cannot be excluded entirely, since, because of lack of material, we did not attempt to demonstrate the isomerism by converting A and B to identical desoxy compounds.

All of the amino alcohols that have been tested so far (Nos. 4, 8, 20, 24, 27, 33, 37, 40 of the accompanying table)[7] show only low analgesic action or none at all. In the instances where a comparison with analogous diethylamino and piperidino compounds was possible, it became apparent that replacement of the diethyl or piperidino group by the morpholino group resulted in a decrease of analgesia in the ratio from 2:1 to about 8:1.

Summary

The synthesis of a series of morpholino alcohols from 2-acetylphenanthrene, 3-acetylphenanthrene, 3-methoxy-9-acetylphenanthrene, 1-keto-tetrahydrophenanthrene and 4-keto-tetrahydrophenanthrene is described.

An Investigation of the Effect of Chemical Structure on Local Anesthetic Action of Diothane Analogs[1]

BY ELSIE M. WALTER[2]

Most local anesthetics in general use contain a benzene ring somewhere in their structure. In fact, many early experimenters claimed that a compound must contain a benzoyl group to exhibit anesthetic action. In 1925, Gilman and Pickens[3] studied the effect of various aromatic rings on the anesthetic action of procaine. They prepared the furan, thiophene, and pyrrole analogs of procaine. Their results indicate that the order of decreasing activity is benzene > pyrrole > thiophene > furan > methyl. More recently, however, Phatak and Emerson[4] prepared various alkyl esters of 2-furoic acid where the alkyl varied from methyl to amyl. They found that all of the compounds possess local anesthetic action which increases with the size of the alkyl from methyl to amyl. The amyl furoate has approximately the same activity as cocaine. It was pointed out by the authors that the corresponding benzoates show either incomplete or no anesthetic action.

Since very little work has been done on the effect of substituting various aromatic rings for the benzene ring in the structure of local anesthetics, it was decided to prepare some furan analogs of Diothane (piperidinopropanediol diphenylurethan hydrochloride[5]) and compare their

physiological action with that of the corresponding benzoyl compounds. The difuroate, dibenzoate, diacetate, dicinnamate, and difuranacrylate of piperidinopropanediol were prepared and tested pharmacologically. The dibenzoate was previously reported by Pyman.[6] The remaining compounds have not been reported before.

Experimental

1-Piperidinopropane-2,3-diol dibenzoate was prepared from 1-piperidinopropane-2,3-diol and benzoyl chloride by the Schotten–Baumann reaction according to the method of Pyman,[6] but it was recrystallized from petroleum ether instead of alcohol. The piperidinopropanediol used in all the reactions was made from the previously described specially purified piperidine.[7] The dibenzoate formed needle-like white crystals, m. p. 64–65°, uncorr., as reported by Pyman.[6] The hydrochloride was prepared by dissolving the free base in ether and introducing gaseous hydrogen chloride. The gummy, white hydrochloride on washing with anhydrous ether became solid and was ground to a fine white powder; m. p. 126–130°, uncorr.

Anal. Calcd. for $C_{22}H_{26}O_4NCl$: Cl, 8.78. Found: Cl, 8.84.

1-Piperidinopropane-2,3-diol difuroate was prepared from piperidinopropanediol and furoyl chloride in the same manner as the dibenzoate. The ester was decolorized with charcoal in ether solution. It was precipitated as a fluffy white solid by evaporating the ether solution to a small volume and adding petroleum ether. It can also be crystallized from ether in white needle-like crystals; m. p. 73–74°, uncorr. The hydrochloride was prepared in the same manner as the dibenzoate hydrochloride; m. p. 163–164.5°, uncorr.

Anal. Calcd. for $C_{18}H_{22}O_6NCl$: Cl, 9.19. Found: Cl, 9.28.

1-Piperidinopropane-2,3-diol diacetate was prepared by slowly adding with stirring 32 g. (0.2 mole) of piperidinopropanediol to 45 g. (0.44 mole) of acetic anhydride kept in an ice-bath. After the addition was completed, the mixture was heated to 75° and then allowed to stand at room temperature for about five hours. After neutralizing with sodium carbonate in an ice-bath, the ester was extracted with ether and the solution was dried over sodium sulfate. After removing the ether, the diacetate remained as a colorless oil which becomes orange upon exposure to light and air. The hydrochloride was prepared in the usual manner and stored in a desiccator, since the ester hydrolyzes readily on exposure to moisture; m. p. 128–133°, uncorr.

Anal. Calcd. for $C_{12}H_{22}O_4NCl$: Cl, 12.68. Found: Cl, 12.80.

1-Piperidinopropane-2,3-diol dicinnamate could not be prepared by the Schotten–Baumann reaction because of the hydrolysis of cinnamoyl chloride. An attempt to produce it from the diacetate by the Perkin reaction failed also. Condensation of the alcohol and acid chloride was successful in benzene but the resulting ester did not crystallize and could not be completely freed of benzene. Condensing the acid chloride and the alcohol without a solvent was the most satisfactory method.

Seven grams (0.044 mole) of cinnamoyl chloride was melted and 3.2 g. (0.02 mole) of piperidinopropanediol were added slowly with stirring. The material formed a clear yellow viscous mass. After cooling and washing with numerous portions of dry ether and standing for several days under ether the crude hydrochloride crystallized. This was purified by neutralizing with the theoretical quantity of 5% sodium hydroxide, extracting with ether, precipitating with 2 *N* hydrochloric acid, and regenerating the free base with sodium hydroxide. The hydrochloride was prepared by treating the free base, in absolute ether, with hydrogen chloride gas, freeing from excess hydrochloric acid by washing with ether, and crystallizing from water; m. p. 159–161°, uncorr.

Anal. Calcd. for $C_{26}H_{30}O_4NCl$: Cl, 7.78. Found: Cl, 8.10.

1-Piperidinopropane-2,3-diol difuranacrylate was prepared similarly to the dicinnamate. Furanacrylic acid was prepared according to the method of Gibson and Kahnweiler[8] and was converted into the acid chloride according to the method of T. Sasaki.[9] Three and two-tenths grams (0.02 mole) of piperidinopropanediol was added slowly with stirring to 6 g. (0.044 mole) of melted furanacryloyl chloride. The crude hydrochloride was a very viscous light brown oil. The free base, obtained by neutralizing the hydrochloride with the theoretical amount of sodium hydroxide, extracting with ether, and decolorizing with charcoal, was also a heavy viscous oil. The purified hydrochloride was obtained similarly to that of the dicinnamate and was a colorless oil when first prepared but became colored in a few hours. It has resisted attempts to crystallize it.

Anal. Calcd. for $C_{22}H_{26}O_6NCl$: Cl, 8.14. Found: Cl, 8.19.

Pharmacological.—The following table roughly evaluates the strength of the compounds as local anesthetics. The tests were made with a solution of the hydrochlorides in distilled water. The time in minutes required for the production of sensory anesthesia in the exposed sciatic nerve of the frog, and the duration of anesthesia after one-minute application of the solution to the cornea of the rabbit are given.

Ester	Concn., %	Frog sciatic onset, min.	Rabbit cornea Onset, min.	Rabbit cornea Duration, min.
Dibenzoate	1	2	2	7
Difuroate	1	4	2.5	4
Diacetate	1	..	..	No action
Dicinnamate	<1	2	2.5	6–7
Difuranacrylate	1		1.5	8–8.5
Difuranacrylate	2	..	1.5	13
Procaine	1			Incomplete

The dibenzoate caused irritation of the eye. The dicinnamate caused a milky film to appear over the cornea, sloughing of the tissue, and about twelve hours later, marked conjunctival irritation and swelling of the eyelids. The difuroate and the difuranacrylate seemed to have a lachrymatory effect, but caused very little, if any, irritation of the eyes. There was considerable difficulty in obtaining a solution of the dicinnamate. A few drops of hydrochloric acid were used to produce the 1% suspension for testing on the cornea, and a 25% solution of propylene glycol was required to produce the 1% solution for testing on the sciatic nerve of the frog.

It will be seen that the dibenzoate was more active than the difuroate, which agrees with the findings of Gilman and Pickens.[3] However, introduction of a double bond appears to reverse this order, the difuranacrylate being more active than the dicinnamate. In the furan series, the introduction of the double bond gave an expected increase in activity, the furanacrylate being twice as active as the furoate. A similar increase in activity is not found on comparing the dicinnamate with the dibenzoate, but this may have been due to the low solubility of the dicinnamate and the precipitation on application to the eye. The dicinnamate showed rapid penetration when applied to the nerve. As was expected, the diacetate was inactive. The furan compounds have the advantage over the benzene analogs of being more soluble and less irritating.

Acknowledgment.—The author wishes to express her sincere appreciation for the advice, criticism and assistance given her by Drs. Elton S. Cook of the Institutum Divi Thomae, Robert S. Shelton of the Wm. S. Merrell Co., and E. F. Farnau of the University of Cincinnati. The author wishes to thank Mr. N. M. Phatak for the pharmacological tests.

Summary

The diacetate, dibenzoate, difuroate, dicinnamate, and difuranacrylate of piperidinopropanediol were prepared. The results of the pharmacological tests indicate that the furan ring has a favorable effect on anesthetic action. It apparently increases the solubility and decreases the irritation in this series of compounds.

Addition Reactions of Unsaturated Alpha-Ketonic Acids. V

BY MARIE REIMER AND ELIZABETH CHASE

Earlier papers in this series[1] have shown that the behavior of the unsaturated side-chain of benzalpyruvic acid is influenced strongly by methoxyl groups in different positions in the benzene ring: the stability of the dibromo addition products, the tendency to formation and the stability of hydrates, the color of the compounds alone and in solution in concentrated sulfuric acid show decided variation in the different compounds. Most striking is the fact that a methoxyl group in the para position entirely inhibits the photochemical reaction so conspicuous a characteristic of benzalpyruvic acid and its esters[2] and noticeable to a less degree with the *o*- and the *m*-methoxy-substituted acids. Because of the prevalence of methoxyl groups in natural products and because of differences in activity noticed when methoxyl replaces hydrogen in several different classes of compounds,[3] it becomes of interest to determine whether the blocking of the sunlight reaction is a function of the *p*-methoxyl group, as such, or whether and to what extent other groups in the para position in the benzene ring have the same effect. Such studies are now under way in this Laboratory.

The present paper deals with benzalpyruvic acid in which there is a methyl group in the para position. The methyl group was chosen because of certain well-known similarities in the influence of methyl and methoxyl: the effect on orientation in the benzene ring, on ease of substitution and on the coupling reaction,[4] for example. These, however, are influences of these groups on hydrogen of the ring. In reactions involving a side-chain wide differences have been described, not-

ably the greater effect of the methoxyl over that of the methyl group on dissociation into free radicals of hexaarylethanes[5] and of phenylated hydrazines[6] and the increased "migration aptitude" of the anisyl group.[7] In the case here studied differences have been noted. The *p*-methylbenzalpyruvic acid adds bromine readily to form a dibromide more stable than that of the *p*-methoxy compound but less so than that of the unsubstituted acid. It forms an unstable hydrate: that of benzalpyruvic acid is stable while the *p*-methoxy acid forms no hydrate. The methyl substituted acid is slowly affected by sunlight. The color changes with sulfuric acid are not so marked as with the methoxy acid. In all these reactions the effect of the methyl group is seen to be intermediate between that of methoxyl and of hydrogen in the para position.

Experimental Part

4-Methylbenzalpyruvic acid was prepared by mixing 17.6 g. (0.2 mole) of pyruvic acid with 24 g. (0.2 mole) of toluic aldehyde and adding slowly, with stirring, 55 cc. (0.23 mole) of a 25% solution of potassium hydroxide in methyl alcohol. The temperature was kept at about 10°. Toward the end of the reaction a yellow color developed and the yellow condensation product crystallized out. After standing overnight, this was filtered and washed with methyl alcohol and with ether; yield of pure product, 95%. From a cooled, saturated aqueous solution of this potassium salt, hydrochloric acid precipitated an acid which crystallized from boiling benzene in bright canary yellow plates melting at 127°. The acid is fairly soluble in boiling water, more soluble in the usual organic solvents.

Anal. Calcd. for $C_{11}H_{10}O_3$: C, 69.47; H, 5.26. Found: C, 69.86; H, 5.37.

If the acid is allowed to crystallize slowly from dilute aqueous solution it separates in long shining yellow needles which soften about 80° and melt 100–110°. The needles rapidly become opaque and then melt at 127°. This loss of water is so rapid that no significant analyses could be obtained.

On exposure of the pure acid to the sunlight, the odor of *p*-tolualdehyde is at once apparent showing oxidation of the acid at the ethylenic linkage. The yellow color of the acid fades slowly. After several weeks' exposure the pale tan amorphous product was dissolved in benzene, the sirupy solution filtered and allowed to evaporate at room temperature. From the dark shellac-like mass which resulted none of the original acid nor any other crystalline product could be separated. It is undoubtedly a mixture of oxidation and polymerization products. The acid is perfectly stable in the dark.

The methyl ester of *p*-methylbenzalpyruvic acid, prepared readily by dissolving the acid in a small volume of cold methyl alcohol saturated with hydrochloric acid, crystallized from boiling methyl alcohol in slender pale yellow needles melting at 81°.

Anal. Calcd. for $C_{12}H_{12}O_3$: C, 70.56; H, 5.88. Found: C, 70.70; H, 6.16.

After long exposure of the ester to bright sunlight about one-half was regained unchanged. The residue was a heavy reddish oil, evidently a mixture of products like that obtained from the acid.

The ethyl ester, prepared in the same way, did not crystallize from the alcohol–acid mixture. When the reaction mixture was poured into iced sodium carbonate solution an oil separated which quickly solidified. The solid separates from a slightly warmed concentrated solution of ethyl alcohol to which a few drops of water have been added in light yellow shining plates melting at 44–46°. From a more dilute solution it crystallizes slowly in stiff yellow needles of the same melting point.

Anal. Calcd. for $C_{13}H_{14}O_3$: C, 71.56; H, 6.42. Found: C, 71.22; H, 6.53.

Reactions with Bromine

4-Methylbenzalpyruvic Acid Dibromide, $CH_3C_6H_4CHBr-CHBrCOCOOH$.—To the pyruvic acid dissolved in iced, dry chloroform, one molecular proportion of bromine was added drop by drop. The decolorization was rapid. Toward the end of the reaction the dibromo addition product separated out as a nearly white, granular solid, which, after washing with cold chloroform, melted at 145–147°. A further quantity was obtained from the filtrates; yield 84%. The compound can be crystallized from benzene but a purer product is obtained by adding an equal volume of low boiling ligroin to the warm benzene solution.

Anal. Calcd. for $C_{11}H_{10}O_3Br_2$: C, 37.71; H, 2.86. Found: C, 37.76; H, 3.73.

The methyl ester of the dibromo acid may be prepared by dissolving the acid in the smallest possible quantity of methyl alcohol, saturated with hydrogen chloride or with an ethereal solution of diazomethane. It separates from methyl alcohol in shining plates melting at 86–87°.

Anal. Calcd. for $C_{12}H_{12}O_3Br_2$: C, 39.56; H, 3.29. Found: C, 39.64; H, 3.53.

β-Bromo-4-methylbenzalpyruvic Acid, $CH_3C_6H_4CH{=}CBrCOCOOH$.—On boiling the dibromo acid for a few minutes with water and allowing the filtered solution to cool, crystals of the unsaturated acid separated in colorless needles. The compound does not crystallize with water as do the corresponding bromo-*p*-methoxyl- and the unsubstituted bromobenzalpyruvic acids. It separates from boiling benzene in fine, colorless needles melting at 182°.

Anal. Calcd. for $C_{11}H_9O_3Br$: C, 49.07; H, 3.34. Found: C, 48.90; H, 3.28.

The methyl ester cannot be prepared by action of methyl alcohol and hydrogen chloride. This is also the case with all other β-bromobenzalpyruvic acids so far studied. It is obtained readily by action of diazomethane in ethereal solution. It separates from boiling methyl alcohol in colorless crystals melting at 77°.

Anal. Calcd. for $C_{12}H_{11}O_3Br$: C, 50.88; H, 3.88. Found: C, 50.91; H, 3.75.

Oxidation of β-bromo-4-methylbenzalpyruvic acid in dilute alkaline solution with a slight excess of hydrogen peroxide gave in good yield the corresponding bromomethylcinnamic acid. The acid separates from hot ethyl alcohol or from benzene in long, fine, shining needles with a characteristic asbestos-like texture. After repeated crystallization the substance melts at 192°. This is the melting point of the bromo-4-methylcinnamic acid described by Gattermann[8] and listed in Beilstein[9] as α- or β-bromo-4-methylcinnamic acid. The acid prepared as just described from the β-bromo ketonic acid must be α-bromo-4-methylcinnamic acid. In order to test its identity with Gattermann's acid the latter was prepared from *p*-methylcinnamic acid.

4-Methylcinnamic acid was obtained readily by hydrogen peroxide oxidation of 4-methylbenzalpyruvic acid dissolved in a 1% solution of sodium carbonate. After standing overnight the yellow color of the ketonic acid had disappeared and dilute acid precipitated from the solution an almost quantitative yield of the methylcinnamic acid. It crystallized from methyl alcohol in colorless, stocky crystals melting at 198–199° and readily formed a methyl ester melting at 58°. When bromination was carried out in boiling carbon bisulfide solution, as described by Gattermann, a dibromo addition product separated on cooling. This melted with decomposition at 192°, and, on treatment with a 25% solution of potassium hydroxide in methyl alcohol, yielded an unsaturated bromo acid melting also at 192°, all as described by Gattermann. This acid crystallized from benzene in shining silky needles with an asbestos-like texture. A mixed melting point determination proved the acid identical with that obtained by oxidation of β-bromo-4-methylbenzalpyruvic acid. This acid, therefore, described in Beilstein as α- or β-bromo-4-methylcinnamic acid, is the α-bromo acid.

Its methyl ester, prepared by use of diazomethane, separates slowly from ether in large flat plates melting at 36–37°.

Anal. Calcd. for $C_{11}H_{11}O_2Br$: C, 51.76; H, 4.31. Found: C, 51.66; H, 4.54.

The methyl ester of the 4-methylcinnamic acid dibromide (192°) separates from methyl alcohol in shining prisms melting at 101°.

Anal. Calcd. for $C_{11}H_{12}O_2Br_2$: C, 39.28; H, 3.57. Found: C, 39.62; H, 3.88.

When the bromination of 4-methylcinnamic acid was carried out slowly in iced chloroform in the usual way, about one-third of the product had crystallized out by the time the last drops of bromine were added. This product, after washing with cold chloroform, consisted of fine shining crystals melting with slow decomposition at 180–182°. Repeated analyses of samples from different preparations showed the substance to contain a little more than one-half the amount of bromine for the dibromo addition compound so that it was thought to be impure α-bromo-4-methylcinnamic acid. Heating the substance with potassium acetate in methyl alcohol, however, yielded an oil with a strong odor of bromostyrene, and, as the only acid product, the original unbrominated 4-methylcinnamic acid. The substance, melting 180–182°, is then a mixture of 4-methylcinnamic acid and a dibromo addition product which is decomposed completely by treatment with potassium acetate. As Gattermann's 4-methylcinnamic acid dibromide, melting at 192°, gives a quantitative yield of α-bromo-4-methylcinnamic acid under the same treatment and even when warmed with a 25% solution of potassium hydroxide, this substance formed by reaction of bromine in cold chloroform must be an isomeric dibromide. Such a compound was postulated by Gattermann to account for his poor yield of dibromide. We have been no more successful than he in obtaining the substance in pure condition.

The chloroform filtrates from this reaction deposited about a 50% yield of the 192° dibromo addition product.

Reactions with Excess of Bromine

When *p*-methoxybenzalpyruvic acid[3] was treated with bromine in methyl alcoholic solution for the purpose of forming the methyl hypobromite addition product, no such reaction took place. The products were found to be β-bromoanisalpyruvic acid accompanied by its methyl ester brominated in the ring. For purposes of comparison this experiment was repeated with 4-methylbenzalpyruvic acid. The products were in large yield β-bromo-4-methylbenzalpyruvic acid. A small amount of impure residues on oxidation in hot solution of potassium permanganate gave terephthalic acid. There had been, then, no bromination in the ring.

By direct action of excess of bromine in boiling carbon bisulfide solution or on long standing at room temperature, there was also no ring substitution. These experiments show a very definite resistance to bromination in the ring when methyl instead of methoxyl is present in the para position to the unsaturated side-chain.

Reaction with Concentrated Sulfuric Acid.—The yellow color of 4-methylbenzalpyruvic acid and of its methyl and ethyl esters changes rapidly in solution in concentrated sulfuric acid to a reddish-orange then to deep red and finally to a dark brown color. The bromine compounds, all colorless, change to a greenish-yellow and finally to a faint violet. None of the colored products compare in brilliancy with those of the methoxy-substituted compounds.

Summary

For purposes of comparison with other para-substituted benzalpyruvic acids, the para methylbenzalpyruvic acid has been studied.

The Use of Added Protein in the Determination of the Activity of Tyrosinase

BY MARK H. ADAMS AND J. M. NELSON

Tyrosinase is generally defined as the enzyme which catalyzes the aerobic oxidation of certain monohydric phenols such as tyrosine and *p*-cresol, and ortho-dihydric phenols such as catechol and its derivatives. In attempting to isolate the enzyme in a highly purified form, or to determine its relative amounts in tissues, a satisfactory method for its quantitative estimation becomes necessary.

Two principal methods have been used in the past to determine its activity. One involves the determination by chemical means of either the rate of disappearance of the substrate, or the rate of formation of some of the reaction products. The other depends on manometric measurements of the rate of oxygen uptake by the enzyme–substrate system. The latter is the simpler and is sufficiently accurate if conditions are such that the rate of oxygen absorption remains constant for about half an hour. Due to its simplicity the manometric appears to be the favored method. As substrate catechol has been used by Richter,[1] Kubowitz,[2] and Keilin and Mann.[3] Graubard and Nelson[4] preferred to use *p*-cresol in place of catechol, because the rate of oxidation is slower and tends to remain constant over a longer period of time. They used the Warburg form of respirometer[5] with flat-bottomed 50-cc. reaction flasks, the apparatus being run at about 90 complete oscillations per minute; temperature 25°. The reaction mixtures consisted of 4 cc. of 0.1% *p*-cresol, a desired volume of the enzyme solution, 2 cc. of phosphate (0.2 *M*)–citrate (0.1 *M*) buffer, and sufficient water to make the final volume in the reaction flask 8 cc.; *p*H of the reaction mixture was 6.2. The unit of enzyme activity was defined as the amount of enzyme needed to induce the above system to absorb oxygen at the rate of 10 cu. mm. per minute. Their best preparations of tyrosinase had a dry weight of about 0.1 mg. per unit of activity. With preparations of this degree of purity, they found that the rate of oxygen uptake was directly proportional to the amount of enzyme used, provided the latter was in the range of 0.5 to 2 units.

Since then methods of purifying tyrosinase preparations have been improved greatly so that preparations are now available having a dry weight of 0.0015 mg. per unit of activity. In the case of these highly purified preparations of tyrosinase the Graubard and Nelson method was found to be no longer satisfactory, due to the occurrence of considerable inactivation of the enzyme.

In working with highly active preparations of tyrosinase it also was observed that inactivation often occurred when the solutions were diluted. Saul and Nelson[6] observed a similar loss in activity when highly purified preparations of yeast invertase, having a *p*H value on the acid side of the optimum *p*H 4.5, were diluted. When, however, a little protein was added to the enzyme solution, either before or after dilution, this abnormal decrease in activity almost vanished. With this influence of added protein in mind, gelatin was added to dilute solutions of highly purified tyrosinase preparations, and large increases, often several hundred per cent., in activity were noted. When sufficient *p*-cresol was used in the reaction mixture the new value for the activity remained constant throughout a wide range of dilutions.

It will be noticed by means of curves IV and V in Fig. 2 that an increase in added gelatin from 1 to 5 mg. furnishes no additional protection to the enzyme against inactivation. Since in both instances only half (600 cu. mm.) of the theoretical total oxygen uptake (3 atoms, 1244 cu. mm.) occurred it is evident that it is not possible to overcome the inactivation entirely by adding gelatin, and if the oxidation of the *p*-cresol is to be carried to completion, more enzyme would have to be used. The protein contained in the enzyme preparation seems also to exert to some extent an influence on the activity similar to that exerted by gelatin. Thus the data for curve VI in Fig. 2 were obtained by using 2.5 times as much tyrosinase preparation (no gelatin added) as in the experiment represented by Curve I. Yet the ac-

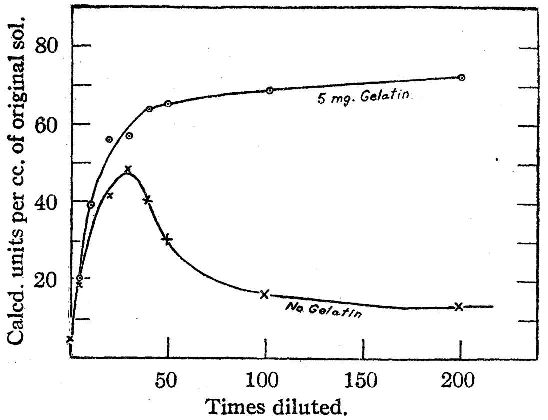

Fig. 1.—Showing change in activity of a tyrosinase preparation (*Psalliota campestris*) on dilution, and the influence on the activity when 5 mg. of gelatin was added to the reaction mixtures (modified Graubard and Nelson method). The increase in activity up to a dilution of 30 times the original volume was probably due to lack of sufficient oxygen. The activity was determined by taking manometric readings of the oxygen uptake at five-minute intervals. Usually a lag occurred in the rate of oxygen uptake at the beginning of the reaction. This was especially true in the case of more highly purified preparations. For this reason the rate of oxygen uptake was allowed to increase gradually until a maximum value was reached. The maximum rate remained practically constant for thirty to sixty minutes and was used in the calculation of the activity in terms of units, as defined by Graubard and Nelson. Temperature 25°. *p*H of reaction mixture 7.0. 1 unit of preparation used had a dry weight of 0.005 mg.

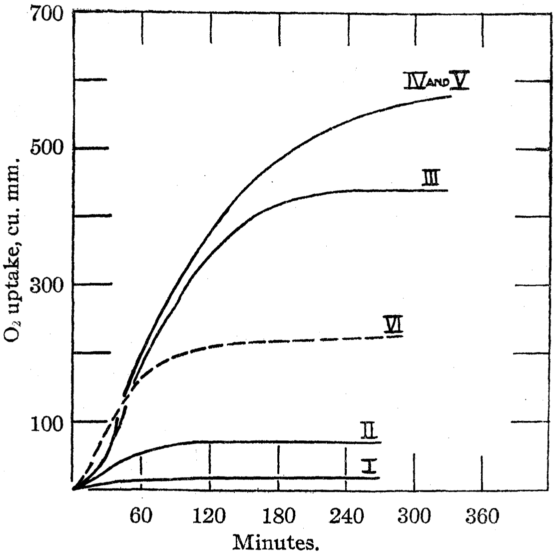

Fig. 2.—Showing the effect of different amounts of gelatin on the activity of tyrosinase. Mg. of gelatin present in the reaction mixtures contained in Warburg flasks: I, 0.0; II, 0.01; III, 0.1; IV, 1.0; V, 5.0. All reaction flasks contained same amount of enzyme, 4 mg. of *p*-cresol, *p*H 7.0 and amounts of gelatin indicated. Total volume 8 cc. Temperature 25°. Activity determined as described in legend of Fig. 1. Theoretical oxygen uptake for 4 mg. of *p*-cresol (3 atoms of oxygen) = 1244 cu. mm. Curve VI differs from Curve I in that twice as much enzyme preparation was used, but no gelatin just as in the case of Curve I.

tivity calculated on the basis of Curve VI was 0.3 unit compared to roughly 0.05 unit when calculated by means of Curve I. In other words, by using 2.5 times as much enzyme the activity was increased about 6 times. Likewise, Curve VI shows a total oxygen uptake (220 cu. mm.) which is about 10 times the total oxygen uptake in the case of Curve I (18 cu. mm.), thereby indicating less inactivation when more enzyme was used. The addition of 0.1 mg. of gelatin (Curve III) brought the initial rate of oxygen uptake nearly up to the maximum value, obtained when 1 mg. of gelatin was used (Curve IV). This explains why Graubard and Nelson were able to get activities roughly proportional to the concentration of enzyme used, since their most active preparation had about 0.1 mg. of protein per unit.

TABLE I

Protein	Activity units per cc.
No protein	0.18
Gelatin 5 mg.	.70
Egg albumin 5 mg. (before dialysis)	.40
Egg albumin 5 mg. (after dialysis)	.70
Serum albumin 5 mg.	.69
Hemoglobin 5 mg.	.74
Casein (saturated soln.)	.73
Oxglobin 5 mg. (before dialysis)	.05
Oxglobin 5 mg. (after dialysis)	.69
Catalase (concd. preparation)	.67
Ivory soap 5 mg.	.23
Gum arabic 50 mg.	.67
Agar-agar 1 mg.	.30

Just why gelatin exerts a protective action on the activity we are unable to state. Almost any protein, in the native or denatured condition, seems to have much the same effect as shown in Table I.

A comparison of four different brands of gelatin gave similar results. Ivory soap had very little effect on the enzyme's activity, whereas agar-agar did cause a noticeable increase of about 0.12 unit. It was not possible to use a greater amount of agar due to its tendency to form a gel. Gum arabic in amounts of 0.1 mg., which is comparable to the amount of protein necessary for maximum protection, exerted practically no influence on the enzyme's activity. Only by using large amounts, 50 mg., was it possible to obtain an effect comparable to that of 0.1 mg. of protein.

TABLE II

SHOWING THE INFLUENCE OF *p*H ON THE ACTIVITY OF TYROSINASE (*Psalliota campestris*) IN THE PRESENCE OF 5 MG. OF GELATIN, TEMPERATURE 25°

*p*H of reaction mixture	4.0	4.5	5.0	5.5	6.0
Activity, units per cc.	0.0	0.20	0.55	0.69	0.76
*p*H of reaction mixture	6.5	7.0	7.5	8.0	
Activity, units per cc.	0.81	0.88	0.90	0.88	

From the data in Table II it will be observed that the change in rate of oxygen uptake is quite marked in the more acid range of *p*H but approaches a maximum around *p*H 7. Beyond *p*H 7 there is danger of autoxidation and for this reason *p*H 7 is the better hydrogen ion concentration for determining activity of tyrosinase toward *p*-cresol, rather than *p*H 6.2 originally used by Graubard and Nelson. Furthermore, the above data indicate no optimum *p*H value for the enzymatic oxidation of *p*-cresol, which is not in line with results reported by Graubard and Nelson. Due to an oversight the last-named investigators failed to mention the use of borate buffer in the more alkaline range. Since then this buffer has been shown to exert a retarding influence on the rate of oxygen uptake, and thus explains the apparent optimum *p*H. Narayanamurti and Ramaswami Ayyar[7] also reported an optimum *p*H value of 6.5 in the oxidation of tyrosine by tyrosinase (from the bean *Dolichos lab lab*). They also used borate buffer for the more alkaline *p*H range.

The data in Table III show that there is a gradual increase in oxygen uptake with increase in concentration of *p*-cresol used. Changing the rate of oscillation of the Warburg apparatus to more than 90 complete oscillations did not influence the rate of oxygen uptake.

TABLE III

SHOWING THE INFLUENCE OF CONCENTRATION OF *p*-CRESOL ON THE RATE OF OXYGEN UPTAKE

Temperature 25°. *p*H of reaction mixture 7.0. Same amount of enzyme used in all experiments. 5 mg. gelatin. Reaction volume 8 cc.

p-Cresol, mg.	0.0	1.0	2.0	3.0	4.0	5.0
Activity, units per cc.	.0	0.36	0.58	0.72	0.83	0.94

In the light of the results obtained in this study it was decided to modify the method of Graubard and Nelson as follows. Reaction mixture: 1 cc. of an aqueous solution containing 4 mg. of *p*-cresol, added to the reaction mixture from the side-arm of the reaction flask at zero time; 2 cc. of (0.1 *M*) citrate–(0.2 *M*) phosphate buffer solution (*p*H of reaction mixture, 7.0); 1 cc. of an aqueous solution containing 5 mg. of gelatin; 1 cc. of enzyme solution and sufficient volume of water to make total reaction volume 8 cc.

Summary

1. The importance of protein concentration in the determination of the activity of highly purified preparations of tyrosinase has been pointed out.

2. The method of Graubard and Nelson for determining the activity of tyrosinase toward *p*-cresol has been modified to conform to the influence of protein.

On the Nature of the Enzyme Tyrosinase

BY MARK H. ADAMS AND J. M. NELSON

In the literature on oxidases from the time of Bourquelot to the present, tyrosinase has been generally considered capable of performing two quite distinct oxidative functions: one, the introduction of a hydroxyl group ortho to the already existing hydroxyl in certain monohydric phenols; and two, the oxidation of certain ortho-dihydric phenols to the corresponding ortho-quinones. Several theories have been proposed to account for these two types of activity. Onslow[1] favored the view that tyrosinase is really a catechol oxidase, and that the oxidation of the monohydric phenols is due to a secondary reaction in which *o*-quinones serve as the oxidizing agent. Richter[2] states "The oxidation of *p*-cresol therefore appears to be essentially a secondary oxidation in which the formation of an *o*-quinone is involved, rather than a direct oxidation of the cresol." Keilin and Mann[3] also believe that the monophenolase activity is due to the catechol oxidase (polyphenolase) plus some "factor" probably of the *o*-quinone type as suggested by Onslow.

Against Onslow's theory may be cited the

experience of Pugh,[4] who obtained from slugs (*Arion ater*) an oxidase which catalyzes the oxidation of catechol but not *p*-cresol. If the oxidation of *p*-cresol is dependent on *o*-quinones, then a mixture of this enzyme and homoquinone should bring about the oxidation of the *p*-cresol. This however, was found not to be the case. Workers in these Laboratories have had similar experience. When the oxidase from sweet potatoes (*Batatas batatas*), which also brings about the oxidation of catechol but not *p*-cresol, was added to a mixture of catechol and *p*-cresol, only the catechol was oxidized.

The oxidation of catechol when catalyzed by tyrosinase is very rapid, and when the rate of oxygen uptake is measured by means of the Warburg form of respirometer, difficulty is often encountered in securing accurate readings. If the rate of oxidation is reduced by using less enzyme, then considerable inactivation of the enzyme is apt to occur, especially in the case of the more highly purified preparations. Richter and Kubowitz[5] as well as others have ascribed the inactivation of the enzyme to presence of *o*-benzoquinone formed in the oxidation of the catechol. To avoid inactivation, Richter carried on the oxidation of the catechol in the presence of reagents such as aniline which react with the quinone as it formed and thereby prevent its action on the enzyme. Kubowitz, on the other hand, oxidizes the catechol in the presence of a reducing system, thereby changing the quinone as it is formed back to catechol. An objection to Kubowitz's reducing system, which consists of hexosemonophosphate, Negelein's Zwischen Ferment and Coferment II, is that very few laboratories have it on hand. Richter's use of aniline is not satisfactory since Wagreich and Nelson[6] have shown that even in the presence of aniline considerable inactivation is apt to occur.

Graubard and Nelson (unpublished) have shown that although tyrosinase is without action on hydroquinone, it can be made active if a small amount of catechol is added. This is readily understood since the oxidation–reduction system of catechol–*o*-benzoquinone has a higher potential than the system hydroquinone–*p*-benzoquinone. The *o*-benzoquinone being reduced by the hydroquinone back to catechol, causes the latter to play the role of an oxygen carrier. In a sense the hydroquinone can be looked upon as serving the same purpose as the reducing system used by Kubowitz, but having the advantage of being more generally available. Furthermore, the enzyme seems to suffer less inactivation when the catechol–hydroquinone system is used. Judging from Kubowitz's data, his rates of oxygen uptake remained constant for only ten to fifteen minutes, while when catechol–hydroquinone is used the rates remain constant for over half an hour.

The activity of tyrosinase preparations with respect to catechol was determined by the use of the Warburg form of respirometer[7] using 50-cc. flasks and 90 complete oscillations per minute; temperature 25°. Reaction mixtures consisted of 1 cc. of an aqueous solution containing 5 mg. of hydroquinone and 0.1 mg. of catechol (added from the side-arm of the flask at zero time). In the flask were: 2 cc. of (0.1 *M*) citrate–(0.2 *M*) phosphate buffer (*p*H of reaction mixture 7.0); 1 cc. of aqueous solution containing 5 mg. of gelatin; enzyme solution and sufficient water to make the total volume equal to 8 cc. The amount of enzyme required to cause the rate of oxygen uptake to equal 10 cu. mm. per minute was defined as one "catechol unit." The rate of oxygen uptake was usually directly proportional to the amount of oxidase used, provided the enzyme had been purified sufficiently to remove the naturally occurring substrates, and the amount of enzyme was less than two catechol units. As would be expected, the amount of catechol used affects the rate of oxygen uptake. The data represented in Fig. 1 were obtained by using 5 mg. of hydroquinone and amounts of catechol varying from 0.01 to 0.3 mg. It will be noted that beyond 0.1 mg. of catechol the increase in the rate of oxygen uptake tends toward a maximum, and explains why the mixture of 0.1 mg. of catechol and 5 mg. of hydroquinone was selected for use in the method described above.

When a tyrosinase preparation also contains laccase, then obviously this method for determining the activity of tyrosinase toward catechol is no longer applicable. The presence of laccase can be detected readily since such preparations catalyze the oxidation of hydroquinone when no catechol is present.

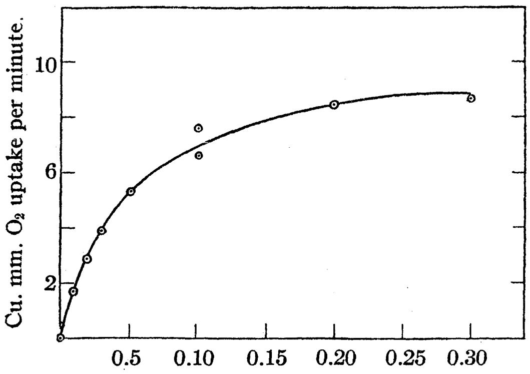

Fig. 1.—Showing the change in rate of oxygen uptake when varying amounts of catechol were used in the presence of 5 mg. of hydroquinone.

The addition of gelatin was found to be necessary in measuring the activity of tyrosinase preparations toward catechol, just as it was found necessary in the *p*-cresol method described in the previous paper. In one instance the addition of gelatin caused a 50% increase in the rate of oxidation of the catechol–hydroquinone reaction mixture. The effect of the gelatin varies with the purity and concentration of the enzyme.

Since the use of the catechol–hydroquinone mixture as a substrate depends on the oxidation of catechol, while the method described in the previous paper involves the oxidation of *p*-cresol, it was decided to compare the activities of different tyrosinase preparations with respect to the two substrates. In Table I are given the relative catechol and *p*-cresol activities for preparations of tyrosinase obtained from different sources. The activities toward catechol were obtained by using that amount of tyrosinase solution equal to 1 unit when *p*-cresol served as the substrate.

TABLE I

Source	Activity toward *p*-cresol	Activity toward catechol–hydroquinone
Lactarius piperatus	1 unit	0.08 unit
Irish potato	1 unit	.67 unit
Puff ball	1 unit	.05 unit
Psalliota campestris	1 unit	.64 unit
Sweet potato	0.0 unit	1.00 unit

It is evident from the values given in the table that the tyrosinases from the various sources are not identical. On the basis of one *p*-cresol unit, the potato and *Psalliota campestris* enzymes are roughly eight to ten times as active toward catechol as are the enzymes of the puff ball and *Lactarius piperatus*.

Several possible explanations for these differences in activities toward the two substrates suggest themselves: first, that each source yields a tyrosinase which is unique (if this were the case then the relative activity of the enzyme toward *p*-cresol as compared with that toward catechol should remain unchanged during any number of purification processes); second, that the tyrosinase preparations in reality consist of a mixture of two enzymes, one acting on *p*-cresol, or perhaps on both *p*-cresol and catechol, the other acts exclusively on catechol; third, that some accompanying substance, non-enzymatic in nature, as suggested by Keilin and Mann, enables the catechol oxidase to bring about the oxidation of the *p*-cresol.

To test the first and third possibilities a tyrosinase preparation (*Psalliota campestris*) was subjected to series of purification operations: precipitation with acetone, precipitation with ammonium sulfate, adsorption to kaolin and alumina, foreign proteins removed by gentle heat, and thorough dialysis against distilled water at frequent stages during the process. The activities with respect to the catechol–hydroquinone mixture and to *p*-cresol were measured at the different stages of purification and the ratios of the two activities are given in Table II.

TABLE II

Showing loss in catechol activity in contrast to loss in *p*-cresol activity when a tyrosinase preparation from the common mushroom was subjected to the following purification.

Stage of purification	Catechol units/ *p*-cresol units
After first acetone precipitation	3.2
After second acetone precipitation	2.2
After ammonium sulfate precipitation	2.5
After adsorption to kaolin	1.6
After adsorption to alumina	1.5
Highly purified preparation	0.64

The data in Table II show that by this particular method of purification it is possible to increase relatively the ratio of the *p*-cresol activity to the catechol activity about five times. Keilin and Mann, on the other hand, using a somewhat different procedure in purifying their tyrosinase (polyphenolase) preparation (also from *Psalliota campestris*), obtained a highly purified preparation very low in *p*-cresol activity compared to its catechol activity.

In adsorbing the tyrosinase to alumina, mentioned above, an insufficient amount of the latter was used, thereby leaving some of the enzymatic activity still remaining in the residual solution.

The activity in the latter solution was found to have five catechol units to each *p*-cresol unit, instead of 1.5 catechol to one *p*-cresol unit in the case of the material adsorbed to the alumina. In other words, the activity toward the *p*-cresol appears to be more readily adsorbed to the alumina than the part which brings about the oxidation of the catechol. By repeating the treatment with insufficient alumina, it was possible to obtain, as shown by the data in Table III, preparations very high in catechol activity compared to the activity toward *p*-cresol.

TABLE III

Showing the preferential adsorption of the activity toward *p*-cresol by alumina at *p*H 5.

		p-Cresol units per cc.	Catechol units per cc.	Catechol units / *p*-cresol units
Orig. crude prepn.		43	53	1.3
After adsorptions	first	13.5	30	2.2
	second	5.3	22.5	4.3
	third	2.0	17.4	8.7
	fourth	0.58	5.4	9.3

Likewise, it was possible to increase the activity toward *p*-cresol more than toward catechol by eluting that part of the tyrosinase preparation which was adsorbed to alumina. For this purpose a series of adsorptions, followed by elutions by means of secondary sodium phosphate, were performed and solutions were obtained having as high as 3 *p*-cresol units to one catechol unit, whereas the original solution contained about 4 *p*-cresol units to 5 of the catechol units. Furthermore, the substance responsible for the *p*-cresol activity did not pass through a dialyzing membrane, and was completely precipitated from solution when the latter was made 0.6 saturated with ammonium sulfate.

The facts that the activity toward *p*-cresol can be concentrated by absorption techniques relatively more rapidly than the activity toward catechol, that it does not dialyze through semipermeable membranes, and that it is completely precipitated by ammonium sulfate, all point toward the probability that the aerobic oxidation of *p*-cresol is catalyzed by an enzyme different from the one which brings about the oxidation of catechol.

As further support for this view may be cited the effect of gentle heat. A tyrosinase preparation containing 73 catechol units and 11.5 *p*-cresol units, or 6.4 catechol to 1 *p*-cresol unit, was heated for five minutes at 60°. The catechol activity dropped to 6.5 units and the *p*-cresol activity to 0.3 unit, making the ratio of the two activities 22 catechol units to 1 *p*-cresol unit, thus showing that activity toward *p*-cresol suffered more inactivation than the activity toward catechol.

If the catalytic activity toward *p*-cresol were due to some non-enzymatic factor plus catechol oxidase, as is believed to be the case by some, then the addition of catecholase to a solution of tyrosinase preparation from the wild mushroom, *Lactarius piperatus*, which is rich in *p*-cresol activity and poor in catechol oxidase, thereby containing a relatively high concentration of the factor, should cause an increase in the *p*-cresol activity greater than the sum of *p*-cresol activities of the two preparations. The data given in Table IV, however, show that the activities of the two preparations were just additive and mutually independent.

TABLE IV

Units	1 cc. *Lactarius piperatus* prepn.	1 cc. *Psalliota campestris* prepn.	1 cc. each prepn.
Catechol	0.10	1.47	1.56
p-Cresol	1.05	0.23	1.26

To make certain that the lack of increase in the *p*-cresol activity could not be ascribed to the *Lactarius piperatus* preparation containing a "factor" not suitable for enabling the catechol oxidase, obtained from *Psalliota campestris*, to oxidize *p*-cresol, experiments like those corresponding to the data in Table IV, were repeated using two preparations both from *Psalliota campestris*. Again the two activities were additive and independent of each other.

TABLE V

Units	1 cc. *Psalliota campestris* No. L	1 cc. *Psalliota campestris* No. 70	1 cc. of each prepn.
Catechol	0.52	1.44	1.90
p-Cresol	1.03	0.24	1.22
	Prepn. No. L heated at 60° for 5 min.		
Catechol	0.27	1.44	1.65
p-Cresol	.15	0.24	0.43
	Prepn. No. L acidified to below *p*H 3.5 for 5 min.		
Catechol	0.0	1.44	1.40
p-Cresol	.0	0.24	0.28

Furthermore, if the activity toward *p*-creso is due to some "factor" plus catechol oxidase then a preparation that had been inactivated should regain its activity toward *p*-cresol on the addition of some active catechol oxidase. To test this possibility preparation No. L was inactivated both by heat and with acid, after which it was added to preparation No. 70 and the activities again measured. In neither instance was there any indication of a non-enzymatic factor which operated with the catechol oxidase in bringing about the oxidation of *p*-cresol.

If there is a "factor" which together with catecholase catalyzes the aerobic oxidation of monohydric phenols, such as *p*-cresol, it is not nonenzymatic, since it has so many properties common to enzymes. Thus it is adsorbable to alumina and kaolin, completely precipitated by ammonium sulfate, does not pass through semipermeable membranes, is heat labile, readily inactivated by acid, and by methods generally employed in the purification of enzymes it has been possible to separate it partially from catechol oxidase.

It should be mentioned that so far the adsorption to alumina and kaolin has failed to affect the ratio of catechol oxidase to the activity responsible for the oxidation of *p*-cresol in the case of tyrosinase preparations obtained from the wild mushrooms, *Lactarius piperatus* and the common pasture puff ball, *Calvatia cyathiformis*. Both of these preparations were rich in activity toward *p*-cresol and poor in catechol oxidase.

Summary

1. The ratio of the activities toward catechol and *p*-cresol in tyrosinase preparations from the common mushroom, *Psalliota campestris*, can be varied by adsorption of the enzymes to alumina and kaolin.

2. By means of partial adsorption it is possible to obtain preparations in the residual solution rich in catechol oxidase and poor in activity toward *p*-cresol.

3. The ratio of the activity toward *p*-cresol to that toward catechol was greater in the elutate from the adsorption than in the original solution.

4. The activity toward *p*-cresol possesses properties common to enzymes in general. It is heat labile, inactivated by dilute acids, does not pass through semi-permeable membranes, and can be precipitated from solution by ammonium sulfate.

5. The catechol activity and the activity toward *p*-cresol are mutually independent.

6. So far attempts to affect the ratio of the catechol and *p*-cresol activities of tyrosinase preparations from the mushroom, *Lactarius piperatus* and the puff ball, *Calvatia cyathiformis*, have been unsuccessful.

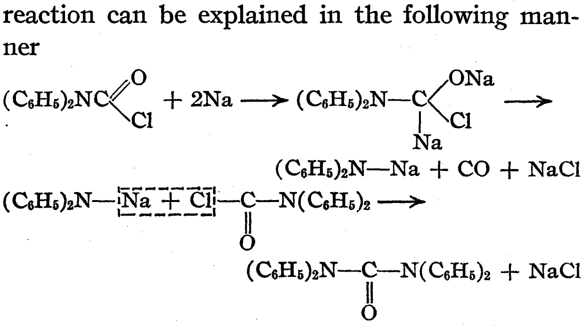
Reactions of Sodium and Potassium on Acid Chlorides

BY IRWIN A. PEARL, THEODORE W. EVANS AND WILLIAM M. DEHN

In a prior article[1] it was reported that diphenylcarbamine chloride treated with sodium in boiling toluene yielded tetraphenyloxamide. Further work now has shown conclusively that the reaction follows the more interesting course to form tetraphenylurea and carbon monoxide.[2] That tetraphenyloxamide was not first formed in the reaction was proved by the following experiments. Tetraphenyloxamide, prepared from diphenylamine and oxalyl chloride by the method of Stolle,[3] was treated with atomized sodium in boiling toluene under the same conditions as was the diphenylcarbamine chloride. No tetraphenylurea could thus be found, or from tetraphenyloxamide by heating for two hours at 195°. The reaction can be explained in the following manner



$$(C_6H_5)_2NC<^{O}_{Cl} + 2Na \longrightarrow (C_6H_5)_2N{-}\underset{\underset{Na}{|}}{C}<^{ONa}_{Cl} \longrightarrow$$

$$(C_6H_5)_2N{-}Na + CO + NaCl$$

$$(C_6H_5)_2N{-}\boxed{Na + Cl}{-}\underset{\underset{O}{\|}}{C}{-}N(C_6H_5)_2 \longrightarrow$$

$$(C_6H_5)_2N{-}\underset{\underset{O}{\|}}{C}{-}N(C_6H_5)_2 + NaCl$$

Proof of this type of mechanism was obtained by treating diphenylcarbamine chloride with an excess of sodium in toluene and obtaining sodium diphenylamine in the residue. These observa-

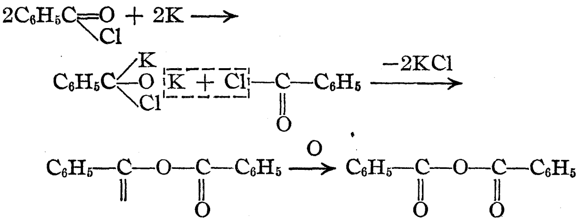
tions led to a study of the reaction of sodium and potassium on other acid chlorides.

Sodium reacts with benzoyl chloride in anhydrous ether solution to give ethyl benzoate as the main product. This reaction, with other metals, was reported by Varvoglis.[4] However, sodium or potassium reacts with benzoyl chloride in dry xylene to give benzoic anhydride and sodium chloride. This unique reaction, in which oxygen is obtained from the atmosphere, can be explained in the following simple manner



In like manner phthalyl chloride and succinyl chloride react with potassium or sodium in dry xylene to give phthalic anhydride and succinic anhydride in 70 and 60% yields, respectively. *p*-Toluenesulfonyl chloride reacts with potassium to give di-*p*-tolyldisulfone and potassium chloride according to the following

$$2CH_3—C_6H_4—SO_2Cl + 2K \longrightarrow CH_3—C_6H_4—SO_2—SO_2—C_6H_4—CH_3 + 2KCl$$

Experimental

Preparation of Tetraphenylurea.—To a mixture of atomized sodium in toluene was added one mole of diphenylcarbamine chloride and this mixture was boiled for a short time. The precipitated sodium chloride was filtered off and large, jewel-like crystals, in 66% yield, separated from the cooled filtrate. Recrystallization from toluene gave crystals melting at 182–183°. A mixed melting point with pure tetraphenylurea, prepared by the method of Michler and Zimmermann,[5] showed no depression. The gas evolved during the reaction was collected and analyzed. It proved to be carbon monoxide. Further proof that this compound is the urea and not the oxamide was obtained by the analytical data. In the prior paper there was given only the nitrogen value, which agreed equally well with either compound.

Calcd. % for	$(C_6H_5NCO)_2$	$(C_6H_5N)_2CO$	Found
C	79.6	82.4	82.3
H	5.1	5.5	5.9
N	7.1	7.7	7.5
O	8.2	4.4	4.3 diff.

Reaction of Diphenylcarbamine Chloride with Excess of Sodium.—Diphenylcarbamine chloride was added to an excess of atomized sodium in boiling toluene for thirty minutes. The mixture was filtered and well washed with toluene. The filtrate and washings were evaporated to a small volume and, upon cooling, yielded crystals of tetraphenylurea melting at 182–183°. Part of the sandy precipitate from the original filtration was treated with water. Diphenylamine melting at 50–52° separated. The rest of this sandy precipitate was treated with benzoyl chloride and, after warming, washed well with dilute sodium carbonate solution; recrystallizing from alcohol yielded crystals of benzoyldiphenylamine melting at 176–177°. When potassium was substituted for sodium in this experiment, the same results were obtained.

Reaction of Benzoyl Chloride and Sodium in Anhydrous Ether.—A mixture of 1.1 g. of atomized sodium in 50 cc. of dry xylene was decanted and after washing with absolute ether the sodium was covered with 50 cc. of absolute ether. To this mixture was added 7 g. of benzoyl chloride. The flask was stoppered and allowed to stand for ten days with occasional shaking. The contents were then filtered and the ethereal filtrate was evaporated. A residue of 6.5 g. of ethyl benzoate boiling at 210–213° was obtained.

That ethyl benzoate was not formed by the reaction of benzoyl chloride with absolute ether was proved by a mixture of the two without sodium. The benzoyl chloride was recovered quantitatively with no trace of ethyl benzoate.

Reaction of Benzoyl Chloride and Potassium in Anhydrous Xylene.—Two grams of potassium was atomized in 50 cc. of dry xylene and allowed to cool. To this was added 7 g. of benzoyl chloride and the mixture was heated occasionally for two days. After disappearance of all the potassium, the potassium chloride was filtered off and the xylene filtrate was evaporated on the steam-plate. A heavy oil was obtained and, on standing, this yielded light colored crystals. After drying on a porous plate and recrystallizing from ether, they melted at 41–42°. A mixed melting point with pure benzoic anhydride showed no depression.

Reaction of Phthalyl Chloride and of Succinyl Chloride with Potassium and Sodium.—A mixture of 10.1 g. of phthalyl chloride and 4.0 g. of atomized potassium in 100 cc. of xylene was heated to boiling and allowed to stand for three weeks. The potassium chloride was filtered off and the filtrate yielded 5.3 g. (70%) of phthalic anhydride. Recrystallization from benzene gave white needles melting at 130–131°. A mixture with pure phthalic anhydride melted at the same temperature.

Six grams of succinyl chloride and 2 g. of sodium were treated in the same manner for eight weeks. A yield of 2.5 g. (60%) of succinic anhydride melting at 116–118° was obtained. Recrystallization from absolute alcohol yielded crystals melting at 118–119°. A mixture with pure succinic anhydride melted at the same temperature.

Reaction of *p*-Toluenesulfonyl Chloride with Potassium or Sodium.—To a mixture of 4 g. of atomized potassium and 100 cc. of warm xylene was added gradually 19 g. of *p*-toluenesulfonyl chloride. The vigorous reaction taking place after each addition was allowed to subside before the next addition. After all the chloride was added the

---

[4] Varvoglis, *Ber.*, **70**, 2391 (1937). This author treated acid chlorides in absolute ether with a large number of metals. Of all the metals tried, only iron and zinc were effective, and these yielded ethyl esters of the respective acids. On the basis of this work, potassium and sodium probably would have been predicted to be without action.

[5] Michler and Zimmermann, *ibid.*, **12**, 1166 (1879). These authors prepared the urea by treating diphenylcarbamine chloride with diphenylamine.

mixture was allowed to cool. All the potassium had disappeared and the reaction mixture was thick with precipitate. The mixture was filtered and the precipitate was dried. The precipitate was treated with water and extracted with ether. The ethereal extraction upon evaporation yielded 3 g. of crude di-*p*-tolyldisulfone melting at 214–218°. Recrystallization from benzene yielded crystals melting at 220–221°.

Summary

1. Diphenylcarbamine chloride and sodium or potassium yield tetraphenylurea and carbon monoxide with the intermediate formation of sodium or potassium diphenylamine.

2. Benzoyl chloride and sodium or potassium in anhydrous ether yield ethyl benzoate.

3. Acyl chlorides with sodium or potassium in xylene yield acid anhydrides.

4. *p*-Toluenesulfonyl chloride yields di-*p*-tolyldisulfone when treated with sodium or potassium in xylene.

The Catalytic Properties of Charcoal. II. Further Studies on the Indophenol Reaction

BY JAMES F. O'BRIEN, VINCENT TKAC AND CLAUDE SCHWOB

The unusual factors encountered in a previous study of the activity of charcoal in catalyzing the hydrogen peroxide oxidation of a mixture of α-naphthol and *p*-phenylenediamine at *p*H 4.5 to form indophenol[1] prompted us to continue our studies of this interesting reaction.

Two aspects of this oxidation particularly suggest further investigation. What is the cause of the decrease in yield of the indophenol after one-half minute? What is the role of the charcoal in these oxidative reactions? In the present paper we attempt to give a partial answer to the first question. The third paper of this series will treat of certain findings relative to the second question.

We first repeated the original work[1] under carefully controlled conditions, using a so-called "pure" sucrose charcoal. At both 30 and 40° we confirmed our former findings, the yield being at a maximum at one-half minute and then decreasing to a value which remained constant after seven minutes. As before, the indophenol was found to be strongly adsorbed by the charcoal so that the latter and the filtrate were analyzed separately. Figure 1 shows the amount of indophenol present at various times. The charcoal furnished the bulk of the indophenol (curve 1), but a definite peak at one-half minute shows in the filtrate curve (curve 2).

TABLE I

Time, min.	Temp. coeff.	*E*, cal.
0.25	1.083	1400
.5	1.138	2300
1	1.198	3300
2	1.238	3900
4	1.239	3900
7	1.239	3900
14	1.241	3900
28	1.245	4000

The ratio of the total yields of the reaction at 40° to those of the reaction at 30° at corresponding times gives us a series of numbers which are akin to temperature coefficients (Table I). It will be noticed that these ratios increase linearly with time until, after two minutes, they approach a constant value. A rough calculation of the apparent energies of activation for these reaction times was made by substituting these coefficients in the Arrhenius equation. It is to be emphasized that Hinshelwood[2] and others have pointed out that such a substitution cannot give the true energy of activation for a heterogeneous reaction. It is interesting to note, however, that the values obtained for E as well as for the temperature coefficients show that two distinct processes are going on in this reaction, one predominating in the first two minutes, the second one after that. The energy of activation was likewise determined for the uncatalyzed formation of indophenol at 30 and 40° (Fig. 1, curves 5 and 6), and found to be approximately 5000 cal.

The progressive increase in the value of E for the catalyzed reaction suggests either of two possibilities: the charcoal suffers poisoning as the

---

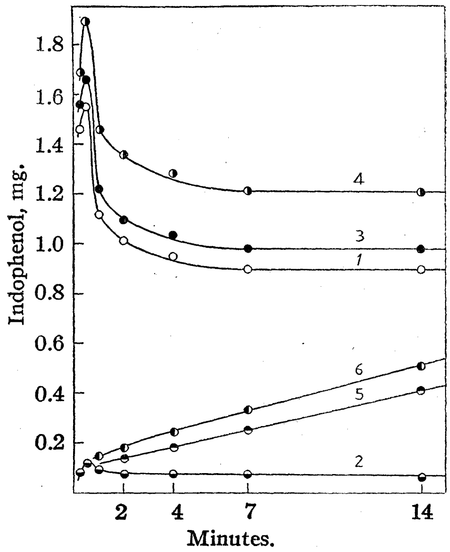

Fig. 1.—Curve 1, indophenol obtained from charcoal at 30°; curve 2, indophenol in the filtrate (30°); curve 3, total yield at 30°; curve 4, total yield at 40°; curve 5, yield at 30° in the absence of charcoal; curve 6, yield at 40°, no charcoal. The maximum yield in curve 4 is approximately 5% of the theoretical.

reaction progresses, or the indophenol is destroyed by a secondary reaction. Were the former true it seems likely that the amount of indophenol present would not decrease with time but, rather, would increase owing to the uncatalyzed reaction. The gradual destruction of indophenol remains as the only possibility consistent with the experimental facts, and we believe, on the strength of the following work, that this destruction not only takes place, but that the presence of charcoal is necessary. If this last is true, the addition of some charcoal-inhibiting agent when the reaction has proceeded one-half minute should prevent any subsequent falling off in yield.

The inhibitors tested were amyl alcohol and potassium cyanide, added when the reaction had progressed exactly one-half minute. As seen in Fig. 2, curve 2, the addition of amyl alcohol poisoned the charcoal to some extent, resulting in a constant yield much greater than that of the uninhibited reaction. The addition of potassium cyanide (Fig. 2, curve 3) completely stopped the destruction of indophenol and permitted a gradual increase in yield. This indicates that the removal of the charcoal from the field of action by means of cyanide not only prevents the destruction of indophenol but allows its formation to proceed at the same rate as the uncatalyzed reaction (compare the latter portion of this curve with Fig. 1, curve 5).

What is the nature of this catalyzed destruction of indophenol? Recently, other investigators,[3] working on the catechol–tyrosinase reaction, obtained results similar to ours when insufficient enzyme was used to promote the oxidation of catechol, an effect which they attributed to secondary reactions between catechol and quinone. We felt it necessary to determine whether a similar condition would account for our results, that is, whether the reaction which destroys the indophenol involves excess reagents. Reducing the substrate concentration to one-quarter of the value used in former experiments, a curve was constructed for the reaction at 30° (Fig. 2, curve 4). The filtrate yields were negligible. Multiplying the constant value (1.38 mg.) obtained here by four to permit direct comparison with the other curves gives a constant yield value of 5.5 mg. This shows that in the presence of sufficient charcoal we have the apparent anomaly of lessened indophenol destruction. This can only be interpreted as proof that excess reagents are involved in the destruction of indophenol. Conversely, with substrate concentrations double those of the original experiments, final indophenol yields were obtained which were much lower than those formerly obtained.

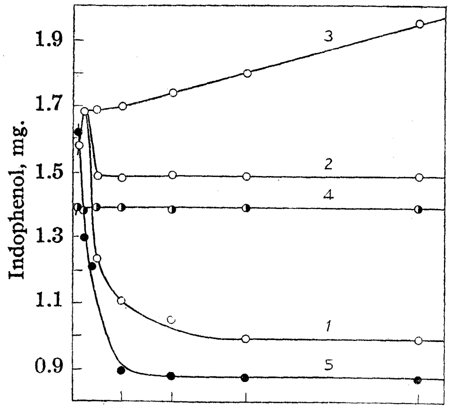

Fig. 2.—Curve 1, same as curve 3, Fig. 1; curve 2, effect of amyl alcohol; curve 3, effect of potassium cyanide; curve 4, one-quarter concentrations; curve 5, double concentrations.

Hence, we are led to believe that the indophenol destruction is catalyzed by charcoal and in-

---

[3] Dawson and Nelson, THIS JOURNAL, 60, 250 (1938).

volves a reaction with excess reagents (α-naphthol, *p*-phenylenediamine, and/or hydrogen peroxide). In fact, we found that indophenol adsorbed on charcoal is destroyed more rapidly when suspended in dilute hydrogen peroxide containing either α-naphthol or *p*-phenylenediamine than in the presence of peroxide solution only. Although, due to the difficulty of obtaining a sufficiently concentrated solution of pure indophenol in water, these experiments are at best qualitative, they are in good agreement with the above work.

What is the role of the peroxide? The catalytic effect of charcoal in promoting the oxidation by air or oxygen of many chemical individuals is well known. It was thought desirable to investigate the indophenol reaction in the absence of hydrogen peroxide, using air as the oxidant. This is analogous to the action of the enzymes known as oxidases as distinguished from peroxidases, and we consequently favor the use of the name "oxidase action" to denote this particular catalytic role of charcoal.

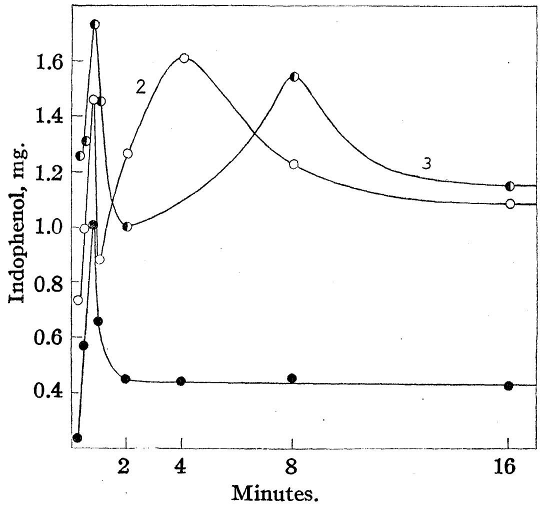

Fig. 3.—Curve 1, total indophenol yield at *p*H 4.5; curve 2, *p*H 6.5; curve 3, *p*H 7.5.

We first performed an experiment at *p*H 4.5 and 20°. The curve obtained (Fig. 3, curve 1) bears a striking resemblance to the peroxidase curves. Hence, we are inclined to think that the same factors predominate whether hydrogen peroxide or oxygen be the oxidant. Among these factors, the disappearance of indophenol is especially interesting. If peroxide is one of the substances involved in the disappearance of the dye, air must be an equally good reagent. However, if we consider the results of the quarter concentration peroxidase experiment (Fig. 2, curve 4), it becomes evident that neither peroxide nor oxygen is of as great importance in the destruction of indophenol as the other reagents. In that experiment, reducing the amount of α-naphthol and *p*-phenylenediamine without reducing the quantity of peroxide and having the reaction mixture fully exposed to air, resulted in comparatively little destruction of indophenol.

Variation in the hydrogen-ion concentration in the oxidase experiments led to results which are worth noting. The data concerning *p*H changes presented here apply only to oxidase action since it is probable that, due to the well-known catalase properties of charcoal, some oxidase action is likely to take place during the peroxidase reaction,[4] resulting in data difficult of interpretation. Moreover, the peroxidase reaction at *p*H's higher than 4.5 does not lend itself readily to kinetic study due to its rapidity.

A decrease in acidity to *p*H 6.5 in the oxidase reaction led, as was expected, to an increased yield of indophenol (Fig. 3, curve 2). More important, however, is the shape of the curve, two maxima now being evident, one at three-quarters of a minute, the other at four minutes. These results prompted us to increase further the *p*H to 7.5. Again an increased yield was noted, and again a second maximum appeared, but at eight minutes instead of four (Fig. 3, curve 3).

While performing these experiments, it was noted that ten or twelve seconds after the start of the reaction a deep red color (indophenol) appeared throughout the reaction mixture, only to disappear in three or four minutes. The presence of charcoal in suspension tends to obscure this color, but it is plainly visible by means of transmitted light.

These observations, while scarcely sufficient as a basis for theorizing, nevertheless have tempted us to formulate the following explanation as a working hypothesis to guide further experimentation.

We believe that each oxidase curve is of the same type, and is the resultant of two actions, reaching a maximum simultaneously or nearly so at *p*H 4.5, but successively at a higher *p*H. Let us consider the latter curves. The charcoal in some way activates the oxygen in solution,[5]

---

[4] That this combined catalase–oxidase action is not the sole catalytic effect in the peroxidase reaction has been pointed out previously,[1] and will be discussed more fully in Paper III of this series.

[5] This activation of oxygen by charcoal is suggested by experiments to be described in the next paper of this series.

and perhaps one or more of the reagents, so as to make possible a fast reaction in the body of the solution. This reaction, as evidenced by the red color, reaches a peak in a few seconds, at which point the indophenol produced is adsorbed by the charcoal, and begins to undergo degradation by reacting with the excess reagents under the catalytic influence of the charcoal. A second reaction on the charcoal surface now becomes dominant and the indophenol produced is adsorbed quickly. This second reaction, sensitive to hydrogen-ion concentration, produces the second rise in the curve. However, as the indophenol accumulates, the rate of destruction increases and the curve drops again.

We have, as yet, no explanation which we feel we can offer for the constancy of the final indophenol yield in all the above reactions. It is interesting to note that this value remains constant for at least twenty-four hours in every case.

Experimental

The charcoal used in this investigation was prepared from reagent-grade sucrose. It was carbonized in porcelain casseroles and activated at red heat in silica crucibles for fifteen minutes. The ash content was found to be less than 0.02%. Constant temperature baths maintained the system at 30 or 40 ± 0.03 or 20 ± 0.4°. In general, the method described in the previous paper[1] was used for determining the catalytic activity of the charcoal. It was noted that the filtrate was not appreciably colored upon filtration, but, rather, that the indophenol color appeared only after a few minutes. Although a mild vacuum was used to provide an increased filtering speed, we attribute most of the filtrate yield to a reaction between excess reagents after and during filtration. Another modification of the original procedure consisted in using 36 cc. (six 6-cc. portions) of toluene to extract the charcoal.

In the oxidase experiments we simply omitted the hydrogen peroxide. All buffers were of the citrate type, checked by means of a glass electrode.

In the reactions involving inhibitors either 2.0 cc. of a 2% solution of amyl alcohol in water, or 0.7 cc. of a 2% aqueous solution of potassium cyanide was added one-half minute after the start of the reaction. For curves 4 and 5 in Fig. 2, only the concentrations of the α-naphthol and *p*-phenylenediamine were altered.

A concordance of results of 4 to 5% was consistently obtained, and each point on the curves represents the average of at least three determinations. Near the region of each maximum in the curves the time was varied slightly so as to fix the point of greatest yield.

Summary

1. The peroxidase activity of charcoal in catalyzing the formation of indophenol has been reinvestigated.

2. It now appears that the observed destruction of indophenol after one-half minute is due to a reaction involving excess reagents and catalyzed by charcoal.

3. The oxidase activity of charcoal in the indophenol reaction has been investigated. This action is very similar to the peroxidase action. It is suggested that the formation of indophenol takes place both in solution and on the surface of the charcoal.

The Catalytic Properties of Charcoal. III. A Comparison of the Oxidative Properties of Various Charcoals. The Effect of Charcoal Hydrosols on Hydrogen Peroxide and Oxygen

BY JOSEPH F. KEEGEL, WILLIAM A. SURUDA AND CLAUDE SCHWOB

1. A Comparison of the Properties of Various Charcoals.—This Laboratory has been investigating the properties of charcoal for several years.[1] We have used mainly purified animal charcoal and sucrose charcoal. The findings of several investigators[2] have suggested the possibility that other charcoals might be more suitable as catalysts. Moreover, it is one of the aims of this series of investigations to attempt a standardization in the use of charcoal as a catalyst, a need which we believe pressing since, in so far as we have noticed, no two investigators have used exactly the same charcoal.

Hence, in this phase of the investigation we endeavored to find conditions under which charcoals of various kinds may be prepared in a manner easily duplicated without special equipment. Next, we tested these charcoals for catalytic activity in decomposing hydrogen peroxide (cata-

[2] (a) Rideal and Wright, *J. Chem. Soc.*, 1813 (1926); (b) Zylbertal, *Biochem. Z.*, **236**, 131 (1931).

lase action), in promoting oxidations with hydrogen peroxide (peroxidase action) and with oxygen (oxidase action). For purposes of comparison, the same charcoals were tested in standard adsorption experiments.

Because we wished that the preparation of our charcoals be simple, a temperature of only 590 to 600° was chosen for activation. While this is a rather low and certainly not optimum temperature,[3] it gave some excellent charcoals.

Four kinds of charcoal were prepared as suggested by the work of Rideal and Wright.[2a] These were made (a) from pure sucrose (yielding a charcoal designated as "C–C" charcoal), (b) from a sucrose–urea mixture (C–N charcoal), (c) from a sucrose–ferric chloride mixture (C–Fe charcoal), and (d) from sucrose with the addition of both the iron salt and urea (Fe–C–N charcoal).

Catalase activity was determined by measuring the rate of evolution of oxygen from an 0.25 molar solution of hydrogen peroxide in the presence of 100 mg. of charcoal. The specific reaction rate was calculated from the data by assuming a unimolecular reaction.

The oxidase activity was determined according to the method of O'Brien, Tkac and Schwob,[1b] the results reported being the final constant yield of indophenol.[4] The peroxidase activity, reported similarly, was also obtained by methods developed in this Laboratory.[1a,b]

In the adsorption experiments two substrates were employed, benzoic acid and acetic acid. The former was used in the method of Miller,[5] and the latter was used in determining the familiar Freundlich adsorption isotherm. Table I summarizes our results.

TABLE I

Charcoal	Miller test, %	Isotherm[a]		Catal.	Oxid.	Peroxid.
		K	n	$K \times 10^4$	mg.	mg.
C–C	8.17	0.17	0.48	9.0	0.063	0.15
C–N	5.96	.076	.51	23	.12	0.45
C–Fe	16.9	.41	.39	21	.69	1.35
Fe–C–N	10.9	.11	.60	170	.72	3.4

[a] In $x/m = Kc^n$, where c = molar concentration at equilibrium.

A second set of charcoals was then prepared in order to test the reproducibility of the charcoals. Tests showed agreement within 4 to 9% for most of the properties with the notable exception of the catalase activities of the C–N and C–Fe charcoals, which were approximately 25% greater for the second batch, and the peroxidase activity of the C–Fe charcoal which was 15% higher than that of the original batch. However, these deviations were not large enough to disturb the relations between the various properties.

It is evident from Table I that the C–Fe charcoal is the best adsorbent and the C–N one is the poorest for both substrates. There seems to be no direct relation between adsorptive power and catalytic effect since the Fe–C–N charcoal is the most active catalyst with the C–Fe one second and the unpromoted C–C charcoal poorest. What is especially striking is that the various charcoals show very much the same order of activity for all three catalytic processes. The one exception is the standing of the C–N and C–Fe charcoals as regards catalase action. The difference, however, is very small.

We cannot legitimately theorize with such limited data at hand, but we readily are led to think that there is some process common to all three catalytic actions. On thermodynamic grounds we should expect a catalyst good for the decomposition of hydrogen peroxide to be equally good for its formation. Does this indicate that oxidase action involves the formation of a peroxide as postulated by Lamb and Elder?[6] Then what is the function of charcoal in influencing reactions in the presence of peroxide? This question we attempt to answer in the second part of this paper.

2. The Effect of Charcoal Sols on the E. m. f. Produced by Hydrogen Peroxide Solutions. The Function of Charcoal in Oxidative Reactions.—In order to gain some idea of the role of charcoal in the so-called peroxidase reactions it is necessary to find some method which will enable us to estimate the relative oxidizing power of hydrogen peroxide in the presence and absence of charcoal. This immediately suggests the use of oxidation–reduction potentials. However, it has been pointed out that the oxidation–reduction potential of peroxide cannot be measured directly by the usual means.[7] Ort and his collaborators[8] have found that the voltages

---

developed in peroxide–sugar solutions are greatly affected by certain amino acids. The results of this investigation led these workers to the conclusion that an active, easily oxidized form of glucose exists in such solutions, but no conclusion was drawn as to the effect of the amino acid on the hydrogen peroxide.

In the first paper of this series[1a] we attempted a measurement of the voltages developed in hydrogen peroxide solutions in the presence of charcoal sols in order to determine whether the presence of colloidal charcoal had any influence upon the peroxidase reaction. Although the hypothesis involving the presence of colloidally dispersed charcoal has not been found necessary to explain our more recent results, the method seemed a suitable one for leading us to at least a partial answer to the question: what is the function of charcoal in oxidative processes?

By measuring the potentials developed across a bright platinum electrode and a saturated calomel electrode immersed in peroxide solutions with and without the addition of charcoal sols of various kinds, we can determine the specific effect of the charcoal upon the peroxide alone, as distinguished from any effect upon the reagents or products of any reaction we may choose to employ to test charcoal activity. The need for such work was felt especially in this Laboratory when we had to postulate the existence of an active form of oxygen in solution in order to explain the shape of the oxidase curves obtained in a previous study.[1b]

When we attempted to measure the potentials of peroxide solutions of different concentrations, we obtained widely varying results which were not duplicable. The voltages as read directly ranged from 0.56 to 0.45 v. for peroxide solutions varying between 0.5 and 0.05%. In the presence of charcoal sols, however, the voltage was easily measured and reproduced. This effect may be due to a speeding up of the attainment of equilibrium in a manner analogous to the effect of charcoal on the oxygen electrode.[6] Another effect is noted when the amount of charcoal sol added is varied and the concentration of the peroxide kept constant at 0.2%. The voltage progressively decreases as shown in Fig. 1, which also illustrates the irreproducibility of peroxide potentials in the absence of sufficient charcoal. Similar results were obtained with charcoal sols prepared in various ways from a wide variety of "pure" and commercial activated charcoals. In every case (some 150 experiments) the same type curve was obtained.

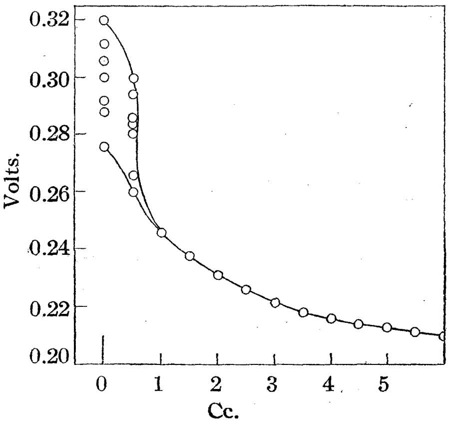

Fig. 1.—Voltage obtained from 0.2% hydrogen peroxide in the presence of varying amounts of charcoal hydrosol. With less than one cc. of sol the voltages were not duplicable.

In order to prove that it was the charcoal surface which produced this effect we studied the action of various charcoal poisons. Amyl alcohol prevented any dropping off of the voltage, and showed marked stabilizing power, giving an unvarying and reproducible voltage reading of 0.216 ± 0.0004 v. in the presence of varying amounts of charcoal. Potassium cyanide produced the same pair of results, but at a reduced voltage (0.027 v.). These findings indicate that it is an easily poisoned surface of charcoal which activates the hydrogen peroxide.

The explanation proposed for the shape of some of the oxidase curves obtained in this Laboratory[1b] is based upon experiments which indicate that charcoal will have the same effect upon oxygen. If air or oxygen is bubbled through distilled water a constant voltage is obtained between platinum and calomel electrodes after about fifty minutes (0.300 v. for oxygen, 0.260 v. for air). When the water is replaced by charcoal sol the voltages obtained are lower and become constant in a shorter time (0.250 v. for oxygen, 0.220 v. for air, in thirty-five minutes).

In view of these findings we believe that charcoal, independently of its possible effects upon the other reagents, has a definite effect upon hydrogen peroxide and oxygen, an effect which may be made to account in part for the oxidase and peroxidase properties of charcoal.

It may be objected that the peroxidase properties of charcoal are due solely to a combination of catalase and oxidase properties. This cannot be the case in the oxidation of uracil by hydrogen peroxide in the presence of charcoal[9] as shown in a previous paper.[1a] There we also stressed the fact that colloidal charcoal has definite peroxidase activity while lacking marked catalase activity. The latter property has now been investigated for a large number of charcoal sols. While 44 cc. of a 0.25 molar solution of hydrogen peroxide in a 100-cc. Pyrex flask liberated 3.0 cc. of oxygen in twenty minutes, when the water was replaced by a wide variety of charcoal sols, the yield of oxygen varied between 3.1 and 4.3 cc., a very small increase.

Experimental

Preparation of the Charcoals.—Approximately 190 g. of reagent-grade sucrose was suspended in 200 cc. of water in a porcelain vessel and heated until charring was complete. After grinding in an agate mortar, the product was activated for one hour in porcelain crucibles at 590 to 600°. Urea was added in the proportion of 5 parts to 95 of sucrose, while ferric chloride was added to the extent of 3%. The charcoals containing iron were washed repeatedly with distilled water until free from chloride before being activated.

Catalase Activity.—This was measured in a 100-cc. Pyrex flask, containing 100 mg. of the charcoal to be tested, 24 cc. of water, and 20 cc. of *p*H 7.5 citrate buffer. In a side-arm 1 cc. of superoxol was placed so that tilting the flask introduced it into the solution. The oxygen was measured in a 10-cc. gas buret while the flask was shaken 90 times per minute. In testing the charcoal hydrosols, the buffer and charcoal were omitted, and either 44 cc. of water or of charcoal hydrosol and 1 cc. of superoxol were used.

Preparation of the Charcoal Hydrosols.—Two general methods were used, the one described in the first paper of this series,[1a] and a new one involving the use of no diluent or foreign substance.[10] Some of the sols were stabilized with gelatin. In all cases the results were qualitatively the same as shown in Fig. 1, which represents the data for a gelatin protected sol obtained by the sodium chloride-grinding method. These sols contained in the neighborhood of 0.003 mg. of charcoal per cc.

Electrometric Measurements.—This work was performed as described originally[1a] except that only 4 cc. of 0.5% hydrogen peroxide was used. The results were duplicable within 3 mv. if one or more cc. of sol was present.

Summary

1. Several charcoals have been prepared and compared in catalase, peroxidase, oxidase and adsorptive properties.

2. The charcoals tested stand in the same order of activity for all three catalytic processes.

3. By electrometric means charcoal sols have been found to cause some activation of hydrogen peroxide and oxygen.

4. The catalase activity of the charcoal hydrosols prepared has been found to be very slight.

Studies in Organo-silicon Synthesis. I. The Wurtz Reaction with Silicon Chlorides

BY WALTER C. SCHUMB, JOSEPH ACKERMAN, JR., AND CHARLES M. SAFFER, JR.

Although numerous alkyl and aryl silanes have been prepared, and the field of organo-silicon chemistry has been explored extensively by Kipping and other investigators, it seemed worth while in the opinion of the writers to make a comparative study of compounds containing the linkages Si–C, Si–Si, and Si–X, leading to further knowledge of the stability of these bonds and of the reactivity of substituent groups as affected by the nature of the environment of the silicon atom.

The preparation of compounds of the type R_4Si and $R_3Si–SiR_3$, where R may be either alkyl or aryl, is generally effected by the Wurtz synthesis from SiX_4 and R_3SiX, where X is halogen. In some unpublished work[1] it had been determined that the Wurtz reaction, when applied to *p*-chlorobiphenyl and Si_2Cl_6, did not lead to the formation of hexaxenyldisilane but splitting of the Si–Si linkage occurred, and good yields of tetraxenylsilane were obtained. It was thought of interest, therefore, to determine whether this synthesis would be applicable to the preparation of other hexasubstituted disilanes, or whether cleavage of the Si–Si bond invariably would result.

The first synthesis tried was the preparation of hexaethyldisilane, $(C_2H_5)_3Si–Si(C_2H_5)_3$, which previously had been prepared by Friedel and Laden-

---

[1] J. Ackerman, Jr., S. B. Thesis, M. I. T., 1936.

burg[2] by the interaction of hexaiododisilane with diethylzinc in a sealed tube. Kraus and Nelson[3] also prepared it by the action of sodium on $(C_2H_5)_3SiBr$. By the reaction of sodium and hexachlorodisilane, Si_2Cl_6, with ethyl bromide the only product we obtained was tetraethylsilane, $(C_2H_5)_4Si$; no hexaethyldisilane could be isolated. With *n*-amyl chloride, Si_2Cl_6 and sodium, tetra-*n*-amylsilane was formed, a compound hitherto undescribed in the literature, which proved to be identical with the compound formed from $SiCl_4$, sodium and *n*-amyl chloride.

As aryl examples, the reaction of Si_2Cl_6 and sodium with chlorobenzene and with *p*-chlorobiphenyl gave tetraphenylsilane and tetraxenylsilane (a new compound), respectively, but no hexa-substituted disilanes. Hence it was concluded that hexaalkyl- and hexaaryldisilanes cannot be prepared from Si_2Cl_6 by this method of synthesis, since the Si–Si bond invariably is ruptured, leading to the formation of tetrasubstituted monosilanes. It may be argued that under gentler conditions of reaction, such as the avoidance of excess alkali metal, or lower temperatures, fission of the Si–Si bond might not occur; but we have observed no such cleavage when hexaphenyldisilane was treated with excess sodium in boiling xylene or benzene for ten hours with or without the addition of chlorobenzene, indicating that excess of sodium is not the cause of the splitting of the Si–Si linkage. At lower temperatures the reaction studied merely failed to proceed at a noticeable rate.

It seemed of considerable interest to determine the effect of employing a compound containing the more stable Si–O–Si configuration in the Wurtz synthesis. For this purpose, the reaction of Si_2OCl_6 with sodium and chlorobenzene was investigated. Somewhat unexpectedly, tetraphenylsilane was found to be the product formed. With ethyl bromide, Si_2OCl_6 and sodium, tetraethylsilane alone was isolated. Thus the Si–O–Si configuration likewise is broken up when it is subjected to the Wurtz reaction with alkyl or aryl halides.

Further studies in the synthesis of these compounds with the Grignard reagent are in progress.

Experimental

I. Reactions with $SiCl_4$. Tetraxenylsilane.—This substance was prepared according to the method employed in the preparation of tetraphenylsilane by Polis[4] from 45 g. of *p*-chlorobiphenyl, 10 g. of silicon tetrachloride and 12 g. of sodium wire in 250 cc. of anhydrous ether. A yield of about 90% of crude tetraxenylsilane was obtained when the ether was evaporated and the remaining solids extracted with hot benzene. The tetraxenylsilane was recrystallized several times from benzene in the form of long, glistening, colorless needles with 2 mols of benzene of crystallization. At 80° the needles lost benzene and became opaque. The benzene-free product melts at 274° (corr.). It is insoluble in water, alcohol, ether, and cold benzene. Its solubility in boiling benzene is 5 g. per liter, and it is more soluble in hot xylene. When rubbed in a mortar it becomes electrified.

Anal. Calcd. for $Si(C_{12}H_9)_4$: C, 89.9; H, 5.67; Si, 4.39; mol. wt., 640. Found: C, 90.0; H, 5.80; Si, 5.0; mol. wt. (camphor s. p.), 630.

Tetra-*n*-amylsilane.—This compound was prepared by the interaction of 85 g. of *n*-amyl chloride, 34 g. of silicon tetrachloride and 38 g. of sodium wire in 200 cc. of anhydrous ether. The general method followed was that employed by Taurke[5] in the preparation of tetraisoamylsilane. When the crude product was distilled, the largest fraction came over between 290 and 320°, corresponding to a yield of 80%, and after repeated distillation boiled at about 305°. The sample was washed with concentrated sulfuric acid to remove any silicols or silicones,[6] then with water, and finally dried with calcium chloride. It then boiled at 318° (corr.), $d^{32}{}_4 = 0.8252$, $n^{25}{}_D = 1.4510$. The purified material is a colorless, odorless oil, soluble in benzene, ether, absolute alcohol, cyclohexane, and xylene. It is practically insoluble in reagent alcohol and in water. It is not hydrolyzed in contact with water.

Anal. Calcd. for $Si(C_5H_{11})_4$: C, 76.8; H, 14.2; Si, 9.0; mol. wt., 312. Found: C, 76.4; H, 14.3; Si, 8.9; mol. wt. (cyclohexane s. p.), 309, 320.

II. Reactions with Si_2Cl_6.—These reactions were carried out in a dry atmosphere with 14 g. of Si_2Cl_6 and 20 g. of sodium wire in 300 cc. of anhydrous ether, together with the desired alkyl or aryl halide. The Si_2Cl_6 used boiled at 90° at 125 mm. and melted from −1 to 0°; the absence of any silicon tetrachloride was thus assured. In the case of the alkyl silanes the reaction product was extracted with ether and, after evaporation of the ether, the liquids were vacuum distilled to hinder formation of the corresponding silicones (trialkylsilicyl oxides).

Reaction with Ethyl Bromide.—Forty-nine grams of the alkyl halide was used with the reactants as described above. No reaction was noted even after several hours of refluxing. However, on addition of a few drops of ethyl acetate a gentle reaction ensued and was allowed to continue with warming for three days. (Kipping and Lloyd[7] report similar difficulty in the preparation of tetraethylsilane from silicon tetrachloride, by sodium and ethyl bromide, obtaining only a small yield.) The ether extract, after treatment with water to destroy excess hexachlorodisilane and evaporation of the ether, gave 2 cc. of a colorless oil. After two fractionations 0.8 cc. was obtained boil-

[7] Kipping and Lloyd, *J. Chem. Soc.*, **79**, 456 (1901).

ing at 150° (Emich method)[8] (b. p. of tetraethylsilane, 150–152°). Mol. weight, calcd., 144; found (cyclohexane s. p.), 135, 139. The substance therefore was concluded to be tetraethylsilane. No material boiling higher than 160° was observed, which excludes the formation of hexaethyldisilane, b. p. 250°.

Reaction with *n*-Amyl Chloride.—Thirty-five grams of *n*-amyl chloride was used, and a vigorous reaction gave a 60% yield of a crude oil. On purification this proved to be identical with the tetra-*n*-amylsilane prepared above from silicon tetrachloride and *n*-amyl chloride; b. p. 305–312°; mol. wt. calcd., 312; found (cyclohexane s. p.), 302.

Reaction with Chlorobenzene.—Thirty-five grams of chlorobenzene was used. The solid reaction products were extracted with xylene, the melting points of each crystallization fraction rising from 218 to 229 and 231° (corr.) for the highly purified product. The recorded melting point of tetraphenylsilane is 233° (corr.). A yield of about 60% was obtained. A mixed melting point of the product with some pure tetraphenylsilane gave no depression (231°), while known mixtures of tetraphenylsilane and hexaphenyldisilane gave marked depressions: mol. wt. calcd. for $Si(C_6H_5)_4$, 336; found (camphor s. p.), 340, 343.

Reaction with *p*-Chlorobiphenyl.—Eighty grams of *p*-chlorobiphenyl, used in a manner similar to the reaction of this substance with silicon tetrachloride, gave a 60% yield of tetraxenylsilane in the form of glistening needles, melting at 270° after repeated crystallization. A mixed melting point with a known sample of tetraxenylsilane gave no depression. The compound was, therefore, characterized as tetraxenylsilane.

Anal. Calcd. for $Si(C_{12}H_9)_4$: C, 89.9; H, 5.67. Found: C, 89.7, 89.9; H, 5.63, 5.87.

III. Reactions with Si_2OCl_6.—The Si_2OCl_6 had been prepared by Mr. A. B. Levine in this Laboratory by the simultaneous action of chlorine and oxygen upon heated silicon, followed by a series of careful fractional distillations. The purified substance, melting at −35°, was analyzed for chlorine and silicon, the results being in good agreement with the theory. 16.5 g. of Si_2OCl_6 and 20 g. of sodium wire were used in each of the following experiments.

Reaction with Chlorobenzene.—Forty-five grams of chlorobenzene was used. The purified needles obtained by repeated crystallization from xylene and benzene gave a product melting at 227° (uncorr.). A yield of approximately 60% was obtained. A mixed melting point (227°) with tetraphenylsilane, m. p. 228° (uncorr.), gave no depression.

Anal. Calcd. for $Si(C_6H_5)_4$: C, 85.71; H, 6.01; mol. wt., 336. Found: C, 85.74; H, 6.17; mol. wt. (camphor s. p.), 339, 346, 330.

Thus it is to be concluded that the main product of the reaction is tetraphenylsilane. A small amount of material from the ether washings of the product gave a melting point of 148°, corresponding exactly with the recorded melting point of triphenylsilicol, $(C_6H_5)_3SiOH$.

Reaction with Ethyl Bromide.—The same sluggish reaction was observed as in the case of hexachlorodisilane and with silicon tetrachloride. Fifty grams of ethyl bromide was used. One cc. of an oil, boiling between 150 and 158° (Emich method),[8] was obtained. No material boiling above 165° was found. Molecular weight, calcd. for $Si(C_2H_5)_4$, 144; found, 150, 154. The compound therefore was characterized as tetraethylsilane.

IV. Molecular Weight Determinations with Cyclohexane and Camphor.—Cyclohexane, because of its large cryoscopic constant and miscibility with alkyl silanes, was used in the usual Beckmann freezing point apparatus. The molecular weights of the solid compounds (aryl silanes) were determined using camphor, in a modification of the Rast method.[9] A few milligrams of the compound was mixed with ten times as much camphor in a small Pyrex test-tube. The tube was then sealed off and the substances melted together in an oil-bath. The solidification point can be determined directly, *i. e.*, by observing the mixture in the original oil-bath, or by observing the solidification point of the substance in a melting point tube. The second method was checked to determine whether or not sublimation of a small amount of camphor from the melting point tube affected the results. The same results were obtained in both cases.

V. Silicon Analysis.—The percentage of silicon in the compounds was determined by a modification of the method described by Marvin and Schumb:[10] 0.5 gram of the sample was introduced from a weighed pipet into a nickel crucible half full of a fusion mixture, consisting of sodium peroxide and sugar charcoal. More of the mixture was added and, after ignition in the usual manner, the sodium silicate present in the fusion product was then analyzed, the silicon being determined as silicon dioxide.

Summary

1. Hexasubstituted alkyl and aryl disilanes and hexasubstituted silicyl oxides could not be prepared from hexachlorodisilane and trichlorosilicyl oxide, respectively, by the Wurtz synthesis. Instead, the Si–Si linkage invariably was broken, leading to the formation of tetrasubstituted monosilanes.

2. The Wurtz reaction was carried out with hexachlorodisilane and ethyl bromide, *n*-amyl chloride, chlorobenzene and *p*-chlorobiphenyl yielding, respectively, the tetrasubstituted silanes, $Si(C_2H_5)_4$, $Si(n\text{-}C_5H_{11})_4$, $Si(C_6H_5)_4$ and $Si(C_{12}H_9)_4$. No substituted disilanes could be detected.

3. Likewise the Wurtz reaction, applied to trichlorosilicyl oxide and ethyl bromide or chlorobenzene, resulted in the breaking of the Si–O–Si linkage, giving tetrasubstituted silanes.

4. Tetraxenylsilane and tetra-*n*-amylsilane were prepared from both tetrachlorosilane and hexachlorodisilane.

The Ethane Equilibrium

BY R. N. PEASE AND A. M. BYERS, JR.

Storch and Kassel[1] have suggested that the experimental data on the position of equilibrium in the reaction

$$C_2H_4 + H_2 \rightleftarrows C_2H_6$$

are in error because of the occurrence of side-reactions in general, and particularly because the alleged presence of propylene has interfered with the analytical determination of ethylene. As to the latter, a correction would decrease the calculated ethylene concentration, and increase the value obtained for the equilibrium constant. This would lead to better agreement with quantum-statistical calculations in which free rotation about the C–C band in ethane is assumed.

As a matter of fact, Travers and Hockin[2] state explicitly that no C_3 hydrocarbons are found on fractionation of the products. Nevertheless, in view of the interest attaching to the question of free rotation in ethane, an additional test seemed desirable. We have, therefore, carried out a series of experiments in which ethane–ethylene–hydrogen mixtures were circulated through a reaction tube at 600°, and the mixture subsequently fractionated in a modified Podbielniak still.

The net result was that in no case was a fraction obtained condensing between −88° and room temperature which contained more than 10% of the total olefin. Moreover, since the paraffin hydrocarbon accompanying this was shown by combustion analysis to be ethane, it is more than likely that at least a part of this residuum was ethylene. We therefore feel safe in saying that considerably more than 90% of the total olefin is certainly ethylene. Similarly we can say that no appreciable amount of volatile paraffin higher than ethane is present. This holds equally for starting material consisting of either ethane alone, or ethylene plus hydrogen, or of a near-equilibrium mixture of all three.

Although we were not especially interested in adding to the already numerous data on the equilibrium constant, the results that were obtained may be reported. These appear in Table I. Our final runs were made at 600° (with close temperature control and measurement). There is one run starting with pure ethane, one run with a 50% ethylene–hydrogen mixture and four runs with near-equilibrium mixtures. The times given are the total times of circulation. We are not prepared to convert these to actual heating times, since the method of circulation consisted of "thermal siphoning" (flow due to difference in density between hot and cold gas) and the constants of the apparatus were not accurately determined. Judging from other equilibrium data, our longest time (one hundred and eighty minutes) is equivalent to something less than thirty minutes of actual heating. About 400 cc. of gas was used in each experiment.

TABLE I

EQUILIBRIUM MEASUREMENTS AT 600°

Time, min.	Final press., atm.	Composition, % C_2H_6	C_2H_4[a]	H_2	CH_4	N_2	"K_P," atm.
		Ethane side					
180	0.602	67.9	15.3	14.4	1.0	1.4	51.2
		Ethylene–hydrogen side					
180	0.734	28.5	20.6	43.9	6.4	0.6	4.3
		Near-equilibrium mixtures (C_2H_4–H_2 side)					
30	0.858	58.2	19.5	20.6	0.7	1.0	16.9
60	.968	60.2	16.8	16.5	5.4	1.0	22.4
120	.902	64.8	15.2	17.3	2.1	0.6	27.3
180	.952	63.2	13.8	16.1	5.1	1.7	29.9

[a] "C_2H_4" = total olefin.

The results for the "near-equilibrium" mixture indicate a value somewhat greater than 30 for the equilibrium constant at 600°. This is in good agreement with previous determinations (see below).

It is perhaps not generally appreciated that the experimental data for the equilibrium constant of this reaction are in excellent agreement not only among themselves, but also with Third Law calculations based on thermal data alone (except for the entropy of hydrogen). Kemp and Pitzer[3] have, to be sure, emphasized the latter point by a calculation of the entropy of ethane based on a single value of the equilibrium constant. However, the concordance goes far beyond this.

We may calculate the equilibrium constant from thermal data as follows. For ΔH°_{298}, Kistiakowsky finds −32,575 cal. by direct measure-

---

[1] Storch and Kassel, THIS JOURNAL, **59**, 1240 (1937).

[2] Travers and Hockin, *Proc. Roy. Soc.* (London), **136A**, 1 (1932).

[3] Kemp and Pitzer, THIS JOURNAL, **59**, 276 (1937).

ment,[4] whereas Rossini obtains −32,783 cal. from heats of combustion.[5] We take $\Delta H^\circ_{298} = -32{,}675 \pm 100$ cal. as the average value. Heat capacities of the three gases between 250 and 400° A.[6] are in agreement with the equation

$$\begin{aligned}\Delta C_P &= \Delta\Gamma_0 + \Delta\Gamma_1 T\\ &= -6.77 + 0.0074T\end{aligned}$$

The "conventional" value of ΔH°_0 is then −30,986 cal.

Recent experimental measurements of the entropies of ethylene[7] and ethane,[8] together with the statistical value for hydrogen,[9] give

$$\begin{aligned}C_2H_4\colon S^\circ_{298} &= 52.48 \pm 0.10 \text{ e. u.}\\ H_2\colon S^\circ_{298} &= 31.23 \pm 0.01 \text{ e. u.}\\ C_2H_6\colon S^\circ_{298} &= 54.85 \pm 0.20 \text{ e. u.}\\ \Delta S^\circ_{298} &= -28.86 \pm 0.20 \text{ e. u.}\end{aligned}$$

Then

$$\Delta F^\circ_{298} = -24{,}072 \text{ cal.}$$

The estimated error in this quantity is ± 150 cal.

For the integration constant, I, in the equation

$$\Delta F^\circ = \Delta H^\circ_0 - \Delta\Gamma_0 T \ln_e T - {}^1/_2\, \Delta\Gamma_1 T^2 + I\,T$$

one then obtains

$$I = -14.274$$

Thus

$$\Delta F^\circ = -30986 + 6.77T \ln_e T - 0.0037T^2 - 14.274T$$

and

$$\log_{10}K = +\frac{6774}{T} - 3.408 \log_{10}T + 0.000809T + 3.120$$

Experimental equilibrium data have been obtained by Frey and Huppke[10] at 400, 450 and 500° using a chromium oxide catalyst; by Videnski and Vinikova[11] at 500°, also using a chromium oxide catalyst; by Travers and Pearce[12] between 550 and 620°; and by Pease and Durgan[13] at 600, 650 and 700°.

These data represent altogether about 150 individual measurements over a 300° temperature range, and a range of pressures from about 0.5 to 2 atm. Among the experiments are some in which equilibrium was approached from either side, and also with varying ratios of ethylene to hydrogen. As already mentioned, it cannot be maintained that the analytical measurements are in serious error. There is admittedly the possibility that all measured equilibria are displaced by the side-reactions yielding methane and liquid products. However, it would be extraordinary if under all the conditions studied (especially in the work of Travers and Pearce), the displacement should have been of the same magnitude. All things considered, therefore, it is difficult to see how the experimental determinations can be seriously in error.

The comparison of experimental and theoretical values is given in Table II. The agreement is very satisfactory. A somewhat better fit would be obtained by decreasing slightly the integration constant of the free energy equation. However, any such change would fall well within the estimated uncertainty of ± 150 cal. in ΔF^0_{298}.

TABLE II

EXPERIMENTAL AND CALCULATED VALUES OF THE EQUILIBRIUM CONSTANT

$$K_P = \frac{x_{C_2H_6}}{x_{C_2H_4}x_{H_2}}\,\frac{1}{P_{\text{atm.}}}$$

Temp. °C.	°Abs.	K_P Exptl.	Calcd.	Observer
400	673	12000	12530	F
450	723	1800	2162	F
500	773	420	465	F
		320	465	V
550	823	135	121	T
570	843	65.4	73.8	T
590	863	41.0	45.7	T

620	893	22.4	23.5	T
650	923	12.2	12.6	P
700	973	5.0	4.8	P

(F = Frey; V = Videnski; T = Travers; P = Pease)

It may be recalled that the entropy data on which the free energy equation is based favor a high potential barrier against internal rotation in ethane.[3] The assumption of a low barrier (or free rotation) leads to values of K_P at 600° which are two to three times larger than the experimental.[14] As already indicated, there is no obvious reason why the experimental data should be in error by anything like this amount.

The question as to whether some gross error has been made in the assignment of the seventeen normal modes of vibration and the corresponding

frequencies for the ethane molecule is one which the authors are not prepared to discuss. If such an error has not been made, there would seem to be a flat contradiction between the thermodynamic data (including heat capacity measurements for gaseous ethane[15]) on the one hand, and on the other, the spectroscopic data as analyzed by Bartholomè and Karweil.[16] In addition, there is the difficulty in accounting theoretically for the high potential barrier apparently demanded by the thermodynamic data.[17]

However this contradiction may be resolved, the authors wish to emphasize that in dealing with the problem the experimental data on the ethane equilibrium cannot be ignored.

Summary

Additional experiments on the ethane–ethylene–hydrogen equilibrium have been carried out to determine whether the presence of volatile hydrocarbons higher than ethylene and ethane could have invalidated previous analytical work, as suggested by Kassel and Storch.[1] The evidence is that the error is certainly less than 10%, confirming the conclusion of Travers and Hockin.[2]

A comparison of all experimental values with values based on the Nernst Heat Theorem (and the Third Law) emphasizes the internal consistency of the data.

It is concluded that there is no good ground for ignoring the experimental data on the ethane equilibrium in dealing with the question of free rotation in the ethane molecule.

Fluorinated Derivatives of Propane. II

BY ALBERT L. HENNE AND ELBERT C. LADD

Three chlorinated derivatives of propane (C_3Cl_8, $CHCl_2CCl_2CCl_3$ and $CCl_3CHClCCl_3$) have been synthesized and subjected to fluorination. Three monofluorides, three difluorides and two trifluorides have thus been made. These new compounds are described, their structural formulas established and the course of the fluorination thereby demonstrated.

Extending to the propane series the investigations which have covered methane and ethane compounds is not a mere expansion, because the propane molecule offers a new position on its center carbon atom, and because the increased distance between its ends affects the course of the fluorination. As the ultimate purpose is the synthesis of fluorinated derivatives of much greater length, it is essential to learn the effect that the position and the distance of the fluorinated groups exert upon the molecule as a whole.

Synthesis.—The heptachloropropanes were synthesized by condensing chloroform with tetrachloroethylene, or carbon tetrachloride with trichloroethylene, in the presence of aluminum chloride. From asymmetrical heptachloropropane, a treatment with potassium hydroxide gave hexachloropropylene, and the latter combined with chlorine to yield octachloropropane. This method, originated by Prins,[1] has been improved, as described in the experimental part, but it cannot be extended to the condensation of fluorinated molecules of methane and ethylene, for the reasons previously reported.[2]

The chlorinated propanes were thoroughly purified before subjecting them to fluorination. This precaution was taken because fluorination gives only one of the possible isomers at each stage, and the isolation of the fluorinated compounds in a pure state is much facilitated by starting from well-defined material. The fluorination was performed as indicated in the experimental part, but the isolation, purification, analysis and description of the new compounds followed the methods of preceding papers[3] and the results have been tabulated.

The reason for describing the fluorination procedures in detail is that chlorinated propanes may split into one molecule of chlorinated methane and one of chlorinated ethylene, which is merely the reverse of the condensation reaction by means of

---

[1] Prins, *J. prakt. Chem.*, [2], **89**, 416 (1914).

[2] I, Henne and Newman, THIS JOURNAL, **60**, 1697 (1938).

[3] *Ibid.*, **56**, 1726 (1934); **58**, 402, 404, 882, 884, 887, 889 (1936); **59**, 1200, 1400, 2434 (1937).

which they have been synthesized. Consequently, the fluorination products contain compounds resulting from the fluorination of the split products, which complicate the separation and affect the yields. The fluorinated methane derivatives are volatile and escape the field of reaction; the other by-products are $CCl_2{=}CCl_2$ and products derived therefrom, namely, CCl_3CCl_3, CCl_3CCl_2F, CCl_2FCCl_2F and CCl_2FCClF_2, on the one hand, and $CHCl{=}CCl_2$ and its derivatives, namely, $CHCl_2CCl_3$, $CHCl_2CCl_2F$ and $CHCl_2CClF_2$ on the other hand. It should be emphasized that this splitting is quite important with the chlorinated propanes, but vanishes rapidly with increasing fluorination of the molecules, as is evident from the fact that the by-products are related to the starting materials, and not to their fluorinated derivatives.

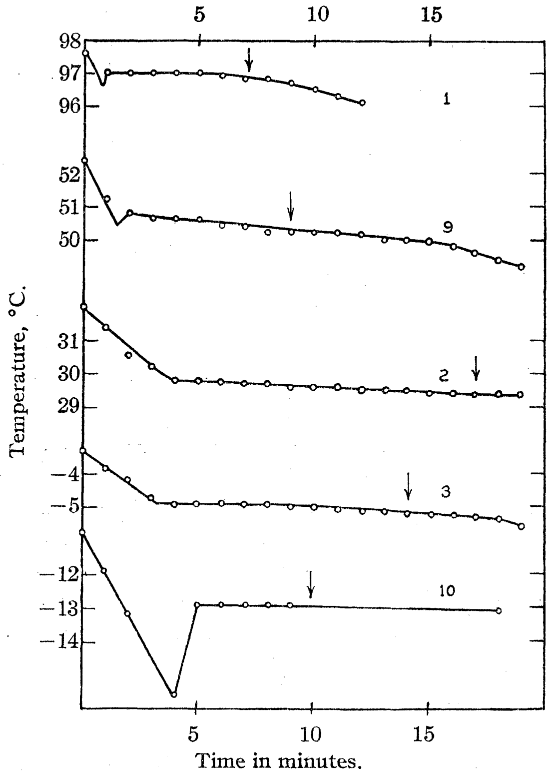

Fig. 1.—Freezing curves. Numbers refer to compounds in Table I. Arrows denote end of stirring.

Determination of Structure.—In the determination of the structural formulas advantage was taken of the fact that fully halogenated compounds are crystalline, in contrast with compounds which have hydrogen in the molecule. Even with only one hydrogen atom present, the compounds are liquids, and become glassy at very low temperatures only. It was, therefore, practical to substitute the hydrogen by chlorine and isolate the resulting fully halogenated compound in a state of high purity by alternating fractional distillation and fractional crystallization. A second step of the determination consisted in synthesizing three derivatives, $CCl_3CCl_2CCl_2F$, $CCl_3CCl_2CClF_2$ and $CCl_3CF_2CCl_3$, as described elsewhere.[4] The third step was the reaction with zinc in alcohol. This, however, requires qualification.

In general, when a polyhalogenated compound is treated with zinc in alcohol, two atoms of halogen are removed and a derivative of ethylene is formed. It has, so far, been an inflexible rule that the heavier halogens are removed preferentially, and an analysis of the zinc salts produced is then sufficient to establish the nature of the removed halogens. However, in the present case, the situation was complicated by the fact that all the resulting ethylenic compounds proved unstable, some of them exceedingly so; therefore, the procedure had to be modified in order to retain its significance. When the zinc reactions were performed, the tests for chloride and fluoride ions were made at repeated intervals, as soon as the reaction started, and it was found that at that stage zinc chloride only was produced. Conversely, when the reaction was allowed to proceed to completion, it was always found that some fluorine had been removed from the organic molecules, and also that much less fluorine than chlorine had combined with the zinc; therefore, it was held that significance would be attached only to the tests performed in the early stages of the zinc reaction, when the concentration of reaction products in the alcohol was still small, and the decomposition of the ethylenic compounds minimized.

Results of the Structure Determination.—Synthetic $CCl_3CCl_2CCl_2F$ melts at 97° and is identical with the product obtained by fluorinating C_3Cl_8 (No. 1 in table).

The monofluoride (No. 7) formed from *s*-C_3HCl_7 yields zinc chloride only in a treatment with zinc in alcohol, and by chlorination in sunlight it gives the compound melting at 97°. Moreover, it gives a mixture of ethylenic compounds boiling over a 3° range, after treatment with alcoholic potassium hydroxide, and this mixture treated with chlorine yields the compound melting at 97°, exclusively. Its formula is therefore $CCl_3CHClCCl_2F$.

The monofluoride (No. 4) obtained from asymmetrical C_3HCl_7, treated in the same ways, yields $ZnCl_2$ only, is transformed into the compound melting at 97° by chlorination, gives, with potassium hydroxide, a single ethylenic derivative boiling over a 0.2° range, the chlorination of which yields again the derivative melting at 97°. Therefore its formula can only be $CHFClCCl_2$-CCl_3 or $CHCl_2CCl_2CCl_2F$ and a choice can be based only on analogy with preceding cases. In view of the fact that CCl_3 groups have always been much more easily fluorinated than $CHCl_2$ groups, and of the fact that the experimental conditions used are regarded as inadequate to attack the $CHCl_2$ group, the second formula is adopted.

The difluorides are, without exception, identical whether obtained directly, or from the monofluorides. Therefore, one of their fluorine atoms is located on an end carbon. By chlorination in sunlight, the difluoride (No. 5) from *a*-C_3HCl_7 gives a compound melting at 51°, identical with synthetic $CCl_3CCl_2CClF_2$. Its formula is therefore either $CHF_2CCl_2CCl_3$ or $CHCl_2CCl_2CClF_2$, and the latter is chosen for the reasons given in discussing the monofluoride. These reasons become even more convincing when comparing the plausibility of a $CClF_2$ group in contrast to a CHF_2 group.

The difluoride (No. 8) obtained from *s*-C_3HCl_7 must be $CCl_2FCHClCCl_2F$, because it yields zinc chloride only, in a zinc treatment, and because its chlorination yields a compound melting at 30°, identical with the difluoride (No. 2) obtained from C_3Cl_8. The latter must therefore be CCl_2FCCl_2-CCl_2F.

The structure of the trifluorides (Nos. 3 and 6) is not demonstrated, but can be predicted with plausibility. From C_3Cl_8, the trifluoride (No. 3) should be written $CCl_2FCCl_2CClF_2$, mostly because it has a relatively high melting point (−4°) and the only other possible formula, $CCl_2FCClFCCl_2F$ would call for a much lower melting point. From *s*-C_3HCl_7, the trifluoride should be $CCl_2FCHClCClF_2$, mostly because the fluorination of a —CHCl— group has never been performed with antimony fluoride. It is expected that by chlorination in sunlight this trifluoride will yield the compound melting at −4°, and thereby prove the structure proposed for the trifluoride obtained from C_3Cl_8. Finally, from *a*-C_3HCl_7, the trifluoride (No. 6) could be either $CHCl_2CClFCClF_2$ or $CHClFCCl_2CClF_2$ though the ease with which it is obtained miligates somewhat against the latter formula. By chlorination in sunlight, a compound should be obtained with a melting point somewhere between −10 and −15°, as would befit a compound written $CCl_3CClFCClF_2$. This is confirmed by a preliminary experiment which gave a melting point of −13 to −12°.

The above experiments, which are slow and depend on intense sunlight, are under way and will be reported together with the preparation of the tetrafluorides, which is also under way. It is not intended to fluorinate further, as this would merely make new compounds, but shed no additional light on the fluorination course.

Discussion.—The criterion for purity was the freezing curve, whenever possible. These curves are given and speak for themselves. When the compounds formed glasses instead of crystals, the Engler distilling range was used, and found to be 0.2° or less, except in the case of No. 7, which decomposed when distilled at normal pressure and gave a 3° range.

The analyses gave rise to the difficulties reported before, which forced the use of the chlorine/fluorine ratio, instead of the customary percentages. The use of this ratio has the disadvantage that it is much more affected by small experimental errors than are the percentages. Nevertheless, the results leave no doubt as to the identity of the compounds.

The molecular weights, taken by freezing point depression in benzene, gave particularly good values. The molecular refraction was computed by means of the Lorentz–Lorenz formula. The atomic refraction *AR*F was obtained by subtracting from the molecular refraction the required number of carbon increments (2.418), chlorine increments (5.967) and hydrogen increments (1.100), and dividing by the number of fluorine atoms in the compound considered. The atomic refraction increases always with the degree of fluorination; it is much more steady in fully halogenated compounds than in hydrogen bearing derivatives.

Experimental

Preparation of $CHCl_2CCl_2CCl_3$.—Ten gram molecules of tetrachloroethylene, 20 gram molecules of chloroform and 50 g. of aluminum chloride were placed in a 5-liter round-bottomed flask equipped with a reflux condenser and heated to gentle boiling during twenty hours. The reaction mixture was cooled and poured into water, washed, decanted and dried. A fractional distillation yielded, besides the unreacted material recovered, 6.8 gram molecules of *a*-heptachloropropane, boiling at 163–166° at 90 mm.

Fluorination of $CHCl_2CCl_2CCl_3$.—Two procedures were used, the first to obtain a mixture rich in mono- and difluorides, the second a product rich in di- and trifluorides.

First Procedure.—In a one-liter flask 1160 g. of *a*-C_3HCl_7 and 740 g. of SbF_3Cl_2 were placed and vigorously stirred so that the temperature of the mixture would never exceed 50°. After the mixture had cooled to 30°, it was heated slowly to 130–140° and held there for five hours. It was then cooled, poured into water, washed with hydrochloric acid to remove the antimony salts, then with water and dried. These operations gave 907 g. of reaction products containing approximately 60 g. of trifluoride, 315 g. of difluoride and 435 g. of monofluoride.

Second Procedure.—In a 3-liter flask 1970 g. of heptachloride mixed with 1245 g. of SbF_3Cl_2 was heated to 140–150° and held at this temperature for eight hours. The subsequent operations were identical with those of the first procedure and yielded 1740 g. of crude product which separated into 400 g. of trifluoride, and 1000 g. of difluoride, approximately. The remainder of the material was composed of ethylenic derivatives, and of fluorinated compounds of ethane, resulting from the splitting of the propane molecule. The more abundant by-products were $CCl_2{=}CCl_2$, CCl_3CCl_2F, CCl_2FCCl_2F and C_2Cl_6.

Preparation of C_3Cl_8.—Ten gram molecules of $CHCl_2CCl_2CCl_3$ was placed in a 5-liter flask, equipped with an efficient stirrer, and a solution of 600 g. of potassium hydroxide in methanol was added dropwise. The heat evolved is considerable, and the addition of the hydroxide should be slow to avoid splitting the propane molecule. After completion of the addition the mixture was stirred during an additional hour and then washed with water. The hexachloropropylene thus obtained (2300 g.) was treated with a slow current of chlorine, in sunlight, and with the temperature constantly kept below 50°. When crystals of octachloropropane prevented further passage of the chlorine, the mixture was allowed to stand in sunlight until it became snow white. It could then be separated by filtration under suction, but this was not done, on account of the high vapor tension of C_3Cl_8. Fractional distillation was used instead. The unchlorinated product was then returned for a further treatment with chlorine. When the operations were conducted with care, and without localized heating, the yields were quantitative.

Fluorination of C_3Cl_8.—Three procedures have been used, to obtain mixtures rich in mono-, di- and trifluoride, respectively.

First Procedure.—In a round-bottomed flask equipped with an air-cooled reflux condenser, 960 g. of C_3Cl_8, 180 g. of SbF_3 and 40 g. of $SbCl_5$ were heated for eight hours at 140°. The following day 30 g. of SbF_3Cl_2 was added and the heating was continued at 140° for another six hours. During this treatment, the lower layer containing most of the SbF_3 gradually liquefied and dissolved in the upper layer of organic material. The liquid reaction mixture was poured into commercial hydrochloric acid while still hot, and washed free of antimony salt. The crude product, amounting to 910 g., solidified at room temperature. By fractional distillation at 90 mm. it was separated into one-half of monofluoride and one-half of unreacted C_3Cl_8.

Second Procedure.—In a round-bottomed flask equipped with an air-cooled reflux condenser 1500 g. of C_3Cl_8, 560 g. of SbF_3 and 75 g. of $SbCl_5$ were mixed and heated for five hours on a steam-bath. A further quantity of 100 g. of $SbCl_5$ was then added in small portions, and the heating continued for twenty hours. The reaction mixture, which had become progressively homogeneous, was allowed to cool before it was poured into aqueous acid, then washed and dried. The crude product amounted to 1092 g., from which about 750 g. of difluoride was obtained by fractional distillation at 90 mm.

Third Procedure.—In a round-bottomed flask equipped with an air-cooled reflux condenser 1220 g. of C_3Cl_8, 500 g. of SbF_3 and 75 g. of $SbCl_5$ were heated on a steam-bath for twelve hours. A further portion of 80 g. of $SbCl_5$ was added and heating continued on the steam-bath for two hours. The mixture was then cooled, and the liquid layer decanted from the crystalline antimony salts into a flask equipped with a water-cooled reflux condenser, and 400 g. of SbF_3Cl_2 was added. The reaction was then heated to 140° without haste, because the fluorination reaction is quite active at the start. It is advisable to have a pan of ice water ready to chill the mixture if it threatens to escape control. After the temperature of 140° had been reached, the heating was continued for two hours. Then, after complete cooling, the washing, drying and distillation were performed as in the preceding cases. The crude product amounted to 700 g., and contained about 300 g. of trifluoride.

Preparation of $CCl_3CHClCCl_3$.—Trichloroethylene (520 g.), carbon tetrachloride (1220 g.) and aluminum chloride (50 g.) were stirred in a 2-liter flask at 20–30° for forty-eight hours. Access of moisture was prevented by thorough drying at the start, by using a mercury seal on the stirrer, and by protecting the vent with a calcium chloride tube. The reaction mixture was poured cautiously into ice water, vigorously shaken, decanted, washed with water, dried over calcium chloride and subjected to distillation at atmospheric pressure to recover the unreacted materials. As soon as this nears completion, the distillation is pursued at reduced pressure, with a carbon dioxide trap to stop the light boiling compounds. The distillation at 20 mm. gave 551 g. of chlorinated propane, boiling from 126 to 132°; this was a 49% conversion yield. The tar formation amounted to 5%, and the remainder of the ingredients was recovered unreacted. The reaction did not take place at lower temperatures, and resinification increased rapidly at higher temperatures. At 70°, resinification was complete. Consequently, the lower conversion yield was accepted, and the recovered materials were repeatedly re-treated.

Fluorination of $CCl_3CHClCCl_3$.—Two procedures were employed, to obtain products rich in mono- and in difluoride, respectively.

First Procedure.—In a 1-liter round-bottomed flask 500 g. of *s*-heptachloropropane, 120 g. of SbF_3 and 20 g. of $SbCl_5$ were placed, stirred vigorously for three hours and then heated to 70–80° for one hour, with stirring continued. The mixture was cooled, and its liquid layer, after pouring into hydrochloric acid, was washed, dried and distilled at 90 mm. The crude product amounted to 427 g., of which a little more than one-third was monofluoride.

Second Procedure.—Heptachloropropane (916 g.), SbF_3 (520 g.) and $SbCl_5$ (100 g.) were placed in a 1-liter round-bottomed flask and stirred overnight at room temperature. The mixture was then heated for ten hours on a steam-bath, cooled to separate most of the antimony chloride, decanted into acid, washed, dried and distilled at 90 mm. The crude product amounted to 630 g., of which a little more than one-half was the difluoride.

Summary

The syntheses of C_3Cl_8, $CHCl_2CCl_2CCl_3$ and $CCl_3CHClCCl_3$ have been improved. From these compounds, the mono-, di- and trifluorides have been obtained by replacement of chlorine atoms by fluorine. The formulas of the new derivatives have been established experimentally for the mono- and difluorides, and reasoned out for the trifluorides. The properties have been tabulated, together with those of three additional fluorochloropropanes which were synthesized independently for identification purposes. The course of the fluorination has thus been established.

Reaction of Isobutene and Diisobutene with Phenol, with and without Scission of C–C Linkages

BY V. N. IPATIEFF, HERMAN PINES AND B. S. FRIEDMAN

In previous papers[1] it was shown that when diisobutene reacts with benzene in the presence of sulfuric acid, *t*-butyl-, *p*-di-*t*-butyl-, and tri-*t*-butylbenzene are formed. In view of the fact that Niederl and Natelson and co-workers[2,3] failed to notice analogous products observed by others[4] when phenol was treated with diisobutene in the presence of sulfuric acid, it was decided to investigate this reaction.

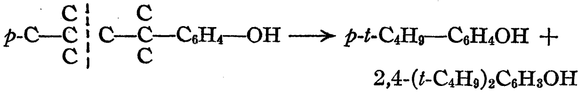
When Natelson's[3] directions were followed closely, the product contained no butylphenol. A compound not previously reported, which appears to be 2,4-di-*t*-octylphenol [2,4-di-($\alpha,\alpha,\gamma,\gamma$,-tetramethobutyl)-phenol], was isolated in addition to the expected *p*-*t*-octylphenol [*p*-(α,α,-γ,γ,-tetramethobutyl)-phenol].

When, however, phenol and diisobutene were treated with a large excess of sulfuric acid and the temperature allowed to rise to 85%, the product was found to contain some *p*-*t*-butylphenol.

The alkylation of phenol with diisobutene in the presence of phosphoric acid required a temperature of 150°; and the yield of *p*-*t*-octylphenol was quite low. *p*-*t*-Butylphenol was isolated and identified.

The production of the *p*-*t*-butylphenol could have taken place by either of two series of reactions

$$\text{Diisobutene} \longrightarrow 2\ i\text{-}C_4H_8 \qquad (A)$$
$$i\text{-}C_4H_8 + C_6H_5OH \longrightarrow t\text{-}C_4H_9\text{-}C_6H_4OH$$
$$\text{Diisobutene} + C_6H_5OH \longrightarrow t\text{-}C_8H_{17}\text{-}C_6H_4OH \qquad (B)$$



$$p\text{-}C{-}\overset{C}{\underset{C}{C}}\ \vdots\ C{-}\overset{C}{\underset{C}{C}}{-}C_6H_4{-}OH \longrightarrow p\text{-}t\text{-}C_4H_9{-}C_6H_4OH + 2,4\text{-}(t\text{-}C_4H_9)_2C_6H_3OH$$

The possibility that reaction could take place by (B) is evidenced by the fact that *p*-*t*-octylphenol heated under pressure to 140° in the presence of 90% phosphoric acid was cleaved to pro-

duce both *p-t*-butylphenol and 2,4-di-*t*-butylphenol. Cleavage also took place at the point of attachment of the octyl group to the nucleus, yielding phenol and octenes.

The alkylation of phenol with isobutene and phosphoric acid at 100° gave good yields of the expected products, *p-t*-butylphenol and 2,4-di-*t*-butylphenol.

Nitration of *p-t*-butylphenol with hot acetic–nitric acids yielded the expected 2,6-dinitro-4-*t*-butylphenol,[5] but the same reagent effected a cleavage of one of the butyl groups in 2,4-di-*t*-butylphenol to form 4,6-dinitro-2-*t*-butylphenol. The structure of the latter compound was established by its synthesis from *p*-nitrophenol by alkylation with isobutene in the presence of phosphoric acid, followed by nitration.

The replacement of a tertiary alkyl group by a nitro group corresponds to the conversion of *t*-amylphenol[6a] and *t*-butylphenol[6b] into picric acid by use of concentrated and fuming nitric acids, respectively.

Experimental Part

Phenol and Diisobutene

Experiment A. Small Quantities of Sulfuric Acid.[3]—To a rapidly stirred mixture of one mole each of phenol and diisobutene in a flask surrounded by an ice-water bath, was added dropwise 2 cc. of 96% sulfuric acid. After the mixture had become viscous, the contents of the flask were heated to 65° and stirred at that temperature for fifteen minutes.

The reaction product was placed along with 4 g. of sodium carbonate in a modified Claisen flask and the various fractions separated by vacuum distillation. The fraction (8 cc.) boiling at 210–215° (29 mm.), n^{20}D 1.5040, failed to crystallize, was soluble in a solution composed of equal parts of methanol and 50% aqueous potassium hydroxide. It yielded an oil when nitrated. It probably is di-*t*-octylphenol.

Anal. Calcd. for $C_{22}H_{38}O$: C, 83.02; H, 11.94; mol. wt., 318. Found: C, 82.53; H, 12.02; mol. wt., 314.

No trace of *p-t*-butyl- or 2,4-di-*t*-butylphenols was found.

Experiment B. Large Quantities of Sulfuric Acid.—A mixture of two moles each of phenol and diisobutene was placed in a flask surrounded with an ice-bath. To this was added with stirring 78 g. of 96% sulfuric acid. The time of addition was one minute; the temperature inside of the flask rose to 85°. After fifteen minutes of stirring the temperature fell to 0°. The product was washed with water, dried over anhydrous sodium sulfate, and separated by vacuum distillation. The fraction (8 cc.) boiling at 141–152° (26 mm.) consisted chiefly of *p-t*-butylphenol, m. p. 100° after recrystallization from heptane. Mixed melting point with authentic sample was 99–100°.

Nitration.—One-half gram of *p-t*-butylphenol was treated with 2 cc. of a mixture of equal volumes of concentrated nitric acid and glacial acetic acid. After five seconds the vigorously reacting mixture was poured onto crushed ice. The solid product was separated by filtration, washed with water; recrystallized from dilute ethanol it yielded 2,6-di-nitro-4-*t*-butylphenol, m. p. 95–96°.

Experiment C. Phosphoric Acid.—Ninety-two grams of phenol, 57 g. of diisobutene, and 50 g. of 90% phosphoric acid were placed in the glass liner provided with a capillary[7] and heated at 150° for six hours in an Ipatieff type rotating bomb. The bomb was charged with 20 atmospheres of nitrogen in order to keep the material within the glass liner during the run. The product was washed with water, dried, and upon distillation in vacuum yielded, besides phenol, 22 g. of unreacted diisobutene, 16 g. of *p*-($\alpha,\alpha,\gamma,\gamma$-tetramethobutyl)-phenol (b. p. 169–181° (28 mm.), m. p. 84–85°) and 4 g. of *p-t*-butylphenol.

Phenol and Isobutene with Phosphoric Acid.—Isobutene was passed into a rapidly stirred mixture of 94 g. of phenol and 30 g. of 89% phosphoric acid kept at 100° until 100 g. was absorbed. The product after being washed with water, dried, and distilled under reduced pressure, yielded 84 g. (40% yield based on phenol) of *p-t*-butylphenol, m. p. 99–101°, and 62 g. (30% yield based on phenol) of 2,4-di-*t*-butylphenol 143–147° (20 mm.), n^{20}D 1.5080. The latter solidified only after being seeded with some authentic (Eastman) 2,4-di-*t*-butylphenol; m. p. and mixed m. p. 55°.

Nitration of the dialkylated phenol with acetic–nitric acid yielded 4,6-dinitro-2-*t*-butylphenol, yellow plates from dilute ethanol; m. p. 123–124°; mixed m. p. with specimen prepared from *p*-nitrophenol (see below) by alkylation and nitration was 122–123°.

Calcd. for $C_{10}H_{12}O_5N_2$: C, 50.00; H, 5.00; N, 11.66. Found: C, 50.11; H, 5.13; N, 11.35.

***p*-($\alpha,\alpha,\gamma,\gamma$-Tetramethobutyl)-phenol with Phosphoric Acid. (A) At 200°.**—One hundred and twenty-two grams of *p*-($\alpha,\alpha,\gamma,\gamma$-tetramethobutyl)-phenol, b. p. 170–175° (28 mm.), and 25 g. of 90% phosphoric acid were heated for five hours at 200° under nitrogen pressure (20 kg./sq. cm.) in an Ipatieff rotating bomb equipped with a glass liner. The product was washed with a small quantity of saturated sodium sulfate solution, dried over anhydrous sodium sulfate, and distilled under reduced pressure.

The fraction (9 g.) boiling at 62–130° (30 mm.) was extracted with alkali and found to contain 4 g. of phenol and 7.5 cc. of hydrocarbons. The identity of the phenol was established by converting it to 2,4,6-tribromophenol, m. p. and mixed m. p. with authentic sample 91–92°. The hydrocarbons were separated by distillation into the following fractions: 1, 4.3 cc., 100–115°, n^{20}D 1.4189; 2, 1.0 cc., 115–125°, 1.4233; 3, 0.8 cc., 126–165°, 1.4300; 4, 1.0 cc., 165–185°, 1.4446. Fraction No. 1 is probably a mixture of octenes.

Anal. Calcd. for C_8H_{16}: C, 85.63; H, 14.37. Found: C, 85.74; H, 14.15.

The fraction (32 g.) boiling at 135–143° (28 mm.) was extracted with 10% potassium hydroxide. The alkali in-

soluble material (12 g.) consisted chiefly of 2,4-di-*t*-butylphenol identified by conversion into the nitro derivative described in the preceding experiment. The alkali soluble material, recrystallized from heptane, melted at 101°. Mixed with an authentic sample of *p*-*t*-butylphenol, it melted at 100–101°.

(B) **At 140°.**—One hundred grams of *p*-($\alpha,\alpha,\gamma,\gamma$-tetramethobutyl)-phenol and 25 g. of 90% phosphoric acid heated six hours at 140° in an autoclave under 20 atmospheres of initial nitrogen pressure yielded 2 g. of phenol, 5.6 cc. of hydrocarbons, a 6-g. fraction containing 2,4-di-*t*-butylphenol, and a 12-g. fraction containing *p*-*t*-butylphenol.

Synthesis of 4,6-Dinitro-2-*t*-butylphenol.—Fifteen grams (0.107 mole) of *p*-nitrophenol, 18.6 g. (0.33 mole) of isobutene and 17.5 g. of 90% phosphoric acid was placed in a glass liner and heated at 100° for four hours in an Ipatieff type rotating bomb. All of the isobutene reacted to yield a product containing, besides unreacted *p*-nitrophenol, a tarry substance. The reaction mixture was diluted with water and extracted with ether. The ether solution was treated with 10% potassium hydroxide; the 2-*t*-butyl-4-nitrophenol was precipitated by bubbling carbon dioxide through the yellow alkali solution. The precipitate was separated by filtration and washed with water. When purified by recrystallization from dilute alcohol (norite), it formed colorless flakes, m. p. 138.5–139.5°, yield 15%.

Anal. Calcd. for $C_{10}H_{13}NO_3$: N, 7.17. Found: N, 7.22.

Forty milligrams of the 2-*t*-butyl-4-nitrophenol was heated on a water-bath for two minutes with 0.5 cc. of concentrated nitric acid and 1.0 cc. of acetic acid. The reaction mixture was diluted with crushed ice and water, and the product taken up with ether. The ether solution was washed with water and evaporated on a water-bath. The residue, recrystallized from dilute alcohol, formed yellow plates, m. p. 122–123°; mixed m. p. with a specimen formed by nitration of 2,4-di-*t*-butylphenol was 122–123°. Mixed m. p. with picric acid was 95°.

Summary

4-*t*-Butylphenol and 2,4-di-*t*-butylphenol have been obtained in the alkylation of phenol with diisobutene at higher temperatures either with phosphoric acid or a large excess of sulfuric acid as catalyst.

When *p*-($\alpha,\alpha,\gamma,\gamma$-tetramethobutyl)-phenol was heated under pressure with phosphoric acid, the side chain was cleaved to produce phenol, octenes, *p*-*t*-butylphenol, and 2,4-di-*t*-butylphenol.

Phenol was readily alkylated by isobutene in the presence of phosphoric acid at 100° to produce *p*-*t*-butylphenol and 2,4-di-*t*-butylphenol in 40 and 30% yields, respectively.

Preparation of Some Lower Alkyl Chlorides from the Corresponding Alcohols Using Zinc Chloride and Concentrated Hydrochloric Acid

BY ATHERTON M. WHALEY AND J. E. COPENHAVER

Because of the importance of the alkyl chlorides, this study was undertaken to determine the best procedure for the zinc chloride and hydrochloric acid method. This paper deals principally with *n*-propyl, *n*-butyl and *s*-butyl chlorides. Excellent reviews of the preparation of alkyl chlorides by this method are given by Dehn and Davis,[1] Norris and Taylor[2] and Clark and Streight.[3] The procedure of Norris and Taylor generally has been used and requires six to seven hours to produce 64–66% yield of butyl chloride, for example, from three moles of butyl alcohol. By the method described below, the yield was raised to 76–77% and the time shortened to one hour.

The above investigators, as well as Guyer, Bieler and Hardmier,[4] have found that approximately two moles of zinc chloride for each mole of alcohol, which conclusion was confirmed in this investigation. It was found that long contact of the alkyl chlorides with the zinc chloride–hydrochloric acid mixture caused decomposition and polymerization, and better results were obtained by removing them from the reaction flask as soon as formed. Many catalysts have been tried by other workers but none seemed to be more effective than zinc chloride, hence it has been used throughout this investigation.

Experimental

The reaction flask for a one-mole run was a one-liter round-bottomed, short-necked flask, attached to an up-

right water-jacketed condenser, which acted as a fractionating column. This must be efficient and long enough to give ease of control of the reflux. The top of this carried a thermometer and a goose-neck connecting an efficient downward condenser. This condenser was attached to a 200-cc. trap, surrounded by an ice–salt mixture, from which the hydrogen chloride escaped into a water absorber. A second trap, similarly cooled, increased the yield from 3–5%. Rubber stoppers were used throughout.

Two moles of zinc chloride was dissolved completely in two moles of concentrated hydrochloric acid, cooling if necessary to prevent the loss of hydrogen chloride. This solution and one mole of alcohol were mixed thoroughly in the reaction flask and heated on a paraffin-bath. It usually required from ten to fifteen minutes for the reaction to start, which was determined by vigorous boiling. The best average bath temperatures for the three chlorides were as follows: *n*-propyl, 138–140°; *n*-butyl, 150–155°; *s*-butyl, 125–130°. This temperature was kept as low as possible to reduce polymerization. By the water in the jacket, the reflux temperature was controlled so that it was approximately the boiling point of the alkyl chloride and never allowed to rise higher than 1–2° above that point. For the three chlorides, these temperatures were respectively: 45–50, 68–80 and 65–69°. When evolution of the chlorides slackened, the temperature of the bath was raised to 160°. The reaction time averaged from fifty to sixty minutes for *n*-propyl and *n*-butyl and thirty minutes for *s*-butyl chloride.

The crude alkyl chloride, which averaged from 90–95% yield, was washed with cold water, repeatedly with small portions of concd. sulfuric acid[5] and finally with very dilute sodium carbonate, the latter being added very little at a time to prevent emulsions. The alkyl chlorides were dried over calcium chloride.[6]

Distillation was made from a 200-cc. flask with a 23-inch (58 cm.) punched-in column, at a rate of one to two drops per second and the product collected at a maximum over a 2° range. The foreshot usually contained some unsaturated derivatives and a slight residue remained in the flask. The yields averaged as follows: *n*-propyl, 70–72%; *n*-butyl, 76–77% and *s*-butyl, 83%.

Discussion

Our results agree with those of Dehn and Davis, that all of the zinc chloride must be dissolved before the reaction is started and with Norris,[7] that more than 1.25 moles of zinc chloride per mole of alcohol is necessary, and, further, that too large an excess of hydrochloric acid decreases the yield. Too much zinc chloride causes polymerization and less prolongs the reaction time. Dry-Ice around the receivers produces larger crude yields, due principally to dissolved hydrogen chloride. *i*-Butyl alcohol was used in one experiment but excessive rearrangement and polymerization cut the yield to 10%, the bath being held at 130° and the reflux temperature at 60–70°. The crude product boiled from 55–180°. One three-mole run with *n*-butyl alcohol gave the same consistent percentage yield. It was shown that the mechanical loss from washing and distilling averaged from 5–8% by running a blank on known quantities of propyl alcohol, propyl chloride and water. This loss was less for butyl chloride because of its lower vapor pressure.

The authors wish to express their sincere appreciation to Dr. E. Emmet Reid, Research Advisor at the University of South Carolina, for his valuable suggestions and help in the course of this investigation.

Summary

A procedure is given for the preparation of *n*-propyl, *n*-butyl and *s*-butyl chlorides, by the zinc chloride–hydrochloric acid method, in better yields and in a much shorter time than has been reported previously.

The Alkylation of Naphthalene with Alcohols and Boron Fluoride. The Mechanism of the Reaction

BY CHARLES C. PRICE AND JOSEPH M. CISKOWSKI

The alkylation of benzene by alcohols in the presence of boron fluoride has been reported by McKenna and Sowa[1] to yield, in addition to monoalkylated benzene derivatives, disubstituted products in which the second alkyl group entered the ring para to the one already present. Since this orientation differed from that usually reported for Friedel–Crafts alkylation, the present investigation was undertaken to determine whether a difference in orientation might exist in the case of naphthalene as well. It was of particular interest to investigate this possibility since it might lead to a method for preparing the α-alkylnaphthalenes, in contrast to the readily available β-isomers prepared by the Friedel–Crafts reaction.

Naphthalene was alkylated smoothly and rapidly on passing boron fluoride into a suspension of the hydrocarbon in isopropyl, cyclohexyl, *t*-butyl, or benzyl alcohol. The reaction was usually quite rapid, exothermic and accompanied by the development of a color characteristic of the alcohol used. This color always faded on washing with dilute alkali to remove the catalyst. The reaction is superior to the Friedel–Crafts reaction in these instances in that a cleaner product is obtained with a larger yield, frequently in a much shorter time.

The monoalkylated material, however, consisted chiefly of the β-isomer except in the case of benzyl alcohol, in which case α-benzylnaphthalene was the chief product, accompanied by a small amount of the β-isomer. Roux[2] has reported the preparation of β-benzylnaphthalene from the hydrocarbon and benzyl chloride at 160°. Even in this case, however, the α-isomer results when the reaction is carried out at 90° for only a very short time.

Sowa[3] has proposed that the mechanism for alkylation reactions using boron fluoride as a catalyst, with esters and ethers as well as alcohols, consists primarily in the formation of an olefinic hydrocarbon to which the aromatic compound then adds under the influence of the catalyst. In support of the view is the fact that olefins may be condensed with aromatic compounds to form the corresponding alkylated product. Slanina, Sowa and Nieuwland[4] have reported this reaction but the boron fluoride was always used in conjunction with a co-catalyst, the most effective of which was sulfuric acid. This acid, of course, could readily convert the olefin to the alcohol or its sulfate.

Naphthalene was therefore treated with an olefin, cyclohexene, in the presence of boron fluoride alone. A moderately good yield of β-cyclohexylnaphthalene was obtained, indicating that direct, catalytic addition of an aromatic compound to an olefin is possible in the presence of this catalyst.

Two experimental facts, however, cannot be accounted for on the basis of the olefin mechanism. In the first place, it has been found that cyclohexanol, which reacts with naphthalene readily, can be recovered quantitatively after treatment with boron fluoride under conditions considerably more drastic than those required for alkylation. Not even traces of the olefin were detected.

Secondly, the formation of an olefin as an intermediate is impossible in the case of the benzyl group, which may be introduced as readily as any secondary or tertiary alkyl groups.

It therefore seems quite apparent that the ease of reaction is dependent not on the ease of olefin formation but on the frequently parallel activity of the alcoholic hydroxyl group. It is a well-known fact that benzyl and allyl alcohols, the only primary alcohols condensing readily with aromatic compounds, behave in a manner similar to secondary and tertiary alcohols in reactions involving replacement of the hydroxyl group.

Therefore, a much more likely mechanism for the catalytic effect of the boron fluoride may be still further weakening of the carbon–oxygen bond in the association complex formed between the catalyst and the oxygen-containing organic

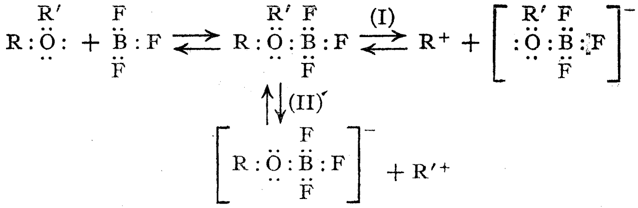
[4] Slanina, Sowa and Nieuwland, *ibid.*, **57**, 1547 (1935).

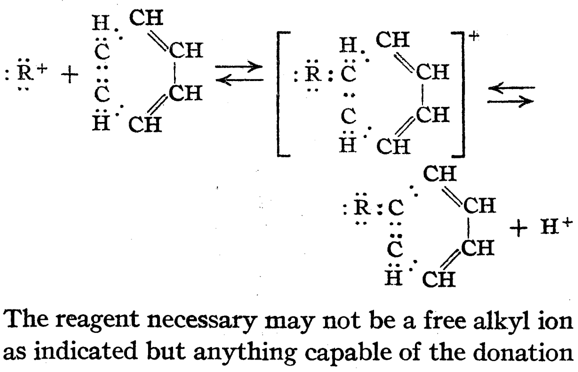
molecule. This may be represented by the following scheme in which R represents an alkyl group while R′ may be a hydrogen atom, an alkyl group or an acyl group.



That the bonds to the oxygen are actually weakened in this complex is demonstrated by the fact that the boron fluoride–alcohol complexes are strong acids, the hydrogen–oxygen bond having been weakened so as to become almost entirely ionic. Since this bond has been weakened enough to ionize it does not seem unreasonable that the carbon–oxygen bond might also ionize at least to a limited extent.

With mixed ethers the mode of ionization will depend on the two alkyl groups present. For instance, benzyl ethyl ether would be expected to ionize more readily to give the benzyl ion than the ethyl ion. In the case of esters apparently the only dissociation is according to (I) since esters in the presence of boron fluoride have been reported as alkylating agents but not acylating agents.[3b]

The positive carbonium ion thus produced may then be considered to be the active alkylating agent. Actually, of course, a free alkyl ion need exist only momentarily in the mixture just as a free hydrogen ion may have only a fleeting existence. For convenience, however, we may write the reaction using the free ion.[4a]



The reagent necessary may not be a free alkyl ion as indicated but anything capable of the donation of such an ion to the aromatic nucleus. The equations are written as reversible since, at least in the case of the Friedel–Crafts reaction, the reversibility is well known.

The ionic nature of this latter reaction seems to be a well-established fact. Dougherty[5] suggested that ionization of the alkyl halide was a portion of the catalytic effect of aluminum chloride.

$$:\ddot{\underset{..}{R}}:\ddot{\underset{..}{X}}: + AlCl_3 \rightleftarrows :\ddot{\underset{..}{R}}^+ - [XAlCl_3]^-$$

Wertyporoch,[6] however, did not believe, as Dougherty had proposed, that any further activation of the aromatic nucleus was necessary. Substantiation of this modification of Dougherty's views on the reaction is obtained from the kinetic study of a Friedel–Crafts alkylation by Ulich and Heyne.[7] They found definite evidence for the formation of the complex between alkyl and metal halides and, in fact, were able to derive the equilibrium constant for its formation.

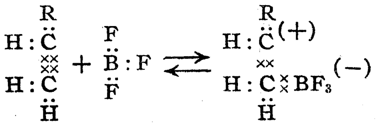
$$C_3H_7Cl + MCl_3 \rightleftarrows C_3H_7Cl{\cdot}MCl_3$$

The rate of the alkylation was directly proportional to the concentration of this complex and of the hydrocarbon, indicating that any further function of the catalyst in activating the latter is negligible.

$$dx/dt = K'[C_3H_7Cl{\cdot}MCl_3][C_6H_6]$$

The rearrangements taking place in the alkyl radical during either the Friedel–Crafts reaction or alkylation with boron fluoride offer no difficulties on the basis of the reaction scheme as outlined. The products are always those predicted by Whitmore's theory of molecular rearrangements,[8] since in every case the electron deficiency in the alkyl ion has migrated from a primary to a secondary or from a secondary to a tertiary carbon atom.

The reaction of the olefins themselves may also be accounted for on the basis of the electron affinity of boron fluoride or aluminum chloride.



This complex, like the alkyl cation, has a carbon atom deficient in a pair of electrons and could react with the unsaturation of the benzene ring in a similar manner, even though in this case the active intermediate has no resultant charge.

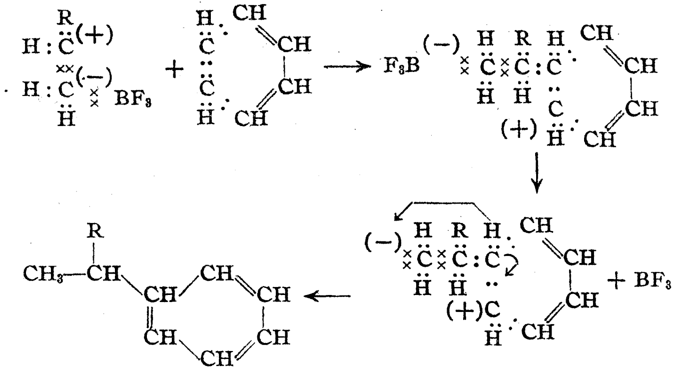
[4a] Since the preparation of this paper for publication Dilthey [*Ber.*, **71**, 1350 (1938)] has suggested this same mechanism for acylation by the Friedel–Crafts reaction.

[5] Dougherty, THIS JOURNAL, **51**, 576 (1929).

[6] Wertyporoch and Firla, *Ann.*, **500**, 287 (1933).

[7] Ulich and Heyne, *Z. Elektrochem.*, **41**, 509 (1935).

[8] Whitmore, THIS JOURNAL, **54**, 3274 (1932).

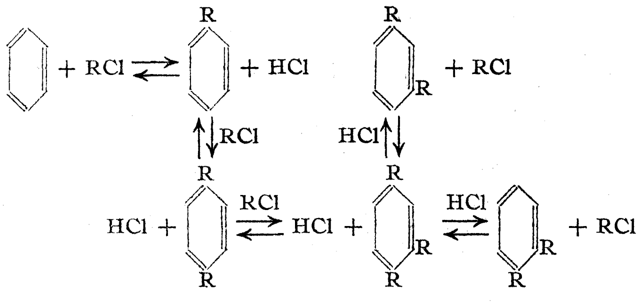


The final step, after the dissociation of the boron fluoride, is merely the α,γ-shift of a proton. Experimental confirmation of the reversible association of boron fluoride with one pair of electrons of an olefinic linkage is anticipated.

This same general mechanism may be used to account for the catalytic polymerization of olefins with boron fluoride or aluminum chloride. In this case the olefin–metal halide complex would associate with the double bond of a second olefin molecule rather than one of an aromatic ring as above.

The mechanism for alkylation and acylation of aromatic compounds is thus analogous to that for bromination[9] which also takes place through the intermediate addition of an electron deficient ion, the bromine cation, followed by elimination of a proton.

It is necessary, however, to account for the fact that aluminum chloride leads to the formation of predominantly meta as well as ortho and para dialkylated material from benzene whereas with boron fluoride the para isomer is formed almost exclusively. This difference may be due to the fact that the Friedel–Crafts reaction is reversible. When alcohols rather than alkyl halides are used, however, the water formed may hydrolyze the catalyst and thus prevent reversibility. The formation of a meta-dialkylbenzene in spite of the ortho–para-directing influence of the first group to enter may then be accounted for by the reaction scheme shown.[10]



Actually the reversal of the alkylation may be considered to be the substitution of hydrogen in place of an alkyl group. In 1,3,4-trialkylbenzene the 1- and 3-groups both orient the incoming hydrogen to the 4-position so this is the alkyl group which would most easily be replaced, thus forming, of course, the meta-dialkylbenzene. Replacement of the 1-alkyl group, taking place to a lesser extent, would be the source of the ortho-isomer, which is not reported in the case of the boron fluoride–alcohol reaction.

Experimental

Alkylation of Naphthalene.—Since the procedures used were quite similar, the results for the various alcohols have been summarized in Table I. In each instance naphthalene (50 g.) was suspended in the alcohol and boron fluoride gas[11] was passed in until two layers separated (fifteen to thirty minutes). The reaction mixture was allowed to stand for periods varying from five minutes to two days and then washed with dilute alkali, filtered from any starting material which may crystallize (5–10 g.), dried and fractionally distilled. The reaction mixtures always developed a color dependent on the alcohol used. With cyclohexyl the color was red, with tertiary butyl purple, with isopropyl green, and with benzyl blue. It always faded on addition of alkali to hydrolyze the catalyst.

That the triisopropylnaphthalene should have the same boiling point as the β-isopropyl derivative seems quite astonishing but this point was checked several times.

Attempted Dehydration of Cyclohexanol.—Cyclohexanol was saturated with boron fluoride and kept at 100° for an hour and a half but no cyclohexene was formed although the temperature was above that required for the alkylation of naphthalene in one-third this time. The alcohol–boron fluoride complex was decomposed with dilute alkali and the alcohol recovered quantitatively. Its identity was checked by the preparation of the phenylurethan deriva-

(10) Baddeley and Kenner [*J. Chem. Soc.*, 303 (1935)], have suggested this mechanism but claimed their experimental work was not in agreement. From 1,2,4-tri-*n*-propylbenzene, on treatment with aluminum chloride, they obtained a considerable quantity (35–40%) of *m*-di-*n*-propylbenzene as well as the symmetrical trisubstituted derivative. The results were interpreted against the mechanism, however, since the authors claimed (apparently with little experimental evidence) that the migrating alkyl group had undergone no isomerization. Nightingale and Smith (96th Meeting of the American Chemical Society, Milwaukee, Sept. 5, 1938) have reported that such isomerization does occur during the migration of the butyl groups in rearrangements of 1,3-dimethyl-4-butylbenzenes. *m*-Xylene was one of the products in each case. The experimental evidence, therefore, seems entirely in agreement with this mechanism.

(11) The compressed gas was obtained from the Harshaw Chemical Co., Cleveland, Ohio, and found most convenient and satisfactory.

tive, m. p. 82°. This seems to prove that under conditions of rapid and easy alkylation no olefin formation occurred.

Cyclohexylnaphthalene from Cyclohexene.—That olefins will react with naphthalene in the presence of boron fluoride alone, however, was demonstrated by bubbling this catalyst through 50 g. of naphthalene in 48 cc. of cyclohexene for an hour and a half. No layers separated in this case. After standing for a day the mixture was washed with water and alkali, 15 g. of naphthalene was recovered and the mixture dried and distilled. A yield of 20 g. (35%) of β-cyclohexylnaphthalene was obtained. It was identified by its physical constants and the melting point of its picrate.

Summary

The alkylation of naphthalene with alcohols using boron fluoride as a catalyst leads to the formation of the β-alkyl derivatives, with the exception of benzyl alcohol which yields largely α-benzylnaphthalene.

A mechanism for the catalytic effect of boron fluoride in aromatic alkylation is proposed involving the formation of alkyl cations which may then react with the aromatic nucleus.

A mechanism is suggested for the formation of meta-dialkylbenzene from the alkylation of benzene by the Friedel–Crafts reaction.

URBANA, ILLINOIS RECEIVED JULY 5, 1938

[CONTRIBUTION FROM RÖHM & HAAS COMPANY, INC.]

Friedel-Crafts Condensation with Arylalkylene Ether Chlorides

BY HERMAN ALEXANDER BRUSON AND JOHN W. EASTES

While attempting to treat β-phenoxy-β′-chlorodiethyl ether with anhydrous aluminum chloride so as to form a possible chain condensation product by the elimination of hydrogen chloride from a plurality of molecules according to equation (A)

$$C_6H_5—O—C_2H_4—O—C_2H_4Cl \xrightarrow{AlCl_3} C_6H_5—O—C_2H_4—O—C_2H_4(—C_6H_4—O—C_2H_4—O—C_2H_4)_x—C_6H_4—O—C_2H_4—O—C_2H_4\ldots + HCl \quad (A)$$

it was observed that practically no reaction occurred at temperatures as high as 70°, and that the starting material could be recovered substantially unchanged.

The unusual resistance of the ether linkages to splitting by the aluminum chloride, and the failure of the terminal aliphatically bound chlorine atom to react with the phenyl nucleus at temperatures of about 50–60°, where Friedel–Crafts reactions ordinarily take place with ease, suggested the possibility that other typical alkylating or acylating agents would condense probably with the benzene ring according to the customary synthesis, so as to alkylate or acylate the phenyl nucleus without affecting the ether linkages or the terminal chlorine atom.

Such compounds, where the alkyl group is of sufficient chain length and of the proper configuration, are intermediates for the synthesis of newer detergents and wetting agents, and are of interest also in other fields of organic research.[1]

---

(1) Bruson, U. S. Patents (a) 2,097,441; (b) 2,098,203; (c) 2,107,366; (d) 2,107,367; (e) 2,115,250; (f) 2,115,192.

It was therefore of interest to try various alkylating and acylating agents upon aryloxyalkylene ethers of the type $R{-}O{-}CH_2CH_2Cl$ and $R{-}O{-}CH_2CH_2{-}O{-}CH_2CH_2Cl$ where R is an aryl nucleus.

It was found that aromatic ether chlorides of this type condensed with acid anhydrides, acyl halides, alkyl halides or olefinic compounds in the presence of anhydrous aluminum chloride to yield the corresponding nuclear acyl or alkyl derivatives without any appreciable scission of the ether linkages or elimination of the terminal chlorine atom.

Phthalic anhydride, for example, condensed with β-phenoxy-β′-chlorodiethyl ether to give β-chloroethoxyethoxybenzoyl-*o*-benzoic acid (I). Similarly, β-phenoxyethyl chloride yielded the corresponding acid (II). Both are crystalline compounds. Attempts to obtain the next higher homolog (III) by the use of β-phenoxyethoxy-β′-chlorodiethyl ether yielded a sirupy acid.

$$\mathrm{C_6H_4(COOH){—}CO{—}C_6H_4{—}O{—}CH_2{—}CH_2{—}O{—}CH_2CH_2Cl} \quad \mathrm{(I)}$$

$$\mathrm{C_6H_4(COOH){—}CO{—}C_6H_4{—}O{—}CH_2CH_2Cl} \quad \mathrm{(II)}$$

$$\mathrm{C_6H_4(COOH){—}CO{—}C_6H_4{—}O{—}CH_2CH_2{—}O{—}CH_2{—}CH_2{—}O{—}CH_2CH_2Cl} \quad \mathrm{(III)}$$

The tendency for these compounds to form is so great that they may be obtained even when benzene is employed as an "inert" solvent for the reactants since no appreciable quantity of benzoyl-*o*-benzoic acid is formed under the conditions used.

The introduction of an ortho substituent, namely, a chloro, methyl, or methoxy group in the phenyl radical of the chloro alkylene ether used, did not prevent the condensation from taking place, the corresponding compounds IV, V and VI being obtained in crystalline form. However, the presence of a para alkyl substituent (methyl) prevented the condensation under the same conditions. It is believed therefore that the para position to the phenol ether link, is the position occupied by the entering phthaloyl group.

$$\mathrm{C_6H_4(COOH){—}CO{—}C_6H_3(Cl){—}O{—}CH_2CH_2{—}O{—}CH_2CH_2Cl} \quad \mathrm{(IV)}$$

$$\mathrm{C_6H_4(COOH){—}CO{—}C_6H_3(CH_3){—}O{—}CH_2CH_2{—}O{—}CH_2CH_2Cl} \quad \mathrm{(V)}$$

$$\mathrm{C_6H_4(COOH){—}CO{—}C_6H_3(OCH_3){—}O{—}CH_2CH_2{—}O{—}CH_2CH_2Cl} \quad \mathrm{(VI)}$$

The condensation of β-(2-naphthoxy)-β′-chlorodiethyl ether with phthalic anhydride likewise yielded the corresponding chloroethoxyethoxy naphthoyl-*o*-benzoic acid (VII) in crystalline form.

In a similar manner, succinic anhydride and maleic anhydride each were condensed with β-phenoxy-β′-chlorodiethyl ether to form the corresponding chloroethoxyethoxybenzoylpropionic acid (VIII) and chloroethoxyethoxybenzoylacrylic acid (IX), respectively.

$$\mathrm{ClCH_2CH_2{—}O{—}CH_2CH_2{—}O{—}C_6H_4{—}CO{—}CH_2CH_2COOH} \quad \mathrm{(VIII)}$$

$$\mathrm{ClCH_2CH_2{—}O{—}CH_2CH_2{—}O{—}C_6H_4{—}CO{—}CH{=}CH{—}COOH} \quad \mathrm{(IX)}$$

Finally, β-phenoxy-β′-chlorodiethyl ether condensed with acetic anhydride or acetyl chloride to yield chloroethoxyethoxyphenyl methyl ketone (X) and with *n*-butyl chloride to give butylphenoxyethoxyethyl chloride (XI), both of which were oils.

The unusual stability of the linkages and the terminal chlorine atom in the beta-aryloxy ether chlorides of the type $R{-}O{-}CH_2CH_2Cl$ and $R{-}O{-}CH_2CH_2{-}O{-}CH_2CH_2Cl$ was still more striking when attempts were made to alkylate the aromatic nucleus by means of olefins or alcohols.

Diisobutylene condensed readily with β-phenoxy-β′-chlorodiethyl ether in the presence of concentrated sulfuric acid to give the corresponding β-(*p*-*t*-octylphenoxy)-β′-chlorodiethyl ether (XII), which was identical with the product obtained by the half etherification of β,β′-dichlorodiethyl ether and *p*-α,α,γ,γ-tetramethylbutylphenol.[1b]

Furthermore, even at temperatures as high as 180° it was possible to alkylate the aromatic nucleus of these ethers with a long chain higher alcohol, in the presence of surface-active siliceous clays ("Tonsil") without appreciable splitting off of hydrochloric acid or scission of the ether linkages. In this manner, octanol-2 condensed with β-phenoxy-β′-chlorodiethyl ether to yield *s*-octyl phenoxyethoxy-ethyl chloride (XIII); and lauryl alcohol condensed with β-phenoxyethyl chloride to yield dodecylphenoxyethyl chloride (XIV). In these compounds the position and the configuration of the alkyl groups has not been determined.

Experimental

(I) β-Chloroethoxyethoxybenzoyl-*o*-benzoic Acid.—(a). To a mixture of 50 g. of phthalic anhydride, 90 g. of anhydrous powdered aluminum chloride and 250 cc. of carbon disulfide in a 1-liter 3-necked flask fitted with a sealed stirrer and reflux condenser, there was added gradually 68 g. of β-phenoxy-β′-chlorodiethyl ether[2] while stirring the reaction mixture. The temperature was maintained at gentle refluxing during the addition and for five hours

---

thereafter, during which time hydrogen chloride was evolved copiously. The carbon disulfide was then distilled off on a water-bath and the residue decomposed with 250 cc. of 3 *N* hydrochloric acid on ice, giving a white precipitate which was filtered off and dried. It was purified by dissolving in 10% soda solution, filtering and extracting the oil impurities from the filtrate with ether. After removal of the ether by boiling, the clear, alkaline solution obtained was acidified with hydrochloric acid. The waxy precipitate which at first formed gradually solidified to a hard white mass; yield 72 g., after recrystallization from glacial acetic acid. The compound formed colorless crystals, m. p. 123–124°.

Anal. Calcd. for $C_{18}H_{17}O_5Cl$: C, 62.00; H, 4.91; Cl, 10.18. Found: C, 62.44; H, 4.58; Cl, 10.16.

(b). By adding 45 g. of aluminum chloride in small portions at a time to a solution of 67 g. of β-phenoxy-β′-chlorodiethyl ether and 49 g. of phthalic anhydride in 400 cc. of dry benzene while stirring and cooling with tap water, stirring thereafter for eight hours at 25–30°, and decomposing with ice and hydrochloric acid in the usual manner followed by steaming off the benzene, there was obtained 40 g. of the above chloroethoxyethoxybenzoyl-*o*-benzoic acid, m. p. 124°, and containing 10.09% Cl, indicating that no appreciable quantity of benzoyl-*o*-benzoic acid was formed.

(II) β-Chloroethoxybenzoyl-*o*-benzoic Acid.—A mixture consisting of 49 g. of phthalic anhydride and 90 g. of anhydrous aluminum chloride in 200 cc. of carbon disulfide was treated with 52 g. of β-phenoxyethyl chloride as described in (Ia) above and worked up in the same manner. The product crystallized from benzene in colorless crystals, m. p. 145°.

Anal. Calcd. for $C_{16}H_{13}O_4Cl$: C, 63.05; H, 4.30; Cl, 11.65. Found: C, 62.69; H, 4.18; Cl, 10.05.

(IV) 4-(β-Chloroethoxyethoxy)-3-chlorobenzoyl-*o*-benzoic Acid.—Seventy-eight grams of β-(2-chlorophenoxy)-β′-chlorodiethyl ether was added slowly to a mixture of 49 g. of phthalic anhydride and 90 g. of anhydrous aluminum chloride in 200 cc. of carbon disulfide. The reaction mixture was stirred and heated for five hours on a steam-bath under reflux and then worked up as described in (I). The product crystallized from glacial acetic acid in colorless crystals, m. p. 85°.

Anal. Calcd. for $C_{18}H_{16}O_5Cl_2$: C, 56.38; H, 4.20; Cl, 18.52. Found: C, 56.46; H, 4.37; Cl, 17.5.

(V) 4-(β-Chloroethoxyethoxy)-3-methylbenzoyl-*o*-benzoic Acid.—Seventy-one grams of β-(2-methylphenoxy)-β′-chlorodiethyl ether was added slowly to a mixture of 49 g. of phthalic anhydride and 90 g. of aluminum chloride in 200 cc. of carbon disulfide and after heating for five hours the product worked up as above; crystals, m. p. 87–88.5° (from acetic acid).

Anal. Calcd. for $C_{19}H_{19}O_5Cl$: C, 62.89; H, 5.29; Cl, 9.79. Found: C, 62.31; H, 5.33; Cl, 10.00.

(VI) 4-(β-Chloroethoxyethoxy)-3-methoxybenzoyl-*o*-benzoic Acid.—Seventy-seven grams of β-(2-methoxyphenoxy)-β′-chlorodiethyl ether was added gradually to a mixture of 49 g. of phthalic anhydride and 90 g. of anhydrous aluminum chloride in 200 cc. of carbon disulfide. After four hours of boiling on a steam-bath while stirring under reflux, the product was worked up as above; colorless crystals, m. p. 188–190° (from acetic acid).

Anal. Calcd. for $C_{19}H_{19}O_6Cl$: C, 60.25; H, 5.07; Cl, 9.37. Found: C, 60.13; H, 4.90; Cl, 9.40.

(VII) (2-β-Chloroethoxyethoxy)-naphthoyl-*o*-benzoic Acid.—Seventy-six grams of β-2-naphthoxy-β′-chlorodiethyl ether was added slowly to 49 g. of phthalic anhydride and 90 g. of aluminum chloride in 200 g. of carbon disulfide. The mixture was stirred and boiled for six hours under reflux and worked up in the usual manner. The product was crystallized first from benzene and then from glacial acetic acid; colorless crystals, m. p. 125°.

Anal. Calcd. for $C_{22}H_{19}O_5Cl$: C, 66.25; H, 4.82; Cl, 8.91. Found: C, 66.22; H, 4.63; Cl, 8.84.

(VIII) 4-(β-Chloroethoxyethoxy)-benzoyl-β′-propionic Acid.—To a gently refluxing mixture of 33 g. of succinic anhydride, 90 g. of aluminum chloride and 200 cc. of carbon disulfide there was added gradually 67 g. of β-phenoxy-β′-chlorodiethyl ether while stirring. Refluxing was continued for five hours thereafter. The product was then decomposed with ice and hydrochloric acid. After two crystallizations from benzene and three recrystallizations from ethylene dichloride, the pure compound was obtained in colorless crystals, m. p. 97–98°.

Anal. Calcd. for $C_{14}H_{17}O_5Cl$: C, 55.91; H, 5.69; Cl, 11.81. Found: C, 55.94; H, 5.60; Cl, 11.63.

(IX) 4-(β-Chloroethoxyethoxy)-benzoyl-β′-acrylic Acid.—Sixty-seven grams of β-phenoxy-β′-chlorodiethyl ether was treated with a mixture of 33 g. of maleic anhydride and 90 g. of aluminum chloride in 250 cc. of carbon disulfide for five hours. The product was decomposed with ice and hydrochloric acid and the crude waxy acid obtained purified by dissolving in a *cold* solution of 50 g. of sodium carbonate in 1200 cc. of water and filtering. The clear filtrate upon acidification with dilute hydrochloric acid gave a yellow precipitate of the crude product. This was recrystallized from benzene giving pale yellow crystals, m. p. 100°.

Anal. Calcd. for $C_{14}H_{15}O_5Cl$: C, 56.30; H, 5.06; Cl, 11.88. Found: C, 56.24; H, 5.05; Cl, 11.45.

(X) β-(4-Acetylphenoxy)-β′-chlorodiethyl Ether.—(a). A solution consisting of 34 g. of acetic anhydride and 67 g. of β-phenoxy-β′-chlorodiethyl ether was added slowly to a well-stirred mixture of 90 g. of aluminum chloride and 200 cc. of carbon disulfide cooled in an ice-bath. Stirring was continued for one hour in the ice-bath and then for two hours at room temperature with occasional cooling when the temperature tended to rise. The reaction mixture was decomposed with iced 3 *N* hydrochloric acid and the carbon disulfide distilled off. The residual oil was washed and distilled under vacuum. The product came over at 210–222° (10 mm.) as a yellow oil.

Anal. Calcd. for $C_{12}H_{15}O_3Cl$: C, 59.36; H, 6.23; Cl, 14.63. Found: C, 60.04; H, 6.09; Cl, 14.30.

(b). The same compound was obtained from 50 g. of aluminum chloride in 200 cc. of carbon disulfide treated with a mixture of 16.5 g. of acetyl chloride and 67 g. of β-phenoxy-β′-chlorodiethyl ether.

(XI) β-Butylphenoxy-β′-chlorodiethyl Ether.—A solution of 31 g. of *n*-butyl chloride and 67 g. of β-phenoxy-β′-chlorodiethyl ether was added slowly to a stirred mixture of

45 g. of aluminum chloride and 200 cc. of carbon disulfide. The mixture was then refluxed on the steam-bath for sixteen hours, after which the carbon disulfide was removed by distillation. The residue was decomposed with iced dilute hydrochloric acid, the oil layer separated, washed, and distilled *in vacuo*. The product distilled over at 170–185° (9 mm.) as a colorless oil.

Anal. Calcd. for $C_{14}H_{21}O_2Cl$: C, 65.45; H, 8.27; Cl, 13.83. Found: C, 66.44; H, 8.02; Cl, 13.35.

(XII) **β-(*p*-(α,α,γ,γ-Tetramethylbutylphenoxy))-β′-chlorodiethyl Ether.**—To a solution of 100 g. of β-phenoxy-β′-chlorodiethyl ether and 56 g. of diisobutylene (b. p. 100–104°) there was added dropwise during forty-five minutes while stirring and occasionally cooling, 20 g. of 98% sulfuric acid. The mixture was then stirred for seven hours at room temperature and allowed to stand for eighteen hours. The thick oil obtained was warmed with 145 cc. of 10% sodium hydroxide solution, the oil layer separated, washed and distilled *in vacuo*. The fraction of b. p. 157–167° (1 mm.) was the desired product; yield 107.5 g. or 68%.

Anal. Calcd. for $C_{18}H_{29}O_2Cl$: Cl, 11.34. Found: Cl, 11.68.

(XIII) **β-(*s*-Octylphenoxy)-β′-chlorodiethyl Ether.**—A mixture consisting of 180 g. of β-phenoxy-β′-chlorodiethyl ether, 117 g. of octanol-2 and 20 g. of "Tonsil" clay was heated with stirring for four hours at 160–175° under reflux attached to a water trap. The clay was then filtered off and the *s*-octylphenoxyethoxyethyl chloride, b. p. 175–185° (3 mm.), isolated by vacuum distillation; yield 60%.

Anal. Calcd. for $C_{18}H_{29}O_2Cl$: Cl, 11.34. Found: Cl, 10.78.

(XIV) **β-Dodecylphenoxyethyl Chloride.**—A mixture consisting of 56 g. of β-phenoxyethyl chloride, 66.5 g. of lauryl alcohol and 15 g. of "Tonsil" clay was boiled with rapid stirring for three and one-half hours under a reflux condenser attached to a water trap. The temperature gradually rose from 165 to 195° during this period. Heating was continued for sixteen hours at 180–195°. The mixture was then cooled, diluted with toluene and filtered hot by means of a Büchner funnel. The filtrate was fractionated under reduced pressure. Dodecylphenoxyethyl chloride distilled over at about 185–195° (1 mm.) as a colorless oil, the chlorine analysis of which indicated a purity of 97.5%.

Summary

Aromatic alkylene ether chlorides or polyalkylene ether chlorides of the type R–(O-alkylene)$_n$Cl readily undergo Friedel–Crafts nuclear alkylation or acylation reactions without splitting the ether links, loss of the terminal chlorine atom, or appreciable polymeric intercondensation. A number of acylations with phthalic, succinic, maleic and acetic anhydrides and alkylations with butyl chloride, capryl alcohol, diisobutylene and lauryl alcohol are described.

The Effect of the Composition of the Medium upon the Growth of Yeast in the Presence of Bios Preparations. II. The Response of Several Strains of Saccharomyces Cerevisiae[1]

BY JAMES B. LESH, L. A. UNDERKOFLER AND ELLIS I. FULMER

In a previous communication from these Laboratories[2] data were presented showing that, for the one strain of yeast employed, the presence of magnesium sulfate markedly increased the growth of the yeast in the presence of Bios II or a mixture of Bios II and Bios I (*i*-inositol). The present paper deals with the response of several strains of *Saccharomyces cerevisiae* to the above-mentioned reagents. While 23 strains of yeast were studied during the present investigation, data are presented here for only the 13 of these which can be obtained readily from standard sources: these strains are listed in Table I.

Lucas,[3] Williams, Warner and Roehm,[4] Williams and Saunders,[5] Stantial[6] and Farrell[7] have noted significant differences among various strains of yeast as to their response to various Bios preparations, but the effect of magnesium sulfate had not been considered previously. Magnesium sulfate is a customary ingredient of most media used for growing yeast. However, the media developed in these Laboratories by Fulmer, Nelson and Sherwood[8] for the growth of yeast in the

absence of bios do not contain this salt since it was found to be of no advantage. The marked difference in the response of yeast to bios preparations added to Clark's medium (used by Miller and co-workers) which contains magnesium sulfate, and to Medium C or Medium D, which do not, led to the study reported in the previous paper.[2]

The basal medium used in the present investigation was Medium C, developed by Fulmer, Nelson and Sherwood,[8] and contained per 100 cc., 0.188 g. of ammonium chloride, 0.100 g. of dipotassium phosphate and 5 g. of sucrose. Preliminary tests showed the optimum *p*H (after sterilization) to be 6.2. In order to assure the proper *p*H, the medium was made 0.0025 *N* with hydrochloric acid before sterilization. All media were sterilized at 15 lb. (1 atm.) pressure for fifteen minutes. In all experiments, 25 cc. of medium was used in 125-cc. Erlenmeyer flasks. The basal medium was made up in concentrations five-fourths of that given above. Twenty cc. was placed in each flask and made up to 25 cc. by the addition of solutions to be tested or of distilled water. The concentration of *i*-inositol (Bios I) was 0.032 mg., and that of magnesium sulfate 100 mg. (0.008 *M*) per 100 cc. of medium. The Bios II, per 100 cc. of medium, was equivalent to 4.0 cc. of the original extract which had been prepared from malt sprouts by the method of Lucas.[3]

In order to make direct comparisons of the cultures it was necessary to standardize the method of preparing the inoculum. Since several of the strains grew slowly, or not at all, in Medium C, the technique of Miller, Eastcott and Maconachie[9] was adopted. The cultures were transferred daily, for four days, in a medium containing 2% dextrose and 0.5% peptone. The twenty-four-hour culture, from the fourth transfer, was filtered rapidly on a small sterile filter. The yeast was then washed three or four times with sterile distilled water and a portion suspended in sufficient sterile Medium C so that 1 cc. contained the proper number of cells for inoculation of each experimental flask. The yeast count in the various media was determined by means of a Thoma–Zeiss counting chamber after twenty-four hours of incubation at 30°. When the count = 1 there are 250,000 cells per cc. Inoculations were made such that the initial count was one.

In Table II are given the actual counts in the Control (Medium C), together with the relative counts in the control medium and the control to which had been added (a) Bios II, (b) Bios II and *i*-inositol, (c) Bios II and magnesium sulfate and (d) Bios II, inositol and magnesium sulfate. Growth was also determined in the control to which had been added magnesium sulfate, inositol and both magnesium sulfate and inositol; since no increased growth was obtained over the controls the values are not included in the table.

TABLE II

Relative growth of various strains of *Saccharomyces cerevisiae* in Medium C (control) and in the control to which Bios II, inositol and magnesium sulfate had been added. (When the count = 1 there are 250,000 cells per cc.).

Medium strain	Actual count in control	Control	Bios II control	Inositol Bios II control	$MgSO_4$ Bios II control	$MgSO_4$ inositol Bios II control
5	3	1	15	22	10	14
6	2	1	3	5	1	10
7	1	1	11	15	14	19
9	2	1	2	2	4	4
10	5	1	14	21	19	88
11	6	1	4	4	8	19
16	4	1	21	21	25	38
18	10	1	1	2	2	13
19	3	1	1	4	22	27
22	1	1	21	40	46	100
26	12	1	2	2	15	25
41	5	1	3	4	6	14
42	7	1	5	7	4	51

It is at once evident that the various strains of yeast show wide differences in response to the different media. For convenient comparison the various strains may be divided into the following three groups:

Group I. The addition of magnesium sulfate with Bios II does not give increased growth. This group includes strains Nos. 5, 6 and 42. With these strains the counts were actually de-

---

[9] W. L. Miller, Edna V. Eastcott and J. E. Maconachie, THIS JOURNAL, 55, 1502 (1933).

creased by the addition of the magnesium sulfate.

Group II. The addition of inositol with Bios II does not give increased growth. This group includes strains Nos. 9, 11, 16 and 26.

Group III. Growth is increased under the conditions given for Groups I and II. These include Nos. 7, 10, 18, 19, 22 and 41.

The above data and groupings show that discrepancies in published results of bios studies may be due largely to differences in the strains of yeast employed and in the composition of the medium. For example, if a strain of yeast belonging to Group I were grown in a medium containing magnesium sulfate, Bios II would give increased counts in the presence of Bios I (inositol); that is, the complementary effect of Bios I and Bios II, as described by Miller and co-workers, would be demonstrated. If, however, a strain of Group II or Group III were employed under the same conditions, the Bios II would be potent in the absence of Bios I and their complementary effect would not be apparent.

Summary

The effect of Bios II, inositol (Bios I) and magnesium sulfate alone and in combinations on the growth of thirteen strains of *Saccharomyces cerevisiae* is reported. On the basis of the marked differences in response to the different media by the various yeast strains they are separated into three distinct groups.

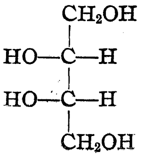
The Production of *l*-Erythrulose by the Action of Acetobacter suboxydans upon Erythritol

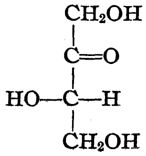
BY ROY L. WHISTLER AND L. A. UNDERKOFLER

The use of microörganisms for the production of ketose sugars has made possible the extension of carbohydrate investigations to include several of the rare ketoses which are now easily obtainable in pure form. *l*-Erythrulose was first produced from *meso*-erythritol by Bertrand[1] who employed the "sorbose bacterium" or *Acetobacter xylinum*. Müller, Montigel and Reichstein,[2] using the same organism, recently have converted erythritol to *l*-erythrulose in approximately 60% yield, and have isolated in pure form 50% of the sugar produced.

The present communication deals with the optimum conditions for the production of *l*-erythrulose by the action of *Acetobacter suboxydans* upon *meso*-erythritol, and for the isolation of the erythrulose produced. This organism has been found to effect practically quantitative conversion of the alcohol to the sugar in a short time. It is of interest to note that, although the configuration of the *meso*-erythritol, I, is such that the formation of both *d*- and *l*-erythrulose might be expected, only the *l*-erythrulose, II, is produced by the organism. No organism yet studied has been found to oxidize *meso*-erythritol to *d*-erythrulose.



I



II

It was found that Bertrand's[1] method of purification of the *l*-erythrulose by passage through the bisulfite addition compound was not accomplished easily since complete removal of the sodium bisulfite and recovery of pure unaltered sugar was very difficult. Purification by precipitating the sugar from alcoholic solution through the addition of ether and then distilling the sirup in a molecular still was found most suitable.

Experimental

Methods.—The culture of *Acetobacter suboxydans*, listed as No. 621, was secured from the American Type Culture Collection, and is the same culture previously used in studies reported from these Laboratories.[3,4] The stock cultures are carried on yeast extract–glycerol–agar slants. The cultures used for inoculations in the present experi-

ments were kept active by transfer each twenty-four hours into a medium containing 0.5 g. of yeast extract (Difco powdered product) and 3 g. of erythritol per 100 ml. All media were sterilized in the autoclave for twenty minutes at fifteen pounds (1 atm.) steam pressure, and all cultures were incubated at the optimum temperature of 28°. Preliminary studies were made using 10 ml. of medium in 50-ml. Erlenmeyer flasks. In each case the inoculum consisted of 3 ml. of the twenty-four hour culture of the organism per 100 ml. of fresh medium, measured from a sterile pipet. All fermentations were run in duplicate, and the values reported are the averages for the duplicate determinations. The course of the conversion of the erythritol into erythrulose was followed by determination of copper reduction values by means of the Shaffer–Hartmann[5] sugar titration method.

After isolation of erythrulose had been accomplished, an equation was derived experimentally which permitted calculation of the yields of erythrulose from the copper reduction values previously obtained. This equation was obtained as follows: weighed samples of the sirupy erythrulose were diluted and aliquots of 50 ml. heated with 50 ml. of mixed Fehling's solutions in 500-ml. uncovered Erlenmeyer flasks. The flames were so adjusted as to bring the mixtures to a boil in exactly four minutes, boiling was continued for exactly two minutes and the flasks were then cooled promptly in running water. The cuprous oxide was titrated by the Shaffer–Hartmann method. All reagents, including the Fehling's solutions, were made up exactly as directed by Shaffer and Hartmann.[5] The copper reduction values so obtained were plotted against weight of erythrulose, giving a straight line for amounts of the sugar between 20 and 100 mg. The equation for this line is

$$E = 0.831\ R + 4.380$$

where E represents mg. of erythrulose corresponding to R mg. of copper. This equation provides a convenient method for the calculation of erythrulose from analytical data. Since the erythrulose was recovered as a sirup which did not crystallize, the purity was based on the optical rotation given by Müller, Montigel and Reichstein.[2] Any inaccuracy involved here would mean a corresponding error in the above equation, which must therefore be considered subject to revision if a purer product be secured.

The Development of the Medium.—Employing the proportion of yeast extract which previously had been found optimum for the production of sorbose from sorbitol and of dihydroxyacetone from glycerol,[3,4] *i. e.*, 0.5 g. per 100 ml., media were prepared in which the concentrations of erythritol were varied. After inoculation and incubation, duplicate flasks of each medium were analyzed and the yields ascertained after intervals of three, four, seven and thirty days. The maximum yields were obtained after four to seven days, a slight decrease being sometimes observed after thirty days. The yields after seven days with 3, 4.5, 6, 9, 12, 15 and 18 g. of erythritol per 100 ml. were, respectively, 96, 99, 92, 61, 42, 30 and 18% of erythrulose.

An investigation on the influence of surface–volume ratio on the yield of erythrulose was made, employing different volumes of medium containing 4.5 g. of erythritol and 0.5 g. of yeast extract per 100 ml. in 125-ml. Erlenmeyer flasks. Incubation was for four days. When 10, 20, 30 and 40 ml. of medium were used, the respective surface–volume ratios (sq. cm. area per 1 cc. volume) were 3.18, 1.59, 1.06 and 0.80, and the yields were 98, 97, 93 and 92% of erythrulose.

From the data it may be concluded that the optimum concentration of erythritol in the medium is about 4.5 g. per 100 ml., and that maximum yields are obtained when the ratio of surface to volume of medium is high. Since the conversion of the erythritol to erythrulose was found to be practically quantitative in four days under these conditions when the medium contained 0.5 g. of yeast extract per 100 ml., no attempt was made to improve the medium by variation of the concentration of yeast extract, by addition of salts or by adjustment of the *p*H of the medium (*p*H 6.1 for the medium as prepared).

The Recovery of *l*-Erythrulose.—Thirty-five grams of yeast extract and 335 g. of *meso*-erythritol were dissolved in distilled water to make 7000 ml. of medium which was distributed in quantities of 200 ml. in 2-l. Erlenmeyer flasks. The sterilized medium in each flask was inoculated with 6 ml. of a twenty-four hour culture of *Acetobacter suboxydans* in similar medium, and incubated for nine days at 28°. According to the Shaffer–Hartmann titration, 95% of the erythritol had been converted to *l*-erythrulose.

To each 2000 ml. of the fermented medium were added 15 g. each of Norite, calcium carbonate and infusorial earth and the mixture was well shaken. The liquid was then separated by means of a supercentrifuge. To the recovered liquid was added 10 g. of Norite, the mixture passed through the supercentrifuge and the recovered liquid again passed through the centrifuge for the third time. The light yellow liquid, which was almost free of bacteria or other suspended material, was evaporated under reduced pressure at 35° to a volume of 200 ml. Six hundred ml. of absolute alcohol was added with stirring and the mixture filtered. The filtrate was evaporated under reduced pressure at 30° to a thick sirup of light yellow color, $[\alpha]^{30}\text{D}$ +10.0 (*c*, 2.4 in water). The sirup was taken up in alcohol and a small quantity of ether added. On standing in the refrigerator 2% of the original erythritol separated. On the addition of a little more ether a small quantity of a sirup having a low positive optical rotation separated. Further addition of ether precipitated erythrulose as a light yellow sirup. This sirup was taken up repeatedly in alcohol and precipitated with ether. The resulting sirup was distilled in a molecular still at 90–95° to produce a colorless sirup, $[\alpha]^{30}\text{D}$ +11.31 (*c*, 4.0 in water). By this procedure 87.4% of the erythrulose present in the original fermented liquid, as determined by the Shaffer–Hartmann titration, could be recovered as a sirup.

Summary

A procedure has been given for the production of *l*-erythrulose by the action of *Acetobacter suboxydans* upon *meso*-erythritol and for the isolation of the sugar from the fermented medium.

Analyses of Glacial and Preglacial Woods[1]

BY WILLIS A. GORTNER

Minnesota has been subjected to five glaciations. The Nebraskan glaciation (*ca.* 700,000–1,000,000 years ago),[2] the Kansan glaciation (*ca.* 500,000 years ago), the Illinoian glaciation (*ca.* 175,000 years ago), the Iowan glaciation (*ca.* 75,000 years ago) and the Wisconsin glaciations. The late Wisconsin ice sheet probably retreated from the middle part of Minnesota about 20,000 years ago. The advance must have taken place considerably earlier and the Peorian interglacial period probably came to an end in northern Minnesota 40,000–50,000 years ago.

In each of the interglacial periods forests developed only to be overridden by the ensuing ice sheets. In certain instances the wood from the interglacial or preglacial forests has been so preserved in the underlying clays as to be readily identifiable as to species and to be truly "wood," *i. e.*, fossilization had not taken place. The present communication deals with the chemical analyses of certain such specimens and supplements and extends similar analyses by Mitchell and Ritter[3] on three fossil woods from gravels of Miocene age in California.

Experimental

Materials. Specimen A—Pre-Nebraskan Spruce Wood.—This wood was secured *in situ* in the Nebraskan glacial till exposed in a highway cut 1.8 miles east of St. Charles, Minnesota. Figure 1 shows the specimens which were selected for analysis. All samples selected for analysis floated on water and after washing free of clay were dried and ground.

Specimen B—Pre-Nebraskan Spruce Wood.—This specimen was found in 1932 at a depth of 55 feet on the south bank of the Cottonwood River near New Ulm, Minnesota. It is shown in Fig. 2.

Specimen C—Peorian (last interglacial) Age Spruce Wood.—This was found at the bottom of a well sunk through 17 feet of lacustrine "clay" which formed in the bed of glacial Lake Agassiz and 70 feet of glacial till (ground moraine of late Wisconsin) in southeastern Kittson County near Bronson, Minnesota. It is shown in Fig. 2.

Specimen D—Peorian Age Spruce Wood.—This specimen was part of a larger "log" found beneath the Wisconsin gravel stratum at a depth of eleven feet, three miles north of Bottineau, North Dakota. It is shown in Fig. 2.

Methods.—The methods used are for the most part those recommended by Bray[4] with such modifications as were necessitated by the nature of the samples. All woods were reduced in a Wiley mill to pass a 40-mesh screen. Ash was determined on 3-g. samples. The alcohol–benzene soluble portion, pentosans, lignin (72% sulfuric acid method), and Cross and Bevan cellulose techniques followed procedures previously described.[5]

Certain of the glacial woods did not respond to the Cross and Bevan cellulose methods, since the lignin chloride formed a jelly-like mass. Mitchell and Ritter also noted this phenomenon in their fossil woods. In the present series of analyses the cellulose content of such woods was determined by a "hypochlorite method" in which the sample was extracted with a sodium hypochlorite solution in a centrifuge tube followed by extracting with 3% sulfurous acid, then with water, then with 2% sodium sulfite solution with repeated extractions, washing and centrifuging until a pure white fiber mat of cellulose was obtained. As an alternative method the cellulose was hydrolyzed with sulfuric acid and the resulting glucose determined volumetri-

TABLE I

SHOWING THE AVERAGE ANALYSES OF THE DIFFERENT WOOD SAMPLES

All Calculations on Basis of Oven-Dry Material

	Wood analyzed				
Approximate age in years	Modern white spruce 0 %	Peorian age (Specimen D) 40,000 %	Peorian age (Specimen C) 40,000 %	Preglacial (Specimen B) 800,000 %	Preglacial (Specimen A) 800,000 %
Ash	0.24	2.98	2.37	5.97	10.47
Lignin	29.73	39.03	53.38	79.23	66.41
Pentosans	9.63	7.21	7.77	2.23	2.10
Alcohol–benzene soly.	1.38	0.71	1.49	1.07	2.91
Cross and Bevan cellulose	60.70	42.30	[a]	[a]	[a]
"Hypochlorite" cellulose	....	35.07	27.10	[b]	
"Sugar" cellulose	65.50	54.75	31.45	4.01	12.21
Holocellulose	70.92	53.79	44.88	13.30	23.68
Total of lignin + ash + holocellulose	100.89	95.80	100.63	98.50	100.56

[a] Not run for these three woods, due to formation of a lignin–chloride jelly which prevented chlorination or washing.

[b] No further determinations by this method; lignin–chloride jelly formed.

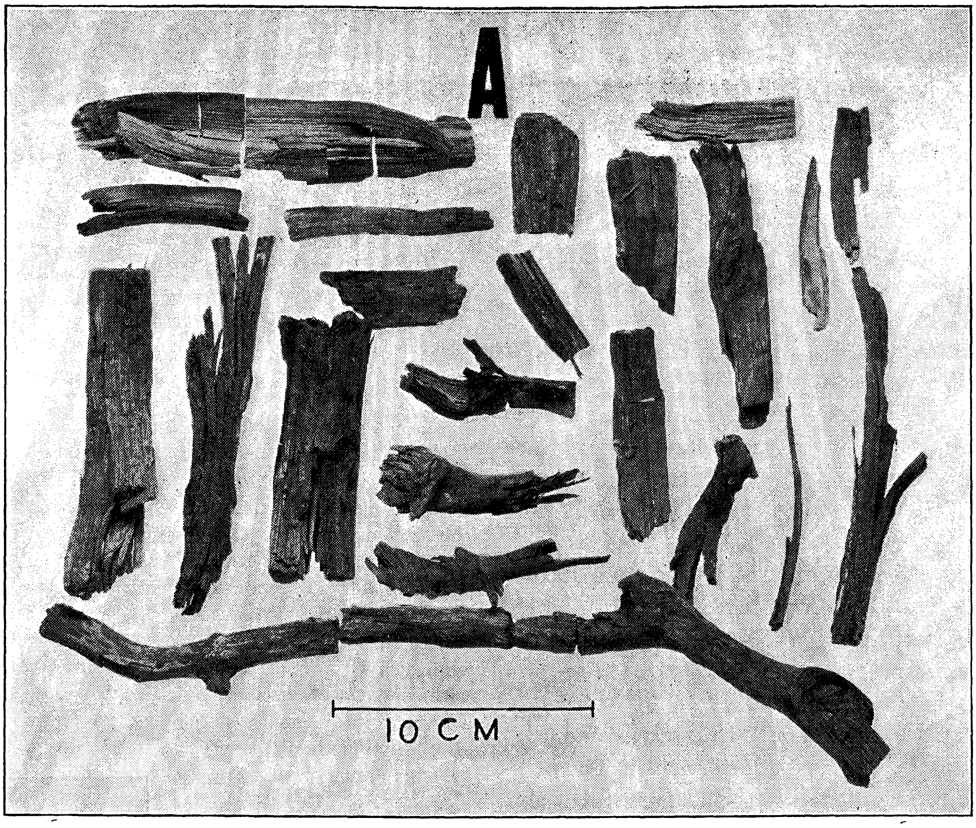

Fig. 1.—Specimen A, preglacial spruce wood.

cally.[6] This value was converted to "cellulose" by the appropriate factor. All woods were also analyzed for total carbohydrates by the "holocellulose" method of Ritter and Kurth.[7]

The Experimental Data.—Table I shows the analytical data and includes for comparison purposes parallel analyses of wood from a recently cut white spruce. These data represent the averages of closely agreeing triplicate or duplicate determinations. The range in duplicate or triplicate analyses for the glacial woods was within the limits allowable for comparable analyses in the pulp and wood-using industries.

Discussion

Ash.—The ash content increases with the age of the wood. This is probably due to the infiltration of mineral matter during the long periods that the wood was buried in the earth.

Cellulose.—The trends in "holocellulose" and "sugar" cellulose are essentially parallel, although no explanation is available for the marked decrease of "sugar" cellulose (4–12%) for the preglacial woods which show a holocellulose content of 13–23%. Possibly the reducing sugars titrated were not glucose, or some other change had taken place so that other compounds than reducing sugars were formed by hydrolysis of the "cellulose" residue. In general, there is a parallelism in the trends shown by all the "cellulose" methods, although the absolute values for any particular sample are not exactly alike.

Pentosans.—Pentosans decrease with age in about the same ratio as cellulose decreases. Possibly these residual "pentosans" are in reality uronic acids which are calculated as pentosans in the methods of analysis. In any event both cellulose and pentosan-like compounds have shown remarkable stability.

Lignin.—There is an apparent increase in lignin. This is probably largely the result of a loss of other wood constituents and is probably not due to an actual increase in lignin *per se*. Assuming a constant lignin value (no change in lignin with age of burial) of 30%, there would remain in the preglacial woods only 7–15% of the holocelluloses and only 9–10% of the pentosans which were present when the glacier overthrew and buried

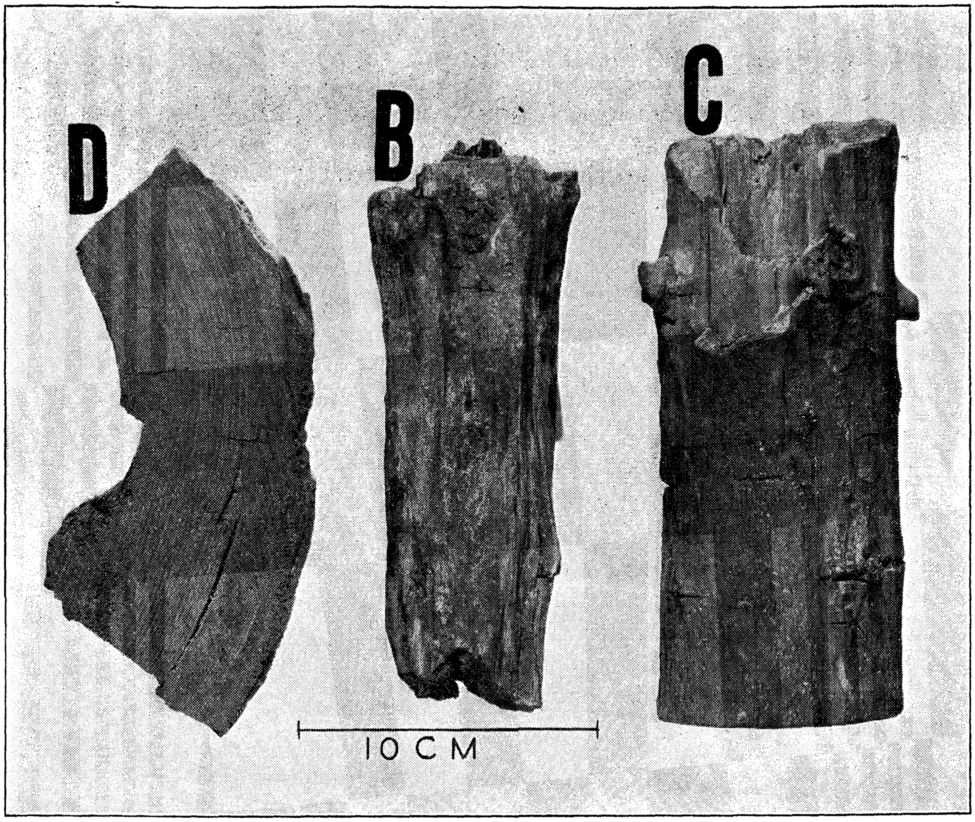

Fig. 2.—Specimen B, preglacial spruce wood; specimens C and D, Peorian age spruce wood.

the forest. It is therefore evident that lignin, or lignin-like complexes, are much more stable than are the cellulose–pentosan complexes.

The above analyses and conclusions parallel in a remarkable degree the analyses and conclusions of Mitchell and Ritter[3] in their studies of the fossil pine and cedrus woods of Miocene age. Apparently after being buried for a few hundreds of thousands of years wood reaches somewhat of an equilibrium with its environment, so that subsequent changes take place extremely slowly. Our analyses of wood of Peorian age indicate an intermediate degree of alteration.

Acknowledgment.—The writer wishes to thank Dr. C. O. Rosendahl, of the Department of Botany, University of Minnesota, for providing and identifying all samples of wood, and for assisting in the planning and executing of these experiments. Sincere thanks are also due Dr. S. I. Aronovsky for outlining appropriate laboratory techniques and for supervising the analytical operations.

Summary

Two samples of preglacial spruce wood (Pre-Nebraskan) and two samples from the Peorian interglacial period were analyzed in comparison with modern white spruce.

The analyses show an increased ash content with age of burial, presumably due to the infiltration of inorganic salts from the earth. The pentosans and cellulose decrease with increase in age of the wood, with lignin showing an apparent increase. It is believed that this lignin increase is only apparent and is due to the decrease in the cellulosic constituents. Correcting to a constant lignin basis, there still remain in the wood which has been buried in the earth for 700,000–1,000,000 years approximately 7–15% of the original "holocelluloses" and 9–10% of the original "pentosans."

The Relation between Equilibrium Constants in Water and in Other Solvents

BY I. M. KOLTHOFF, J. J. LINGANE AND W. D. LARSON

The equilibrium constants, in two different solvents, of a reaction

$$aA + bB + \cdots \rightleftharpoons dD + eE + \cdots \qquad (1)$$

are related to the distribution coefficients of the various components between the phases by the equation

$$K''/K' = D_{\mathrm{A}}^{\mathrm{a}}D_{\mathrm{B}}^{\mathrm{b}}\cdots/D_{\mathrm{D}}^{\mathrm{d}}D_{\mathrm{E}}^{\mathrm{e}}\cdots \qquad (2)$$

In this equation, which was first derived by Nernst,[1] K' and K'' are the equilibrium constants in the first and second solvents, respectively, and D is the distribution coefficient between the two phases of a given reaction component.[2]

The distribution coefficient of a given component is defined as the ratio of the activities of the component in the two phases at distribution equilibrium. For example, the distribution coefficient of component A is defined by

$$D_{\mathrm{A}} = (a'_{\mathrm{A}}/a''_{\mathrm{A}})_{\mathrm{equil.}} \qquad (3)$$

in which the superscipts (′) and (″) refer to the first and second phases, respectively.

If reaction (1) involves only *uncharged* substances the various distribution coefficients can be determined accurately by classical methods, and hence an experimental test of eq. (2) can be made easily. However, if the reaction involves *ionic* components, such an experimental test is much more difficult, because it is impossible to determine unambiguously the *absolute* value of the distribution coefficient of a single species of ion.

The transfer of a single ionic species between two phases would involve a certain amount of electrical work in addition to purely mechanical work (difference in chemical potential between the two phases). The amount of electrical work will depend on the difference in the electrical potentials of the two phases (phase boundary potential), and since this potential difference cannot be determined in an exact way, the absolute value of the distribution coefficient of a single ionic species never can be evaluated unambiguously. Detailed discussions of this subject have been given by Guggenheim,[3] Brönsted[4] and Donnan and Guggenheim.[5]

In an ingenious study of the ionization constants of various acids in water and ethanol, Bjerrum and Larsson[6] attempted to determine the distribution coefficients of individual ionic species by measuring the e. m. f. of cells comprised of an indicator electrode for the ion in question in water and in ethanol. They tried to eliminate the potential at the junction of the two solvents by the use of concentrated salt bridges. Values obtained in this way are approximate only, because it is impossible to eliminate completely the liquid junction potential.

Fortunately, a knowledge of the absolute values of individual ionic distribution coefficients is not essential, because it is possible to determine the products and quotients of individual ionic distribution coefficients in an exact way and these suffice for the purpose.

From the solubilities s_1 and s_2 of a uni-univalent salt AB in two solvents we find

$$D_{\mathrm{A}}D_{\mathrm{B}} = \left(\frac{s_1}{s_2}\right)^2 \frac{\gamma'_{\mathrm{A}}\gamma'_{\mathrm{B}}}{\gamma''_{\mathrm{A}}\gamma''_{\mathrm{B}}} \qquad (4)$$

in which γ denotes the activity coefficient.

From the values of the standard electrode potentials of an ion i in two solvents, the ratio of the distribution coefficient of that ion to the distribution coefficient of the hydrogen ion between the two solvents is given by the relation

$$E^{0\prime} - E^{0\prime\prime} = \frac{RT}{F}\ln\frac{D_{\mathrm{H}}}{D_{\mathrm{i}}} \qquad (5)$$

in which $E^{0\prime}$ and $E^{0\prime\prime}$ represent the standard electrode potentials of the ion i in solvents 1 and 2, respectively.

In the present study the ionization constants of several weak acids in water, methanol and ethanol are compared. If pK represents the negative logarithm of the ionization constant, it can be shown from equation (2) that

$$pK'' - pK' = \Delta pK = \log D_{\mathrm{H}}D_{\mathrm{A}} - \log D_{\mathrm{HA}} \qquad (6)$$

The single primes refer to water, and the double primes to alcohol, while the subscripts H, A and

HA refer to hydrogen ion, the anion of the weak acid and undissociated part of the acid, respectively. The product $D_H D_A$ was found as follows. The solubility of the silver salt of the acid was determined in water and in the two alcohols. These data gave $D_{Ag} D_A$ for water–ethanol and water–methanol, using equation (4). By means of the values of the standard electrode potentials of the silver ion in water, methanol and ethanol[7] the value of the ratio D_H/D_{Ag} was calculated by equation (5). The product of $D_{Ag} D_A$ by D_H/D_{Ag} is $D_H D_A$. The value of D_{HA} was calculated from the solubility ratios of the uncharged acid, allowing for the ionized part if necessary, and assuming that the saturated solutions behave ideally.

Experimental

Ethanol and methanol (anhydrous commercial products) were refluxed over silver oxide, distilled and dehydrated with magnesium by the method of Lund and Bjerrum.[8]

The density of each lot of alcohol treated in this way was determined in a 100-ml. pycnometer with which the density of a given sample could be checked to within ±3 units in the fifth decimal place. The water content of our methanol samples ranged from 0 to 0.03%, while that of ethanol varied from 0.01 to 0.07%. The specific conductance at 25° of the methanol varied from 2.9 to 5.0 × 10^{-6} cm.$^{-1}$ ohm^{-1}; the range in the corresponding values for ethanol was from 0.4 to 1.2 × 10^{-7} cm.$^{-1}$ ohm^{-1}. The conductance of the alcohol was subtracted from the observed specific conductance where necessary.

The acids used in this study were recrystallized and tested for purity.

The silver salts of the acids were precipitated from solutions of the corresponding sodium salts with a slight excess of silver nitrate. These precipitates were washed thoroughly and recrystallized from hot water. The coarsely crystalline products obtained in this way were washed with water, then with ethanol, and air dried.

Saturated solutions of these silver salts were prepared in conductance cells through which a stream of previously dried nitrogen, saturated with the vapor of the solvent, was led to provide stirring. When the conductance had become constant, samples of the saturated aqueous solutions were withdrawn and analyzed for silver by the Volhard method except in the case of salicylate and picrate, where the potentiometric method was used. The solubilities in ethanol and methanol were determined by the conductance method, except in the case of silver picrate solutions which were titrated potentiometrically with thiocyanate. The conductance cells were of the type used by Kolthoff and Willman.[9] Their cell constants were determined in the usual way.

Results

The solubilities of the silver salts in methanol and ethanol were computed from the specific conductances of the saturated solutions by the successive approximation method. For these computations it was necessary to know the equivalent conductance of the ions of each silver salt at the concentrations in the saturated solutions. These values were obtained from the equivalent conductances of the corresponding alkali salt, of silver nitrate or perchlorate, and of the alkali nitrate or perchlorate by means of the Kohlrausch relation

$$\Lambda_{AgA} = \Lambda_{NaA} + \Lambda_{AgNO_3} - \Lambda_{NaNO_3}$$

The required values for the alkali salts in ethanol were taken from the work of Goldschmidt,[10] and those for silver nitrate, silver perchlorate, alkali nitrates, and alkali perchlorates in ethanol from the data of Barak and Hartley.[11] The necessary data for the alkali nitrates and silver nitrate in methanol were taken from the results of Frazer and Hartley,[12] and those for sodium salicylate in methanol from the measurements of Goldschmidt and Aas.[13]

There are no data in the literature for the conductances of the alkali nitrobenzoates and benzoates in methanol; accordingly, they were measured in this study. These results are given in Table I.

conductances of the ions at that concentration were computed with the aid of the Kohlrausch rule. Successive approximations were made in this way until a constant value for the solubility was obtained. A summary of the results is given in Table II. The solubilities are given in moles per liter.

In order to compute the ionization constants of the acids in methanol and ethanol from those in water by means of equation (6), it was necessary to know the distribution coefficients of the uncharged acids. Also, for comparison of the calculated and observed values of the ionization constants in the alcohols, it was necessary to have directly determined values of these constants in the alcohols. The required data are available in the literature, except the solubilities and dissociation constants of the three nitrobenzoic acids in methanol.

These solubilities were determined by titrating samples of the saturated solutions, after dilution with water, with standard baryta solution, using phenolphthalein as indicator.

Bright and Briscoe[14] determined the acidity constants of the nitrobenzoic acids in water–methanol mixtures, and extrapolated the values to 100% methanol. These constants given by Bright and Briscoe, together with the value of the ionization constant of benzoic acid in Table IV, give 7.4, 8.0, and 8.1, respecitvely, for the values of *pK* for *o*-, *m*- and *p*-nitrobenzoic acids. Since the extrapolation involves an uncertainty, and the measurements involve an interphase potential, the ionization constant of *o*-nitrobenzoic acid was determined by us by the conductivity method. The calculation was made in the classical way by means of the Ostwald dilution formula. Since the ionic strength of the solutions was very small, no correction was applied for the activity of the ions.[15]

For the calculation of the degree of dissociation, α, values of the equivalent conductance of the acid at infinite dilution were calculated in the usual way from conductance data for the potassium salt of the acid (Table I), hydrochloric acid,[16] and potassium chloride.[17] The values obtained are given in Table III. The average value of K of 6×10^{-8} or a pK of 7.22 corresponds reasonably well with the value 7.4 computed from the acidity data of Bright and Briscoe. In Table III, κ is the specific conductance, Λ the equivalent conductance, and α the degree of dissociation.

Table III

Ionization Constant of *o*-Nitrobenzoic Acid in Methanol at 25°

0.1520	1.76	0.116	6.4	6.2
.1025	1.44	.140	7.7	6.1
.0755	1.19	.158	8.7	5.8
			Average	6.0

A summary of the solubility and ionization constant data for the various acids at 25° in water, methanol, and ethanol is given in Table IV. The solubilities, s, are given in moles per liter of solution. K represents the ionization constant.

With these data it is possible to compute pK values for the several acids in methanol and ethanol by means of equation (6), and to compare them with the experimental values. The results are given in Table V. The data needed for the calculations are given in the previous tables. The distribution coefficients of the un-ionized part of

the acids, D_{HA}, were computed from the solubility data for the acids, assuming that the activity coefficients for the uncharged molecules were unity in all three solvents. The values of D_{HA} in water were corrected for the amount of dissociation. The values of $D_H D_A$ needed for these calculations were obtained by multiplying the values of $D_{Ag} D_A$ given in Table II by D_H/D_{Ag}. These latter values were computed from the standard electrode potentials of silver in the three solvents by means of equation (5). In water, the value 0.7996 v.[18] for the electrode potential of silver and the values 0.764[7] v. and 0.749[7] v. in methanol and ethanol, respectively, were used. The values 3.99 and 7.15 for D_H/D_{Ag} were found for water–methanol and water–ethanol, respectively.

Discussion.—From the results in Table V it is seen that the calculated values of *pK* are in fair agreement with the experimentally determined ones. The differences between the two are no larger than the uncertainties in the experimentally determined constants and in the various assumptions and approximations which have been made. The agreement is of the same order as that obtained by Bjerrum and Larsson[6] in ethanol.

Acknowledgment.—We are indebted to the Graduate School of the University of Minnesota for a grant which enabled us to carry out this investigation.

Summary

It has been pointed out that the product and the quotient of the distribution coefficients of ions between two solvents can be determined in an exact way. When these values are known it is possible to calculate equilibrium constants in one solvent from the known values in water.

The ionization constants of six acids in methanol and ethanol were calculated from distribution data and the values of the constants in water. The values calculated in this way were found to be in fair agreement with the experimentally determined ionization constants in methanol and ethanol.

Ionization Constants of Acid–Base Indicators in Methanol

BY I. M. KOLTHOFF AND L. S. GUSS[1]

The equilibrium constant in a buffer system containing a small amount of an acid–base indicator is given by the expression

$$K' = \frac{(aI_b)(aA)}{(aI_a)(aB)} = \frac{cI_b\ cA}{cI_a\ cB}\,\frac{f_{Ib}\,f_A}{f_{Ia}\,f_B} = K\,\frac{f_{Ib}\,f_A}{f_{Ia}\,f_B} \quad (1)$$

in which a denotes the activity of the component, c the concentration, I_b the basic form and I_a the acid form of the indicator, A and B the acid and basic forms of the buffer, K' the thermodynamic equilibrium constant, while K is the corresponding and experimentally determinable concentration "constant," the value of which varies with the ionic strength of the solution. By extrapolating the values of K found at small ionic strengths to an ionic strength of zero, the value of K' is found. This method of evaluation of K' is similar to that used by Guggenheim and Schindler[2] in aqueous solutions.

In sufficiently dilute solution, the limiting Debye–Hückel expression gives the relation between activity coefficient and ionic strength. In methanol at 25°, this becomes

$$-\log f_{\text{ion}} = 2.0z^2\sqrt{\mu} \quad (2)$$

In the range in which the limiting expression is applicable, equation 1 gives us

$$pK' = pK - \log\frac{f_{Ib}\,f_A}{f_{Ia}\,f_B} = pK - 4.0(z_{Ia} - z_A)\sqrt{\mu} \quad (3)$$

where z_{Ia} and z_A are the charges of the indicator acid and the buffer acid, respectively. If the values of pK are plotted against the square root of the ionic strength, the slope of the curve should be $4(z_{Ia} - z_A)$ in the range where the limiting expression holds. Table I lists values of this slope for various types of indicator and buffer acids.

TABLE I

VALUES OF $4.0(z_{Ia} - z_A)$

Type of buffer acid	Type of indicator acid Cation	 Uncharged	 Anion
Cation	0.0	−4.0	−8.0
Uncharged	4.0	0.0	−4.0
Anion	8.0	4.0	0.0

Having obtained by extrapolation the value of pK, the thermodynamic ionization constant, K_I, of the indicator can be calculated if the dissociation constant of the acid, K_A, is known since

$$pK_I = pK' + pK_A$$

Although there are many data in the literature on the acidity constants and concentration ionization constants of acids in methanol, only few studies have been carried out at sufficiently small ionic strengths to allow the determination of the thermodynamic ionization constant. In the present work, the values of Goldschmidt and coworkers,[3] who determined the constants by the conductivity method, have been adopted as the most reliable values. The constant of veronal, which is not given in the literature, has been determined by the colorimetric procedure described in this paper, using the pK_I value which has been found previously in another buffer. In a similar way, the ionization constants of other acids in methanol have been determined.

Experimental

Reagents.—A good grade of synthetic methanol free of aldehydes was dehydrated by the method of Lund and Bjerrum[4] followed by distillation over sulfanilic acid to remove traces of alkaline impurities. The density of the final product was measured with a 100 ml. pycnometer. Freshly distilled products gave values of d^{25}_4 0.78651. No sample whose density was above 0.78661^{25}_4 was used, the latter value corresponding to less than 0.04% water. The presence of a trace of water has a negligible effect on indicator equilibria in buffered solutions.

The sulfonphthaleins were furnished through the courtesy of Hynson, Westcott and Dunning and were used without further purification. Thymolbenzein was obtained from a collection of the late Dr. W. R. Orndorff of Cornell University. Other indicators were purified by conventional methods.

Lithium chloride was precipitated from a saturated solution in methanol by hydrogen chloride, then fused in platinum in an atmosphere of hydrogen chloride. Sodium bromide and sodium nitrate were recrystallized from water and dried to constant weight at 110°. All other reagents were purified by conventional methods.

Sodium methoxide solutions were prepared by dropping pure sodium into methanol and, after solution was complete, diluting up to the desired strength. Solutions of acids were prepared by weight and checked by titration with sodium hydroxide. Solutions of lithium chloride and

sodium bromide were prepared similarly and checked by titration with silver nitrate.

Method.—Accurately measured volumes of a solution of the suitable buffer acid and of sodium methoxide were introduced into a test-tube to give an intermediate color to the indicator investigated. If desired, a certain amount of a neutral salt was added to obtain a certain ionic strength, then 0.05 ml. of 0.04% indicator solution and the mixture made up to 5.0 ml. with methanol. The fraction of the indicator in the alkaline form was then measured by the method of Gillespie[5] and the value of pK calculated from the ratio of the concentration of acid and basic forms of the indicator and the composition of the buffer. These values were then plotted against the square root of the ionic strength, and extrapolated to zero concentration, using the limiting Debye–Hückel expression for the final extrapolation.

Results.—For example, a solution was 0.02 N in benzoic acid, 0.0199 N in sodium benzoate, 0.20 M in lithium chloride and 0.01% in brom cresol green (added as the sodium salt). The ratio of cI_b/cI_a was found to be 0.96 and the ratio of cB/cA in the buffer was 0.99. Hence

$$K = 0.96/0.99 = 0.975$$

and $pK = 0.01$.

As an illustration, in Table II are listed the data obtained in a study of the behavior of brom phenol blue in salicylate buffers. The results of other determinations have been summarized in Table III. The values of pK given were obtained by interpolation from curves in which pK was plotted against the square root of the ionic strength. The first column gives the values obtained on extrapolating to zero ionic strength. The superscripts refer to neutral salts in the solution, 1 referring to lithium chloride, 2 to sodium bromide and 3 to sodium nitrate.

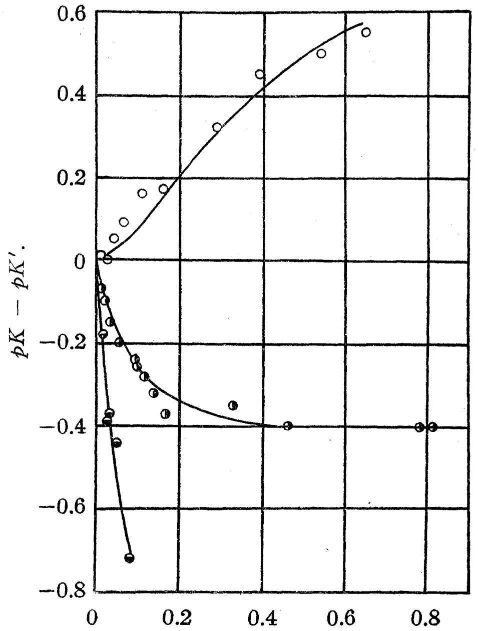

Fig. 1.—Brom cresol green in ○, tartrate, ◑, benzoate, and ◒, ammonium buffers.

The behavior of various indicator–buffer systems is shown more clearly in the figures. Figure 1 shows the behavior of brom cresol green in its alkaline range in various types of buffers. This behavior is typical of the sulfonphthaleins. For convenience, $pK - pK'$ has been plotted against the square root of the ionic strength. In Fig. 2, the behavior of the azo indicators, methyl yellow and methyl orange is illustrated. Figure 3 shows the behavior of methyl red in its two color change intervals. Figure 4 illustrates the two color changes of thymolbenzein and of thymol blue in its acid range.

Discussion

1. The sulfonphthaleins in their alkaline range approach the behavior predicted on the basis of the limiting Debye–Hückel expression, as the ionic strength approaches zero. This is evidenced by the slope of the lines given in Fig. 1. With increasing ionic strength, the pK values vary in some regular way. With buffers of the type A–B$^-$ (A is an uncharged acid, B$^-$ is the

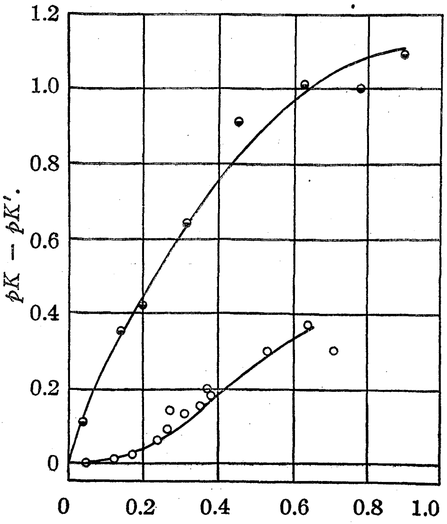
corresponding univalent anion base), a limiting slope of −4 is obtained. With increasing ionic strength, the *pK* values decrease less than demanded by the limiting expression. This is to be expected as the latter in methanol will only be valid at very small ionic strengths. When the ionic strength has become of the order of 0.06, the *pK* values remain practically constant with increasing ionic strength. This behavior is typical of all of the sulfonphthaleins and can be interpreted on the basis of the structures of the sulfonphthaleins as originally proposed by Lund[6] and supported by the work of Schwarzenbach.[7] According to Lund, the structural changes of a sulfonphthalein in its various color change intervals is represented by



Square root of ionic strength.

Yellow form Alkaline form

Thus, the yellow form is a hybrid ion with one extra negative charge and the alkaline form a hybrid ion with two extra negative charges. Bjerrum[8] postulated that the charges on a hybrid ion are sufficiently displaced that, in a fairly concentrated solution, it behaves as two ions. Güntel-

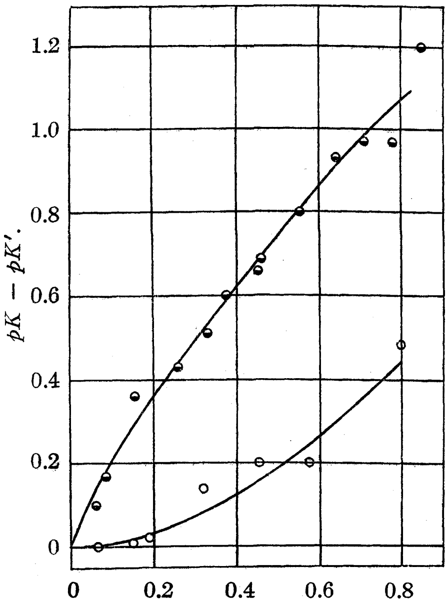

Fig. 3.—Methyl red in ○, benzoate and ◒, trichloroacetate buffers.

berg and Schiödt[9] showed that the behavior of methyl orange with varying ionic strength could be explained by such a hypothesis. The same reasoning should apply to any highly charged ion, with widely displaced charges. Thus, we might assume that at higher ionic strengths the electrical work required to build up n individual charges will be n times as great as that required to build up a single charge. In the yellow form of the sulfonphthaleins, n is equal to 3 and in the alkaline form, equal to 4. At high ionic strengths, we then may write the following relation for the activity coefficient

$$-\log f_n = -n \log f_1 \qquad (4)$$

in which f_1 is the activity coefficient of a univalent ion.

For univalent ions in fairly concentrated solutions, the Debye–Hückel expression might be written

$$-\log f_1 = f(\sqrt{\mu}) + B \qquad (5)$$

where B is some function of the ionic strength. It seems fair to assume that B will be of the same magnitude for ions of a conjugate acid–base system. Applying the above to the sulfonphthaleins in buffers of the type A–B$^-$ at higher ionic strength, we find

$$\begin{aligned} pK &= pK'' - \log f_{\overset{=}{-}} + \log f_{\overset{=}{=}} - \log f_- + \log f_0 \\ &= pK'' - 3\log f_1 + 4\log f_1 - \log f_1 = pK'' \qquad (6) \end{aligned}$$

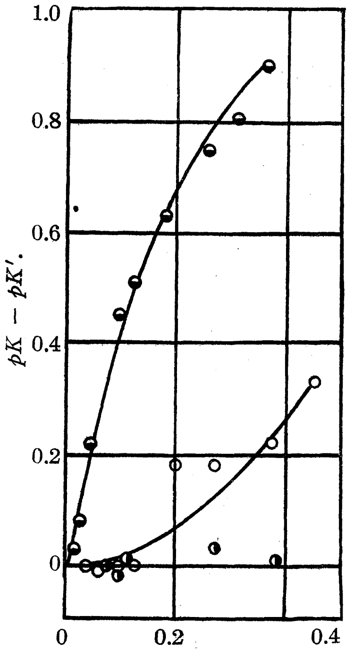

Fig. 4.—Thymolbenzein in ○, veronalate, and ◒, trichloroacetate and ◑, thymol blue in trichloroacetate.

in which pK'' is not the true thermodynamic constant since the relation in equation 4 will not permit extrapolation down to infinite dilution. According to the above interpretation, pK becomes constant at relatively high ionic strengths, which is in agreement with experimental results.

The above considerations are also of practical importance. If the pK values of sulfonphthaleins in various alcohols are determined in buffer solutions of the type A–B$^-$ with an ionic strength of about 0.1, the result of a 5- to 10-fold dilution will be a very small effect upon the pK measured. Extrapolation of those data to an ionic strength of zero, however, would lead to an erroneous result. Kolthoff,[10] who investigated the sulfonphthaleins in ethanol, has applied such an extrapolation. From this discussion, it is clear that his data need correction.

In buffers of the type A$^-$–B$^=$, the pK values of the sulfonphthaleins should become constant and independent of the ionic strength when the latter is very small. Actually, this was found to be the case with brom cresol green in bitartrate–tartrate buffers at ionic strengths below 0.001. When the ionic strength becomes greater than

---

[9] E. Güntelberg and E. Schiödt, *Z. physik. Chem.* **135**, 393 (1928).

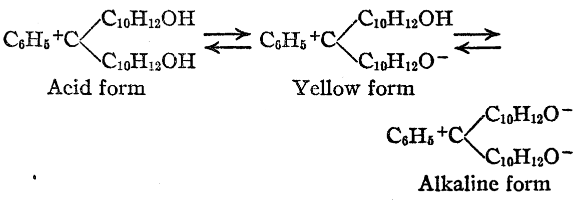
[10] I. M. Kolthoff, *J. Phys. Chem.*, **35**, 2732 (1931).

this, the pK values increase. This is in agreement with the above considerations.

The tremendous effect of the ionic strength upon the pK values in buffers of the type A^+–B is also in agreement with the predictions based on the above discussion. At low ionic strengths, the curve has the slope of -8 required by equation 3 (see Fig. 1). At higher ionic strengths, the theory of individual charges seems again applicable.

The behavior of thymol blue in its acid range is in agreement with the structure proposed by Lund. The pK values found in trichloroacetate buffer were found to be constant up to an ionic strength of 0.1.

2. In connection with what has been said of the sulfonphthaleins, the behavior of thymolbenzein in its two color changes is of interest. On the basis of the work of Lund and Schwarzenbach, the structural changes may be represented by



$$C_6H_5{}^+C\begin{cases}C_{10}H_{12}OH\\C_{10}H_{12}OH\end{cases} \rightleftarrows C_6H_5{}^+C\begin{cases}C_{10}H_{12}OH\\C_{10}H_{12}O^-\end{cases} \rightleftarrows C_6H_5{}^+C\begin{cases}C_{10}H_{12}O^-\\C_{10}H_{12}O^-\end{cases}$$

In its acid range, in a buffer of the type A–B^-, we would have

$$pK = pK'' - \log f_+ + \log f_\mp - \log f_- + \log f_0$$

At small ionic strengths, this leads to

$$pK = pK' + 4\sqrt{\mu}$$

The slope of 4 actually was observed in trichloroacetate buffers. At high ionic strengths, we would expect to find $pK = pK''$ and independent of μ. Although the slope did increase, it still had a positive value at an ionic strength of 0.126.

In the alkaline range, with the same type of buffer, the following relation should hold at higher ionic strengths

$$pK = pK'' - \log f_\mp + \log f_\mp - \log f_- + \log f_0 = pK''$$

Actually the pK was found to be constant up to an ionic strength of about 0.01. Above this, pK increased. More work should be done in order to interpret the behavior of the benzeins at higher ionic strengths.

3. The behavior of azo indicators and of neutral red in buffers of the type A–B^- is in agreement with the postulates given in the introduction of this paper. The slope of the pK line of methyl yellow against the square root of the ionic strength in trichloroacetate buffers and of neutral red in salicylate buffers approaches the value calculated on the basis of the limiting Debye–Hückel expression (Table I and Fig. 2). At greater ionic strengths, the pK values of both indicators increase less than calculated on the basis of the limiting expression, which is to be expected since the latter disregards ionic diameter. With both indicators, the deviations are greater with lithium chloride than with sodium bromide.

The behavior of methyl orange in trichloroacetate buffer (Fig. 2) is explained readily by the hybrid character of the acid form of the indicator. At small ionic strengths, the pK values become constant, but pK increases at greater ionic strengths. In the latter case we have

$$pK = pK'' - \log f_\mp + \log f_- - \log f_- + \log f_0 = pK'' - 2 \log f_1$$

While the behavior of methyl yellow in *o*-chloroanilinium buffer is quite normal, the behavior of methyl orange in the same buffer is abnormal. A limiting slope of pK against the square root of the ionic strength of 4 was expected, but as seen from the data in Table III, the pK was found to be sensibly independent of ionic strength. Whether this result is to be attributed to a specific interaction between methyl orange and the buffer has not been investigated.

Methyl red has two color changes, in the acid range from red to orange and in the alkaline range from orange to yellow. The latter corresponds to the color change in water from so-called Red II to yellow, but is less pronounced in methanol. In the acid range (trichloroacetate buffer), the change of the pK at small ionic strengths is similar to that of methyl yellow and neutral red (see Fig. 3), but at higher ionic strengths the pK does not increase as much as that of other indicators. In the alkaline range (benzoate buffers), the pK becomes constant at small ionic strengths and increases at larger ionic strengths. The salt effect is almost identical with that of methyl orange in trichloroacetate buffer. The salt effects in the acid and alkaline ranges are best explained on the assumption that the orange form (comparable with Red II in water) is present as a neutral amino acid and not as a hybrid ion. This behavior is in agreement with the change of the indicator constant, pK_I, on going from water to methanol. The pK_I of methyl red in water is 5.0, and in methanol ($pK_{I(2)}$), 9.2. The change of 4.2 cor-

responds to that of an uncharged carboxylic acid. On the other hand, the behavior of methyl orange in this respect (3.5 in water, 3.8 in methanol) indicates conclusively the hybrid ion structure of the acid form. From their work on the indicator constants in water–ethanol mixtures, Baggesgaard-Rasmussen and Reimers[11] arrived at the conclusion that the Red II form of methyl red or the orange form in alcohol has the amino acid and not the hybrid ion structure. Kolthoff[12] and Thiel[13] came to the opposite conclusion from a consideration of the salt effect in water. In agreement with the former conclusion is the fact that the temperature has hardly any effect on the intermediate color of methyl red in a benzoate buffer in water or in methanol. If the orange form had a hybrid structure the color should shift to a yellow on increasing the temperature.

4. The effect of small amounts of water

[13] A. Thiel, A. Dassler and F. Wülfken, *Ber.*, **56**, 1667 (1923).

should be negligibly small as long as the concentration of the water is not great enough to affect the properties of the solvent appreciably. From a large number of experiments, a few examples of which are listed in Table IV, it is seen that the presence of 1% water in a buffer solution hardly affects the indicator–buffer equilibrium.

In Table V is given a summary of the values of the negative logarithms of the ionization constants of indicators, pK_{I}, at an ionic strength of zero. The values, naturally, are no more reliable than the pK_{A} values from which they were calculated. The pK_{I} of Tropeoline 00 has been obtained from experiments in dilute hydrochloric acid solutions in methanol, which will be reported in a subsequent publication.

In Table VI is given a list of the pK_{A} values of various acids at $\mu = 0$, which were calculated from the extrapolated pK' values and the pK_{I} values of Table V.

Summary

1. Thermodynamic ionization constants of a number of indicators and of acids have been determined in methanol, and the effect of ionic strength studied.

2. The behavior of the sulfonphthaleins and thymolbenzein is in agreement with modern views of their structures.

3. In agreement with Baggesgaard-Rasmussen and Reimers, it was found that the behavior of methyl red is best explained on the basis of the existence of the free amino acid form, and not of the hybrid form, although the salt effect is not entirely accounted for by this interpretation.

4. The behavior of other indicators is in agreement with present concepts. At very small ionic strengths, the salt effect can be accounted for quantitatively by the limiting Debye–Hückel expression.

Specific Heats and Heat of Fusion of Tellurium Tetrachloride

BY K. J. FREDERICK AND J. H. HILDEBRAND

A calculation of the internal pressure of tellurium tetrachloride by the senior author[1] shows that this tetrachloride differs from all others in the magnitude of its molecular field, which is near to that of iodine. It is to be expected, therefore, that solutions of these two substances with each other should be nearly ideal, provided that they do not react and that the former does not have a more or less ionic field, which may prove to be the case. The freezing point diagram for this system is now being constructed in this Laboratory. In order to evaluate the data, however, it is necessary to have reliable figures for the specific heats and heats of fusion. Data for iodine recently have been reported by us[2] and this paper presents similar results for tellurium tetrachloride, for which no determinations of the quantities are to be found in the literature.

Preparation and Purification of Sample.—The material used was purified by fractional distillation, the final fraction distilling at a mean temperature of 390° under atmospheric pressure. Its melting point was 224.1°. The purified material was enclosed in small Pyrex glass capsules, evacuated before sealing. The capsules had an external diameter of 12 mm., an internal diameter of 10 mm., and a length of approximately 6 cm. The ratio of weight of tellurium tetrachloride to weight of glass was about 1.4. Two different capsules were prepared and each one was used in a considerable number of the runs. The average free space in the capsules was 1.7 cc. Calculations indicate that the tellurium tetrachloride vapor in the capsules was a negligible factor.

Method.—The apparatus and method used in these determinations were the same as described in the account of the work with iodine. The higher melting point of the tellurium tetrachloride necessitated further calibration of the thermocouple in the furnace and the melting point of tin was used for this purpose.

Results and Discussion.—The value of the heat capacity of the calorimeter was 11.3 ± 0.4 cal. per degree. Runs on the Pyrex glass used in making the capsules showed that its specific heat for the interval 25–250° could be

expressed within ± 0.3% by the equation

$$c_p = 0.186 + 5.5 \times 10^{-5}(t - 25) + 1.15 \times 10^{-6}(t - 25)^2$$

The results of the runs made on solid and liquid tellurium tetrachloride are given in Table I. The column headed $H-H_{298.1}$ represents the number of calories evolved in cooling one mole from the temperature in the other column down to 25°. The data listed in the tables are plotted in Fig. 1.

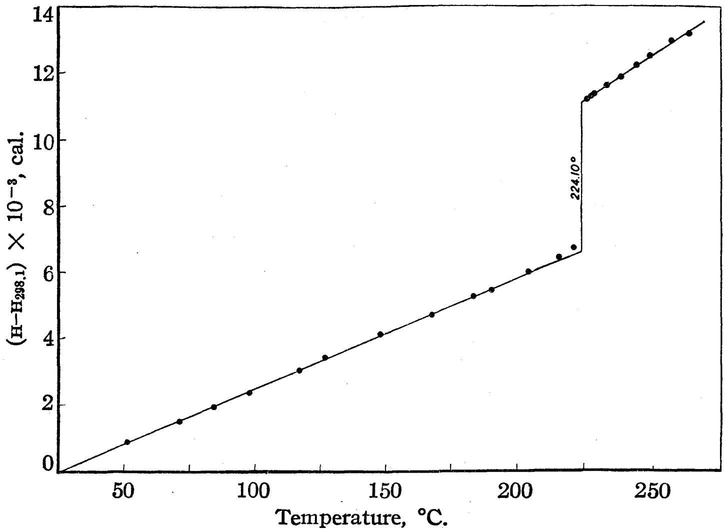

Fig. 1.

The two values obtained for the solid just below the melting point are abnormally high due to some pre-melting. If these two are neglected, the rest of the results for the solid range follow a linear relationship within experimental error. The slope of this line is the molal heat capacity of solid tellurium tetrachloride in the interval 25–224.1° and is 33.1 ± 0.3 cal. per mole. A straight line was also found to fit the data for liquid tellurium tetrachloride within experimental error. This gives a molal heat capacity of liquid tellurium tetrachloride of 55.0 ± 0.5 cal. per mole for the interval 224.1–265°.

TABLE I

Temp., °C.	$H-H_{298.1}$, cal./mole Solid	Temp., °C.	$H-H_{298.1}$, cal./mole Liquid
51.06	847.3	226.20	11,204.7
71.10	1491.3	227.80	11,312.9
84.32	1920.6	229.03	11,366.3
97.91	2331.3	233.28	11,604.4
116.94	3010.3	238.63	11,879.1
126.72	3399.8	244.40	12,224.1
148.36	4110.5	249.36	12,510.4
168.10	4705.5	256.85	12,964.7
184.63	5263.8	263.10	13,169.2
190.65	5466.3		
204.82	5980.5		
216.10	6410.3		
221.60	6720.0		

The heat of fusion of tellurium tetrachloride at the melting point is 4510 ± 30 cal. per mole. The entropy of fusion is 9.07 cal. per degree. This agrees excellently with the entropies of fusion of silicon tetrachloride, 9.08; titanium tetrachloride, 9.00; tin tetrachloride, 9.11; obtained by Latimer.[3]

Summary

Employing the method of mixtures, the heat of fusion of tellurium tetrachloride at the melting point was found to be 4510 ± 30 cal. per mole, the molal heat capacity of solid tellurium tetrachloride in the interval 25–224.1°, 33.1 ± 0.3 cal. per mole, and the molal heat capacity of liquid tellurium tetrachloride in the interval 224.1–265°, 55.0 ± 0.5 cal. per mole.

The Distribution of Minute Amounts of Material between Liquid Phases

BY D. C. GRAHAME AND G. T. SEABORG

It frequently happens in chemical investigations that a knowledge of the behavior of very small amounts of material in solution, either alone or accompanied by larger amounts of other substances, becomes of considerable importance. Particularly in the use of radioactive substances as indicators for chemical investigations or in the identification of newly discovered artificially prepared radioactive isotopes is it desirable to know what chemical behavior may be expected of minute quantities of radioactive matter in the absence of appreciable amounts of its inactive isotopes. The work of Fajans, Paneth, Hahn and others[1] has led to the formulation of rules concerning the adsorption or coprecipitation of minute amounts of material upon precipitates formed under various conditions. Studies of this sort lead to qualitative conclusions only and do not permit any very accurate prediction as to the behavior of untried substances. It seemed likely, on the other hand, that minute amounts of material would distribute themselves between liquid phases in a simple manner owing to the absence of adsorption phenomena so characteristic of the solid phase. It could not be foretold, of course, whether the walls of the containing vessel or the dust particles inevitably present in the solution would exhibit sufficient adsorption of the microcomponent to influence the experimental results.

I. Partition of Gallium Chloride between Ether and Hydrochloric Acid

Experimental Details.—Ether (99.5%) was dried with anhydrous calcium chloride and metallic sodium, then distilled in an all-glass still (b. p. 34.4 ± 0.2°). Hydrochloric acid, 6 *N*, was distilled in an all-glass still and shaken with ether to remove possible traces of gallium chloride. Chemically pure zinc chloride was dissolved in 6 *N* hydrochloric acid and freed from gallium by repeated extractions of gallium chloride with fresh ether prepared as above. The solution so prepared was evaporated to remove hydrochloric acid, redissolved in doubly-distilled water and electrolyzed between a carbon cathode and platinum anode to give a thin deposit of gallium-free zinc. The zinc was bombarded in air with 8.0 Mev deuterons from the Berkeley cyclotron to form, among other things, radioactive isotopes of gallium. From the intensity of the radioactivity produced ($\sim 10^{-2}$ millicuries of sixty-eight minute gallium) we estimate that the amount of gallium formed was about 10^{-12} g.[2] The sample of zinc containing this gallium was dissolved in 6 *N* hydrochloric acid (prepared as above) and shaken with 25 cc. of ether, whereby most of the radio-gallium was extracted as gallium chloride.

This ether extract was shaken several times with 6 *N* hydrochloric acid (saturated with ether) to remove traces of zinc chloride from the ether solution after which the distribution ratio of the gallium chloride remaining in the ether was determined in the following manner. To the ether solution in a cylindrical separatory funnel an approximately equal volume of 6 *N* hydrochloric acid (saturated with ether) was added. The mixture was brought to a temperature of 20.0 ± 0.1° in a water thermostat and shaken thoroughly to establish equilibrium between the liquid phases. After the volumes had been marked, the aqueous layer was drawn off very carefully into a second separatory funnel and shaken again at 20° with an equal volume of ether already in equilibrium with 6 *N* hydrochloric acid. The two ether extracts thus obtained were evaporated to dryness on shallow copper trays of identical size and shape which could be placed in a reproducible manner under a Lauritsen type quartz fiber electroscope or under a thin-walled Geiger–Müller counter. In order to obtain a fairly uniform deposit on the copper trays, a few drops of alcohol were added to the ether during the evaporation process and the solution was rocked back and forth by hand during the final stages of the evaporation. Gentle heating hastened the evaporation, but the solution was not boiled.

The ratio of the intensities of the radiations from the radioactive gallium on the trays gave a measure of the relative amounts of gallium chloride present in the two ether extracts. From this ratio and a knowledge of the volumes of the ether and aqueous phases, it was possible to calculate by a method of successive approximations the distribution ratio of the gallium chloride between the two liquid phases. Because of the extreme thinness of the deposits on the trays self-absorption of the radiation by the body of the sample did not need to be considered in most instances. In certain experiments, however, the amount of material present in the trays was sufficient to absorb an appreciable fraction of the β-particles emitted by the sample. In such cases the relative intensities were estimated with a Geiger counter under conditions such that only γ-rays were detected. The counting rate was then practically independent of the thickness of the samples over the range of thicknesses used.

Results.—There are two known isotopes of gallium formed by the bombardment of zinc with deuterons, with half-lives of sixty-eight minutes

---

[1] A summary and discussion of these investigations is found in Hahn's "Applied Radiochemistry," Cornell University Press, Ithaca, N. Y., 1936.

[2] This estimate also takes into account the fact that other isotopes of gallium (radioactive and non-radioactive) are formed during the bombardment.

and eighty-three hours, respectively. Both were observed in these experiments (in addition to another which will be mentioned later), and since a distribution coefficient for gallium chloride could be obtained from either, measurements were made with one or the other or both. The results obtained are presented in Table I. Column 2 gives the approximate molal concentration of gallium chloride in the ether phase of the first extract. Column 3 gives the half-life of the radioactive body on which the experiment was conducted, and column 4 gives the distribution coefficient, K, expressed as the ratio of the molal concentration in the ether phase to that in the aqueous phase in equilibrium at 20°. The probable error in the distribution coefficient, estimated from the internal consistency obtained in duplicate runs, is about ±10%. Experiment 4 differed from the others in that 7 mg. of gallium chloride was added to the radioactive sample at the beginning of the experiment. The result so obtained indicates that the distribution of gallium chloride between ether and hydrochloric acid is the same at extremely low concentrations of gallium chloride as at ordinary concentrations.

TABLE I

DISTRIBUTION RATIO OF GALLIUM CHLORIDE BETWEEN ETHER AND HCl ($\sim 6\ N$)

Expt.	Initial concn. of $GaCl_3$	Half-life	Distribution ratio K
1	$\sim 10^{-12}$	68 min.	18.1
2	$\sim 10^{-12}$	83 hr.	19.0
3	$\sim 10^{-12}$	68 min.	17.5
4	0.0016	83 hr.	16.9

II. Distribution of Manganous Chloride between Ether and Hydrochloric Acid

Experimental Details.—A solution in ether of manganese-and-cobalt-free ferric chloride was prepared by dissolving sublimed ferric chloride in ether and extracting manganese and cobalt by repeatedly shaking the solution with fresh, triply-distilled (in Pyrex) 6 N hydrochloric acid. The experiments to be described show that such a procedure really does reduce the concentration of manganous chloride and cobalt chloride to extremely low values. The purified ether solution was irradiated with fast neutrons from the Berkeley cyclotron to form, among other things, very small amounts ($\sim 10^{-15}$ g.) of radio-manganese. This ether solution (volume, 82 cc.) was then shaken with two 13-cc. samples of triply-distilled 6 N hydrochloric acid, and great care was exercised to avoid contaminating the second hydrochloric acid extract with any of the first extract that may have escaped removal from the separatory funnel. From the behavior of manganese chloride in ordinary amounts, one would expect that 99.97% of the radio-manganese would appear in the first hydrochloric acid extract. To test this, the hydrochloric acid extracts were purified as follows, and their activity measured with a Geiger counter. Ferric chloride was removed from the two extracts by shaking with ether. Manganese chloride and monosodium hydrogen phosphate were added to each solution to serve as carriers for the subsequent precipitations and concentrated nitric acid was added to oxidize to phosphate any radio-phosphorus in the solution. (Radio-phosphorus and radio-chlorine were always present as a result of the action of neutrons on the chlorine originally present.) Phosphates were then removed by precipitation as $(NH_4)_3PO_4 \cdot 12MoO_3$ and manganese was recovered as $MnO(OH)_2$ by the action of sodium hydroxide and bromine water. A further purification of the $MnO(OH)_2$ was effected by dissolving it in an acidified solution of hydrogen peroxide and reprecipitating from concentrated nitric acid with potassium chlorate.

Results.—Measurements on the radioactivity of the two manganese samples showed that nearly all of the radio-manganese appeared in the first extract. Nevertheless, a very slight activity (0.7% of that in the first extract) appeared in the second extract, which was not to be expected from the extremely small distribution coefficient of manganese chloride between ether and 6 N hydrochloric acid (see below). It seems very probable, however, that traces of radio-silicon (half-life two and four-tenths hours) formed from the walls of the vessel may have entered the solution and been precipitated in part along with the manganese dioxide. Because of this uncertainty the conclusion to be drawn from this experiment is only qualitative. Thus, minute amounts of manganese chloride may be extracted from ether, at least qualitatively, in the same manner as manganese chloride in larger amounts.

It may be remarked, however, that the ether used to remove the ferric chloride from the first hydrochloric acid extract showed no detectable radio-manganese, a result to be expected if minute amounts behave in the same manner as larger amounts.

III. Distribution of $(NH_4)_2Co(SCN)_4$ between Water and Amyl Alcohol

Experimental Details.—Cobalt-free ammonium thiocyanate solution was prepared by shaking a 40% solution of the C. P. salt several times with doubly-distilled *s*-amyl alcohol. This procedure removed any cobalt which might be present, together with about half of the ammonium thiocyanate.

Cobalt-free iron was deposited in a thin film on a pure silver plate by electrolyzing (with a platinum anode and a silver cathode) a water solution of cobalt-free ferric chloride prepared as before. A scrupulously clean porous alundum cup prevented excessive diffusion of chlorine from the anode to the cathode. The film of iron so formed was bombarded in air with deuterons to form radio-cobalt with a half-life of eighteen hours, together with small amounts of radio-manganese, radio-iron, and long-lived radio-cobalt isotopes. The silver plate on which the iron was deposited also became strongly radioactive due to the formation of short-lived silver isotopes and due to the formation of a radio-cadmium isotope (half-life 7.2 ± 0.5 hrs.) heretofore observed only from the action of protons on silver. Part of the iron film was dissolved, after bombardment, with pure 6 *N* hydrochloric acid. The acid evidently reached the silver backing in places, for radio-cadmium, dissolved from the surface of the silver, was detected easily in all of the samples. To the solution of iron in hydrochloric acid, doubly-distilled (in Pyrex) 6 *N* nitric acid was added to oxidize ferrous iron, the solution was shaken with ether to remove the iron, evaporated to dryness, and taken up in ammonium thiocyanate solution prepared as described above. The distribution coefficient (between this solution and pure doubly-distilled *s*-amyl alcohol (b. p. 118.0 ± 0.5°) of the minute amounts of $(NH_4)_2Co(SCN)_4$ thus formed ($\sim 10^{-12}$ g.), was determined in substantially the same manner as that described above for gallium chloride. One difference lay in the fact that the two amyl alcohol extracts were finally shaken with dilute ammonium hydroxide solution which brought the radio-cobalt back into the aqueous layer. This was at once a convenience and a further test of the principle under consideration. In these extractions, of course, relatively large amounts of ammonium thiocyanate are transferred along with the ammonium cobaltothiocyanate.

Results.—The results so obtained are presented in Table II. Experiment 6 was identical with 5 except that ordinary pure iron, containing traces of cobalt, was used for the bombardment. Within the limits of the experimental error the results are the same, indicating again that very low concentrations of matter behave in partition processes like the same substances at ordinary concentrations.

Table II

Distribution Ratio of $(NH_4)_2Co(SCN)_4$ between *s*-Amyl Alcohol and Aqueous Ammonium Thiocyanate Solution

Expt.	Initial concn. of $CoCl_2$	Distribution ratio *K*
5	$\sim 10^{-12}$	10.9
6	$\sim 10^{-5}$	10.05

The samples obtained in experiment 5 were found to contain appreciable amounts of radio-cadmium (7.2 ± 0.5 hr.), and an approximate value for the distribution ratio of cadmium between *s*-amyl alcohol and ammonium thiocyanate solution was obtained ($K = 0.15$). Qualitative experiments with inactive cadmium salts in ordinary amounts showed a similar behavior.

The chemical identity of the seven and two-tenths-hour period here obtained was established by separating cadmium, manganese and cobalt from a new sample by adding carriers for the radio-elements and precipitating each in a conventional manner. The seven and two-tenths-hour period was found in the cadmium precipitate, and its radioactive properties were substantially the same as those reported by Ridenour, Delsasso, White and Sherr,[3] who produced this radioactive body by bombarding silver with protons.

IV. Distribution Ratios of Several Metallic Halides between Ether and Hydrochloric Acid

Since the hydrochloric acid used in the experiments listed in Table I had been shaken with ether several times, its quantitative composition was not accurately known. A series of experiments was performed in which the composition of the two phases could be easily and accurately reproduced. In these experiments the concentration of the substance whose distribution ratio was being measured was always small, but no effort was made to remove all traces of the element before the bombardment.

Experimental Details.—Hydrochloric acid of known concentration (standardized with anhydrous sodium carbonate) was shaken with an equal volume, at 20°, of dried ether. The heat of mixing was removed by cooling in a thermostat at 20°, and the two liquid phases were used at the compositions thus obtained. Experiments with gallium chloride were made in the manner already described except that traces of gallium originally present in the c. p. zinc chloride were not removed before bombardment. Measurements on ferric chloride were made in the presence of 0.01 *M* inactive iron. Experiment 14 with cobaltous chloride was made from a very active sample of long-lived radio-cobalt in which inactive cobalt was also present to the extent of about 10^{-7} mole per liter of solution. The ether and aqueous phases were evaporated and compared. Experiment 15 was carried out in the same manner with two and six-tenths-hour radio-manganese and the result checked by colorimetric experiments with inactive manganous chloride.

Results.—The results of these experiments are presented in Table III. The distribution ratio, *K*, for gallium chloride is seen to reach a maximum at about 5.5 *N* as originally reported by Swift.[4] His values do not agree very well with those in Table III, however, perhaps because his method of preparing the ether-saturated hydrochloric acid differed from that used in the present research. Experiments 12 and 13 were carried out in order to determine whether any marked

13	$FeCl_3$	47 da.	5.00	23
14	$CoCl_2$	Long	5.5	$\sim 10^{-4}$
15	$MnCl_2$	2.6 hr.	6.0	$\sim 10^{-4}$

difference existed between the distribution ratios of ferric and gallium chlorides. Although experimental difficulties rendered the results from ferric chloride rather uncertain, there appears to be a marked difference between the results obtained for the two trichlorides. The somewhat anomalous behavior of ferric chloride in distribution processes noted by Dodson, Forney and Swift[5] was observed in these experiments, and was taken into account in calculating the distribution coefficients given in Table III. No elements other than iron were found to display anomalous behavior of this sort.

The completeness with which cobaltous chloride and manganous chloride may be held in the aqueous layer during an extraction is shown by the results of experiments 14 and 15. The values of *K* obtained in these two experiments may be regarded as upper limits.

Discussion.—It has been shown at ordinary concentrations that the activity coefficient of an ion in aqueous solution is determined by the ionic strength of the solution surrounding it and not by its own particular concentration. The results presented in Tables I and II may be considered as experimental evidence supporting this proposition at extremely low concentrations, since the ionic strength was essentially the same at the two concentrations studied. In the ether phase, also, the activity must have remained proportional to the concentration at the lowest concentrations attained, a result to be attributed, no doubt, to the presence of a relatively large amount of hydrochloric acid dissolved in the ether.

A result of considerable interest was obtained during one of the experiments with radio-cobalt and radio-cadmium. When a hydrochloric acid solution containing traces of radio-cobalt and radio-cadmium together with inactive iron in relatively enormous concentration was shaken with ether, the iron was readily and almost completely removed. The ether extract, however, showed no detectable radioactivity, indicating that the ether in removing 10^8 times as much iron as there was cobalt or cadmium in the solution showed no tendency to carry with it the other components of the solution. As a means of separating certain pairs of substances, extraction processes are evidently much superior to ordinary precipitation processes.

During the course of the experiments with radio-gallium a radioactive substance of half-life roughly seven and one-half hours was observed in addition to the well-known sixty-eight-minute and eighty-three-hour gallium isotopes. A description of the radioactive properties of the seven and one-half-hour body will be published elsewhere, but it is desired to note here that its chemical identity was established by showing that the distribution ratio of its chloride between ether and hydrochloric acid was always the same as that observed under the same conditions for the other radioactive isotopes of gallium present at the same time. This constitutes very strong evidence that the seven and one-half-hour period is due to an isotope of gallium rather than to some impurity present in the bombarded zinc.

The facts here presented indicate that in certain cases extraction processes may be used to advantage in the separation and identification of artificially produced radioactive elements. The advantages of such methods over the more conventional precipitation processes are: (1) no "carrying down" of unsuspected radioelements in unpredictable ways; (2) high concentration of the radioactive substance in the evaporated extract, thus eliminating self-absorption of the radiation and changes in the physical properties of the sample on standing; (3) chemical identification of the radioactive element by its distribution ratio, particularly if other known radioactive isotopes of the element are present. Extraction processes employing ammonium thiocyanate and amyl alcohol are of less value because they are less specific in their action.

We are greatly indebted to Professor E. O. Lawrence of the Department of Physics and to the staff of the Radiation Laboratory for the preparation of the radioactive substances used in this research.

---

Summary

1. The distribution of minute quantities (*ca.* $10^{-12} - 10^{-15}$ g.) of soluble substances between liquid phases is shown in the cases studied to be quantitatively the same as that observed for the same substances in ordinary small concentrations.

2. Distribution ratios of several metallic halides between ether and hydrochloric acid are determined at low concentrations by the use of radioactive substances.

3. It is shown that the technique here employed may be of use in separating and identifying artificially prepared radioactive substances without the use of a non-radioactive carrier.

Infrared Absorption Studies. VII. Complex Formation Due to Hydrogen Bonding

BY A. M. BUSWELL, W. H. RODEBUSH AND M. F. ROY

In an earlier paper[1] a considerable discussion was given of the conditions under which hydrogen bonding might occur. It was observed that for a hydrogen atom to be capable of forming a "bond" it must be active to a degree (*i. e.*, ionizable in the proper solvents). Furthermore, a generalization due to Venkateswaran[2] was noted. This generalization is that the shift of the fundamental absorption band when hydrogen forms a bond is the greater, and the band itself is the broader, the more active the hydrogen. In order to test the generalizations above it seemed to be desirable to examine compounds containing hydrogen that lay at either extreme of the range of activity. The two which seemed best suited for this purpose are chloroform and hydrogen chloride.

Ether Hydrochloride.—The existence of the ether–hydrogen chloride complex has been known for a long time and it was formerly characterized by organic chemists as an oxonium compound. More recently it has been recognized that it must be in the nature of a hydrogen bonded complex

$$R_2O \longleftarrow HCl$$

Of course by analogy with ammonium compounds, it might be supposed to be ionic in character. Undoubtedly a solution of hydrogen chloride in ether does show some conductance but the amount of ionization cannot be appreciable in a solvent of low dielectric constant for ions of small radius, and no typical salt-like crystal is formed as is the case with ammonium chloride.

Recently a number of spectroscopic studies have tended to confirm the foregoing conclusions. Walkenstein and Syrkin[3] have noted the absence of the Raman lines of hydrogen chloride in ether solutions. West and Edwards[4] have reported the absence of the harmonic at 1.7 μ for hydrogen chloride in ether. Similarly, West and Arthur[5] found no Raman lines for hydrogen chloride in ether solution.

Gordy and Martin[6] have observed the infrared spectrum of hydrogen chloride in ether, dioxane, and ethyl acetate and have found a broad intense band around 4 μ which they attribute to hydrogen bonding between the hydrogen chloride and the solvent.

In the investigation just mentioned the substance to which the hydrogen chloride bonds is used as the solvent. Since the solubility of hydrogen chloride is not large, this procedure has the obvious disadvantage of introducing an excess of solvent and hence a heavy absorption due to C–H in the region of the H–Cl absorption. It is necessary to work with thin layers of solution and as a result it is not possible to make definite observations upon the H–Cl vibration.

In our work we have avoided the above difficulty by using long cells containing a dilute solution of hydrogen chloride and ether in carbon tetrachloride. By changing the concentration of both hydrogen chloride and ether it is possible to produce and observe marked changes in the degree of association between the two substances.

Experimental

An 0.08 molal solution of ether in carbon tetrachloride was saturated with hydrogen chloride under a pressure slightly greater than atmospheric.

[6] W. Gordy and P. C. Martin, *ibid.*, **5**, 1075 (1937).

This solution was then diluted with carbon tetrachloride to the required concentrations and the ratio of the absorption of the solution to the absorption of a solution containing the same amount of ether but no hydrogen chloride was recorded. The hydrogen chloride concentration was determined for each solution by titration of a sample taken at the time the cell was filled. It was not possible in this procedure to maintain absolute constancy for the product of concentration times cell length. Molal absorption coefficients are plotted for the hydrogen chloride in Figs. 1 and 2.

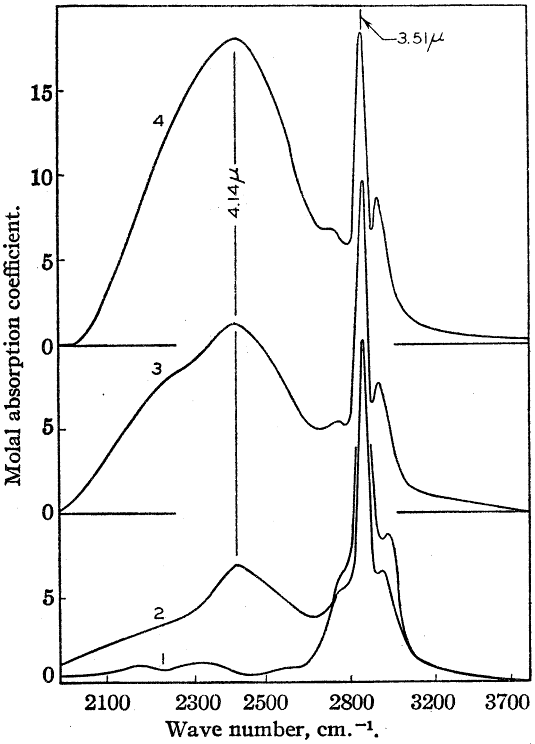

Fig. 1.—(1) 0.129 *M* HCl in CCl_4 *vs.* CCl_4 in 0.158-cm. cell; (2) 0.0264 *M* HCl in 0.02 *M* ether *vs.* 0.02 *M* ether in 0.640-cm. cell; (3) 0.0687 *M* HCl in 0.04 *M* ether *vs.* 0.04 *M* ether in 0.325-cm. cell; (4) 0.154 *M* HCl in 0.08 ether *vs.* 0.08 *M* ether in 0.158-cm. cell.

Discussion of Results

In all of the absorption curves (Fig. 1) for hydrogen chloride in carbon tetrachloride solutions of ether, the hydrogen chloride fundamental is quite evident at 3.51 μ. For the most concentrated solution of both hydrogen chloride and ether (Curve 4), a broad and intense band with a maximum at 4.14 μ is observed. As the concentrations of the hydrogen chloride and ether are decreased simultaneously (Curves 3 and 2), this band decreases in intensity and approaches the absorption for hydrogen chloride itself (Curve 1).

The inference is that hydrogen bonding between the hydrogen chloride and ether molecules causes a shift of the hydrogen chloride fundamental to 4.14 μ. As the concentrations are diminished the amount of H-bonding is decreased and the 4.14 μ band is correspondingly less intense.

The intensity of the hydrogen chloride fundamental decreases slightly as the concentrations increase, but this decrease is not enough to be given any particular significance.

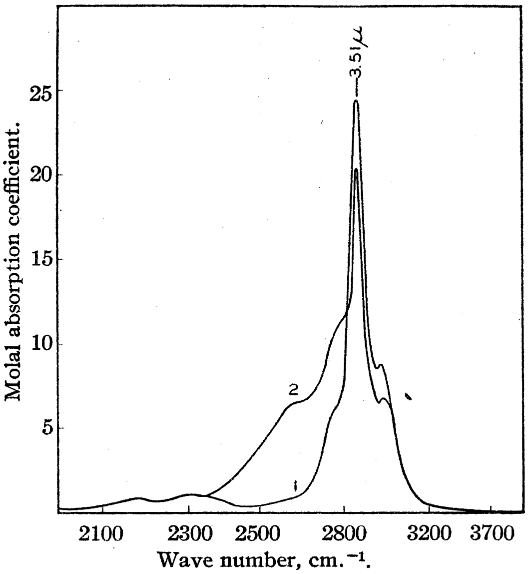

Fig. 2.—(1) 0.129 *M* HCl in CCl_4 *vs.* CCl_4 in 0.158-cm. cell; (2) 0.150 *M* HCl in 0.2 *M* anisole *vs.* 0.2 *M* anisole in 0.158-cm. cell.

The absorption of hydrogen chloride in the carbon tetrachloride solution of anisole is only slightly different from that for hydrogen chloride in carbon tetrachloride (Fig. 2), although the concentrations of both the hydrogen chloride and anisole are greater than the highest ones used in the case of ether. The absorption on the long wave side of the hydrogen chloride fundamental is somewhat increased but there is no intense absorption as there was even at the lower concentrations of ether.

It appears that there is a smaller tendency for the anisole to act as donor in the formation of hydrogen bonds than is the case with ether.

Hydrogen Bonding Involving Chloroform.—The tendency of chloroform to form complexes with a large number of substances such as ethers and ketones has been recognized by many investigators. Recently Huggins[7] has reviewed this evidence and explained it as due to hydrogen bonding. More recently Zellhoefer, Copley and Marvel[8] have studied exhaustively the tendency of chloroform to form complexes by the very simple method of solubility measurements and have adduced an enormous amount of evidence in favor of the activity of the hydrogen in chloroform. Since the hydrogen in chloroform is probably the least active of any hydrogen which is known to form bonds, it may be expected according to the rule of Venkateswaran that the shift in absorption would be so small as to be difficult of observation. Our first experiments showed that this is so, particularly with a molecule such as ether which has a strong C–H absorption. For that reason a considerable amount of our work was done with quinoline in which the absorption due to the aromatic C–H is less and is located at a somewhat different wave length than that for chloroform.

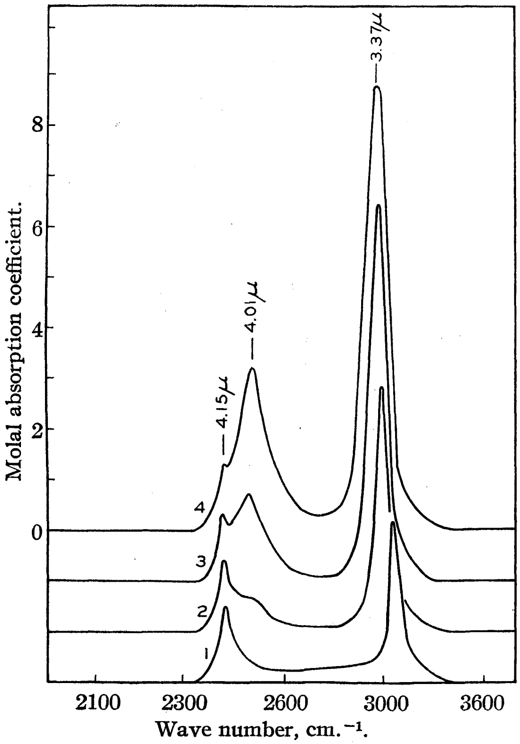

Fig. 3.—Quinoline–$CHCl_3$: (1) 4 *M* $CHCl_3$ in CCl_4 *vs.* CCl_4 in 0.0374-cm. cell; (2) 0.25 *M* $CHCl_3$–0.25 *M* quinoline *vs.* 0.25 *M* quinoline in 0.640-cm. cell; (3) 1 *M* $CHCl_3$–1 *M* quinoline *vs.* 1 *M* quinoline in 0.158-cm. cell; (4) 4 *M* $CHCl_3$–4 *M* quinoline *vs.* 4 *M* quinoline in 0.0374-cm. cell.

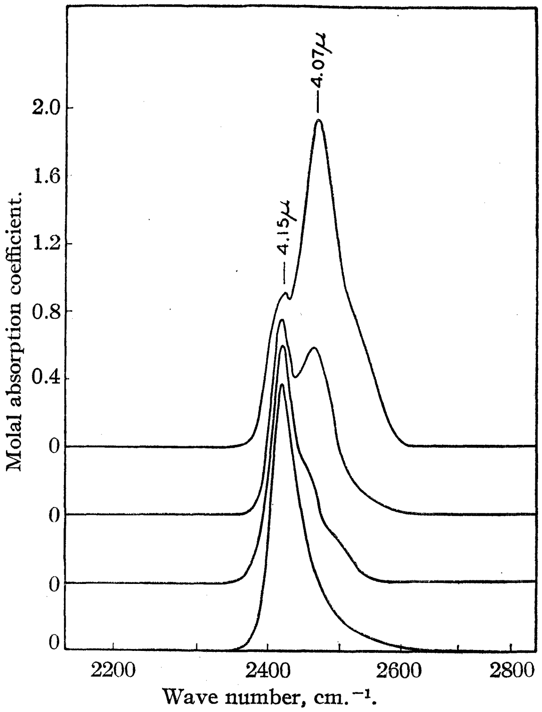

Fig. 4.—Acetone–$CHCl_3$: (1) 4 *M* $CHCl_3$ in CCl_4 *vs.* CCl_4 in 0.0374-cm. cell; (2) 0.25 *M* $CHCl_3$–0.25 *M* acetone *vs.* 0.25 *M* acetone in 0.640-cm. cell; (3) 1 *M* $CHCl_3$–1 *M* acetone *vs.* 1 *M* acetone in 0.158-cm. cell; (4) 4 *M* $CHCl_3$–4 *M* acetone *vs.* 4 *M* acetone in 0.0374-cm. cell.

Solutions containing various concentrations of chloroform and quinoline, chloroform and acetone, and chloroform and ether in carbon tetrachloride were studied. In Figs. 3, 4 and 5 the absorption due to chloroform only is plotted since the control cell in these experiments contained not the pure solvent but a solution containing the same concentration of the substance other than the chloroform of the pair that was being studied. In the solutions of chloroform and quinoline it was possible to observe the C–H absorption of the chloroform with precision. At low concentrations the absorption was of the same wave length and intensity as for solutions of chloroform alone in carbon tetrachloride. As the concentration was increased the absorption shifted toward longer wave lengths and increased in intensity. In a solution 4 molal with respect to chloroform and quinoline, the maximum absorption is at 3.37 μ as compared with 3.28 μ for chloroform alone and the height of the peak has increased nearly three-fold. This would appear to be conclusive evidence for the formation of a hydrogen bond between chloroform and quinoline. Upon inspection of Fig. 3,

---

[8] G. F. Zellhoefer, M. J. Copley and C. S. Marvel, This Journal, **60**, 1337 (1938).

one's attention is attracted immediately to the absorption at 4.15 μ. This absorption increases with increasing concentration but is shifted to shorter wave lengths, which is contrary to any previous behavior noted. The positive identification of this relatively weak absorption is necessarily not easy. It is presumably an overtone or combination frequency and, since it is about the same for bromoform, one suspects it to be connected with the hydrogen.

Voge and Rosenthal[9] have assigned the value 1225 cm.$^{-1}$ as the frequency in wave numbers of the perpendicular vibration in chloroform which involves mainly the hydrogen atom; 2400 cm.$^{-1}$ or 4.15 μ would therefore be a reasonable value for the second harmonic. The fact that this frequency is affected by complex formation is confirmatory of the foregoing. It is easy from a rather crude mechanical picture of the hydrogen bond to argue that, while the stretching frequency should be lowered, the bending frequency should be increased, when a hydrogen bond is formed. However, these conclusions must be admittedly tentative until confirmed by further study.

In solutions of acetone and quinoline the same results confirmatory of complex formation are obtained but they are of much smaller magnitude. While the fundamental C–H frequency shows marked increase in height, the shift in wave length is barely observable. Similarly the behavior of the 4.15 μ absorption is less striking. In solutions of ether and chloroform it is impossible because of the strong absorption of the ether to observe the C–H fundamental but the harmonic at 4.15 μ shows quite clearly the same behavior as for chloroform and quinoline.

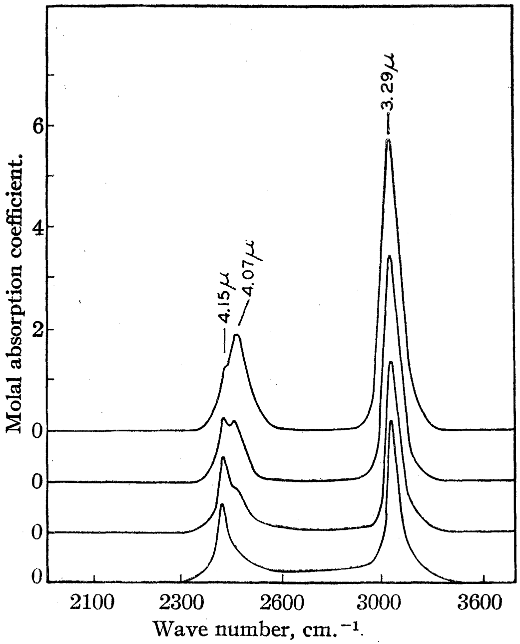

Fig. 5.—Ether–$CHCl_3$: (1) 4 *M* $CHCl_3$ in CCl_4 *vs.* CCl_4 in 0.0374-cm. cell; (2) 0.25 *M* $CHCl_3$–0.25 *M* ether *vs.* 0.25 *M* ether in 0.640-cm. cell; (3) 1 *M* $CHCl_3$–1 *M* ether *vs.* 1 *M* ether in 0.158-cm. cell; (4) 4 *M* $CHCl_3$–4 *M* ether *vs.* 4 *M* ether in 0.0374-cm. cell.

Summary

The tendency of hydrogen chloride and chloroform toward complex formation with ether and other substances through hydrogen bonding has been investigated. These two compounds stand at opposite extremes in the scale of activity of the hydrogen. The rule of Venkateswaran has been verified for the shift of the fundamental frequency of the hydrogen. An absorption band which shifts to shorter wave lengths upon bond formation has been observed in the case of chloroform and this absorption has been ascribed tentatively to the second harmonic perpendicular vibration of the hydrogen.

Methyl Tetronate, Methyl α-Chlorotetronate, Methyl α-Bromotetronate and Methyl α-Iodotetronate

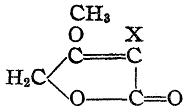
BY W. D. KUMLER

The tetronic acids are closely related structurally to ethyl acetoacetate and may be considered as derivatives of this compound. It is well known that when ethyl acetoacetate is treated with sodium and an alkyl halide the resulting substituted ethyl acetoacetate usually has the alkyl group attached to carbon. It was of interest to make some esters of the tetronic acids to see whether the alkyl group is attached to oxygen or to carbon. The first attempts at esterification of α-bromotetronic acid using dry hydrogen chloride and absolute alcohol failed,[1] and α-chlorotetronic acid resulted from the reaction. In a later experiment after passing hydrogen chloride through the solution for two weeks some evidence of esterification was obtained but the compound was not isolated in a pure state. Esterification by treating sodium α-bromotetronate with alkyl halides was not successful except in the case of *p*-nitrobenzyl bromide.[2] Diazomethane, however, reacted rapidly with all of the acids and the methyl esters that resulted could be isolated in a relatively pure state.

The carbon and hydrogen analysis in the case of methyl tetronate and the halogen analysis in the case of the other esters correspond to a lactone structure for the compounds and do not fit a hydroxycarboxylic acid ester structure. A methoxy estimation was carried out on the compounds to determine the position of the methyl group. If it is on the oxygen the percentage of methoxy found would be expected to be near the theoretical. If it is on the carbon the percentage found should be zero. The percentage of methoxy found shows that the compounds are oxygen esters.

	% Methoxy	
	Found	Calcd.
Methyl tetronate	25.6	27.2
Methyl α-chlorotetronate	19.6	20.9
Methyl α-bromotetronate	15.8	16.0
Methyl α-iodotetronate	12.6	12.9

The structure of these esters is then



where X is hydrogen, chlorine, bromine or iodine. This structure conforms to that found for the free acids and their salts.[2]

Experimental

The methoxy estimations were carried out using a semi-micro adaptation of the method of the British Pharmacopoeia, 1932. No empirical corrections were made for the incomplete precipitation of the alkyl iodide.[3]

The esters were prepared by suspending the corresponding acids in dry ether cooled to 0° and adding an excess of a solution of diazomethane in dry ether, also cooled to 0°. The excess diazomethane and ether was then evaporated on a steam-bath and the resulting ester crystallized from dioxane or methyl alcohol until a constant melting point was obtained.

Diazomethane was prepared from nitrosomethyl urea by Arndt's method.[4]

Methyl Tetronate.—M. p. 63°. *Anal.* Calcd. for $C_5H_6O_3$: H, 5.26; C, 52.6. Found: H, 4.96; C, 52.3.[5]

Methyl α-Chlorotetronate.—M. p. 66°. *Anal.* Calcd. for $C_5H_5O_3Cl$: Cl, 23.9. Found: Cl, 23.5.

Methyl α-Bromotetronate.—M. p. 116°. *Anal.* Calcd. for $C_5H_5O_3Br$: Br, 41.4. Found: Br, 41.1.

Methyl α-Iodotetronate.—M. p. 158°. *Anal.* Calcd. for $C_5H_5O_3I$: I, 52.9. Found: I, 52.6.

Summary

Methyl tetronate, methyl α-chlorotetronate, methyl α-bromotetronate and methyl α-iodotetronate have been made by the action of diazomethane on the corresponding acids. A methoxy estimation has been made on the compounds and this indicates that the methyl group is attached to oxygen and not to carbon. The structure of these esters is in accord with that previously found for the free acids and their salts.

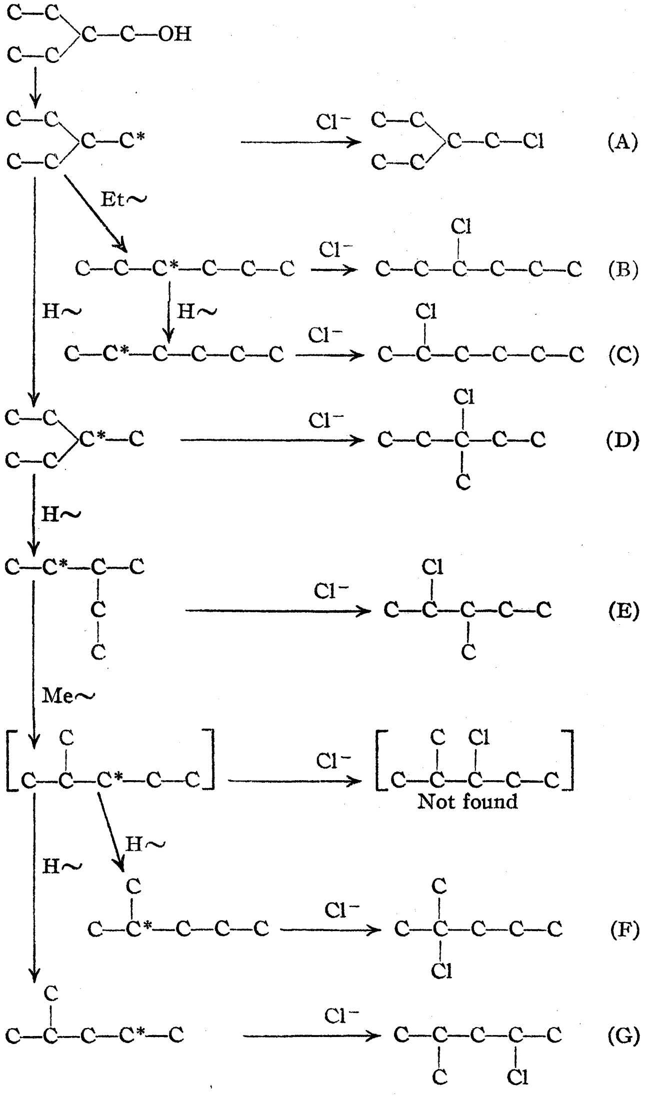
Alkyl Chlorides Obtained from 2-Ethyl-1-butanol

BY FRANK C. WHITMORE AND F. A. KARNATZ

In connection with work in this Laboratory on the course of rearrangements,[1] it was decided to study the conversion of an alcohol of the type R_2CHCH_2OH to the corresponding chloride. While considerable work has been done on the rearrangement of hydrogen during the preparation of halides,[2] there are very few recorded cases of the rearrangement of the carbon skeleton during the replacement of hydroxyl by halogen.[3] Mainly rearranged halides were obtained from *t*-butyl- and *t*-butylmethyl-carbinols.[4] Wallis and Bowman[5] found no primary chloride in the product of the reaction of 2-methyl-2-phenyl-1-butanol with thionyl chloride. No instance of skeletal rearrangement during the preparation of halides from an aliphatic carbinol of the type R_2CHCH_2OH was found in the literature.

When 2-ethyl-1-butanol was treated with zinc chloride and hydrochloric acid,[6] a complex mixture of isomers was obtained in 70–80% yield. The presence of the following hexyl chlorides was established: (A) 2-ethyl-1-chlorobutane, (B) 3-chlorohexane, (C) 2-chlorohexane, (D) 3-methyl-3-chloropentane, (E) 3-methyl-2-chloropentane, (F) 2-methyl-2-chloropentane and (G) 4-methyl-2-chloropentane. The following mechanism based on the concepts current in this Laboratory[1] is given as a possible explanation of the formation of these products. The carbon with only 6 electrons is indicated as C*. The transitory existence is assumed for only one fragment for which the corresponding chloride was not found, namely, $(CH_3)_2CHC^*HCH_2CH_3$. There is strong evidence for its momentary presence in the finding of two chlorides, the structures of which can be derived from it by simple migration of hydrogen. The failure of the formation of a chloride $(CH_3)_2CHCHClCH_2CH_3$ agrees with results obtained by F. Johnston[7] of this Laboratory in which attempts to form chlorides of this type from the corresponding alcohol gave almost entirely the tertiary chloride analogous to (F).



It was necessary to determine whether these rearrangements took place chiefly during, rather than after, the replacement of hydroxyl by chlorine. This was accomplished by putting a

sample of pure 2-ethyl-1-chlorobutane through exactly the same treatment that gave the above mixture from the alcohol. While there was some isomerization of the chloride, over 70% of it was recovered unchanged.

No rearranged halides were obtained by treatment of 2-ethyl-1-butanol with thionyl chloride, 2-ethyl-1-chlorobutane of high purity being isolated in over 80% yield. This result is of interest in contrast to the work of Wallis and Bowman[5] and also to the behavior of neopentyl alcohol, which gives only a 4% yield of unrearranged chloride when treated with thionyl chloride and pyridine.[8]

Experimental

Purification of 2-Ethyl-1-butanol.—The 2-ethyl-1-butanol used in this research was kindly furnished by the Carbide and Carbon Chemicals Corporation. It was purified by two fractionations through an efficient column of the total condensation type,[9] 107 × 2.1 cm., packed with glass helices. A total of 4605 g. of pure carbinol, b. p. 145° (727 mm.) –146° (732 mm.), $n^{20}_{\rm D}$ 1.4220–1, d^{20}_4 0.8326, was obtained from 12,270 g. of the commercial material; yield 37.5%. This gave an α-naphthylurethan, m. p. 63.5–64.5°, which melted at 63–64.5° when mixed with the α-naphthylurethan, m. p. 63–64°, made from a known sample of 2-ethyl-1-butanol obtained by the hydrogenation of ethyl diethylacetate.[10]

Anal. Calcd. for $C_{17}H_{21}NO_2$: N, 5.17. Found: N, 5.22.

Treatment of 2-Ethyl-1-butanol with Thionyl Chloride.—The method of Darzens[11] was used. Addition of 167 g. (1.4 moles) of thionyl chloride to a solution of 102 g. (1 mole) of 2-ethyl-1-butanol in 79 g. (1 mole) of dry pyridine required two hours. The mixture was heated for three and one-half hours at 60–90°; sulfur dioxide was evolved. The crude product was washed with dilute hydrochloric acid, dried with anhydrous potassium carbonate and fractionated to give 99 g. of pure 2-ethyl-1-chlorobutane (82% yield), b. p. 88° (225 mm.), $n^{20}_{\rm D}$ 1.4230, d^{20}_4 0.8914. Conversion to the Grignard compound and treatment with oxygen gave 2-ethyl-1-butanol; α-naphthylurethan, m. p. and mixed m. p., 63–64°.

The only constants found[12] for 2-ethyl-1-chlorobutane are: b. p. 125–127°, $d^{23.5}_{23.5}$ 0.881. The compound was obtained in only 11% yield by the action of 45% hydrochloric acid in a sealed tube at 100°. Rothstein[13] treated 2-ethyl-1-butanol with thionyl chloride and pyridine but gave no data for the product.

Treatment of 2-Ethyl-1-butanol with Hydrochloric Acid and Zinc Chloride.—Many runs were made in order to obtain sufficient product for fractionation; a typical run by our technique is described. One mole, 102 g., of 2-ethyl-1-butanol was added to a solution of 1.25 moles, 171 g., of fused zinc chloride in 2 moles, 202 g., of concentrated hydrochloric acid in a 3-necked flask fitted with a reflux condenser, mercury-seal stirrer, and gas inlet tube leading to the bottom of the flask. The flask was heated in a bath to 80–85° for six and one-half hours. A slow stream of hydrogen chloride was passed into the mixture for the last four hours.

The dark halide layer was separated and washed with 15 cc. of water and 10 cc. of 10% sodium carbonate solution; the color faded markedly on washing. The product was dried with anhydrous sodium sulfate and anhydrous potassium carbonate, and was fractionated from fresh carbonate at 160 mm. pressure to give several fractions.

Fraction	Wt., g.	B. p. (160 mm.), °C.	$n^{20}_{\rm D}$
1	9.0	56–67.7	1.4155
2	16.3	67.7–68.5	1.4180
3	16.6	68.5–69.5	1.4190
4	10.0	69.5–69.6	1.4196
5	14.9	69.6–70.5	1.4198
6	7.4	70.5–71.6	1.4198
7	5.9	71.6–72.7	1.4198
8	7.0	72.7–74.0	1.4195
9	6.5	74.0–75.0	1.4195
10	6.2	75.0–76.5	1.4192
11	3.0	?	1.4198
12	3.0	Residue	
	105.8		

The yield of mixed hexyl chlorides, b. p. 67.7–76.5° (160 mm.), was 90.8 g., or 75%.

The fractions from five such runs were refractionated by parts three times at 160 mm. pressure. In the final distillation, referred to as Distillation B, 297 g. of chlorides was separated into 44 fractions.

Identification of 2-Methyl-2-chloropentane (F).—Fraction 2 from Distillation B, 5.3 g., b. p. 63.5–64.0° (160 mm.), $n^{20}_{\rm D}$ 1.4138, was converted to the Grignard reagent and this was treated with phenyl isocyanate in ether solution. The dimethyl-*n*-propylacetanilide was identified by m. p. and mixed m. p. 70.5–74°.

Anal. Calcd. for $C_{13}H_{19}NO$: N, 6.84. Found: N, 6.89.

The known sample was prepared in the same way from known 2-methyl-2-chloropentane, b. p. 64.5–64.7° (160 mm.), $n^{20}_{\rm D}$ 1.4126, obtained by the action of hydrochloric acid on the corresponding carbinol.

Similarly, fraction 4 from Distillation B, 4.8 g., b. p. 64.7–65.5° (160 mm.), $n^{20}_{\rm D}$ 1.4140, was converted to the Grignard reagent and this was treated with α-naphthyl isocyanate. The α-naphthalide of dimethyl-*n*-propylacetic acid was identified by m. p. and mixed m. p. 116–118°.

Anal. Calcd. for $C_{17}H_{21}NO$: N, 5.49. Found: N, 5.35.

Identification of 4-Methyl-2-chloropentane (G).—Fractions 9–14 from Distillation B, 35.9 g., b. p. 65.5–67.5° (160 mm.), $n^{20}_{\rm D}$ 1.4150–74, were converted to the Grignard reagent and this was treated with oxygen. The crude product remaining after distillation of the ether was heated with a few crystals of iodine[14] to dehydrate any tertiary

carbinols. The residue was dried and was distilled from an 8-cc. distilling flask to obtain a fraction, weight 1.4 g., b. p. 115–128° (734 mm.), $n^{20}\mathrm{D}$ 1.4140. The α-naphthylurethan prepared from this material was found to melt at 94–95° after 2 crystallizations from ligroin and one from dilute alcohol. A mixture with the known α-naphthylurethan of 4-methyl-2-pentanol[15] of m. p. 93.5–94.5°[16] melted at 93.5–95°.

Another sample of crude carbinol, weight 1.68 g., b. p. 100–130° (735 mm.), was obtained in the same way from a similar cut of mixed chlorides, weight 65.0 g., b. p. 65.5–68.0° (160 mm.), $n^{20}\mathrm{D}$ 1.4158–80, from another distillation. This carbinol was oxidized to 4-methyl-2-pentanone with sulfuric acid and dichromate; semicarbazone, m. p. and mixed m. p. 127–131°. The known derivative was obtained from the ketone, b. p. 111–113° (738 mm.), $n^{20}\mathrm{D}$ 1.3967, prepared by the oxidation of synthetic 4-methyl-2-pentanol, b. p. 131° (738 mm.), $n^{20}\mathrm{D}$ 1.4111.

Identification of 3-Methyl-3-chloropentane (D).—A sample of chlorides from the fractionation before Distillation B, b. p. 69.5° (160 mm.), $n^{20}\mathrm{D}$ 1.4202, was converted to the Grignard reagent and this was treated with phenyl isocyanate. Purification gave crystals melting at 86.5–88.5°. A mixture with methyldiethylacetanilide of m. p. 87.5–89° similarly prepared from known 3-methyl-3-chloropentane[17] melted at 86.5–88.5°.

Anal. Calcd. for $C_{13}H_{19}NO$: N, 6.84. Found: N, 7.01.

Identification of 3-Methyl-2-chloropentane (E).—Fractions 29, 31 and 32 of mixed chlorides from Distillation B, wt. 22.9 g., b. p. 71.1–73.3° (160 mm.), $n^{20}\mathrm{D}$ 1.4198–201, were converted to the Grignard reagent and this was treated with oxygen. The crude carbinols were heated with a crystal of iodine[14] for two and one-half hours. The residue was dried and fractionated: (Distillation C).

Fraction	Wt., g.	B. p., °C.	Press., mm.	$n^{20}\mathrm{D}$
1	0.9	51–110	735	1.3900
2	1.2	128–132	735	1.4166
3	2.8	132–133	735	1.4188
4	1.4	?	Reduced	1.4190
5	1.3	Residue		

Yield of secondary hexanols was 5.4 g., or 28% of the theoretical. The α-naphthylurethan prepared from fraction 3 was found to melt at 72–72.5° after four crystallizations from ligroin and one from dilute alcohol. A mixture with a known sample of the α-naphthylurethan of 3-methyl-2-pentanol of m. p. 74.5–75.5°[18] melted at 72–75°. The known specimen was obtained from synthetic 3-methyl-2-pentanol, b. p. 132–132.5° (726 mm.), $n^{20}\mathrm{D}$ 1.4206.

A 1-cc. sample of fraction 3 of the above hexanols was oxidized to the ketones, which were fractionated and converted to 2,4-dinitrophenylhydrazones. A series of crystallizations of these from dilute alcohol gave first the impure derivative for hexanone-3 and then, from the mother liquor, the 2,4-dinitrophenylhydrazone of 3-methyl-2-pentanone, m. p. 67–71°. A mixture with a known sample, m. p. 70.5–72.5°,[19] prepared from a sample of ketone made by oxidation of the synthetic carbinol, melted at 69–72°.

By the same methods, fractions 33–36 of mixed chlorides from Distillation B, 23.9 g., b. p. 69.5–74.5° (160 mm.), $n^{20}\mathrm{D}$ 1.4188–94, were converted to the ketones. These were shaken with 15 cc. of a saturated solution of sodium bisulfite (to remove 2-hexanone, see below), and the addition compound was separated from uncombined ketones by dissolving it in water and extracting this solution with ether. The ether solution yielded a *m*-nitrobenzoylhydrazone melting at 143.5–144.5°. A mixture with a sample of m. p. 145–146° obtained from the known 3-methyl-2-pentanone melted at 144–145°.

Anal. Calcd. for $C_{13}H_{17}N_3O_3$: N, 15.99. Found: N, 15.97.

Identification of 3-Chlorohexane (B).—Fractions 37, 39, 41 and 42 of mixed chlorides from Distillation B, 24.8 g., b. p. 73.5–76.5° (160 mm.), $n^{20}\mathrm{D}$ 1.4187, were converted to the carbinols through the Grignard reagent. Fractionation gave (Distillation D): 1–2, 2.2 g., 34–123° (732 mm.), $n^{20}\mathrm{D}$ 1.370; 3–4, 3.5 g., 124–133.5°, 1.4144–1.4178; 5–6, 5.8 g., 133.5–141°, 1.4186; residue, 1.8 g.

Fractions 4 and 5 failed to give an α-naphthylurethan. The remaining portions of fractions 2, 3 and 4 from Distillation C (described under 3-methyl-2-chloropentane) and fractions 4, 5 and 6 above were combined and oxidized to the ketones. Fractionation gave at 730 mm. (Distillation E): 1, 1.2 g., 67–113°, 1.3978; 2, 1.3, 113–117°, 1.4010; 3, 1.7, 117–124°, 1.4030; 4, 1.0, 124–126°, 1.4080; residue, 1.1 g.

Fraction 2 gave the 2,4-dinitrophenylhydrazone of 3-hexanone, m. p. and mixed m. p., 146.5–148.5°.

Anal. Calcd. for $C_{12}H_{16}N_4O_4$: N, 20.00. Found: N, 19.89.

The known specimen was prepared from the ketone obtained by the oxidation of synthetic (Grignard) 3-hexanol, b. p. 133–134° at 740 mm.

All of the material of the proper boiling range obtained from Distillation B was consumed in unsuccessful attempts to isolate a second derivative for 3-chlorohexane. Hence, it was necessary to make 4 additional runs of 2-ethyl-1-butanol with hydrochloric acid and zinc chloride and to refractionate the hexyl chlorides by parts through column A. A sample of these chlorides, weight 60.1 g., b. p. 74–76° (160 mm.), $n^{20}\mathrm{D}$ 1.4190–97, was converted to carbinols through the Grignard reagent. These were dried and fractionated at 734 mm. pressure to give 5 fractions, 33.2 g., b. p. 131–145° (734 mm.), $n^{20}\mathrm{D}$ 1.4176–1.4210. The carbinols were oxidized to the ketones, washed with sodium bisulfite solution and fractionated. A fraction was obtained, 0.9 g., 110° (733 mm.), $n^{20}\mathrm{D}$ 1.4010, which gave the semicarbazone of 3-hexanone, m. p. and mixed m. p., 110.5–111.5°.

Identification of 2-Chlorohexane (C).—Fraction 4 of the ketones from Distillation E (described under 3-chlorohexane) gave the 2,4-dinitrophenylhydrazone of 2-hexanone, m. p. and mixed m. p., 106–107°.

The aqueous solution of the sodium bisulfite addition compound described under the identification of 3-methyl-2-

(16) Levene and Walti, *J. Biol. Chem.*, **94**, 369 (1931) give m. p. 86–89°; Brooks, THIS JOURNAL, **56**, 1999 (1934), gives m. p. 87–88°.

(17) Kindly furnished by D. E. Badertscher of this Laboratory.

(18) Cottle and Powell, THIS JOURNAL, **58**, 2270 (1936), give 72°.

(19) Drake and Veitch, *ibid.*, **57**, 2624 (1935), give 71.2°.

chloropentane was made alkaline with sodium carbonate and the liberated ketone was distilled. The semicarbazone prepared from this melted at 122–123.5°. A mixture with the known semicarbazone of 2-hexanone of m. p. 124–125° melted at 122.5–124°.

Identification of 2-Ethyl-1-chlorobutane (A).—Fraction 7 of the hexanols from Distillation D (described under 3-chlorohexane) gave the α-naphthylurethan of 2-ethyl-1-butanol, m. p. and mixed m. p. 63–64°.

Fraction 43 of the mixed chlorides from Distillation B, 13.5 g., b. p. 76.5–77.5° (160 mm.), $n^{20}\text{D}$ 1.4198, was shaken with 50 cc. of normal aqueous silver nitrate solution for three hours at room temperature to remove secondary and tertiary halides. The organic material was distilled from the mixture, separated, washed with carbonate solution, dried and fractionated. Treatment of the Grignard reagent with phenyl isocyanate gave crystals melting at 80.5–81.5°. Mixture with a known sample of β-ethylvaleranilide of m. p. 83–84° melted at 80.5–82.5°. The known specimen was prepared in the same way from a sample of 2-ethyl-1-chlorobutane made by the action of thionyl chloride on the carbinol.

Anal. Calcd. for $C_{13}H_{19}NO$: N, 6.84. Found: N, 6.93.

The other fractions were studied without obtaining any evidence for the presence of chlorides other than the seven identified.

Treatment of 2-Ethyl-1-chlorobutane with Zinc Chloride in Hydrochloric Acid.—One mole, 120.5 g., of 2-ethyl-1-chlorobutane, $n^{20}\text{D}$ 1.4228–30, prepared by the action of thionyl chloride and pyridine on 2-ethyl-1-butanol, was stirred vigorously with a solution of 1.25 moles, 171 g., of fused zinc chloride in 2 moles, 202 g., of concentrated hydrochloric acid at 79–87° for seven hours. The halide layer was separated, washed with water and carbonate solution, dried and fractionated. The yield of chlorohexanes recovered was 108.6 g., or 90.0% of the starting material. The yield of unchanged 2-ethyl-1-chlorobutane was 86.1 g.; this is 71.4% of the starting material and 79.2% of the recovered halides. The remainder was rearranged hexyl chlorides.

Approximation of the Percentage of Individual Hexyl Chlorides Present.—Only a rough estimate, based on fractionation data, can be given. 3-Methyl-3-chloropentane (D), present in 35–40% yield, was the most abundant isomer. 2-Chlorohexane (C), 2-methyl-2-chloropentane (F) and 3-methyl-2-chloropentane (E) were present in 5–10%; the remaining isomers, 1–5% each. It is quite possible that other hexyl chlorides, present in smaller quantities, were not identified.

Summary

1. 2-Ethyl-1-chlorobutane is produced by the action of thionyl chloride and pyridine on 2-ethyl-1-butanol without any detectable rearrangement.

2. The action of zinc chloride in hydrochloric acid solution on 2-ethyl-1-butanol gives at least seven different chlorohexanes, namely, 3-methyl-3-chloropentane, 2-methyl-2-chloropentane, 3-methyl-2-chloropentane, 4-methyl-2-chloropentane, 3-chlorohexane, 2-chlorohexane, and 2-ethyl-1-chlorobutane.

3. At least the major part of the rearrangements occurred during the formation of the chlorides.

[CONTRIBUTION FROM THE SCHOOL OF CHEMISTRY AND PHYSICS OF THE PENNSYLVANIA STATE COLLEGE]

Preparation and Properties of 2- and 3-Chloropentanes

BY FRANK C. WHITMORE AND F. A. KARNATZ

Much work has been done on the secondary chlorides and bromides of *n*-pentane.[1] In the present study, it was found that both 2-pentanol and 3-pentanol gave mixtures of 2- and 3-chloropentanes even with as mild treatment as the action of hydrogen chloride gas at room temperature. The amount of rearrangement was considerably less with 2-pentanol.

In order to obtain pure samples of 2- and 3-chloropentanes for the determination of physical constants, it was necessary to use thionyl chloride in the presence of pyridine.[2] There is evidence[3] that this reaction gives least rearrangement. Samples of the two chlorides were obtained, the properties of which showed a maximum difference; namely, for 2-chloropentane, $n^{20}\text{D}$ 1.4069 and d^{20}_{4} 0.8695, and for 3-chloropentane, $n^{20}\text{D}$

1.4104 and $d^{20}{}_4$ 0.8795. The boiling points, 96.8 and 97.8°, are too close together to be of any significance as criteria of purity.

The stability of the chlorides to heat was established by heating samples of them in sealed tubes to 100° for forty-eight hours without obtaining any significant change in refractive index. However, it was found that either chloride could be isomerized to an equilibrium mixture of the two by shaking it with $ZnCl_2$–HCl solution at room temperature for seventy-two hours. The composition of this mixture was about 80% 2-chloropentane.

The physical constants determined were

Experimental

Preparation of 3-Chloropentane.—A solution of 1 mole, 88 g., of 3-pentanol, b. p. 114.5–114.9° (730 mm.), $n^{20}\text{D}$ 1.4100, prepared from methyl formate and ethylmagnesium bromide, in 1.1 mole, 87 g., of dry pyridine, b. p. 113.3–114.5° (735 mm.), was treated with 1.3 moles, 154.8 g., of thionyl chloride (Eastman Kodak Co.), in the cold, over a period of fifty minutes. A heavy white precipitate formed. When addition was complete the ice-bath was removed, and after an hour the flask was warmed in a water-bath from 30 to 53° during two hours to drive off sulfur dioxide.

The reaction mixture, present as two brown layers, was poured on 200 g. of ice, and the layers were separated. The halide layer was washed with 10% sodium carbonate solution and dried. Fractionation at 731 mm. through a total condensation type column, 1.5 × 66 cm., packed with glass helices[4] gave a 46% yield of 3-chloropentane, b. p. 96°, $n^{20}\text{D}$ 1.4104, $d^{20}{}_4$ 0.8795. These values were checked in two similar runs.

Preparation of 2-Chloropentane.—The same procedure was used as for 3-pentanol. The 2-pentanol, 0.50 mole, b. p. 117.9–118.5° (739 mm.), $n^{20}\text{D}$ 1.4058, was prepared by the method of Sherrill, Baldwin and Haas.[1] The yield of 2-chloropentane, b. p. 95° (729 mm.), $n^{20}\text{D}$ 1.4068, was 28%. More non-volatile material was formed than with the 3-compounds.

Treatment of 3-Pentanol with Hydrogen Chloride.—The following is a description of a typical run. One mole, 88 g., of synthetic 3-pentanol, $n^{20}\text{D}$ 1.4100, b. p. 114.7–115.5° (734 mm.), and 10 g. of concentrated hydrochloric acid were saturated with hydrogen chloride at 0°; 25 g. was absorbed. After six weeks at room temperature, the solution was resaturated with hydrogen chloride at 0°; 17.5 g. was absorbed. After standing for an additional fourteen weeks, the layers were separated.

The colorless halide layer, washed with 10% sodium carbonate solution, dried first with sodium sulfate and then with potassium carbonate, was fractionated at 300 mm. to give an 84% yield of 2- and 3-chloropentanes, b. p. 69–69.3°, $n^{20}\text{D}$ 1.4092–1.4096. The constancy of the boiling point assured the absence of any compounds other than 2- and 3-chloropentanes. Judging from the refractive indices, the proportions were about 75% of the 3-chloro and 25% of the 2-chloro compounds.

A mixture of about this composition was obtained also in runs in which 0.01 mole of aluminum chloride, zinc chloride, or ferric chloride was added to the solution. The effect of these salts in this amount on the rate of the reaction was negligible.

Attempted Purification of 3-Chloropentane by Fractionation.—The best fractions from six runs of synthetic 3-pentanol with hydrogen chloride in sealed bottles, $n^{20}\text{D}$ above 1.4094, comprising 300 g., were combined and fractionated very carefully through column N[5] at atmospheric pressure. The time of the distillation was thirty-one and one-half hours. The refractive index of the product rose gradually as the fractionation proceeded but the highest value reached was 1.4100. This indicates that the isolation by distillation of *pure* 3-chloropentane from a mixture with 2-chloropentane is practically impossible.

Treatment of 3-Pentanol with $ZnCl_2$–HCl Solution.—An improved form[6] of the method of Lucas[7] was used. A solution of 2.2 moles, 300 g., of fused zinc chloride in 2.2 moles, 223 g., of concentrated hydrochloric acid was prepared in an ice-bath. This solution was put in a 500-cc. three-necked flask fitted with a stirrer, dropping funnel, and thermometer dipping into the solution. The flask was cooled in an ice–salt bath. One mole, 88 g., of synthetic 3-pentanol, $n^{20}\text{D}$ 1.4100, b. p. 114.3–114.7° (730 mm.), was added over a period of thirty minutes. After the mixture had been stirred for six hours, the dropping funnel was replaced with a gas inlet tube leading to the bottom of the flask, and a stream of hydrogen chloride was passed in with stirring for eight and one-half hours. The temperature of the mixture was kept below −1° throughout the reaction.

The halide layer was separated, washed with water and then with 10% sodium carbonate solution, and dried. Fractionation at 300 mm. gave an 81% yield of chloropentanes, b. p. 68.5–68.7° (300 mm.), $n^{20}\text{D}$ 1.4086–1.4093.

Treatment of 2-Pentanol with Hydrogen Chloride.—A sample of synthetic 2-pentanol, b. p. 117.3–118.3° (739 mm.), $n^{20}\text{D}$ 1.4056, was treated with hydrogen chloride at room temperature according to the procedure described for 3-pentanol. The product was fractionated at 738 mm. to give 8 fractions, b. p. 95–95.5°, $n^{20}\text{D}$ 1.4068–1.4071, $d^{20}{}_4$ 0.8696–0.8705. The yield of chloropentanes was 78.4%. The gradual changes in refractive index and density values show the presence of 3-chloropentane in 5–8% yield.

Identification of the Chlorides.—Samples of the chlorides were converted to the Grignard reagents and these

[4] Wilson, Parker and Laughlin, THIS JOURNAL, **55**, 2795 (1933).

[5] Laughlin, Nash and Whitmore, *ibid.*, **56**, 1396 (1934).

[6] Developed by W. H. James of this Laboratory.

[7] Lucas, THIS JOURNAL, **51**, 248 (1929).

were treated with phenyl isocyanate. The derivative obtained from 3-chloropentane was identified as diethylacetanilide, m. p. and mixed m. p., 125–128°. The derivative obtained from 2-chloropentane was methyl-*n*-propylacetanilide, m. p. and mixed m. p. 94–96°.

Stability toward Heat.—Samples of the two chlorides were heated in sealed tubes at 100° for forty-eight hours. No change in refractive index was noted for either 2- or 3-chloropentane.

Isomerization of Chlorides with $ZnCl_2$–HCl Solution.—A sample of 0.2 mole, 21.3 g., of 2-chloropentane, $n^{20}D$ 1.4069, was shaken with a solution of 0.4 mole, 54.5 g., of fused zinc chloride in 0.4 mole, 40.5 g., of concentrated hydrochloric acid for twenty-four hours at room temperature (26–28°). The layers were separated, and the halide was washed with water, dried, and fractionated to give: nos. 1–3, 15.5 g., 95.5–96° (732 mm.), $n^{20}D$ 1.4076; no. 4, 1.5 g.; residue, 1.4089. Fractions 1–3 were combined and shaken with the same $ZnCl_2$–HCl solution for an additional forty-eight hours. The halide was separated, washed, dried, and distilled as before. The product had an index of 1.4076.

A sample of 0.2 mole, 21.3 g., of 3-chloropentane, $n^{20}D$ 1.40965, was treated according to the same procedure. At the end of the full seventy-two hours, the chlorides had an index of 1.4077.

Judging from the refractive index of the equilibrium mixture obtained from either isomer, its composition is roughly 80% 2-chloropentane.

Determination of Physical Constants.—Refractive indices were measured with a Valentine precision refractometer (Abbe type) calibrated by the Bureau of Standards. Densities were determined with a 4-cc. pycnometer, using a constant temperature bath held within ±0.03 of 20.00°.

The Cottrell boiling points were found using 20-cc. samples of the pure chlorides and a copper–copel thermocouple in the apparatus at the Petroleum Refining Laboratory of The Pennsylvania State College.[8] The 2-chloropentane, $n^{20}D$ 1.40690 and $d^{20}{}_4$ 0.8695, gave the following boiling points at 760 mm.:

Initial—96.84°	20% off—96.88°
5% off—96.84°	40% off—96.88°

The 3-chloropentane, $n^{20}D$ 1.41035 and $d^{20}{}_4$ 0.8795, gave these boiling points at 760 mm.:

Initial—97.76°	20% off—97.82°
5% off—97.76°	40% off—97.82°

The freezing points were determined by cooling samples of the pure chlorides with liquid air. Great difficulty was encountered due to persistent supercooling of the compounds. This trouble was about equally bad whether a simple outfit consisting of a jacketed test tube, wire loop stirrer, and chromel–copel thermocouple or a more refined apparatus[9] at the Petroleum Refining Laboratory was used. The best values are −105–106° for 3-chloropentane and −137–139° for 2-chloropentane.

The viscosities were measured at 20.00° in a microviscometer which used a 3-cc. sample and had a constant of 59040 sec./stoke.[10] Pure samples of the 2- and 3-chloropentanes were used having $n^{20}D$ 1.40690, $d^{20}{}_4$ 0.8695, and $n^{20}D$ 1.41035, $d^{20}{}_4$ 0.8795, respectively. The values obtained, 0.5672 and 0.5845 centistoke, respectively, were checked within 0.1%.

Summary

1. Pure samples of the 2- and 3-chloropentanes were made by the action of thionyl chloride and pyridine on the corresponding alcohols.

2. Various physical constants of these chlorides were determined.

3. The chlorides were found to be stable to heat, but were isomerized to an equilibrium mixture by long shaking with $ZnCl_2$–HCl solution at room temperature.

4. Mixtures of the chlorides were obtained in all cases of the treatment of the carbinols with hydrogen chloride.

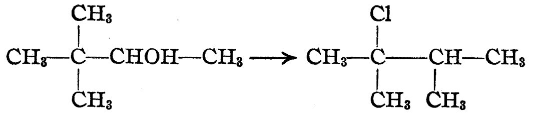
Pinacolyl Chloride from the Chlorination of Neohexane

BY FRANK C. WHITMORE, H. I. BERNSTEIN AND L. W. MIXON

Compounds of the type R_3CCHXR' were unknown prior to the present work. Several attempts have been made to prepare the simplest member of the series, pinacolyl chloride, from pinacolyl alcohol.[1] In each case, the product obtained was dimethylisopropylcarbinyl chloride.[2]



$$CH_3-\underset{CH_3}{\overset{CH_3}{C}}-CHOH-CH_3 \longrightarrow CH_3-\underset{CH_3}{\overset{Cl}{C}}-\underset{CH_3}{CH}-CH_3$$

Earlier workers therefore assumed pinacolyl chloride to be unstable, rearranging to give the tertiary chloride. In the present study, chlorination of neohexane, 2,2-dimethylbutane, gave 11% of the desired chloride, $(CH_3)_3CCHClCH_3$, which proved to be a stable secondary chloride. Refluxing and distillation at atmospheric pressure gave no change. With silver nitrate it behaved as a typical secondary alkyl chloride. It reacted with magnesium to give a Grignard reagent which was converted to a stable chloromercuri derivative. The relation of the preparation and properties of pinacolyl chloride to the rearrangement studies of this Laboratory is similar to that of neopentyl chloride.[3]

Neohexane was prepared from *t*-amyl chloride and methylmagnesium chloride. Chlorination gave, together with pinacolyl chloride, a good yield of *t*-amylcarbinyl chloride and some neopentylcarbinyl chloride.

Experimental

Preparation of Neohexane.—Methylmagnesium chloride was prepared from gaseous methyl chloride, 122 g. (5 moles) of magnesium and 1600 cc. of dry di-*n*-butyl ether. Addition of 610 cc. (5 moles) of *t*-amyl chloride in 1 liter of di-*n*-butyl ether was conducted at 50° for eight hours. Decomposition with ice and distillation of the ether layer gave impure hydrocarbon, b. p. 37–50°. Treatment with concd. sulfuric acid and refractionation produced pure neohexane in 36–39% yield, b. p. 49.5° (740 mm.), $n^{20}\mathrm{D}$ 1.3688.

Chlorination of Neohexane.—Chlorine was added to neohexane at salt–ice temperature until approximately half of the hydrocarbon had reacted. The excess hydrocarbon was removed by distillation. The yield of neohexyl chlorides was 67%. Higher chlorides appeared in only small amount.

Fractionation of Neohexyl Chlorides.—A 28-plate total condensation variable take-off column having a section of 262 × 1.2 cm. packed with glass helices was used. Fraction 1, 66.5 g., b. p. 109–110° (734 mm.), $n^{20}\mathrm{D}$ 1.4180, was pinacolyl chloride, identified by addition of oxygen to the Grignard compound[4] to give pinacolyl alcohol; phenylurethan, m. p. and mixed m. p. 78.5–79.5°. The constants for refractionated pinacolyl chloride are: b. p. (Cottrell) 109.9° (734 mm.), f. p. −0.9°, $n^{20}\mathrm{D}$ 1.4181, $d^{20}{}_4$ 0.8767. Fraction 2, 130.2 g., b. p. 113.5–115°, $n^{20}\mathrm{D}$ 1.4190, was largely *t*-amylcarbinyl chloride with a little neopentylcarbinyl chloride.

Preparation of Pinacolylmercuric Chloride.—The method of Marvel was used.[5] Recrystallization from dilute ethyl alcohol gave m. p. 88.5–90°. *Anal.*[6] Calcd. for $C_6H_{13}HgCl$: Hg, 62.5. Found: Hg, 63.3.

Summary

1. Neohexane was prepared in 36–39% yield from *t*-amyl chloride and methylmagnesium chloride.
2. Chlorination of neohexane gave 11% of pinacolyl chloride. *t*-Amylcarbinyl chloride and neopentylcarbinyl chloride were the chief products.
3. The preparation and stability of pinacolyl chloride accord with other work on molecular rearrangements.

Isomerization during the Preparation of *n*-Amyl Chloride

BY FRANK C. WHITMORE, F. A. KARNATZ AND A. H. POPKIN

Recent studies[1,2] have been made on the formation of isomeric chlorides by the action of zinc chloride and hydrochloric acid on methylneopentylcarbinol and on 2-ethyl-1-butanol. Formation of the equilibrium mixture of 2- and 3-chloropentane on treatment of either with zinc chloride and hydrochloric acid also has been reported.[3]

To determine whether isomerization could occur through the halide, *n*-amyl chloride prepared in 80% yields by the action of thionyl chloride on *n*-amyl alcohol in pyridine was treated with the same reagents. Only 3% of a mixture of 2- and 3-chloropentanes was isolated. The formation of more rearranged products during the replacement of hydroxyl by halogen than by similar treatment of the pure halide with zinc chloride and hydrochloric acid is significant.

The *n*-amyl chloride obtained from thionyl chloride was free from traces of isomerized chlorides, which is in agreement with previously recorded results.[4] The index of refraction $n^{20}\mathrm{D}$ 1.4128 was higher than the values of $n^{20}\mathrm{D}$ 1.41192[5] and 1.4120[6] in the literature. The *n*-amyl chloride recovered from the action of zinc chloride and hydrochloric acid on the pure *n*-amyl chloride had $n^{20}\mathrm{D}$ 1.4120. Moreover, the *n*-amyl chloride obtained from the treatment of *n*-amyl alcohol with zinc chloride and hydrochloric acid had a refractive index range of $n^{20}\mathrm{D}$ 1.4119–1.4121 which was raised to $n^{20}\mathrm{D}$ 1.4128 only after two refractionations through a 12-plate column.[7] It is apparent that the low refractive index values previously recorded for *n*-amyl chloride were due to traces of 2- and 3-chloropentanes.

The synthesis of *n*-amyl alcohol involved the preparation of a large quantity of *n*-butyl bromide by the action of sulfuric acid and hydrobromic acid on *n*-butyl alcohol. A careful investigation of the low boiling by-products gave no indication of the formation of rearranged products in this reaction.

Experimental

Action of Sulfuric Acid and Hydrobromic Acid on *n*-Butyl Alcohol.—*n*-Butyl bromide was prepared by the action of sulfuric acid and hydrobromic acid[8] on 12 moles of a very pure sample of *n*-butyl alcohol.[9] The product was fractionated at 731 mm. to give: fraction 1, 1.4 g., 93°, $n^{20}\mathrm{D}$ 1.4203; 2, 35.3, 96°, 1.4387; 3, 34.3, 98°, 1.4389; 4–5, 72.8, 99°, 1.4390; 6–15, 1270, 99–99.5° (734 mm.), 1.4390–1.4392.

To determine whether *s*-butyl bromide was present as rearranged product, fractions 1–5 were refractionated to give: 16, 7.7 g., 75–98° (734 mm.), $n^{20}\mathrm{D}$ 1.4352; 17, 10.7, 98°, 1.4389; 18–19, 113.8, 99.4–100.0°, 1.4392. Fraction 16 was then refractionated to give: 20, 0.56 g., $n^{20}\mathrm{D}$ 1.4102; 21, 0.9, 1.4366; 22, 0.4, 1.4385. The fractionation was conducted at a vapor velocity too low for significant temperature reading but the refractive index of fraction 20 indicates the depression in the indices to be due to a small amount of olefin with no indication of the presence of *s*-butyl bromide.

Preparation of *n*-Amyl Alcohol.—*n*-Butylmagnesium bromide was prepared by the addition of 685 g. (5 moles) of *n*-butyl bromide to 122 g. of magnesium in 1500 cc. of ether. The Grignard reagent was cooled to salt–ice temperature, a liter of ether added and formaldehyde, generated from paraformaldehyde at 175° and passed through a heated tube, was added until no further test for Grignard reagent was obtained. The complex was decomposed on ice and the product steam distilled. The resulting oil layer was washed with sodium bisulfite solution and dried over anhydrous potassium carbonate. Fractionation at 733 mm. gave: fractions 1–3, 19 g., 129–134°, $n^{20}\mathrm{D}$ 1.3972–1.4081; 4–22, 274 g., 136°, 1.4093; residue 11 g., yield 68%. A similar run was completed and all fractions of constant boiling point and constant refractive index were combined and refractionated at 100 mm. to give a forerun of two fractions, 15 g., 86°, $n^{20}\mathrm{D}$ 1.4080–1.4097; twenty-eight fractions, 87°, 1.4093, and weight 396 g. The constants for pure *n*-amyl alcohol were: 136.8° (734 mm.), 137.8° (760 mm.), using a Cottrell apparatus;[10] $n^{20}\mathrm{D}$, 1.40988 ± 0.00005;[11] freezing point, −78.24°, and d^{20}_4 0.8144.

Action of Zinc Chloride and Hydrochloric Acid on *n*-Amyl Alcohol.—A solution of 819 g. (6 moles) of fused zinc

[3] This suggested the possibility of obtaining 2- and 3-chloropentane as by-products in the preparation of *n*-amyl chloride from the alcohol, zinc chloride and hydrochloric acid. Synthetic *n*-amyl alcohol was treated with zinc chloride and hydrochloric acid to give a 57% yield of *n*-amyl chloride. A 10% yield of a mixture of 2- and 3-chloropentanes was isolated from the low boiling products.

chloride in 606 g. of concentrated aqueous hydrochloric acid was heated for twelve hours at 113–128° with 264 g. (3 moles) of *n*-amyl alcohol. Stirring was conducted rapidly during reaction with vigorous refluxing. The amyl chloride layer was separated, washed with distilled water and a 10% solution of potassium carbonate. The chloride was then dried and fractionated at 736 mm. to give: 1, 2.0 g., 37–91°, $n^{20}\mathrm{D}$ 1.3894; 2, 19, 91–99°, 1.4092; 3, 22, 100–104°, 1.4112; 4, 22.2, 104–105°, 1.4117; 5–10, 105–106.5° (739 mm.), 183.1 g., 1.4119–1.4122. The 183.1 g. (57% yield) of fractions 5–10 was *n*-amyl chloride.

Fractions 2, 3 and 4 were refractionated at 733 mm. to give: 11, 1.2 g., 71–92.2°, $n^{20}\mathrm{D}$ 1.4032; 12, 9.8, 93.2°, 1.4082; 13, 13.2 g., $n^{20}\mathrm{D}$ 1.4092; 14, 11.5, 1.4112; 15, 7.4, 1.4122. Fractions 12, 13 and 14 were again refractionated at 735 mm. to give: 16, 1.5 g., 90–95°, $n^{20}\mathrm{D}$ 1.4071; 17, 11.2, 95°, 1.4084; 18, 11.7, 96°, 1.4092; 19, 2.8, 96–102°, 1.4110; 20, 4.1, $n^{20}\mathrm{D}$ 1.4120; residue, 1.5 g. Fraction 2 was converted to the Grignard reagent, treated with phenyl isocyanate and the complex decomposed with ice and hydrochloric acid. The ether layer, after many recrystallizations from ethyl alcohol, gave methyl-*n*-propylacetanilide, m. p. and mixed m. p. 95–96°, proving the presence of 2-chloropentane. Fractional crystallization of the crystals from the mother liquor yielded a product, m. p. 121–122.5°, which when mixed with known diethylacetanilide, m. p. 127–128°, gave a mixed m. p. of 122–125°. This indicated the presence of 3-chloropentane.

To verify the mixed melting point for diethylacetanilide, the following microscopic analysis was made.[12] The known diethylacetanilide, melting at 127–128°, crystallized in needles from ethyl alcohol (system probably triclinic), gave negative elongation and the following refractive indices (approximate, white light): η_α 1.516–1.519, η_β 1.535–1.540, η_γ 1.627–1.628; sign +, 2V = 32° and extinction angle 26°. The crystal analysis for the diethylacetanilide obtained from the rearranged 3-chloropentane, 121–122.5°, was identical with that of the known, above. Crystal analysis for methyl-*n*-propylacetanilide yielded: $\eta_\alpha > 1.520$, η_γ 1.625–1.630 for white light; sign +, negative elongation and parallel extinction.

Preparation of Pure *n*-Amyl Chloride.—*n*-Amyl chloride free from 2- and 3-chloropentanes was prepared by treating commercial (Sharples) *n*-amyl alcohol in pyridine with thionyl chloride.[13] A solution of 440 g. (5 moles) of fractionated commercial *n*-amyl alcohol, 136° (732 mm.), $n^{20}\mathrm{D}$ 1.4107–1.4109, in 435 g. (5.5 moles) of fractionated commercial pyridine, 113.0° (735 mm.), $n^{20}\mathrm{D}$ 1.5097, was treated with 772.5 g. (6.5 moles) of thionyl chloride at −10°. The reaction mixture was warmed to 104° during six hours and that temperature maintained for one and one-half hours. Sulfur dioxide was liberated at 73–104°. Three similar preparations of varying quantities of reactants failed to yield a sharp decomposition temperature for the alcohol–thionyl chloride complex. Decrease in the rate of thionyl chloride addition to one and three-fourths hours per mole and increase in length of heating period to five hours per mole did not improve the yield of chloride.

The crude chloride was separated in the usual way and fractionated to give at 741 mm.: fractions 1–3, 24.2 g., 106–106.5°, $n^{20}\mathrm{D}$ 1.4122–1.4123; 4–14, 394.7, 106.5°, 1.4126–1.4128; 15, 5.1, 106.5°, 1.4130; residue 56 g. The total halide formed, 424 g., was *n*-amyl chloride in 80% yield. The three additional preparations using thionyl chloride also gave *n*-amyl chloride, $n^{20}\mathrm{D}$ 1.4126–1.4128. The constants for refractionated *n*-amyl chloride were: b. p. 106° (725 mm.), $n^{20}\mathrm{D}$ 1.41280 ± 0.00005, $d^{20}{}_4$ 0.8828; *MR*, calcd., 30.15; obsd., 30.08.

Reaction of *n*-Amyl Chloride with Zinc Chloride and Hydrochloric Acid.—All fractions of *n*-amyl chloride having values of $n^{20}\mathrm{D}$ 1.4126–1.4128 were combined and refractionated through column A to give at 741 mm.: 1, 0.5 g., 91°, $n^{20}\mathrm{D}$ 1.4134; 2–3, 5.9, 96°, 1.4127; 4, 1.2, 102°, 1.4127; 5–19, 503.4, 106°, 1.4127; 20–25, 229.3, 106°, 1.4128. Into a two-necked two-liter round-bottomed flask was placed a solution of 819 g. (6 moles) of zinc chloride in 606 g. of concentrated aqueous hydrochloric acid. To this was added rapidly 319.5 g. (3 moles) of *n*-amyl chloride of fractions 7–11 and 13–17, above. The temperature of the bath was kept at 126–134° for twelve hours with vigorous stirring and rapid refluxing. The resulting chloride layer was separated, washed with distilled water, and a 10% solution of sodium carbonate. The chloride was dried and fractionated at 740 mm. to give: 1, 0.5 g., 32–50°, $n^{20}\mathrm{D}$ 1.3837; 2, 3.9, 50–96°, 1.4085; 3, 9.0, 96–103°, 1.4108; 4, 6.5, 103–105°, 1.4108; 5–6, 16.4, 105°, 1.4109; 7–11, 39.8, 105.2°, 1.4110–1.4114; 12–22, 194.9, 104.5–105.5° (732 mm.), 1.4118–1.4120; residue, 3.5 g.; 14 g. of olefin was collected in a dry ice–acetone trap.

Fractions 2–11 were combined and fractionated at 741 mm. to give: 23, 1.5 g., 56–90°, $n^{20}\mathrm{D}$ 1.4012; 24, 4.6, 1.4086; 25, 4.3, 101–103°, 1.4100; 26, 3.6, 104–105°, 1.4106; 27, 4.4, 105°, 1.4110; 28, 105–106°, 14.2, 1.4119. The remainder was *n*-amyl chloride. Based on fractions 24, 25 and part of 26, the yield of rearranged product is 3%. Fraction 24 was converted to the Grignard reagent, treated with phenyl isocyanate, and worked up in the usual manner. After many crystallizations from ethyl alcohol, methyl-*n*-propylacetanilide was obtained, m. p. and mixed m. p. 95–96°, proving the presence of 2-chloropentane. 3-Chloropentane was also probably present as an isomerization product.

Summary

1. The action of zinc chloride and hydrochloric acid on *n*-amyl alcohol produces *n*-amyl chloride in 57% yield and 10% of a mixture of 2- and 3-chloropentanes.

2. The action of zinc chloride and hydrochloric acid on *n*-amyl chloride yields 3% of a mixture of 2- and 3-chloropentanes.

3. The action of thionyl chloride on *n*-amyl alcohol in pyridine gives *n*-amyl chloride in 80% yield with no rearranged products.

4. A corrected refractive index for *n*-amyl chloride, free of traces of 2- and 3-chloropentanes, is recorded.

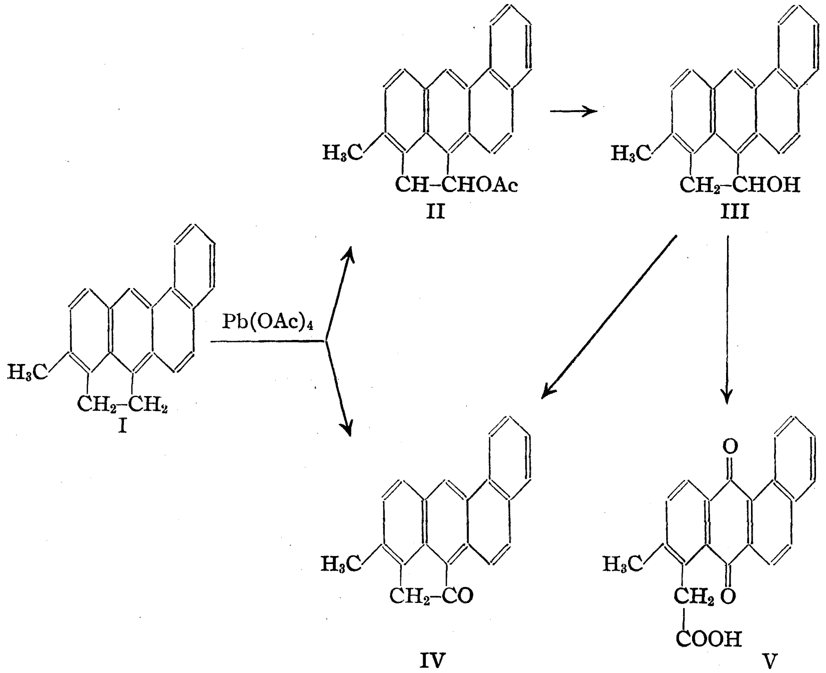
The Oxidation of Methylcholanthrene and 3,4-Benzpyrene with Lead Tetraacetate; Further Derivatives of 3,4-Benzpyrene

BY LOUIS F. FIESER AND E. B. HERSHBERG[1]

In a recent paper[2] we reported that on treatment with lead tetraacetate 1,2-benzanthracene is converted into the 10-acetoxy derivative, 10-methyl-1,2-benzanthracene is attacked in the methyl group giving 10-acetoxymethyl-1,2-benzanthracene, and 1,2,5,6-dibenzanthracene is more resistant to oxidation by the reagent and under comparable conditions is largely recovered unchanged. This specific oxidation reaction provides a means of distinguishing between hydrocarbons of varying degrees of reactivity and of locating a reactive center in a hydrocarbon molecule whether this is in an aromatic nucleus or a side chain. Thus far nuclear oxidation by the reagent has been observed only in the case of the *meso*-acetoxylation of anthracene[3] and 1,2-benzanthracene,[2] and the known examples of the oxidation of an alkyl residue by lead tetraacetate all involve acetoxylation at an activated α-position in a side chain or side ring. The reaction with 10-methyl-1,2-benzanthracene[2] is one instance of the latter type of oxidation, and similar reactions have been observed with toluene,[4] acenaphthene,[5] and tetralin.[6]



On investigating methylcholanthrene and 3,4-benzpyrene, it was found that these powerfully carcinogenic hydrocarbons are highly susceptible to attack by lead tetraacetate. 3,4-Benzpyrene is oxidized rapidly at room temperature in acetic acid–benzene and converted in over 90% yield into a new monoacetoxy derivative. Methylcholanthrene is even more susceptible to attack and in the most satisfactory procedure, adopted because of the sensitivity of the reaction products, the oxidation was conducted under ice cooling. One reaction product, isolated only in small amounts when one equivalent of oxidizing agent was employed, is a rather sparingly soluble and high melting substance having the composition of a keto derivative of methylcholanthrene. The chief product was an acetoxy derivative, and on hydrolysis it gave a neutral alcohol. A relationship between the two substances was easily established, for the alcohol was found to yield the ketone on careful oxidation with sodium dichromate. Further oxidation with the same reagent gave a yellow anthraquinone (vat test) having an acidic group, and this proved to be identical with

6-methyl-1,2-benzanthraquinone-5-acetic acid (V). Cook and Haslewood[7] obtained this acid by the oxidation of methylcholanthrene with sodium dichromate in boiling acetic acid and established the structure by decarboxylation to 5,6-dimethyl-1,2-benzanthraquinone. A comparison of our acid with a sample prepared in this way was made through the sharply melting methyl ester.[8] The alcohol and ketone therefore have the structures III and IV, the oxygen atom being located at the 15-position. Cook and Haslewood evidently had the ketone IV (m. p. 262–263°, corr.) in hand in an impure condition, for they observed that when the hydrocarbon is shaken with dichromate solution at room temperature it is changed into a substance of different crystalline form. They state that "This substance, m. p. 228–229° (dec.), probably an intermediate ketone, was not purified on account of its instability." On repeating the experiment, we found that by repeated crystallization a pure substance can be isolated and that it is identical with 15-keto-20-methylcholanthrene described above. The same ketone is therefore produced by both oxidizing agents. Whether or not the alcohol or its acetate is in each case a precursor of the ketone, the observed acetoxylation in the 15-position must be regarded as an important primary step revealing the site in the molecule most susceptible to oxidation. An oxidizing agent which introduces a hydroxyl group in a protected condition has obvious advantages for the study of primary changes.

15-Hydroxy- and 15-keto-methylcholanthrene are being tested for carcinogenic activity by Dr. M. J. Shear. The analogous alcohol, 10-hydroxymethyl-1,2-benzanthracene, has given a few subcutaneous tumors in mice[9] (slowly). Both the new alcohol, which has an asymmetric carbon atom, and the ketone present many possibilities for the preparation of additional derivatives of interest, and these are being investigated. As shown in Fig. 1, the absorption curve for 15-hydroxy-20-methylcholanthrene is very similar in form to that of the parent hydrocarbon except for a slight displacement of lower values of the extinction coefficient. The determinations, which were carried out in ether solution, using a Spekker photometer, were kindly made by Dr. George I. Lavin of the Rockefeller Institute.

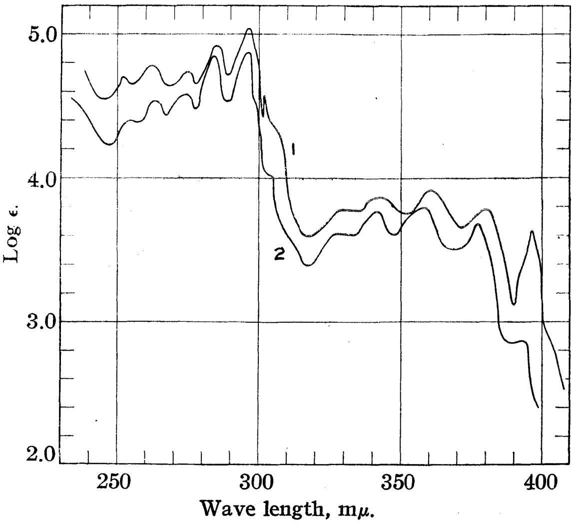

Fig. 1.—Curve 1, 20-methylcholanthrene (I); curve 2, 15-hydroxy-20-methylcholanthrene (III).

Observations concerning the structure and properties of the new acetoxy-3,4-benzpyrene will be reported in a later paper. Another substitution reaction studied is the condensation of the hydrocarbon with methylformanilide in the presence of phosphorus oxychloride in *o*-dichlorobenzene solution.[10] This gave in 90% yield a single, pure aldehyde, and on reduction by the Wolff–Kishner method the aldehyde yielded a methyl-3,4-benzpyrene different from any of the isomers hitherto known but identical with one of two isomers obtained synthetically from the recently described 2,1′-trimethylene-1,9-benzanthrone-10[11] (VI). It is known[12] that in the reaction of benzanthrone itself with various Grignard reagents addition may occur to the carbonyl group, giving a carbinol, and also to the 1,4-conjugated system formed by the carbonyl group and the adjacent nuclear double bond of the naphthalene nucleus. The primary product of 1,4-addition must be a dihydrobenzanthrone, but this evidently undergoes oxidation at some stage, probably in the course of working up the mixture, for the product isolated is a 4-aryl- or 4-alkyl-benzanthrone. We investigated the action of methyllithium on the trimethylenebenzanthrone VI, and from the resulting mixture isolated in 21% yield a pure, crystalline product having the composition of a methyl derivative of the trimethylenebenzanthrone. The analysis shows that the substance is

a product of addition to a conjugated system rather than to the carbonyl group, and in analogy with benzanthrone the probable structure is that of formula VII. It is perhaps conceivable that 1,4-addition occurs to the alternate conjugated system and that the methyl group is at the 4′-position, but this possibility is eliminated by the observation that the hydrocarbon obtained on zinc dust distillation is quite different from the known 4′-methyl-3,4-benzpyrene.[13] The new hydrocarbon therefore can be regarded with reasonable confidence as 6-methyl-3,4-benzpyrene (VIII). After careful removal of the crystalline product from the reaction with methyllithium, zinc dust distillation of the residual oil gave, after purification through the trinitrobenzene derivative, another methylbenzpyrene. This must have come from a carbinol, although in the small-scale experiment the intermediate was not isolated, and the position of the methyl group probably corresponds with that of the carbonyl group of the starting material. A certain assurance is provided by the fact that the final hydrocarbon differs from the 2′-,[11] 3′-,[11] 4′-[13] and 6-isomers, and the substance therefore is regarded as 5-methyl-3,4-benzpyrene (IX). That the same hydrocarbon was obtained from the aldehyde indicates, at least provisionally, that this has the structure X and that in the reaction with methylformanilide 3,4-benzpyrene is substituted at the 5-position. The compounds are being tested for carcinogenic properties by Dr. Shear.[14]

The smooth reaction of 3,4-benzpyrene with methylformanilide illustrates the susceptibility of the hydrocarbon to substitution but provides little distinction in reactivity between this hydrocarbon and pyrene,[10] anthracene,[15] and 1,2-benzanthracene,[15] which also give aldehydes in good yield under comparable conditions. From the present knowledge of the condensation one can say only that 3,4-benzpyrene is more reactive to the reagent than 1,2,5,6-dibenzanthracene, which gives no aldehyde even under forcing conditions,[15] and perhaps that it is also more reactive than 1,2-benzanthracene.[15] In the oxidation experiments with lead tetraacetate 3,4-benzpyrene and methylcholanthrene appear, from qualitative observations of the temperature at which reaction occurs and from the yields, to be distinctly more reactive than any of the hydrocarbons just mentioned or than 10-methyl-1,2-benzanthracene. Both the aldehyde reaction and the oxidation are substitutions, as is the recently reported diazo coupling.[16] The color reaction with benzenediazonium chloride provides a highly sensitive and selective means of recognizing hydrocarbons of particularly highly developed reactivity, and in this test 3,4-benzpyrene and methylcholanthrene stand out in sharp contrast to 1,2-benzanthracene, 10-methyl-1,2-benzanthracene, anthracene, pyrene and in fact to all other polynuclear hydrocarbons examined except those which, like methylcholanthrene, contain an aceanthrene nu-

---

(13) Fieser and Fieser, THIS JOURNAL, **57**, 782 (1935).

(14) From 36 strain A mice given a subcutaneous injection of 10 mg. of crystalline 4′-methyl-3,4-benzpyrene,[13] Dr. Shear obtained 17 tumors, and the average induction time was 28 weeks. At the same dosage, 4′-methyl-1′,2′-dihydro-3,4-benzpyrene[13] gave 5 tumors in 27 strain A mice in an average induction time of 34 weeks. That Domagk, *Med. Chem.*, **3**, 274 (1936), found the compound inactive in a skin painting experiment may mean either that the hydrocarbon belongs to the type much more active to subcutaneous tissue than to the skin or that aromatization occurs in contact with one tissue but not the other.

(15) Fieser and Hartwell, THIS JOURNAL, **60**, 2555 (1938).

cleus. At the time of observing the diazo coupling of methylcholanthrene, the obvious assumption in the absence of evidence was that substitution occurs in the nucleus, probably at the available meso position, but this assumption seems questionable in the light of information which has accumulated in the meantime. The corresponding meso position of 1,2,5,6-dibenzanthracene and of 10-methyl-1,2-benzanthracene is now known to be highly hindered and not readily amenable to substitution,[2,15] and there is little reason to suppose that coupling can occur at other nuclear positions. The lead tetraacetate reaction, however, discloses the fact that a methyl or methylene group attached to the 10-meso position of the 1,2-benzanthracene nucleus constitutes a highly reactive center, and the possibility that diazo coupling occurs at the methylene group of the cholanthrenes merits consideration. The greater reactivity of hydrocarbons having in this position the methylene group of a five-membered ring, as compared with the corresponding methyl compounds, is understandable on the basis of this hypothesis, and a ready explanation is at hand of the common property exhibited by all of the hydrocarbons derived from aceanthrene.

It was pointed out previously[16] that methylcholanthrene is rather sluggish, as compared to structurally related hydrocarbons, in the addition reaction with maleic anhydride[17] and in the catalyzed addition of hydrogen.[18] According to a personal communication from Dr. W. E. Bachmann, 3,4-benzypyrene, if able to add maleic anhydride at all, at least does so far less readily than anthracene and 1,2-benzanthracene. High reactivity, however, is displayed by both of these potent carcinogens in three substitutions of entirely different types. It is important to know how various hydrocarbons compare in the relative degree of susceptibility to substitution, and an approximate estimate can be made from present data on the assumption that all three of the observed reactions are manifestations of the same kind of reactivity. The aldehyde reaction is the least selective of the tests and shows little that is not recognized from other results. The oxidation experiments reveal the course of a typical substitution and indicate that 10-methyl-1,2-benzanthracene reacts in the same way as methylcholanthrene but does so somewhat less readily. The diazo coupling tests emphasize this difference in reactivity, for the pentacyclic hydrocarbon couples and the tetracyclic compound does not. From the results of oxidation it appears that in the highly selective coupling test a moderate difference in the degree of reactivity is considerably magnified. In view of the response of the 10-methyl compound to one reagent, its failure to respond to another reagent under certain restricted conditions can no longer be taken as an indication that it lacks appreciable susceptibility to substitution.

The special significance of these observations is that there are certain points of correspondence between the chemical reactivity of the hydrocarbons in substitutions and their carcinogenic activity. The order of chemical reactivity indicated by the above tests is: methylcholanthrene and 3,4-benzypyrene > 10-methyl-1,2-benzanthracene and 5,10-dimethyl-1,2-benzanthracene > 1,2,5,6-dibenzanthracene. The order of carcinogenic potency, as judged by all available criteria, is exactly the same.[19] The biological tests of simpler models of the methylcholanthrene molecule investigated in this Laboratory and of various other alkyl derivatives of 1,2-benzanthracene synthesized in London and at Harvard have brought out the importance, to the development of carcinogenic properties, of the presence of a methyl or methylene group attached to a meso carbon atom of the parent hydrocarbon, particularly at position 10; the course of the oxidation of methylcholanthrene shows that the side chain attached to the meso position 10 is the most reactive center in the molecule.[20] The superior biological potency of the cholanthrenes as compared with simpler model compounds is reflected in the distinctly higher chemical reactivity of the hydrocarbons containing the five-membered ring. Perhaps the most striking circumstance is that outstanding chemical reactivity of a special kind is encountered in the two compounds which surpass all other known hydrocarbons in the rapidity, as well as regularity, with which they induce tumors in various species and tissues of test animals. It is remarkable that substances of such distinctly different structural types as methylcholanthrene

[19] For a review and analysis of the biological and chemical data on hydrocarbon carcinogenesis, see Fieser, *Am. J. Cancer*, **34**, 37 (1938).

[20] The reactivity manifested at this position is probably attributable to activation by the highly unsaturated center at the end of the quinonoid system of linkages, contrasting with the weaker activating influence on the alternate methylene group exerted by the terminal benzenoid ring.

and 3,4-benzypyrene both belong to the very small group of hydrocarbons capable of coupling rapidly with diazotized *p*-nitroaniline and that they show similar susceptibility to oxidation with lead tetraacetate, even though substitution occurs in one case in the nucleus and in the other in a side chain. That these unusual substances are also endowed to a high degree with the specific ability to initiate malignant growth in animal tissue may not be a mere coincidence. The relationships now observable suggest that the administered carcinogen may undergo some form of substitution reaction, possibly akin to a hydroxylation, and that this constitutes an important step in a complicated chain of events leading eventually to carcinogenesis.[21]

Experimental Part[22]

Oxidation of Methylcholanthrene.—A solution of 3.4 g. of lead tetraacetate in 100 cc. of glacial acetic acid was added dropwise in the course of one hour to a mechanically stirred solution of 2 g. of methylcholanthrene in 200 cc. of benzene, while cooling the reaction mixture with an ice-bath. The solution gradually turned deep orange during the period of the addition and when this had been completed the volume was reduced to about one-third the original by concentration at a pressure of 15–20 mm. and a temperature below 40°. Water was added and the precipitated solid was collected, washed with water, and dried in vacuum at 50°. The product was taken into acetone and after treatment with decolorizing carbon the solution was concentrated to a volume of about 100 cc. and allowed to stand overnight. The crystallizate amounted to 0.14 g. (7%) and consisted of crude **15-keto-20-methylcholanthrene (IV)**, m. p. 230–245°. Three crystallizations from acetone and one from glacial acetic acid gave yellow needles melting constantly at 262–263°. The substance is insoluble in alkali and does not give a vat test.

Anal. Calcd. for $C_{21}H_{14}O$: C, 89.34; H, 5.00. Found: C, 89.18; H, 4.89.

The acetone mother liquors remaining after the removal of the ketone were concentrated and twice treated with ligroin (60–70°) and evaporated. The acetone–ligroin solution then deposited 0.88 g. of **15-acetoxy-20-methylcholanthrene (II)**, m. p. 172–174°, dec., which when recrystallized afforded 0.78 g. of material, m. p. 177.5–178.5°, dec. From the mother liquors there was obtained 0.34 g. of acetate, m. p. 175–177°, dec., making a total yield of 46%. After three crystallizations from acetone–ligroin the acetate formed pale yellow needles melting constantly at 179.5–180.5°, with gas evolution.

Anal. Calcd. for $C_{23}H_{18}O_2$: C, 84.62; H, 5.59. Found: C, 84.50; H, 5.45.

On using two moles of lead tetraacetate the yield of ketone was increased slightly but the acetate was gummy and more difficult to purify.

15-Hydroxy-20-methylcholanthrene (III).—A suspension of 0.5 g. of acetoxymethylcholanthrene in 100 cc. of methanol containing 0.5 g. of potassium hydroxide was refluxed on the steam-bath. The solid dissolved rapidly and after about twenty minutes needles of the free alcohol began to form. After one hour the mixture was cooled and the solid collected, washed with dilute methanol, dilute acid, and water. Dried in vacuum, the solid weighed 0.31 g. (71%) and melted at 207–209° with decomposition (gas evolution). Two crystallizations from acetone–ligroin gave fluffy, very pale yellow needles, m. p. 209–211°, dec.

In another experiment 0.85 g. of the acetate gave 0.55 g. (74%) of alcohol which, after one crystallization from acetone–ligroin, melted at 221–222° without gas evolution. After a second crystallization, however, the material melted at 211–213° with gas evolution, and after a third crystallization the nearly colorless substance melted at 214–216°, dec. This variable behavior is probably due to a pronounced tendency to decompose under the influence of traces of catalyst.

Anal. Calcd. for $C_{21}H_{16}O$: C, 88.71; H, 5.67. Found (214–216° sample): C, 88.41; H, 5.77.

Conversion of the Alcohol into the Ketone.—A solution of 0.19 g. of 15-hydroxy-20-methylcholanthrene in 10 cc. of glacial acetic acid was treated with 90 mg. of anhydrous sodium dichromate and shaken at room temperature for fifteen minutes. The solution was diluted with water and the precipitated ketone was crystallized from acetone. There was obtained 85 mg. (43%) of 15-keto-20-methylcholanthrene in the form of yellow needles, m. p. 262.5–263°. This did not depress the melting point of the above sample.

Dichromate Oxidation of Methylcholanthrene to the Ketone.—A suspension of 0.5 g. of powdered methylcholanthrene and 0.98 g. of anhydrous sodium dichromate in 25 cc. of glacial acetic acid was shaken at room temperature for fifteen minutes and the solid was collected, extracted with warm dilute sodium carbonate solution, and crystallized from acetone. The purification is not easy, but after five crystallizations 70 mg. (13%) of satisfactory ketone was obtained melting at 261.5–262.5°. This gave no depression when mixed with the material obtained by oxidation with lead tetraacetate.

Proof of Structure.—A solution of 0.1 g. of 15-hydroxy-20-methylcholanthrene and 0.5 g. of anhydrous sodium dichromate in 10 cc. of glacial acetic acid was refluxed for ten minutes and water was added. On recrystallization of the precipitate from acetic acid **6-methylanthraquinone-5-acetic acid** was obtained as fluffy yellow needles, m. p. 292–295°, dec.; yield, 45 mg. (39%). The substance gives a vat test and is soluble in dilute sodium carbonate solution. The **methyl ester**, obtained by esterification with methanol and hydrogen chloride, melted initially at 220.5–221.5°, and on recrystallization from benzene–ligroin formed flat yellow needles, m. p. 221.5–222°. A sample prepared by oxidation of methylcholanthrene according to Cook and Haslewood[7] and esterified as above melted at the same temperature and there was no depression on mixing the samples. Bachmann[8] esterified the quinone-acid with diazomethane in xylene and reports the m. p. 213–214°, uncorr.

Oxidation of 3,4-Benzpyrene.—A solution of 4.5 g. of lead tetraacetate in 125 cc. of glacial acetic acid was added

---

[21] For a further discussion of this hypothesis see Ref. 19.

[22] All melting points are corrected. Analyses by the Arlington Laboratories.

to a solution of 2.5 g. of 3,4-benzpyrene in 100 cc. of benzene, both solutions being at room temperature. After standing for one-half hour the benzene was removed by distillation and water was added to saturation. On cooling, 2.78 g. (94%) of greenish-yellow needles separated, m. p. 205.5–207.5°. Recrystallization from glacial acetic acid gave 2.5 g. (85%) of material of m. p. 208.5–209.5°, and repeated crystallization from glacial acetic acid and finally from benzene gave straw-yellow needles, m. p. 209.5–210°. The crystals from acetic acid hold this solvent tenaciously and satisfactory analytical results were obtained only after final crystallization from benzene.

Anal. Calcd. for $C_{22}H_{14}O_2$: C, 85.14; H, 4.55. Found: C, 85.33; H, 4.67.

Reaction of 2,1′-Trimethylene-1,9-benzanthrone-10 (VI) with Methyllithium.—A suspension of methyllithium was prepared from 0.5 g. of lithium and excess methyl chloride in ether and 4.85 g. of the benzanthrone VI was added. The ether was displaced by benzene, and after refluxing for fifteen hours the deep brownish-green solution was decomposed with dilute hydrochloric acid. The benzene layer was separated, washed, filtered and concentrated; it yielded two crops of crystalline product amounting to 1.06 g. (21%) and melting at 217–219°. This substance, regarded as **4-methyl-2,1′-trimethylene-1,9-benzanthrone-10 (VII)**, on further crystallization from benzene–ligroin formed golden-yellow needles, m. p. 220–220.5°.

Anal. Calcd. for $C_{21}H_{16}O$: C, 88.71; H, 5.67. Found: C, 88.67; H, 5.80.

6-Methyl-3,4-benzpyrene.—The ketone VII (0.65 g.) was mixed with 50 cc. of zinc dust and distilled at 250 mm. pressure. The oily product was redistilled at 0.5 mm. and crystallized from ether–alcohol, giving 0.27 g. (44%) of crude hydrocarbon, m. p. 154–156°. After filtering a solution of the material in benzene–ligroin through a tower of alumina, two crystallizations from benzene–ligroin gave light yellow needles, m. p. 171–171.5° (0.11 g.).

Anal. Calcd. for $C_{21}H_{14}$: C, 94.70; H, 5.30. Found: C, 94.47; H, 5.37.

The **picrate** formed silky bronze colored needles from benzene–ligroin and melted at 181.5–182.5°.

Anal. Calcd. for $C_{21}H_{14} \cdot C_6H_3O_7N_3$: N, 8.48. Found: N, 8.34.

The **trinitrobenzene derivative** crystallized as brilliant red needles from benzene-ligroin, m. p. 209–210°.

Anal. Calcd. for $C_{21}H_{14} \cdot C_6H_3O_6N_3$: N, 8.77. Found: N, 8.73.

5-Methyl-3,4-benzpyrene.—The liquors remaining from the methyllithium reaction after removal of the ketone VII were evaporated and the oily residue was distilled with zinc dust as above. On vacuum distillation of the product a yellow solid was obtained which when crystallized from benzene–ligroin melted at 130–155°. For purification this was converted into the trinitrobenzene derivative. After three crystallizations from benzene, which raised the melting point to 227–228°, this was decomposed by adsorption of the nitro component on alumina from benzene. After one crystallization from ligroin and two from ether–absolute alcohol, the hydrocarbon formed yellow plates, m. p. 215.7–216.2°; yield, 75 mg. (2%).

Anal. Calcd. for $C_{21}H_{14}$: C, 94.70; H, 5.30. Found: C, 94.89; H, 5.16.

The **picrate** formed purplish-black needles from benzene–ligroin, m. p. 207–208° (Found: N, 8.51), and the **trinitrobenzene derivative** formed short, brick-red needles from the same solvent mixture, m. p. 230–231° (Found: N, 8.58).

3,4-Benzpyrene-5-aldehyde.—A mixture of 1 g. of 3,4-benzpyrene, 1.1 g. of methylformanilide, 1.1 g. of phosphorus oxychloride, and 1 cc. of *o*-dichlorobenzene was warmed on the steam-bath for two hours; the solution became deep red and hydrogen chloride was evolved. The reaction mixture was poured into an aqueous solution of 5 g. of sodium acetate crystals and the solvent was removed with steam. The residual crystalline solid on crystallization from glacial acetic acid gave 1 g. (90%) of orange-yellow plates, m. p. 201–203°, and after two more crystallizations from benzene–ligroin the melting point was raised to 202.5–203.5°.

Anal. Calcd. for $C_{21}H_{12}O$: C, 90.00; H, 4.32. Found: C, 89.58; H, 4.39.

The **hydrazone** was prepared by adding 1 cc. of hydrazine hydrate in alcohol to a hot solution of 0.45 g. of the aldehyde in the minimum amount of dioxane. After warming for five minutes, more alcohol was added until the product began to crystallize. The hydrazone separated as fine yellow needles, m. p. 219.5–220.5°, dec. Since further crystallization from dioxane–alcohol resulted in decomposition, the original crystallizate, after thorough washing with alcohol, was analyzed.

Anal. Calcd. for $C_{21}H_{14}N_2$: N, 9.52. Found: N, 9.57.

For conversion to **5-methyl-3,4-benzpyrene,** 0.35 g. of the hydrazone was heated with a solution from 1 g. of sodium and 5 cc. of absolute alcohol for ten hours at 210–215°. The product was obtained directly as a solid; it was purified by passage of a benzene solution through a tower of alumina and crystallized from ether–absolute alcohol, giving 0.22 g. (70%) of yellow plates melting at 216.2–216.7° and giving no depression when mixed with the sample obtained from the methyllithium reaction product.

Summary

Methylcholanthrene and 3,4-benzpyrene are oxidized very readily by lead tetraacetate and seem to be more susceptible to attack by this reagent than other polynuclear hydrocarbons studied. 3,4-Benzpyrene gives a single monoacetoxy derivative in nearly quantitative yield, and methylcholanthrene is converted chiefly into the 15-acetoxy compound and in smaller part into 15-keto-20-methylcholanthrene.

On reaction with methylformanilide, 3,4-benzpyrene is converted in excellent yield into a single product which probably is the 5-aldehyde. This has been related to one of two new methyl-3,4-benzpyrenes obtained from products of the addition of methyllithium to a synthetic trimethylbenzanthrone and regarded as the 5- and 6-isomers.

The behavior of polynuclear hydrocarbons in the lead tetraacetate oxidation, aldehyde reaction, and diazo coupling test shows that the most powerfully carcinogenic hydrocarbons of the series possess special susceptibility to substitutions, and certain indications are discernible of a relationship between this specific type of chemical reactivity and carcinogenic activity.

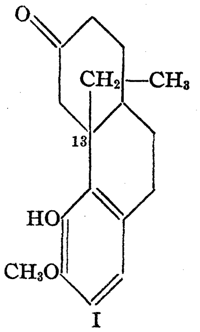
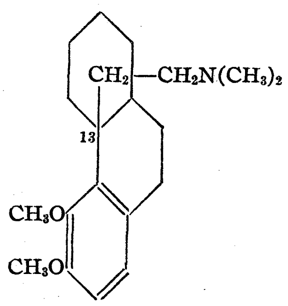
The Synthesis of Phenanthrene and Hydrophenanthrene Derivatives. VIII. Substances Related to Degradation Products of Morphine

BY LOUIS F. FIESER AND H. L. HOLMES

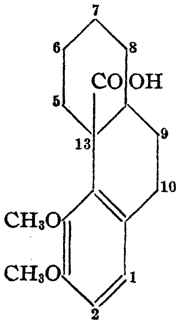
In a previous paper[1] we described a diene synthesis by which it is possible to obtain hydrophenanthrene derivatives having a carboxyl group at a quaternary carbon atom corresponding to the 13-position of the morphine alkaloids. According to the Gulland–Robinson formula for morphine, these alkaloids contain an ethanamine chain joined at the hydrocarbon end to the 13-position of the hydrophenanthrene skeleton, but the exact position of attachment is the one remaining point of uncertainty concerning the structures. The new synthesis provides a possible method of obtaining compounds of known structure which, if the Gulland–Robinson formula is correct, may be obtainable from the alkaloids by degradation, and in the present work we have investigated the possibility of synthesizing suitable compounds.



I



II



III

Degradative work on the alkaloids has not as yet provided many substances which seem within reach by the diene synthesis. A ketoethyloctahydromorphenol methyl ether of the probable structure I (Gulland–Robinson formulation) was obtained by Wieland and Kotake[2] and by Cahn[3] by various degradations, but Cahn encountered difficulties on attempting to reduce the carbonyl group and to methylate the compound. Speyer and Koulen[4] obtained as the methiodide a substance described as dihydrodesoxytetrahydro-α-methylmorphimethine and probably having the structure II, but an attempted Hofmann degradation to the corresponding vinyl compound apparently proceeded anomalously with demethylation at the 4-position and ring formation between the liberated hydroxyl and vinyl groups.[5] Our first objective was the synthesis of the acid III, which may be obtainable from these or other degradation products, and we also made some study of possible methods of lengthening the carbon side chain.

The synthesis of 3,4-dimethoxy-5,6,7,8,9,10,13,14-octahydrophenanthrene-13-carboxylic acid (III) was accomplished by application of the scheme of synthesis previously described. γ-(3,4-Dimethoxyphenyl)-butyric acid (IV) was prepared from veratrole by condensation with succinic anhydride and reduction, by the procedures already reported.[6,7] This acid undergoes cyclization very readily at the position para to one of the methoxyl groups,[8,9] and since it was

desired to effect cyclization of a derivative of the acid at the alternate position, the favored site of substitution was blocked by bromination. Haworth[9] described the bromo acid V briefly, but provided no rigid proof of the structure; this was supplied in the present work by permanganate oxidation to the known 2-bromo-4,5-dimethoxybenzoic acid, identical with a sample prepared from vanillin.[10] The ester of the bromo acid V was condensed with oxalic ester and the product (VI) hydrolyzed with dilute sulfuric acid to the α-keto acid VII. Cyclization with strong sulfuric acid gave in good over-all yield the dihydronaphthoic acid VIII desired for the diene addition reaction. It was observed incidentally that the α-keto acid VII is converted into a crystalline enol acetate on attempted cyclization with acetic anhydride–acid and zinc chloride catalyst.

Since in the examples previously investigated[1] the Diels–Alder reaction had been run only on the esters of α,β-unsaturated acids, our first trials were made with the ester XI (route a). Since attempted esterification of the acid VIII by the Fischer method was unsuccessful, the ester had to be made with the use of diazomethane. As anticipated from the previous observations,[1] the addition of butadiene to the bromo ester XI proceeded poorly, and the best conversion to the hexahydrophenanthrene derivative XII was about 9%, considerable starting material being recovered after heating at 230° for seven days. As in other cases, the reaction with 2,3-dimethylbutadiene proceeded much better (54% yield). The hexahydro ester XII was obtained in a pure crystalline condition and was easily hydrogenated in the presence of platinum catalyst to the octahydro ester XIII, but saponification of the highly hindered ester group could not be accomplished without disturbance of the bromine atom. The bromine was removed, if with difficulty, by hydrogenation of XIII in the presence of a large amount

---

(10) Heap, Jones and Robinson, *J. Chem. Soc.*, 2021 (1927).

of palladium catalyst on barium sulfate with sodium acetate as acceptor for the hydrogen bromide. Saponification of the ester group was then accomplished with sodium ethylate at 180°, giving the desired acid III.

On repeating the whole synthesis with larger amounts, we investigated the possibility of using the free dihydronaphthoic acid VIII in the diene reaction in place of the ester, for an expensive reagent is required for the esterification and the subsequent saponification of the hindered ester group must be conducted in a sealed tube. The free acid can indeed be used, and after some exploration conditions were found permitting a better conversion than obtained with the ester. When heated with about two moles of butadiene in the presence of some benzene at 185–190° for one hundred hours, the acid was converted into the addition product IX in 18% yield, and over 50% of the starting material was recovered in a satisfactory condition. At higher temperatures there was some decarboxylation. The addition evidently proceeded in the same steric manner as before, for esterification of the addition product IX gave an ester identical with the product of the addition of butadiene to the bicyclic ester. Saturation of the double bond of IX and removal of the bromine with hydrogen and palladium catalyst gave the dimethoxyoctahydrophenanthrene-carboxylic acid III, identical with that obtained by the alternate method. The shorter route (b) clearly constitutes the better plan of synthesis, and the end-product can be obtained by this method in reasonable quantity if with a rather generous expenditure of time. The accumulation of a quantity of the diene addition product is a tedious process and the removal of bromine is slow and requires large amounts of catalyst.

It remains to be seen if an acid of the structure III can be obtained by the degradation of morphine, codeine, or thebaine, and if this can be done the stereochemical problem will require consideration. The acid has two asymmetric carbon atoms, but the addition apparently gives only one of the two possible *dl*-mixtures. The material obtained in several preparations by both methods (a) and (b) seemed entirely homogeneous, as did the various intermediates. Alder and Stein[11] have noted that at least in low temperature reactions dienes add to activated double bonds exclusively in the *cis* position but that at elevated temperatures *cis*-addition may be followed by rearrangement to the *trans*-configuration. Models (Stuart) of the two diastereomers of III do not indicate any great difference in the strain, and consequently in the energy content, of the two forms, and a rearrangement from the *cis*-configuration therefore seems improbable. The configuration of the alkaloid ring system at this part of the molecule is not known. A few preliminary attempts were made to effect a resolution, but without success. The trials were confined largely to the unsaturated bromo acid IX, using brucine and strychnine as the resolving agents. Should this become a crucial point in the correlation of synthetic and natural products, a solution of the problem might still be possible in case the resolution of the synthetic acid is found to present really serious difficulty. Sinomenine belongs to a stereochemical series opposite to that of the alkaloids of the morphine group and has been degraded to the optical antipode of dihydrothebainone, and a mixture of the acids from the dual degradation of thebaine and sinomenine should yield the synthetic acid or its diastereomer.

Another possibility would be to utilize the dimethoxyoctahydrophenanthrene-13-carboxylic acid III as the starting point for the synthesis of the degradation product II of Speyer and Koulen,[4] but difficulties are to be anticipated in attempting to convert the carboxyl group into an ethanamine chain because of the hindered nature of the functional group and the opportunity for rearrangement associated with the quaternary location. In the present work we have merely explored, with simpler compounds of the series, some of the possible starting points for a lengthening of the side chain. The experiments were made with the addition products of Δ^1-dihydro-α-naphthoic ester and its 6-methoxy derivative with butadiene and 2,3-dimethylbutadiene, and the following observations concerning ethyl 6,7-dimethyl-5,8,9,10,13,14-hexahydrophenanthrene-13-carboxylate (XV) are typical of the rest. The unsaturated hexahydro ester, m. p. 50°, gave a liquid octahydro compound (XVI) on hydrogenation, and on reduction with sodium and isoamyl alcohol it gave in good yield a crystalline carbinol, XVII (m. p. 74°). On hydrogenation this was converted into the corresponding octahydro carbinol, XVIII (m. p. 69°), which was obtained in a more easily purified condition by the Bouveault reduction of the saturated ester XVI. In these reductions

---

[11] Alder and Stein, *Angew. Chem.*, **50**, 510 (1937).

with sodium and isoamyl alcohol a small amount of the ester invariably was saponified to the corresponding acid, but the yield of carbinol was good (about 70%), and nearly all of the substances were obtained in a crystalline condition. It is of interest that while ethyl abietate can be reduced to abietinol with sodium and ethyl alcohol,[12] the hydrophenanthrene-13-carboxylic esters are not attacked when ethyl alcohol is used.

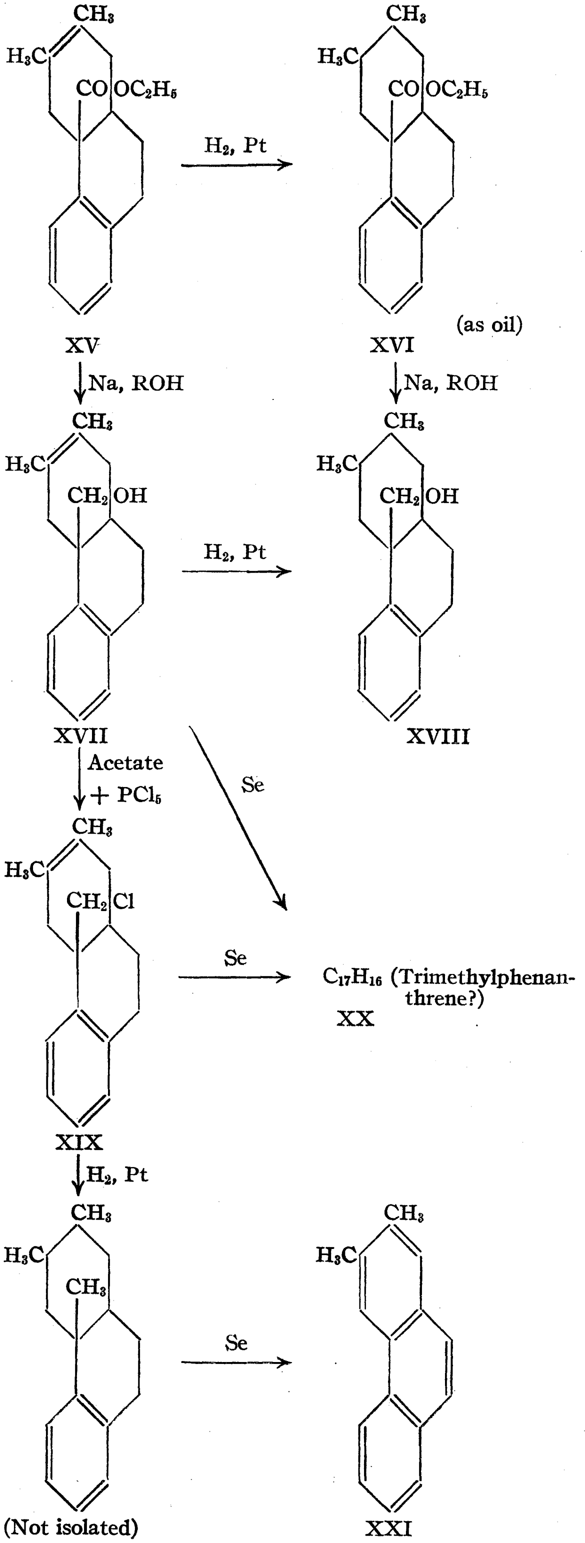
The use of mineral acids was avoided in seeking to transform the carbinols into the corresponding halides, and it was found that the hexahydro carbinol XVII can be converted by the action of phosphorus pentachloride on the liquid acetate into the chloride, XIX. Attempts to convert the chloride into the nitrile, however, were unsuccessful. A Rosenmund reduction of the chloride of one of the 13-carboxylic acids was also tried without success. Selenium dehydrogenation of either the unsaturated chloride (XIX) or the unsaturated carbinol (XVII) seemed to involve some form of rearrangement, for in each case there was obtained in good yield a nicely crystalline product, m. p. 149°, having the composition of a trimethylphenanthrene ($C_{17}H_{16}$). The normal dehydrogenation product, 2,3-dimethylphenanthrene (XXI), was obtained by hydrogenating the unsaturated chloride to the point of replacement of most of the halogen and treating the oily hydrocarbon with selenium. This observation indicates that there probably is no rearrangement of the skeletal structure in the formation of chloride.

Experimental Part[13]

Synthesis of 3,4-Dimethoxy-5,6,7,8,9,10,13,14-octahydrophenanthrene-13-carboxylic Acid (III)

γ-(2-Bromo-4,5-dimethxoyphenyl)-butyric Acid (V).—A solution of 387 g. of γ-(3,4-dimethoxyphenyl)-butyric acid[6,7] (b. p. 210° at 6 mm.) in 2400 cc. of glacial acetic acid was stirred mechanically in a cooling bath and treated with 122 cc. of bromine, added by drops while controlling the temperature to 4°. The bromination product soon began to separate as a pale yellow precipitate. The addition required twenty hours, and after stirring for two hours longer the crystalline bromo acid which had separated was collected and washed well with water. The product was colorless and weighed 469 g. (83%); m. p. 130–134.5°. A purified sample melted at 137.8–138.8° (Haworth,[8] 135–136°, uncorr.).

The ethyl ester, prepared by Fischer esterification, was suitable for use after distillation; b. p. 220–222° (17 mm.); yield from 50 g. of acid, 49.6 g. (91%). The ester crystallizes from ether in elongated, stout prisms, m. p. 49.5–50.5°.



For proof of structure a sample of the ester was refluxed with aqueous alkali and excess permanganate. The acidic product recovered from the filtrate was crystallized from alcohol, giving colorless needles, m. p. 184–185°.

---

[12] Ruzicka and Meyer, *Helv. Chim. Acta*, **5**, 581 (1922).

[13] All melting points are corrected.

There was no depression on admixture with a sample of 2-bromo-4,5-dimethoxybenzoic acid prepared according to Heap, Jones, and Robinson,[10] m. p. 185–186° (compare 185°[14]).

Ethyl α-Oxalyl-γ-(2-bromo-4,5-dimethoxyphenyl)-butyrate (VI).—Forty grams of ethyl γ-(2-bromo-3,4-dimethoxyphenyl)-butyrate was condensed with 20 g. of ethyl oxalate in the usual manner, using sodium ethylate (2.78 g. of sodium). On decomposing the sodium derivative in ice-cold dilute sulfuric acid the condensation product crystallized in long, feathery needles; total yield, 52 g. (96%), m. p. 69–70°. Recrystallized from ether–petroleum ether, it melted at 74.7–75.3°.

Anal. Calcd. for $C_{18}H_{23}O_7Br$: C, 50.31; H, 5.37. Found: C, 50.11; H, 5.38.

α-Keto-δ-(2-bromo-3,4-dimethoxyphenyl)-valeric Acid (VII).—The oxalyl ester VI (42 g.) was refluxed with 18% sulfuric acid (500 cc.) for twenty hours, and on cooling the mixture the keto acid solidified in round nodules. The material was dissolved in sodium carbonate solution and, after clarification, precipitated. The solid weighed 29.1 g. (90%), m. p. 85–87°. Crystallized for analysis from dilute acetic acid the substance formed silky needles, m. p. 93–94°.

Anal. Calcd. for $C_{13}H_{15}O_5Br$: C, 47.15; H, 4.57; Br, 24.13. Found: C, 47.49; H, 4.96; Br, 24.09.

The ethyl ester boils at 225–227° (9 mm.). Both the acid and the ethyl ester give a brownish-black coloration with ferric chloride solution. The **enol acetate**[15] was obtained by refluxing 2 g. of the keto acid with 5 cc. of glacial acetic acid, 5 cc. of acetic anhydride, and 0.1 g. of zinc chloride for one hour, cautiously adding water, and allowing the solution to cool. The reaction product separated in a nearly pure condition (1.9 g.), m. p. 147–149°; on recrystallization from dilute acetic acid it formed slender needles, m. p. 148.4–149°. Saponification of the acetate gave the keto acid, m. p. 93–94°.

Anal. Calcd. for $C_{15}H_{17}O_6Br$: C, 48.27; H, 4.59; neut. equiv., 373. Found: C, 48.42; H, 4.83; neut. equiv., 369.

5-Bromo-7,8-dimethoxy-Δ'-dihydro-1-naphthoic Acid (VIII).—A total of 375 g. of the keto acid VII was cyclized in 65-g. batches, each batch being stirred vigorously with a mixture of 235 cc. of concentrated sulfuric acid and 135 cc. of water at 80° for one-half hour. The keto acid soon melted to a brown gum and the cyclization product then began to separate in a crystalline condition. The mixture was cooled, poured onto ice and water, and on vigorous stirring the product solidified completely in the form of pale buff-colored granules. After thorough washing, the acid was purified through the sodium salt, which crystallizes as flat white plates from a solution containing excess sodium carbonate (40 g. in 750 cc. of water for each 65-g. batch). An aqueous solution of the purified salt (25 g.) on acidification at 60° gave 17 g. (average) of acid, m. p. 168–171°. One crystallization from dilute alcohol raised the melting point to 171.5–172.5°, and the total yield of this material was 196 g. (55%). Further purification gave colorless plates, m. p. 172–173°.

Anal. Calcd. for $C_{13}H_{13}O_4Br$: C, 49.86; H, 4.19; Br, 25.52; neut. equiv., 313. Found: C, 49.92; H, 4.31; Br, 25.31; neut. equiv., 316.

The methyl ester (XI), prepared with diazomethane, distilled at 174–175° (2 mm.) and was obtained as a viscous oil in 97% yield. It slowly solidified on standing, and when purified by crystallization from hexane formed blades, m. p. 76–77°.

5-Bromo-7,8-dimethoxy-1,2,3,4-tetrahydro-1-naphthoic acid was obtained by hydrogenation of VIII in alcohol in the presence of Adams catalyst. It crystallized from dilute alcohol as long, flat needles, m. p. 147–148°.

Anal. Calcd. for $C_{13}H_{15}O_4Br$: C, 49.54; H, 4.84. Found: C, 49.48; H, 4.99.

7,8-Dimethoxy-1,2,3,4-tetrahydro-1-naphthoic Acid.—Hydrogenation of the above compound (0.9 g.) in absolute alcohol (40 cc.) was accomplished in the presence of palladium oxide catalyst (35 mg.) in about three hours. The recovered product (0.6 g.) was bromine free and crystallized from benzene–hexane as elongated prisms, m. p. 119.5–120°.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.08; H, 6.82. Found: C, 66.36; H, 6.66.

Methyl 1-Bromo-3,4-dimethoxy-6,7-dimethyl-5,8,9,10,-13,14-hexahydrophenanthrene-13-carboxylate.—The ester XI (14 g.) was heated with 2,3-dimethylbutadiene (5 g.) at 175–185° for thirty-one hours and the mixture on distillation gave a fraction boiling at 190–205° (2 mm.) and giving 9.6 g. (54%) of crystals from dilute alcohol. Further crystallization from alcohol gave plates, m. p. 154–155°. Some starting material was recovered from the fore-run.

Anal. Calcd. for $C_{20}H_{25}O_4Br$: C, 58.69; H, 6.16; Br, 19.52. Found: C, 58.91; H, 6.14; Br, 19.32.

This substance proved to be very resistant to hydrogenation under various conditions.

Methyl 1-Bromo-3,4-dimethoxy-5,8,9,10,13,14-hexahydrophenanthrene-13-carboxylate (XII).—In the most successful experiments 20 g. of the unsaturated ester XI was heated in a thick-walled Pyrex tube with 15 g. of butadiene at 220–230° for seven days. After several fractional distillations 9.2 g. of starting material was recovered and the bulk of the addition product was collected in an 8.6-g. fraction boiling at 185–196° (3 mm.). On crystallization of this from petroleum ether it gave in the first crop 3.2 g. more starting material, and the next crystallizate consisted of crude addition product (2.4 g.) m. p. 89–100°. Two further crystallizations raised the melting point to 101–103°, and the average yield, not allowing for recovery of considerable starting material, was 8–9%. The mother liquors contained about 3.4 g. of oil which failed to crystallize. The fully purified ester formed elongated prisms, m. p. 105–106°.

Anal. Calcd. for $C_{18}H_{21}O_4Br$: C, 56.70; H, 5.55; Br, 20.96. Found: C, 56.47; H, 5.67; Br, 21.02.

Methyl 1-Bromo-3,4-dimethoxy-5,6,7,8,9,10,13,14-octahydrophenanthrene-13-carboxylate (XIII).—The addition product XII (2.75 g.) in glacial acetic acid (50 cc.) with Adams catalyst (50 mg.) absorbed one mole of hydrogen in

[14] Henry and Sharp, *J. Chem. Soc.*, 2286 (1930).

[15] The analogous enol acetate obtained by this method from α-keto-δ-phenylvaleric acid melted at 98.6–99.1° (Calcd.: C, 68.85; H, 6.03. Found: C, 68.68; H, 6.13); that from α-keto-δ-(4-methoxyphenyl)-valeric acid melted at 89–90° (Calcd.: C, 63.63; H, 6.10 Found: C, 64.03: H, 6.26).

fifteen minutes. The purified product crystallized from ether as fine needles, m. p. 112.5–113.5°.

Anal. Calcd. for $C_{18}H_{23}O_4Br$: C, 56.41; H, 6.06; Br, 20.85. Found: C, 56.45; H, 6.28; Br, 20.61.

Methyl 3,4-Dimethoxy-5,6,7,8,9,10,13,14-octahydrophenanthrene-13-carboxylate (XIV).—For removal of the bromine, 0.65 g. of XIII in 35 cc. of glacial acetic acid was shaken with hydrogen in the presence of 0.1 g. of fused sodium acetate and 2 g. of palladinized barium sulfate.[16] One mole of gas was absorbed in about seventeen hours. After concentration of the filtered solution in vacuum and dilution with water the product separated as a crystalline powder (0.49 g.), m. p. 135–142°. Four recrystallizations from dilute acetic acid raised the m. p. to 141.5–142.5° (previous softening), and crystallization from petroleum ether then gave glistening cubes, m. p. 142.8–143.2°. The substance gave no test for bromine.

Anal. Calcd. for $C_{18}H_{24}O_4$: C, 71.03; H, 7.94. Found: C, 70.85; H, 7.65.

In another experiment the unsaturated bromo ester XII (0.85 g.) was hydrogenated in acetic acid using the palladium catalyst (2 g.). Absorption of gas was rapid at first and then slower, and on working up the product after four hours there was obtained 0.65 g. (94%) of the saturated bromine-free ester, m. p. 142.5–143°.

3,4 - Dimethoxy - 5,6,7,8,9,10,13,14 - octahydrophenanthrene-13-carboxylic Acid (III). Method (a).—The ester XIV (0.2 g.) was heated in a sealed tube with a solution from 0.9 g. of sodium and 15 cc. of absolute alcohol at 175–180° for eighteen hours. The solidified product was taken up in water and the solution was shaken with dimethyl sulfate until neutral, cooled to 0°, and acidified. The acid which separated was taken into ether, extracted from the ether with sodium bicarbonate solution, and obtained on acidification as a cream colored solid; yield, 75 mg. (39%). Evaporation of the ethereal solution gave 0.1 g. of unchanged ester, m. p. 140–141°. The acid crystallized from dilute alcohol in the form of flat needles, m. p. 202.4–203.4°. It is readily soluble in dilute solutions of sodium bicarbonate and ammonia.

Anal. Calcd. for $C_{17}H_{22}O_4$: C, 70.33; H, 7.64; neut. equiv., 290. Found: C, 70.11; H, 7.39; neut. equiv., 286.

1 - Bromo - 3,4 - dimethoxy - 5,8,9,10,13,14 - hexahydrophenanthrene-13-carboxylic Acid (IX).—The best conditions found for effecting the reaction consisted in heating a mixture of 20 g. of 5-bromo-7,8-dimethoxy-Δ^1-dihydro-1-naphthoic acid, 8 g. of butadiene, and 15 cc. of dry benzene in a sealed tube at 185–190° for one hundred hours. The cooled mixture was diluted with 75 cc. of benzene and refluxed for two hours with a solution of 15 g. of sodium carbonate in 200 cc. of water. The pale yellow aqueous layer was separated from the benzene and polymer, decolorized with Norite, and acidified carefully. The precipitated acid was collected, dried, and crystallized from alcohol to separate the reaction product from the more soluble starting material. The crude addition product collected amounted to 4.3 g. (18%), m. p. 248–252°, dec. One recrystallization brought the m. p. to 256–258°, dec., and the purest sample formed small plates, m. p. 260–261° dec. Dilution of the mother liquors gave 11.1 g. of starting material, m. p. 163–164°.

Anal. Calcd. for $C_{17}H_{19}O_4Br$: C, 55.60; H, 5.21; neut. equiv., 367. Found: C, 55.65; H, 5.55; neut. equiv., 364.

Esterification with diazomethane gave a product which when crystallized from ether–petroleum ether melted at 105–106° and gave no depression when mixed with the ester XII prepared by method (a).

1 - Bromo - 3,4 - dimethoxy - 5,6,7,8,9,10,13,14 - octahydrophenanthrene-13-carboxylic Acid (X).—The unsaturated acid IX (1 g.) in glacial acetic acid (65 cc.) with Adams catalyst (30 mg.) absorbed one mole of hydrogen in twenty minutes, and the product, recrystallized from alcohol, formed glistening plates, m. p. 233–234°; yield, 0.7 g. (70%).

Anal. Calcd. for $C_{17}H_{21}O_4Br$: C, 55.28; H, 5.73. Found: C, 54.65; H, 5.93.

Esterification with diazomethane and crystallization from ether gave an ester melting at 112.5–113.5° and identical with the sample of XIII described above.

3,4 - Dimethoxy - 5,6,7,8,9,10,13,14 - octahydrophenanthrene-13-carboxylic Acid (III). Method (b).—The saturated bromo acid X (0.35 g.) in glacial acetic acid (25 cc.) with palladinized barium sulfate (1 g.) and fused sodium acetate (0.1 g.) in two trials absorbed somewhat less than the theoretical amount of hydrogen in twelve to eighteen hours, when the reaction stopped. Three crystallizations from aqueous alcohol gave 0.2 g. (57%) of bromine-free acid melting constantly at 202–203°. This did not depress the melting point of the sample described above, and the ester formed cubes, m. p. 142.5–143.5°, identical with the other sample of XIV.

Concerning Other Diene Addition Products

In preparing a larger quantity of **ethyl hexahydrophenanthrene-13-carboxylate**[1] 90 g. of the unsaturated ester was heated with 30 g. of butadiene at 170–180° for thirty-six hours, giving 26.2 g. (23%) of purified product, b. p. 197–198° (14 mm.), 214–215° (31 mm.). The corresponding acid on hydrogenation in glacial acetic acid solution gave **octahydrophenanthrene-13-carboxylic acid** in 85% yield as small needles from dilute alcohol, m. p. 144–145°.

Anal. Calcd. for $C_{15}H_{18}O_2$: C, 78.22; H, 7.88; neut. equiv., 230. Found: C, 78.59; H, 8.20; neut. equiv., 233.

Ethyl octahydrophenanthrene-13-carboxylate, prepared by hydrogenation of the hexahydride, was obtained as a viscous liquid, b. p. 180–181° (16 mm.).

The yield of **ethyl 6,7-dimethylhexahydrophenanthrene-13-carboxylate**[1] was increased considerably by heating 50 g. of the unsaturated ester with 30 g. of the diene at 170–180° for thirty-six hours; yield, 52.5 g. (74%); b. p. 197–198° (14 mm.). Similarly, **ethyl 3-methoxyhexahydrophenanthrene-13-carboxylate**,[1] b. p. 212–215° (17 mm.), was obtained in 31% yield from 30 g. of ester and 15 g. of butadiene at 150–160° for sixty-three hours. 3-Methoxyhexahydrophenanthrene-13-carboxylic acid[1] (1 g.) on dehydrogenation with selenium (2 g.) at 300–320° for twenty-four hours gave 3-methoxyphenanthrene, m. p. 58.5–59.5°; picrate, m. p. 123–124°.

3-Methoxyoctahydrophenanthrene-13-carboxylic acid, prepared from the hexahydride[1] with Adams catalyst in

acetic acid, formed thin plates from dilute acetic acid, m. p. 174.5–175.5°.

Anal. Calcd. for $C_{16}H_{20}O_2$: C, 73.82; H, 7.75; neut. equiv., 260. Found: C, 74.05; H, 7.90; neut. equiv., 260.

Ethyl 3-methoxy-6,7-dimethylhexahydrophenanthrene-13-carboxylate, prepared from 15 g. of unsaturated ester and 10.6 g. of 2,3-dimethylbutadiene at 120–160° for forty-eight hours and isolated in the usual way, was obtained as a viscous oil, b. p. 197–199° (5 mm.); yield, 17.3 g. (85%). The ester slowly crystallized and when purified from petroleum ether formed crusts of microcrystals, m. p. 67–68°.

Anal. Calcd. for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34. Found: C, 76.74; H, 8.52.

Saponification of the above ester with sodium ethylate at 170° for seventeen hours gave in 72% yield **3-methoxy-6,7-dimethylhexahydrophenanthrene-13-carboxylic acid,** which forms glistening, slender needles from dilute alcohol and melts at 164–165°.

Anal. Calcd. for $C_{18}H_{22}O_3$: C, 75.49; H, 7.74; neut. equiv., 286. Found: C, 75.90; H, 7.83; neut. equiv., 290.

The chloride of this acid was a liquid, b. p. 215° (15 mm.). Dehydrogenation of the acid (1 g.) with selenium as above gave **3-methoxy-6,7-dimethylphenanthrene,** which crystallized in plates, m. p. 119–120° (0.1 g.), from dilute alcohol. The picrate formed reddish-orange needles from alcohol; m. p. 160–162°.

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.41; H, 6.83. Found: C, 86.22; H, 6.71.

Hydrogenation of the unsaturated acid gave **3-methoxy-6,7-dimethyloctahydrophenanthrene-13-carboxylic acid** as long blades, m. p. 204–206°, from dilute alcohol.

Anal. Calcd. for $C_{18}H_{24}O_3$: C, 74.97; H, 8.39; neut. equiv., 288. Found: C, 75.05; H, 8.65; neut. equiv., 288.

Carbinols from the Hydrophenanthrene-13-carboxylic Esters

The following procedure for the preparation of **13-hydroxymethyl-5,6,7,8,9,10,13,14-octahydrophenanthrene** illustrates the general method of conducting the Bouveault reduction of the esters. A solution of 11 g. of ethyl octahydrophenanthrene-13-carboxylate in 250 cc. of isoamyl alcohol was stirred mechanically and kept at 90–95° in a water-bath and 9 g. of sodium was added in small pieces. After the sodium had all reacted the solution was cooled, treated with 8–9 cc. of water added by drops, and stirred for one-half hour at 90–95°. The solvent was then removed by steam distillation, the brown oil extracted with ether, and the washed solution was dried, clarified with Norite, and evaporated. The residual oil was dissolved in petroleum ether (20–40°), and seed was obtained by cooling a portion for several hours in a carbon dioxide bath. The carbinol then crystallized from the main solution on seeding at room temperature, and it was obtained in rosets of fine, feathery needles (colorless). The alkaline layer from the reduction gave an oily product on acidification (1.2 g.), and on purification from dilute alcohol this formed needles, m. p. 144–145°, identical with the sample of octahydrophenanthrene-13-carboxylic acid described above.

The other reductions were conducted in the same manner and the yields, properties, and analyses of the carbinols are recorded in the table. The neutral reaction products usually were not distilled; crystals were obtained by cooling a petroleum ether solution with solid carbon dioxide. The same solvent was used for recrystallization. The presence of the hydroxyl group was shown in representative cases by Zerewitinoff determination (0.88 mole gas) and by the preparation of the acetates, using hydrogen chloride-free acetyl chloride (80% yield). The 6,7-dimethyloctahydro derivative was prepared both by the Bouveault reduction and by hydrogenating the hexahydride in acetic acid in the presence of Adams catalyst; the reaction product in the latter case was not as easily purified as before, but a satisfactory sample was obtained (m. p. 68–69°) giving no depression with the other material. The acidic by-product of the Bouveault reduction, **6,7-dimethyloctahydrophenanthrene-13-carboxylic acid,** has not been described before. It formed long needles from alcohol and crystallized from benzene–hexane in flat prisms, m. p. 189–191°, with some previous softening.

Anal. Calcd. for $C_{17}H_{22}O_2$: C, 79.03; H, 8.58; neut. equiv., 258. Found: C, 79.19; H, 8.95; neut. equiv., 256.

5,6-Dimethyl-13-chloromethylhexahydrophenanthrene (XIX).—The carbinol XVII (4 g.) was converted into the acetate by heating for two hours with one equivalent of purified acetyl chloride and the mixture was poured onto ice and extracted with ether. After washing with bicarbonate solution and water, the solvent was removed and the acetate distilled, b. p. 176–177° (5 mm.); yield, 4.1 g. The viscous oil, which showed no sign of crystallizing, was allowed to stand in dry benzene (10 cc.) with phosphorus pentachloride (12 g.) for two hours, the solution turning brownish-yellow. After refluxing for one-half hour, the mixture was decomposed with ice and water and the product extracted with ether, washed with bicarbonate, dried, and distilled. After several distillations of the yellow oil a fraction was obtained boiling at 196–198° (3 mm.); yield, 2.5 g. (65%).

Anal. Calcd. for $C_{17}H_{21}Cl$: C, 78.30; H, 8.13; Cl, 13.59. Found: C, 77.87; H, 7.76; Cl, 13.19.

In an attempt to prepare the nitrile, 13 g. of the chloride was heated with 2 g. of potassium cyanide in 30 cc. of alcohol at 160–180° for twenty-four hours; repeated distillation gave a fraction boiling at 210–220° (2 mm.) and containing nitrogen (1.8 g.) but this did not solidify and gave only a small amount of oily acidic material on alkaline hydrolysis.

The unsaturated chloride (1.3 g.) absorbed hydrogen fairly rapidly in glacial acetic acid solution in the presence of Adams catalyst, and considerable hydrogen chloride was found to have been produced. The oily reaction product appeared to be a mixture; on dehydrogenation with selenium it gave a solid (0.5 g.), m. p. 59–63°, giving a picrate, m. p. 145–146°. The hydrocarbon recovered from the picrate and crystallized from alcohol formed fluorescent plates, m. p. 77.5–78°. Mixed with **2,3-dimethylphenanthrene** and its picrate, the samples showed no depression.

Dehydrogenation of the unsaturated chloride or carbinol with selenium gave a much less soluble hydrocarbon which after purification by crystallization from alcohol and from hexane formed small scales, m. p. 148–149°. The substance gives a red coloration in alcohol or benzene with picric acid, but no picrate could be isolated. The yield from the carbinol was 66% and from the chloride 35%.

Anal. Calcd. for $C_{17}H_{16}$: C, 92.69; H, 7.32. Found: C, 92.66; H, 7.31.

Summary

As a step toward a proof of the location of the ethanamine chain in the morphine alkaloids, 3,4-dimethoxy-5,6,7,8,9,10,13,14-octahydrophenanthrene-13-carboxylic acid has been synthesized for comparison with a possible degradation product of the alkaloids. The synthesis involves a diene addition to a brominated Δ^1-dihydro-α-naphthoic acid or ester obtained synthetically, the bromine being required to control the direction of cyclization and being removed in the end stages of the synthesis.

In a preliminary study of a possible lengthening of the carbon chain at C_{13}, a number of esters of substituted hexa- and octahydrophenanthrene-13-carboxylic acids have been reduced to the corresponding carbinols.

Meso Aldehydes of Anthracene and 1,2-Benzanthracene

BY LOUIS F. FIESER AND JONATHAN L. HARTWELL[1]

Substitution reactions of polynuclear aromatic hydrocarbons have gained special interest with the observation that the most actively carcinogenic compounds of the hydrocarbon series show a high degree of susceptibility to diazo coupling[2] and to oxidation with lead tetraacetate.[3,4] Another substitution which it seemed of interest to investigate is the reaction with methylformanilide, which Vollmann, Becker, Corell and Streeck[5] recently applied with success for the conversion of pyrene into pyrene-3-aldehyde.

$$ArH + C_6H_5N(CH_3)CHO \xrightarrow{POCl_3} ArCHO + C_6H_5NHCH_3$$

Previous applications of the reaction were concerned chiefly with ortho–para substitutions of phenol ethers and amines, but the above observation shows that a sufficiently reactive hydrocarbon is capable of entering into the condensation. According to a brief report in the patent literature,[6] anthracene also reacts with methylformanilide. The present investigation of other applications of the reaction was undertaken with the idea that information might be obtained on the relative reactivities of carcinogenic hydrocarbons and in the hope of obtaining derivatives of carcinogens having the reactive aldehydic group.

By modifying slightly the procedure of Vollmann, *et al.*,[5] it was found possible to obtain the known 9-anthraldehyde in 92% yield after heating the reaction mixture for two hours on the steam-bath. 1,2-Benzanthracene reacts less readily, for under the same conditions about half of the hydrocarbon was recovered unchanged and

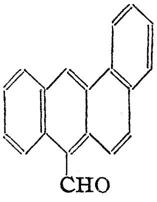
about half converted into an aldehyde. With 1,2,5,6-dibenzanthracene no aldehyde could be isolated even under forcing conditions; after heating the reaction mixture for twenty-four hours in a sealed tube at 155°, for example, 72% of the starting material was recovered. This is a further example of the marked hindrance at both *meso* positions of the hydrocarbon,[3] and the observation shows clearly that the reaction with methylformanilide can be applied only to specific hydrocarbons at specific nuclear positions. The order of susceptibility of the three hydrocarbons to this substituting agent is: anthracene > 1,2-benzanthracene > 1,2,5,6-dibenzanthracene.

For proof of structure the new aldehyde of the 1,2-benzanthracene series was converted through the hydrazone to the corresponding hydrocarbon, which was found to be identical with 10-methyl-1,2-benzanthracene.[7] The substance, therefore, is 1,2-benzanthracene-10-aldehyde (I), the position of substitution being the same as in nitration[3] and in acetoxylation with lead tetraacetate.[3] The hydrocarbon was obtained from the aldehyde in 84% yield, and the yield of aldehyde, based on the 1,2-benzanthracene consumed, was 64%. The 10-methyl compound, which is a valuable agent for the rapid production of experimental sarcomas, thus can be obtained in a simple three-step process from a commercially available starting material in 54% yield.



I

The new aldehyde, which may be of use in the preparation of interesting conjugated compounds, is being tested for carcinogenic activity by Dr. M. J. Shear. 10-Cyano-1,2-benzanthracene, prepared in good yield by dehydration of the oxime, is of interest in connection with the observations reported by Newman.[8] The aldehyde was also converted into the corresponding 10-α-hydroxyethyl compound by reaction with methylmagnesium iodide.

Preliminary to the preparation of these and other compounds derived from the aldehyde, a few trials were made with 9-anthraldehyde. This yielded 9-methyl-, 9-cyano- and 9-α-hydroxyethylanthracene by the above methods, and it was converted also into 9-anthralmalonic acid. This acid is yellow but yields on crystallization under certain conditions an orange substance which probably is a monohydrate; it was also observed that the acid is unusually resistant to decarboxylation. Methyl-9-anthranylcarbinol when heated with potassium bisulfate yielded a colored tar from which anthracene was isolated. Application of the Tschugaeff reaction gave anthracene and 9-ethylanthracene. Bergmann and Bergmann[9] similarly obtained 9-ethylphenanthrene in certain experiments in investigating the Tschugaeff dehydration of the isomeric methylphenanthrylcarbinol. When heated with phosphorus pentoxide in benzene solution, methyl-9-anthranylcarbinol is converted into a high melting product having the composition of an ether: $[C_{14}H_9CH(CH_3)—]_2O$. It yields anthraquinone on oxidation.

Experimental Part[10]

9-Anthraldehyde.—The procedure of Vollmann, *et al.*,[5] for effecting the condensation of methylformanilide with pyrene was found satisfactory for anthracene, but their method of isolating the reaction product was not well adapted to the present case and a more generally applicable method was developed.

One hundred and thirty-five grams of phosphorus oxychloride was added slowly with external cooling to a mixture of 135 g. of methylformanilide, prepared according to Morgan and Grist,[11] and 100 cc. of dry technical *o*-dichlorobenzene, keeping the mixture at about room temperature, and 89.1 g. of anthracene (colorless, m. p. 215–216.4°) was added. The mixture was stirred mechanically and heated on the steam-bath under protection from moisture, applying heat cautiously at first. As the temperature rose the hydrocarbon gradually dissolved, the solution became deep red and hydrogen chloride was evolved. After the first vigorous reaction was over, heating on the steam-bath with stirring was continued for two hours and the viscous mass was transferred to a large flask, mixed with 1 liter of water containing 480 g. of crystalline sodium acetate and steam distilled. The *o*-dichlorobenzene distils rapidly and products other than the aldehyde are largely retained in the aqueous acetate solution. The undissolved residue consisted of a dark oil which on cooling solidified to a mass of yellow crystals. Collected, washed and crystallized from acetic acid, the aldehyde formed long, deep yellow needles, m. p. 98.4–99.4°, total yield, 94.9 g. (92%). Hinkel, Ayling and Beynon[12] give the m. p. 104–105°.

9-Methylanthracene.—The aldehyde was converted in the hydrazone by adding 2.8 g. of hydrazine hydrate in on

portion to a solution of 11 g. of aldehyde in 250 cc. of alcohol at 70°. After heating at the boiling point for five minutes, 10 cc. of water was added. A large crop of yellow needles, m. p. 108–110°, separated on cooling and a further amount was obtained by dilution of the mother liquor; total yield, 9.9 g. (89%). The hydrazone seems to be subject to slight hydrolysis when dissolved for recrystallization in aqueous alcohol (separation of amorphous orange material); the best sample formed orange-yellow needles, m. p. 118–119.5°, but was not analytically pure.

A mixture of 4.4 g. of the hydrazone and a solution from 0.77 g. of sodium and 25 cc. of absolute ethyl alcohol was shaken in a sealed tube until uniform and heated at 200–205° for twenty-one hours. The cooled mixture was poured into water, neutralized with acetic acid, extracted with ether and the dried solution evaporated. Crystallization of the residue from methanol gave 1.5 g. of the known 9-methylanthracene, m. p. 76.3–77.8° (lit.,[13] 79–80°, 81.5°); picrate, m. p. 133–135° (lit.,[13] 137°, dec.).

9-Cyanoanthracene.—The **oxime** was prepared from 15 g. of 9-anthraldehyde in 300 cc. of alcohol by the addition at 75° of a solution of 5.5 g. of hydroxylamine hydrochloride in 50 cc. of water, neutralized with sodium carbonate. Heated on the steam-bath for ten minutes, diluted with water until cloudy and cooled, the solution deposited 15 g. (93%) of yellow needles in two crops. For purification the substance was precipitated from a filtered solution in hot alkali and crystallized from alcohol, giving long yellow needles, m. p. 165–165.5° (Hinkel, Ayling and Beynon,[12] 186–187°). *Anal.* Calcd. for $C_{15}H_{11}ON$: C, 81.42; H, 4.98. Found: C, 81.72; H, 5.08. A solution of 2 g. of the oxime in 10 cc. of acetic anhydride was refluxed for fifteen minutes, and on cooling the mixture went solid with lemon-yellow needles. Washed with acetic acid and petroleum ether, the product melted at 175.5–177.5°; yield, 1.8 g. (98%). Two crystallizations from glacial acetic acid (strong blue fluorescence) raised the m. p. to 177.5–179°. Karrer and Zeller[14] give the m. p. 170–172°.

Anal. Calcd. for $C_{15}H_9N$: C, 88.61; H, 4.46. Found: C, 88.36; H, 4.54.

9-Anthraldoxime Acetate.—Since our sample of the oxime melted considerably lower than reported,[12] this further derivative was prepared for analysis. Acetyl chloride (6 cc.) was added to the oxime (2 g.) in dry ether (50 cc.), and after five minutes 10% sodium carbonate was added by drops until there was no longer a reaction; from the washed and dried ether layer there was obtained a total of 1.65 g. (70%) of crystalline product. The substance forms long lemon-yellow needles from ether, m. p. 131.5–132°.

Anal. Calcd. for $C_{17}H_{13}O_2N$: C, 77.56; H, 4.98. Found: C, 77.29; H, 4.96.

Condensation of 9-Anthraldehyde with Malonic Acid.—A mixture of 10.3 g. of the aldehyde, 6 g. of malonic acid and 0.5 cc. of pyridine was heated on the steam-bath for six hours, and the cooled mixture was extracted with sodium carbonate solution, which left a residue containing unchanged aldehyde. Acidification of the carbonate extract gave a voluminous, deep yellow precipitate (4.1 g.). Crystallization of the crude product from acetic acid–petroleum ether or from methanol–petroleum ether gave chiefly bright yellow needles of **9-anthralmalonic acid,** melting indefinitely at 240–246°, dec.

Anal. Calcd. for $C_{18}H_{12}O_4$: C, 73.97; H, 4.14; neut. equiv., 146. Found: C, 73.86; H, 4.18; neut. equiv., 138.

The dimethyl ester, prepared with diazomethane and crystallized from ether–petroleum ether, formed large transparent yellow prisms, m. p. 134.5–135.5° (87% yield).

Anal. Calcd. for $C_{20}H_{16}O_4$: C, 75.00; H, 5.04. Found: C, 74.97; H, 4.98.

The malonic acid is quite resistant to decarboxylation. Pyrolysis at 250° for five minutes gave a tar, and little change other than hydration (see below) occurred on refluxing the acid with an acetic–hydrochloric acid mixture. After heating in quinoline with copper bronze or basic copper carbonate at temperatures up to 245° (one hour), 22–27% of the starting material was recovered unchanged.

When the crude, deep yellow condensation product was crystallized from a mixture of methanol, ordinary ether and petroleum ether, large orange prisms were obtained, along with some yellow needles, from which they were easily separated. When heated in a capillary tube the orange material turned yellow at about 80° and showed the m. p. 246°, dec. Even at room temperature the orange prisms soon became coated yellow on the surface, and an analysis of partially transformed material is significant only in showing that the carbon and hydrogen values are lower than for the yellow material (Found: C, 71.00; H, 4.37). The neutralization equivalent determined on a fresh sample (162) is close to that required for a monohydrate (155). The orange hydrate gives the yellow needles of the anhydrous acid on crystallization from acetic acid–petroleum ether. The orange prisms on treatment with diazomethane give yellow prisms, m. p. 134.5–135.5°, identical with the dimethyl ester described above.

Methyl-9-anthranylcarbinol.—This was prepared by adding 30 g. of the aldehyde in 300 cc. of benzene to the Grignard reagent from 21.5 g. of methyl iodide and 4.05 g. of magnesium in 400 cc. of ether and refluxing for one-half hour. After adding ammonium chloride solution and working up the product there was obtained in all 29.6 g. (92%) of satisfactory material. Crystallization from ether–petroleum ether gave glistening, colorless needles having a blue fluorescence in daylight and a blue-violet fluorescence in ultraviolet light; m. p. 125–126.5°.

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.46; H, 6.81. Found: C, 86.62; H, 6.62.

The only crystalline product obtained on heating the carbinol with potassium bisulfate was anthracene, and sulfuric acid of various strengths gave only colored tars. In a trial of the Tschugaeff reaction 2.5 g. of the carbinol was treated in xylene with 0.35 g. of sodium, and after refluxing for two days the dark liquid was cooled and treated with 3 cc. of carbon bisulfide, followed by 3 cc. of methyl iodide. After refluxing for about one hour the mixture turned yellow and sodium chloride precipitated. The filtered solution was then evaporated and the product distilled at 23 mm. From the distillate there was obtained a crystalline product, m. p. 215.5–217°, identified as anthracene, and a trinitrobenzene derivative, m. p. 122.5–123.5°,

found to be that of **9-ethylanthracene.** A sample of this hydrocarbon was prepared from anthrone and ethylmagnesium bromide according to Sieglitz and Marx[13] in 89% yield, m. p. 56–58°. **9-Ethylanthracene–trinitrobenzene** from this source crystallized from ether–benzene in the form of bright red needles, m. p. 125.3–125.6° (no depression with the above product).

Anal. Calcd. for $C_{16}H_{14}\cdot C_6H_3O_6N_3$: C, 63.00; H, 4.09. Found: C, 62.71; H, 4.15.

In another attempted dehydration the carbinol (14.5 g.) was refluxed in benzene (250 cc.) with excess phosphorus pentoxide for about one hour, the solution was decanted, and the residue was treated with benzene and water and extracted thoroughly with benzene. The washed and dried benzene solution was concentrated somewhat and passed through a tower of activated alumina. Material collecting in blue and deep yellow zones at the top was discarded while that adsorbed in light yellow and colorless (fluorescent) zones was washed into the filtrate with fresh benzene. The solution was filtered through a fresh tower and concentrated, giving in three crops 8.7 g. (35%) of nearly colorless needles. After further purification by repeated crystallization from benzene–ligroin the substance formed glistening, colorless needles having a blue fluorescence in ultraviolet light and melting at 247.5–248°, with some previous softening.

Anal. Calcd. for $C_{32}H_{26}O$: C, 90.11; H, 6.15. Found: C, 89.67; H, 6.30.

This substance, which evidently is an ether, yielded anthraquinone (mixed m. p.) on oxidation with chromic acid in acetic acid solution. No other crystalline product was obtained as such or as the trinitrobenzene derivative from the oily material from the mother liquor.

1,2-Benzanthracene-10-aldehyde.—The 1,2-benzanthracene employed was prepared as described by Bachmann.[15] The yellow color was removed by two treatments with lead tetraacetate[3] but the method of chromatographic adsorption of the chrysogen on activated alumina from benzene solution seemed more satisfactory for large-scale operation. Colorless material, m. p. 160.5–161°, was obtained in this way with little loss.

Phosphorus oxychloride (24.8 g.) was added at a temperature controlled to 25° to 24.8 g. of methylformanilide and 18.5 cc. of *o*-dichlorobenzene; 21 g. of 1,2-benzanthracene was introduced and the mixture heated on the steam-bath with occasional shaking until the hydrocarbon had dissolved (twenty minutes). After a total of two hours the mixture was processed as above and the solidified residue from the steam distillation crystallized from glacial acetic acid (slow cooling). Yellowish plates of the hydrocarbon and yellow prisms of the aldehyde were deposited together. A separation was accomplished most conveniently as follows. The mixture of crystals was collected, washed, dried, moistened with a little alcohol and shaken thoroughly with about 100 cc. of water. The prisms settle rapidly, leaving the plates suspended, and by decanting the suspension and repeating the flotation several times a fairly clean separation can be effected. The two crude products were dried and crystallized from glacial acetic acid (decolorizing carbon), giving in all 8.3 g. of slightly yellow hydrocarbon, the bulk of which melted at 156–159° (no depression with starting material), and 8.1 g. of aldehyde (64%, based on material consumed), m. p. 147–148°. The aldehyde on further purification formed yellow, prismatic needles, m. p. 147.5–148°.

Anal. Calcd. for $C_{19}H_{12}O$: C, 89.03; H, 4.72. Found: C, 89.00; H, 4.98.

The hydrazone was prepared by adding 1 g. of hydrazine hydrate to a solution of 2.6 g. of the aldehyde in 350 cc. of boiling alcohol and heating the mixture just below the boiling point for fifteen minutes. On cooling, the product separated almost completely in the first crop as yellow needles, m. p. 187.5–188°; yield, 2.2 g. (84%). Recrystallization from absolute alcohol did not alter the m. p.

Anal. Calcd. for $C_{19}H_{14}N_2$: C, 84.42; H, 5.22. Found: C, 84.38; H, 5.38.

10-Methyl-1,2-benzanthracene.—The hydrazone (1.9 g.) was heated in a sealed tube with the reagent from 0.27 g. of sodium and 9 cc. of absolute alcohol for ten hours at 205–210°. After dilution with water and acidification of the mixture, the nearly colorless solid when collected and dried was found to melt at 136.5–139°; yield 1.7 g. (quantitative). One crystallization from acetic acid gave faintly yellow, glistening flat needles, m. p. 139.5–140.5°, which did not depress the m. p. of a synthetic sample,[7] m. p. 140.2–140.8°.

1,2-Benzanthracene-10-aldoxime.—A mixture of 2 g. of the aldehyde, 250 cc. of alcohol, 3.13 g. of sodium acetate crystals and 0.93 g. of hydroxylamine hydrochloride was heated just below boiling for fifteen minutes, and the solution was filtered and cooled. The product which separated (1.7 g.) on recrystallization from absolute alcohol formed crusts of light yellow needles melting at 203.5–204.5°, and remelting at 231–232.5°, dec.

Anal. Calcd. for $C_{19}H_{13}ON$: C, 84.11; H, 4.83. Found: C, 83.82; H, 4.90.

10-Cyano-1,2-benzanthracene.—After refluxing the oxime (1.35 g.) with acetic anhydride for fifteen minutes, the solution set to a thick paste of yellow crystals of the nitrile on cooling; m. p. 188–189.5°, yield, 1.25 g. (99%). Recrystallized from glacial acetic acid, it formed light yellow blades, m. p. 188.5–189.5°.

Anal. Calcd. for $C_{19}H_{11}N$: C, 90.09; H, 4.38. Found: C, 90.47; H, 4.40.

Methyl-10-benzanthranylcarbinol.—Prepared as above from 1,2-benzanthracene-10-aldehyde and methylmagnesium iodide, this carbinol was obtained in a satisfactory crystalline condition from ether–petroleum ether in 56% yield. Recrystallized from methanol it formed nearly colorless prisms, m. p. 148–150°.

Anal. Calcd. for $C_{20}H_{16}O$: C, 90.27; H, 5.92. Found: C, 90.55; H, 5.51.

Summary

Methylformanilide in the presence of a condensing agent reacts less readily with 1,2-benzanthracene than with anthracene, and does not react with 1,2,5,6-dibenzanthracene even under considerably more drastic conditions. The prod-

The Preparation of α- and β-Gentiobiose Octaacetates

BY DELBERT DANIEL REYNOLDS AND WILLIAM LLOYD EVANS[1]

Recent investigations in this Laboratory gave rise to a need for considerable quantities of β-gentiobiose octaacetate. The five most important methods for its preparation are as follows: (1) isolation from gentian root,[2] (2) the action of emulsin on glucose to form gentiobiose, which is then connected to β-gentiobiose octaacetate,[3,4] (3) the catalytic hydrogenolysis of amygdalin followed by acetylation,[5] (4) separation from the commercial mother liquors ("Hydrol") obtained in the manufacture of glucose[6] and (5) the condensation of acetobromoglucose with β-*d*-glucose-1,2,3,4-tetraacetate by means of the Königs–Knorr reaction.[7]

The inferior quality of most gentian root renders the first method undesirable. The second method proved objectionable for two reasons, namely, (1) from ten to twelve weeks are required to complete the synthesis, and (2) emulsin is not readily available. The third method has not been tried in this Laboratory because of the relatively high cost of amygdalin. Since the percentage of gentiobiose in "Hydrol" varies greatly, this method leaves much to be desired.

A yield of 23.4% of the theoretical value has been reported for the fifth method.[7] This low yield may be attributed to numerous possible side reactions. The most probable of these is the reaction of acetobromoglucose with water in the presence of silver oxide to form β-*d*-glucose-2,3,4,6-tetraacetate, silver bromide and water. The water formed in this reaction may react with more acetobromoglucose, thus setting up a series of changes which would continually use up the acetobromo compound. Moreover, the β-*d*-glucose-2,3,4,6-tetraacetate may react with acetobromoglucose in the presence of silver oxide to form a trehalose octaacetate and more water. Accordingly, the yield of the β-gentiobiose octaacetate would be greatly lowered.

It was the purpose of this work to make the latter method a practical one for the preparation of β-gentiobiose octaacetate by reducing these side reactions to a minimum. This may be accomplished only if the reaction is carried out under anhydrous conditions. Such conditions are realized by (1) ensuring complete absence of water at the beginning of the reaction and (2) removal of the water from the reaction mixture as rapidly as it is formed, thus keeping the concentration of water in the reaction mixture relatively small at any given time. A preliminary stirring of the tetraacetate, silver oxide and chloroform with a large excess of Drierite assures complete absence of water when the reaction is begun. The addition of a chloroform solution of acetobromoglucose over a considerable period of time, as opposed to adding it in one large portion, permits only a small amount of water to be formed at any given time. The water formed during the reaction may be removed by employing an effective internal desiccant. Studies in this Laboratory[8] have shown that anhydrous calcium sulfate (Drierite) is an excellent substance for this purpose. Other investigators[9] have used powdered calcium chloride in similar reactions. By proceeding with the foregoing facts in mind, β-gentiobiose octaacetate has been obtained in yields as high as 82% of the theoretical value.

After β-gentiobiose octaacetate had been obtained in good yields, it seemed reasonable to believe that α-gentiobiose octaacetate might be prepared by the same method even though α-*d*-glucose-1,2,3,4-tetraacetate could be obtained

only as a sirup. Since the preparation of 6-trityl-*β-d*-glucose-1,2,3,4-tetraacetate is always accompanied by the formation of the *α*-isomer, the sirupy *α-d*-glucose-1,2,3,4-tetraacetate may be prepared advantageously from this source. This affords a new and convenient method for the synthesis of *α*-gentiobiose octaacetate. Thus the over-all yield of gentiobiose octaacetate is greatly increased.

Experimental Part

Purification of Chloroform.—U. S. P. chloroform (500 cc.) was shaken with 12% sulfuric acid for one hour on a mechanical shaker. The chloroform layer was separated, neutralized by a saturated solution of sodium bicarbonate and washed well with water. It was then shaken for an hour with calcium chloride (100 g.), filtered and distilled. After drying for a short time over phosphorus pentoxide, the chloroform was redistilled and stored over Drierite.

Silver Oxide.—The silver oxide was prepared according to the method of Helferich and Klein.[7]

Trityl Chloride.—The trityl chloride was prepared after the method of Gomberg[10] in a modified apparatus and under such conditions that the pure compound was obtained. A mixture of anhydrous aluminum chloride (150 g.) and dry thiophene-free benzene (500 cc.) was placed in a two-liter wide-mouthed bottle equipped with a mercury-sealed stirrer, a dropping funnel and a side tube leading to a beaker of water. Stirring was begun and a mixture of dry carbon tetrachloride (100 cc.) and dry benzene (70 cc.) was added through the dropping funnel. The solution was stirred for an additional hour and then refluxed in a round-bottomed flask until hydrogen chloride was no longer evolved. It was then cooled and poured into a three-liter separatory funnel containing 350 g. of ice and 300 cc. of concentrated hydrochloric acid. The benzene layer was separated immediately and the water portion extracted with benzene. The combined benzene portions were washed with 1:1 hydrochloric acid solution and then dried over calcium chloride. The benzene solution was decolorized by heating it with Carboraffin. The benzene was removed completely under reduced pressure by heating on a water-bath. The residue was refluxed for twenty minutes with acetyl chloride (200 cc.) and allowed to cool. The trityl chloride crystallized at once in a very pure state: m. p. 112–113° (corr.); yield 230 g. (80%).

6-Trityl-*β-d*-glucose-1,2,3,4-tetraacetate.—6-Trityl-*β-d*-glucose-1,2,3,4-tetraacetate and the corresponding *α*-isomer have been prepared from both trityl chloride and trityl bromide. Experiments in which equivalent quantities of the trityl halide compounds were used gave approximately the same percentage yield of the 6-trityl-*d*-glucose-1,2,3,4-tetraacetates. Since trityl bromide is obtained quantitatively in the detritylation process, its re-use reduces both the cost and time of subsequent preparations.

The trityl chloride method as used by Helferich[11] was modified such that the time of preparation was shortened considerably.

A mixture of anhydrous glucose (120 g.), trityl chloride (193.2 g.) and anhydrous pyridine (500 cc.) was shaken mechanically at room temperature. Solution was effected within five hours. Acetic anhydride (360 cc.) was added in one portion without cooling. After standing for about twelve hours the reaction mixture was poured into ten liters of ice water and stirred vigorously for three hours with a mechanical stirrer. The water was renewed once in the meantime. The white granular precipitate was filtered, washed and air dried. It was then mixed with U. S. P. ether (500 cc.) and filtered. This treatment removed most of the 6-trityl-*α-d*-glucose-1,2,3,4-tetraacetate. The insoluble portion was taken up in hot 95% ethanol. Upon cooling, the 6-trityl-*β-d*-glucose-1,2,3,4-tetraacetate crystallized in fine needles usually of sufficient purity for subsequent use. Recrystallization yielded the pure compound: yield 175 g.; m. p. 166–166.5° (corr.).

The trityl bromide method was carried out as follows: 50 g. of trityl bromide (m. p. 130°) obtained by detritylation of the 6-trityl-*d*-glucose-1,2,3,4-tetraacetate was digested in U. S. P. ether (150 cc.) at room temperature for fifteen minutes to remove most of the impurities. It was then filtered and dried. Thirty-eight grams of trityl bromide was recovered which melted at 151–152° (corr.) with slight softening at 147°.

Thirty-seven grams of trityl bromide thus obtained was shaken for eleven hours at room temperature with anhydrous glucose (20 g.) in dry pyridine (200 cc.). Acetic anhydride (60 cc.) was then added and the reaction mixture allowed to stand for twelve hours, after which it was poured into four liters of ice water and stirred vigorously for about five hours. The water was changed twice during this time. The precipitate was filtered, washed and air dried. It was then dissolved in hot 95% ethanol (800 cc.). The crude product (20.6 g.) after one recrystallization from ethanol (400 cc.) melted at 166–166.5° (corr.); yield 19.7 g.

***β-d*-Glucose-1,2,3,4-tetraacetate.**—*β-d*-Glucose-1,2,3,4-tetraacetate was prepared according to the method of Helferich and Klein[7] except for the method of crystallization. The chloroform solution was concentrated to a very thick sirup. Anhydrous ether was added and the sirup rubbed with a glass rod. The tetraacetate separated immediately as small white crystals. This was further purified by dissolving it in the least possible amount of chloroform and adding anhydrous ether until crystallization began, the crystallization being complete in a very short time.

***β*-Gentiobiose Octaacetate.**—Thirty-five grams (1 mol.) of *β-d*-glucose-1,2,3,4-tetraacetate, silver oxide (25 g.), Drierite (100 g.) preheated at 240° for two hours, and dry, alcohol-free chloroform (100 cc.) were placed in a 500-cc. three-necked round-bottomed flask equipped with a mercury-sealed mechanical stirrer, a calcium chloride drying tube and a dropping funnel. The flask was wrapped in black paper. The contents of the flask were stirred for about one hour to ensure the complete absence of water. After the manner of Helferich, Bohm and Winkler[9] 5 g. of iodine was then added to the reaction mixture. Acetobromoglucose (41.3 g., *i. e.*, 1 mol.) was dissolved in dry, alcohol-free chloroform (150 cc.) and then added through the dropping funnel to the reaction mixture over a course of about one hour. The stirring was then continued for an additional twenty-four hours. The reaction mixture was filtered through a layer of "Filter-Cel" and the residue

(11) B. Helferich, L. Moog and A. Junger, *ibid.*, **58**, 877 (1925).

washed well with U. S. P. chloroform. The filtrate was concentrated under reduced pressure and the white crystalline residue taken up in two liters of hot absolute ethanol. Upon cooling, the *β*-gentiobiose octaacetate separated as very pure white crystalline needles: m. p. 195–196° (corr.); yield 50.5 g., 74.1%.

α-*d*-**Glucose-1,2,3,4-tetraacetate.**—*α*-*d*-Glucose-1,2,3,4-tetraacetate was prepared in a manner similar to that of *β*-*d*-glucose-1,2,3,4-tetraacetate with the following exceptions. The chloroform extract of the tetraacetate was shaken with an ice-cold, saturated solution of sodium bicarbonate in order to remove all acetic acid. It was then washed with ice water, dried over anhydrous sodium sulfate, filtered and concentrated to a thick sirup. The concentrate was taken up in a small amount of methanol and the triphenylcarbinol allowed to separate out. After filtering, the methanol was removed under reduced pressure and the resulting sirup repeatedly taken up in chloroform, and reconcentrated. The sirup thus obtained was dissolved in dry ether and shaken with calcium chloride in order to remove any water or methanol still present. The sirup remaining after the removal of the ether under reduced pressure was used for the preparation of *α*-gentiobiose octaacetate.

α-**Gentiobiose Octaacetate.**—Thirty-eight grams of the *α*-*d*-glucose-1,2,3,4-tetraacetate sirup, silver oxide (15 g.), preheated "Drierite" (75 g.), iodine (5 g.), acetobromoglucose (20 g.) and dry, alcohol-free chloroform (300 cc.) were used in this preparation. The reaction was carried out according to the method described for *β*-gentiobiose octaacetate. The sirup obtained by concentrating the chloroform solution of the reaction products was taken up in absolute ethanol (250 cc.) and rubbed with a glass rod. Crystallization began after a few minutes. A yield of 50.9% (16.8 g.) of *α*-gentiobiose octaacetate was obtained. After two recrystallizations the product melted at 191–192° (corr.) and $[\alpha]^{29.5}_{D}$ +51.6° (*c*, 4.29; *l*, 2; $CHCl_3$) C. S. Hudson and J. M. Johnson[12] reported a m. p. 188–189° (corr.) and $[\alpha]^{30}_{D}$ +52.4° for the product obtained by the action of acetic anhydride and zinc chloride on *β*-gentiobiose octaacetate.

Acknowledgment.—The authors wish to acknowledge the assistance given by William G. Dauben and Harold D. McDowell during the progress of this work.

Summary

1. An improved Königs–Knorr synthesis has increased the yield of *β*-gentiobiose octaacetate from 23.4 to 75–80% of the theoretical.

2. A 50% yield of *α*-gentiobiose octaacetate has been obtained by condensing acetobromoglucose with *α*-*d*-glucose-1,2,3,4-tetraacetate. So far as the authors are aware, this is the first time that a 6-linked *α*-octaacetate has been prepared by this method.

3. The complete synthesis of *α*- and *β*-gentiobiose octaacetates by this method may be completed in approximately one week.

4. Trityl bromide, a side product, has been introduced as a tritylating agent, thus decreasing both the time and cost of preparing the gentiobiose octaacetates.

NOTES

The Activity Coefficient of Perchloric Acid, and a Correction to the Value of the Argentous–Argentic Oxidation Potential in Perchloric Acid

By Don DeVault

The calculation of activity coefficients by Pearce and Nelson[1] from their measurements of the vapor pressure of perchloric acid solutions is apparently incorrect. Rosenfeld[2] has completely recalculated their data, obtaining results varying from 7.0% higher at 0.6 molal to 85.4% lower at 12 molal. Professor Redlich[3] has checked his values.

Professor William C. Bray and I have also recalculated the data. The method which Pearce and Nelson report using gave us activity coefficients about 5% lower than those of Redlich and Rosenfeld. Although we examined a number of possibilities, we could not find the source of disagreement with Pearce and Nelson.

Our values of the activity coefficients agree with those of Redlich and Rosenfeld if we substitute, as did they, activity coefficients of hydrochloric acid for those of perchloric acid at 0.6 molal and lower concentration. This procedure receives justification from the electromotive force measurements of Popoff, Riddich, Wirth and Ough,[4]

---

which show that $\gamma_{HClO_4} = \gamma_{HCl}$ up to 0.4 molal. The difference between the activity coefficients in dilute solution calculated from vapor pressure data directly and calculated from the more extensive hydrochloric acid data indirectly are probably due in the main to experimental error in the former measurements, for the assumption of errors of 0.001–0.006 mm. in the vapor pressure of water above the perchloric acid solutions in the points discarded would bring the calculations into agreement. We choose, therefore, the Landolt–Börnstein values as the most probable ones until more experimental work is done.

The Pearce and Nelson activity coefficient values were used to calculate the potentials of the hydrogen half-cells in perchloric acid and also of the perchloric–nitric acid liquid junctions in a series of researches by Professor A. A. Noyes and collaborators[5–9] on the oxidation potentials of strong oxidizing agents. The corrected activity coefficients lead to values of the argentous–argentic potential in 4 *m* perchloric acid[8] of **1.970** v. at 0.2° and **1.987** v. at 25.0°, changes of −12 and −13 mv., respectively. The corrections to the values in mixed nitric–perchloric acid solutions[8] have the small effect of changing the slope of the line in Fig. 2 (representing an average number of nitrates per silver atom in the argentic nitrate complex) from 1.6 to 1.5.

The hydrogen half-cell and the liquid junction potential corrections are of opposite sign and nearly cancel each other in the measurements of the argentous–argentic potential in nitric acid,[5,8] the cerous–ceric,[6] the thallous–thallic,[7] and the cobaltous–cobaltic[9] potentials in nitric acid. Dr. C. S. Garner[10] has corrected these potentials taking into account the newer Landolt–Börnstein values for the activity coefficient of nitric acid also. The over-all corrections range from −1.3 to +0.6 mv. and are probably negligible in view of the uncertainties in the liquid junction potentials. No other arguments or conclusions in these papers are affected by these changes.

I wish to acknowledge with gratitude the help and advice of Professor Bray, Dr. C. D. Coryell and Dr. C. S. Garner in preparing this note.

The Physical Constants of *cis*-Pentene-2

BY MARY L. SHERRILL AND ELIZABETH H. LAUNSPACH

In a recent article[1] the synthesis of *cis*-pentene-2 by the semi-reduction of pentyne-2 was reported. The designation of this pentene-2 as the *cis* form was based on the method of preparation and the assignment of structure was confirmed by its ultraviolet absorption in the Schumann region.[2] Because the quantity of the pentene-2 was insufficient for column fractionation, it was thought that there might be traces of pentyne present which would have the most marked effect on the boiling point and the density. The work has been repeated and the pentene-2 fractionated twice through a Fenske column (Column A). This column was 35 × 1.5 cm., with 1-turn 4-mm. glass helices. The reflux ratio for the two fractionations of the pentyne-2 was 1:20. The index of refraction was identical with that of the earlier preparation but the boiling point and the density were appreciably lower. The physical constants remained unchanged by the second fractionation and it is believed that the values so obtained constitute the most reliable data for the pure *cis*-pentene-2. Absorption spectrum measurements on this product gave no evidence of the presence of any of the *trans* isomer. These results therefore confirm the assignment of the *cis* structure to the higher boiling pentene-2, as is the case for the higher boiling isomer of butene-2.

The pentyne-2 was prepared in satisfactory yield from 2,3-dibromopentane by the action of alcoholic potassium hydroxide. This reaction takes place in two stages: the first being the formation of the pentyne-2 together with a mixture of 2-bromopentene-2 and 3-bromopentene-2. In the second stage of the reaction with more concentrated potassium hydroxide and prolonged heating at a higher temperature, these bromopentenes are converted into pentyne-2. In some cases appreciable amounts of pentyne-1 were also obtained; by further treatment with alcoholic potash this was transformed into pentyne-2. It is of interest to note that the 2,3-dibromopentane was prepared from pentene-2 which was a mixture of 25% of the *cis* and 75% of the *trans* isomer. In the course of fourteen different preparations of pentyne-2 there was always a 25% yield of pentyne-2 in the first stage of the reaction.

Half mole portions of a constant boiling frac-

tion of pentyne-2 (b. p. 55.9 ± 0.05° at 760 mm., n^{20}_D 1.4040, d^{20}_4 0.7115) were hydrogenated in an alcohol–water solution in the presence of colloidal palladium. Slightly less than the theoretical quantity of hydrogen was used. The pentene with alcohol distilled from the mixture through a Vigreux column at 34–36°. The hydrocarbon (78.5% yield) freed from alcohol had a refractive index n^{20}_D 1.3824. One fractionation through Fenske column A gave (1) 5% boiling at 36.8–37.0° and (2) 90% boiling at 37.0 ± 0.05°; the refractive indices of these fractions were, respectively, n^{20}_D 1.3824 and 1.3822, that of the residue was n^{20}_D 1.3840. In a second fractionation of (2) the entire distillate (98%) boiled constantly at 37.0 ± 0.05°, had a refractive index n^{20}_D 1.3822 and a density d^{20}_4 0.6562. The refractive index of the residue was n^{20}_D 1.3826.

The Specific Heat of "Lucite" (Methyl Methacrylate Polymer)

BY FRANK T. GUCKER, JR., AND WILLIAM L. FORD

We have found the polymerized methyl methacrylate plastic now made by the du Pont Company under the trade name of "Lucite" a useful insulating material in our calorimetric work. Many of its physical properties have been tabulated.[1] For our purposes, the specific heat was important and, since we could not find it listed, we determined it as follows.

Fifteen disks each 3 mm. thick were cut from a Lucite rod, $^3/_8$ inch (9 mm.) in diameter. A small hole was drilled in the center of each. The disks were then threaded on pieces of fine copper wire and suspended from the thermel tubes in one calorimeter of the apparatus developed in this Laboratory[2] for measuring heat capacities of aqueous solutions. The disks were spaced apart to allow free circulation of water, with which the calorimeter was filled to the standard height. The resistance ratio required to balance this calorimeter against the tare was then measured in the usual way, with an accuracy of about 0.01%. The heat capacity of the Lucite was calculated from this ratio and the known heat capacities of the water, the calorimeter and the copper wire. Since the heat capacity of the 3 g. of Lucite was only about 0.3% of that of the whole system, the uncertainty in its value is about 3%. The results of two independent experiments actually agreed somewhat better than that, yielding 0.342 and 0.344, and we may take as the probable value of the specific heat 0.343 (±0.005) cal. deg.^{-1} g.^{-1}.

Although its specific heat is larger than that of Pyrex glass, its density is only half as great, and the heat capacity *per unit volume* is only 82% of that of glass. This factor, in combination with a thermal conductance less than half that of glass, equal transparency, great mechanical strength and easy machining, makes Lucite a useful substitute for glass as an insulating material in calorimetric work.

The Methylation of Sugars

BY B. CLIFFORD HENDRICKS AND ROBERT E. RUNDLE

The importance of fully methylated sugars as reference compounds in carbohydrate chemistry has led to many attempts to find more satisfactory methods for their synthesis. Irvine and Purdie[1,2] used methyl iodide and silver oxide in their preparation. A more generally used method[3] is that of Haworth in which dimethyl sulfate and sodium hydroxide are the reagents used. More recently West and Holden[4] have modified the method of Haworth by using carbon tetrachloride as a solvent, a more concentrated alkali and a different method of hexoside hydrolysis to obtain the free methylated sugar.

The authors found that the concentrated alkali, used by West and Holden for the last step in the methylation, produced sugar decomposition. Their first steps, however, were satisfactory for partial methylation.

Muskat[5] has shown that methylation may be accomplished by using free alkali metal and methyl iodide on a hexoside in liquid ammonia. He used potassium which is expensive and prepared only small amounts of the sugars. If sodium metal is substituted for the potassium the cost is reduced but for larger quantities of reactants the insolubility of the tetrasodium salts

of the hexosides makes it difficult to methylate more than one or two carbons of the sugar. For that reason the procedure here reported uses liquid ammonia only for completing methylation started by the West and Holden process.

Experimental

Forty grams of hexoside with 25 ml. of water was put into a flask equipped with a heavy stirrer, separatory or dropping funnel and attached to a condenser. This mixture was then warmed to 50° by a water-bath. A mixture of 108 ml. of dimethyl sulfate in 150 ml. of carbon tetrachloride was then added and the resulting mixture vigorously stirred. A solution of 92 g. of sodium hydroxide in 130 ml. of water was introduced into the flask by means of the separatory funnel at the rate of one drop in two seconds. This rate was increased in such manner that heat resulting barely raised the reaction mixture to the boiling point of the carbon tetrachloride. After the first half of the alkali solution was used the remainder was added more rapidly and the stirring continued for thirty minutes after the last addition.

The contents of the flask were then treated as directed by West and Holden[4] except the partially methylated sirup was dried thoroughly in preparation for the ammonia methylation. To accomplish this it was dissolved in ethyl ether, this solution dried by calcium chloride and after filtering the ether evaporated under reduced pressure.

The liquid ammonia methylation was done in two unsilvered Dewar flasks of about 750 ml. capacity. Flask number one equipped with separatory funnel, an outlet tube and protected from moisture by some desiccant such as calcium oxide was to contain the sirup. The other flask was connected to the first by a glass tube which extended to the bottom of the second. This second flask also had an outlet tube closed by a clamp by means of which liquid ammonia could be forced into flask one by closing the clamp.

Into the first flask 500 ml. of liquid ammonia was passed direct from the tank. A piece of metallic sodium was added to dry the ammonia, after which the sirup was added. The 150 ml. of liquid in the second Dewar received the shavings of metallic sodium (3–4 g.). The sodium salt of the methylated hexoside was then prepared by forcing small portions of the sodium–ammonia solution into the first flask, containing the sirup, as described above. As the hexoside reacts with the sodium the blue color of the solution clears. Successive additions of the sodium were continued until the blue color persisted for an hour after the last addition. At that point 12 ml. of methyl iodide was added dropwise through the separatory funnel. Less of the iodide was used if less than the prepared amount of sodium–ammonia solution had been previously consumed. The liquid ammonia was then permitted to vaporize off and the residue neutralized by 2 *N* hydrochloric acid. After neutralization 400 ml. more of 2 *N* hydrochloric acid was added and the mixture steam hydrolyzed.[4] The product of this hydrolysis was isolated and crystallized as described by West and Holden.

The authors successfully prepared the following tetramethylhexoses by this combination method.

Tetramethyl- M. p., °C.			α-*d*-Glucose 92.5–93.5	α-*d*-Mannose 49–50	α-*d*-Galactose 70.5–71.5
Specific rotation	Init.	$[\alpha]^{0}\mathrm{D}$	+104.0	+11.5	+146.0
		$[\alpha]^{25}\mathrm{D}$	+104.0	+ 6.3	+150.5
	Final	$[\alpha]^{0}\mathrm{D}$	+ 80.4	+ 2.5	+112.1
		$[\alpha]^{25}\mathrm{D}$	+ 84.8	− 0.2	+119.9

The yield for the tetramethyl α-*d*-glucose was 20–25 g.: for the other two somewhat less. Those two sugars were rather difficult to crystallize[6] though the quantity of sirup in each case was as great as for the glucose.

In this combination method of methylation the amounts of methylating agents used were but slightly more than the theoretical, making the cost comparatively small. The time required was more than for the procedure of West and Holden but much less than that by Haworth's method. The quantities of sugars processed were larger than those used by Muskat.

The Ineffectiveness of β-Aminopyridine in Blacktongue

BY F. M. STRONG, R. J. MADDEN AND C. A. ELVEHJEM

Subbarow, Dann, and Meilman[1] recently reported that β-aminopyridine was highly active in the treatment of blacktongue in dogs. Our attempts to demonstrate the activity of this compound have given uniformly negative results.

The compound was prepared by a Hoffman degradation of nicotinamide according to Pollak,[2] and after being purified by distillation (b. p. 132–134° at 20 mm.) and crystallization from Skelly solve "B," formed glittering, colorless plates, m. p. 61–63°. *Anal.* Calcd. for $C_5H_6N_2$: C, 63.82; H, 6.43. Found: C, 63.80; H, 6.35.

The picrate was prepared in dilute alcohol solution, and after being crystallized from alcohol melted at 200–201°. The chloroaurate precipitated instantly on mixing aqueous solutions of the reactants and was crystallized from 1–1 hydrochloric acid as red-brown needles, m. p. 237–239° (dec.). *Anal.* Calcd. for $C_5H_6N_2 \cdot HAuCl_4$: Au, 45.4. Found: Au, 44.8, 44.8.

The dihydrochloride which was obtained from the free base and concentrated hydrochloric acid was recrystallized twice from concentrated hydrochloric acid and then from absolute alcohol. Colorless, granular crystals of m. p. 170–173°

[1] Subbarow, Dann and Meilman, THIS JOURNAL, **60**, 1510 (1938).

[2] Pollak, *Monatsh.*, **16**, 54 (1895).

were obtained. *Anal.* Calcd. for $C_5H_8N_2Cl_2$: Cl, 42.47. Found: Cl, 42.34, 42.54. Mixed with a sample of β-aminopyridine dihydrochloride kindly sent to us by Dr. Y. Subbarow, the melting point was 173–175°. There thus seems to be no question but that the compound assayed in each laboratory was actually β-aminopyridine.

The following results were obtained when the compound was administered to dogs suffering from blacktongue. The method of producing blacktongue has been described.[3]

1. On 6/13 a 6800-g. dog showing slight symptoms of blacktongue was given 23 mg. of β-aminopyridine orally, and on the next day a further oral dose of 23 mg. was given. During the next two days the symptoms became progressively worse, and the weight dropped 100 g. On 6/15 two 30-mg. doses of nicotinic acid were fed. Two days later the symptoms were much improved and the dog weighed 7200 g. On 6/22 the weight was 8000 g. and the dog was completely cured.

2. On 6/21, 100 mg. of β-aminopyridine was given orally to a 5400-g. dog suffering from severe blacktongue. Two days later the symptoms were slightly worse, and the weight had dropped to 4900 g. One hundred mg. of nicotinic acid was then fed. Four days later the dog weighed 5500 g. and was completely cured.

3. An aqueous solution of β-aminopyridine dihydrochloride containing 6.67 mg. per cc. was adjusted to *p*H 4.4 with sodium hydroxide. A dog which had been kept on the blacktongue-producing diet until its weight had dropped from 5600 g. to 4800 g., but in which symptoms of blacktongue had not yet appeared, was given daily doses of 20, 20, 20, 20, 15 and 15 mg., respectively, of the dihydrochloride by subcutaneous injection of the above solution. During this six-day period (7/7–13) the weight remained at 5000 g., and no symptoms of blacktongue appeared. On each of the four succeeding days (7/13–16) 15 mg. of nicotinic acid were administered by subcutaneous injection. After four days of this treatment the animal's weight had increased to 5600 g., and three days later (7/19) to 6200 g.

4. A 4250-g. dog suffering from rather severe blacktongue was given three 20-mg. doses of β-aminopyridine dihydrochloride on three successive days. Administration was by subcutaneous injection of the above described solution, which had been readjusted to *p*H 1.8 (approximately the *p*H of a solution of 6.67 mg. of the pure dihydrochloride in 1 cc. distilled water). Since the dog weighed only 3800 g. and was much worse on the third day, the dose for the fourth day was increased to 40 mg. On the fifth day of the assay the dog weighed 3400 g., and was in such bad condition that death ensued, despite the injection of 30 mg. of nicotinic acid.

5. A 10-kg. dog was given 100 mg. of β-aminopyridine dihydrochloride daily for three days (7/29–31). The substance was injected subcutaneously in the form of a solution containing 12.3 mg. per cc., *p*H 1.25. The β-aminopyridine used in this case was obtained from Dr. T. Spies, University of Cincinnati. The symptoms of blacktongue which were slight at first had become worse at the end of the third day, and the weight had dropped to 9600 g. The dog was allowed to remain untreated for two more days and the weight dropped to 9100 g., while the symptoms became very severe. One hundred mg. nicotinic acid was then injected (8/2) and after two days the dog weighed 9600 g. and showed definite improvement. On 8/5 50 mg. of nicotinic acid was injected and on 8/8 the weight was 10,100, and the animal was completely cured.

6. A 9200-g. dog was given 100 mg. of β-aminopyridine dihydrochloride daily for three days (8/19–21). The substance was injected subcutaneously in the form of a solution containing 12.3 mg. per cc., *p*H 1.25. The β-aminopyridine dihydrochloride used in this case was obtained from Dr. Y. Subbarow, Harvard University. The symptoms of blacktongue which were slight at first remained unchanged but the weight dropped to 8900 g. The dog was allowed to remain untreated for one more day and the weight dropped to 8400, while the symptoms remained the same. One hundred mg. of nicotinic acid was then injected (8/23) and after two days the dog weighed 9200 g. and the symptoms of blacktongue were markedly improved. On 8/25 100 mg. of nicotinic acid was injected and on 8/29 the animal weighed 10,400 g. and was completely cured.

In this connection it has been found in this Laboratory (unpublished data) that β-aminopyridine cannot replace nicotinic acid as a growth essential for *Staph. aureus.*

It is evident from these results that β-aminopyridine as tested in our laboratory has no activity as compared to nicotinic acid in the treatment of blacktongue.

The Inactivity of β-Aminopyridine in Blacktongue

BY Y. SUBBAROW AND W. J. DANN

Dr. Elvehjem has informed us privately of his findings as reported in the preceding communication and as a result we have re-examined the question of the activity of β-aminopyridine in blacktongue. We have been unable to repeat our earlier observation that small doses of this substance will cure blacktongue, or to account for the cures then obtained. It is, however, clear that our earlier conclusion is incorrect and that β-aminopyridine is not a blacktongue preventive factor.

COMMUNICATIONS TO THE EDITOR

THE QUANTUM YIELD OF CHLOROACETIC ACID HYDROLYSIS

Sir:

Following the report by Rudberg [*Z. Physik*, **24,** 247 (1924)] of a quantum yield of unity for the hydrolysis of monochloroacetic acid in aqueous solution at 2537 Å., this reaction has been employed in a number of cases as an actinometer.

A deviation in the results obtained with the uranyl oxalate and chloroacetic acid actinometers at 2537 Å. has led us to reinvestigate both reactions. A solution 0.01 *M* in uranyl sulfate and 0.05 *M* in oxalic acid gave an average quantum yield of 0.60, in agreement with the value reported by W. G. Leighton and Forbes for this wave length [THIS JOURNAL, **52,** 3139 (1930)]. For a solution 0.5 *M* in monochloroacetic acid, at 25° and an incident intensity of 2×10^{12} to 1×10^{13} quanta/mm.^{2} sec., we find a quantum yield of 0.3 to 0.4 at 2537 Å. This result has been checked on two independent experimental set-ups, using different thermopiles and standard lamps as well as different samples of chloroacetic acid. Amount of hydrolysis was determined in both cases by potentiometric titration of the chloride ion. The results show some variability the source of which has not been located. There seems little doubt, however, but that under our conditions the quantum yield at 2537 Å. is much below unity, and we wish to call this to the attention of any who may be using or considering the use of this reaction as an actinometer.

LOCATION OF OXYGEN IN CERTAIN STEROIDS

Sir:

In certain compounds of a steroid nature which occur in the adrenal gland there is an atom of oxygen which is exceedingly inert whether in the form of a ketone or of a hydroxyl group [Mason, Hoehn, McKenzie and Kendall, *J. Biol. Chem.*, **120,** 719 (1937)]. Consideration of the possible locations for such an oxygen atom led to the conclusion that it must occupy position 11 or 12 of the steroid nucleus [Kendall, Mason, Hoehn and McKenzie, *Proc. Staff Meet. Mayo Clinic*, **12,** 136, 270 (1937); Steiger and Reichstein, *Helv. Chim. Acta*, **20,** 817 (1937)]. Steiger and Reichstein [*Helv. Chim. Acta*, **21,** 828 (1938)] have recently compared the acid (our acid 1) obtained by oxidation of corticosterone (our compound B) with the 3,11-diketo-Δ^4-*etio*-cholenic acid prepared by degradation of digoxigenin and have found it to be different. They consider that this result casts doubt on position 11 as the location of the oxygen atom in question although it is not conclusive in view of the possible isomerism of the steroid skeleton. We have made a similar comparison with 3,12-diketo-Δ^4-*etio*-cholenic acid and have found that the acid derived from corticosterone differs widely in its properties. This result eliminates the possibility that the oxygen atom in question occupies position 12 of a normal steroid nucleus. The close similarity of the behavior of this oxygen atom with that of the oxygen atom of sarmentogenin which has been assigned to C-11 argues for an identity of position. Degradation of sarmentogenin, which is known to differ from digoxigenin only in the configuration of 1 asymmetric center, probably C-9, should yield a definite answer to this problem.

The degradation of desoxycholic acid to 3,12-diketo-*etio*-cholanic acid has been described [Hoehn and Mason, THIS JOURNAL, **60,** 1493 (1938)]. Bromination in acetic acid solution gave 4-bromo-3,12-diketo-*etio*-cholanic acid, m. p. 197–198° (dec.); $[\alpha]^{25}{}_{5461}$ + 109 ± 2°. (Calcd. for $C_{20}H_{27}O_4Br$: C, 58.52; H, 6.64; Br, 19.42. Found: C, 58.40; H, 6.65; Br, 19.19.) This bromo acid lost hydrogen bromide when refluxed with pyridine to yield 3,12-diketo-Δ^4-*etio*-cholenic acid, m. p. 205–207°; $[\alpha]^{25}{}_{5461}$ +240 ± 5°. (Calcd. for $C_{20}H_{26}O_4$: C, 72.68, H, 7.93. Found: C, 72.35; H, 8.24.) Our acid 1 melts at 267–269°; $[\alpha]^{25}{}_{5461}$ +291°. Use of the methyl esters gave better yields and the final product was more readily purified. The ester of the bromo acid melts at 200–201°; $[\alpha]^{25}{}_{5461}$ +170 ± 3°. (Calcd. for $C_{21}H_{29}O_4Br$: Br, 18.79. Found: Br, 18.94.)

Methyl 3,12-diketo-Δ^4-*etio*-cholenate melts at 235–237°; $[\alpha]^{25}_{5461}$ $+242 \pm 2°$. (Calcd. for $C_{21}H_{28}O_4$: C, 73.23; H, 8.19. Found: C, 73.25; H, 8.36.) The methyl ester of acid 1 melts at 178–179°; $[\alpha]^{25}_{5461}$ $+289 \pm 7°$.

NEW BOOKS

An Introduction to Microchemical Methods for Senior Students of Chemistry. By CECIL L. WILSON, M.Sc., Ph.D., Senior Assistant in Chemistry, The Queen's University of Belfast. Chemical Publishing Company of New York, Inc., 148 Lafayette Street, New York, N. Y., 1938. 196 pp. 93 figs. 12.5 × 19 cm. Price, $3.00.

The book is written for the use of senior students in introductory courses on microchemistry. The author will acquaint the students "with the large field covered by microchemistry," but he has no intention of making the students capable "of undertaking advanced work utilizing microchemical methods." The scope of the proposed course is wide as may be derived from the following list of chapters: the compound microscope and its use (35 pp.), crystallization (6 pp.), observation of transition points and Liesegang rings (7 pp.), the polarizing microscope (16 pp.), classification of crystals (9 pp.), crystal tests (6 pp.), spot tests (8 pp.), inorganic qualitative analysis (29 pp.), inorganic gravimetric analysis (16 pp.), inorganic volumetric analysis (4 pp.), the tintometer (3 pp.), the colorimeter (6 pp.), the nephelometer (3 pp.), organic operations (12 pp.), residue- and Kjeldahl determinations (3 pp.), photomicrography (6 pp.), and the spectrograph (10 pp.). It is obvious that the number of suggested experiments must be small in every chapter.

The reviewer is of the opinion that the book would have gained in value if various rather unimportant discussions had been suppressed in favor of a more detailed description of the procedures. Nearly the whole page 169 is devoted to a discussion of the reasons for not including the more important determinations of quantitative organic elementary analysis, but a list of apparatus is missing, and the concentrations of the inorganic solutions listed in the appendix are not indicated.

The introduction contains the statement "...this was the acknowledged motive which first led Pregl to develop his invaluable work on organic microanalysis. Almost at the same time Emich was laying similar foundations in the inorganic branch, his work being at least in part inspired by the spectacular success attained by Pregl."

It may be permitted to recall the facts that Emich started his microchemical investigations before 1900, that Pregl did not enter the field before 1909 and acknowledged in his book that Emich had laid the groundwork, and finally that Pregl's "spectacular success"—obviously the Nobel Prize awarded in 1923—came far too late to have any influence on Emich's numerous contributions to the development of microchemistry.

A. A. BENEDETTI-PICHLER

Katalyse und Determinismus. Ein Beitrag zur Philosophie der Chemie. (Catalysis and Determinism. A Treatise on the Philosophy of Chemistry.) By ALWIN MITTASCH. Verlag von Julius Springer, Linkstrasse 22–24, Berlin W 9, Germany, 1938. ix + 203 pp. 10 figs. 14.5 × 22 cm. Price, RM. 9.60.

This work consists of a discussion of general philosophical problems, especially those in the philosophy of science, *e. g.*, causality, determinism, organicism and teleology. The author takes account particularly of the bearing of what is now known about catalysis as a basis for his considerations. His standpoint is that of a physical chemist who has read widely and carefully in the literature of philosophy and who probably attaches more importance to philosophical speculation than do most chemists.

L. J. HENDERSON

Die Theorie der Komplexität und der Allotropie. (The Theory of Complexity and Allotropy.) By DR. A. SMITS, Professor and Director of the Laboratory of General and Inorganic Chemistry of the University of Amsterdam. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 35, Germany, 1938. xii + 372 pp. 153 figs. 15.5 × 22 cm. Price, RM. 19.50.

The author states that he has set himself the task of setting forth the new material which has accumulated in the sixteen years since the appearance of his book on "The Theory of Allotropy," and of discussing it from the standpoint of the theory of complexity of phases. He has wished to include some of the topics treated in the earlier book, but for reasons of space has omitted some of the chapters, more particularly that chapter dealing in detail with the systems phosphorus and cyanogen.

The early chapters of the book set forth clearly the author's theory of phase complexity and his concept of pseudocomponents, with plentiful diagrams showing the relationship of the unary system at equilibrium to the pseudobinary or pseudoternary systems obtainable when the approach to internal equilibrium can be inhibited. Here, as also in later chapters, it is shown that recent theoretical work has postulated an increasing number of finer differences in atomic or molecular structure which are in accord with the author's theory of a very general occurrence of complexity within a single phase.

The sixth chapter discusses two of the conditions which favor the detection of phase complexity, intensive drying and low temperatures. The discussion of intensive drying omits the consideration of Baker's well-known experiments, which were treated *in extenso* in the earlier book, but gives the author's results on the heat of condensation of benzene vapor, which are in accord with Baker's in showing that intensive drying gives definite evidence that benzene is complex. The separation of ortho and para hydrogen at low temperatures is viewed as a notable example of complexity in a substance as supposedly simple as hydrogen gas.

The later chapters contain discussions, many of them in extended form, of the occurrence of complexity in the cases of acetaldehyde, the ammonium halides, sulfur trioxide, etc. The use of the Raman effect in the study of the various modifications of sulfur trioxide is given in detail.

It hardly needs to be said that Smits' latest book contains a fuller exposition of the data and theory of phase complexity than exists elsewhere, since the theory and much of the data are Smits' own contribution to chemical science. Those who have given little thought to the subject will be surprised at the frequency with which complexity in a phase has been shown to exist, and may well bear the facts in mind when baffling and supposedly inexplicable experimental results turn up. Those who are more familiar with the subject will profit by reading Smits' book, though they may find it occasionally somewhat repetitious. The printing and diagrams are good; page references occasionally are wrong. The "gesenkter Auslandspreis" is RM. 19.50.

Julius Stieglitz
(1867–1937)

JULIUS STIEGLITZ

May 26, 1867–January 10, 1937

Julius Stieglitz, as also his identical twin, Leopold, was born in Hoboken, New Jersey, May 26, 1867. His father, Edward Stieglitz, was a native of Thuringia, Germany; his mother, Hedwig (Werner) Stieglitz, of New York.

The father came to America in 1849 when he was fifteen years of age and settled in New York City where he was in a short time established as a successful importer of woolen goods and after due time became a man of considerable wealth.

Other children of the woolen merchant and his wife were Alfred, older by three years than the twins, as they were always referred to in childhood, and three sisters, Agnes, Flora, and Selma.

The father is remembered as an austere and stern man, but always very fair toward his children. Neither father nor mother had had much formal schooling but, with a keen interest in literature, music, and art, they gradually acquired that self-made education that led, as is often the case, to a high degree of culture.

Julius' father early determined to give his sons the best possible education and all the advantages he had lacked in his youth. With this incentive, when the twins were four years old, the family moved across the Hudson to New York City where a home was established at No. 14 East 60th Street.

The schooling of the twins began at the Charlier Institute in New York. Here instruction was largely in the French language. German was much spoken in the family circle. Later the twins were sent to the city schools where their English was developed. There by hard work, they soon led their class and maintained this standard until 1881 when the work of the primary schools was completed.

The family treasures a story at which they still laugh; in an old fashioned spelling match of those days for the schools of the city, Julius had come through the contest with flying colors until only himself and one other contestant were left, when he was tripped on the word, "Israelite."

In 1873 the father took Alfred, the oldest son, on a vacation trip which included a visit to Lake George, New York. He was so pleased with the splendid scenery of the place and the very good fishing he found there that he decided to make this the site for his summer residence. The following year he brought the family to the Fort Henry Hotel on the lake. Some years later the beautiful estate, "Oak Lawn," was acquired which became the beloved center of family life. Here the entire Stieglitz family gathered, together with a host of friends: musicians, artists, actors, and other brilliant and talented people drawn together by kindred interests. The dinner table, at which rarely less than eighteen were present, was presided over by the mother, a typical matriarch full of gentle kindness, wit, and unlimited hospitality. The entire family was a large clan which kept in touch with each other for fifty years.

At the age of fourteen, having finished the elementary school, the twins were ready for high school. The father, thinking always of the greatest good for his sons, knowing of the superior advantages of German schools at that time and convinced of the broadening influence of travel and life abroad, interrupted his business and took his entire family to Germany.

The twins were placed in the famous Real Gymnasium at Karlsruhe.

Here all was new; they were far from home for the first time. The going was hard at first, the language caused uncertainty for a while; but, at the end of six months, most of the difficulties cleared up and before long, as in New York, they were at the top of their classes. They maintained this position throughout their five years at the Real Gymnasium.

During the Karlsruhe period they found a home with Professor Trautlein who was director in the Karlsruhe Gymnasium (not the Real Gymnasium). This turned out to be a most happy and genial connection. The family and their friends were given to philosophical discussions. These greatly interested and stimulated the twins.

Aside from their studies, there were other interests and diversions in the life at Karlsruhe. The study of music which had been taken up earlier was now continued. Julius studied the cello under Lindner, first cellist at Beyreuth and a noted teacher; Leopold studied the violin. These lessons pleased the twins much since they had real talent for music.

Social dancing and skating to music offered further entertainment in winters. Bicycling in the Black Forest and hiking in Switzerland were their favorite summer pastimes.

At the age of eighteen, Julius fell in love with a girl who was, later, to become his wife. Nothing was more natural than that Leopold should enjoy the same good fortune with the sister, with like ultimate result. The young ladies were Anna Maria and Elizabeth Stieffel, daughters of a German Lutheran family.

The writer, from personal knowledge, can vouch for the beauty, wit, charm, and vivacity of Mrs. Julius Stieglitz, whom he came to know well in later years.

These early engagements were most fortunate for the twins. If the seven years that were to elapse before marriage seemed long to Julius, the wait had its compensations. He devoted himself assiduously and with undivided attention to his studies in order to hasten the day when he should be able to claim his beloved Anna.

During all these years of study the twins remained in Europe. Their father often advised them but left the decision of their careers to their own free choice. It is true that his advice was strongly against their entering business. He wrote that his inquiries led him to think that the most promising professions in the future would be in engineering, medicine, and chemistry. This advice the three sons took seriously. By 1886, when the course at Karlsruhe was finished, the older brother, Alfred (see "Who's Who"), had already begun his studies in engineering.

Leopold chose medicine as his life work and doubtless Julius would have preferred this profession also but for one consideration that, as the years passed by, had become more and more apparent.

As far back as memory extended he and his brother had been to every one, "The Twins." They were so much alike in appearance as to defy identification except by their most intimate friends. Their mentalities were equal; their tastes and dispositions were identical; what one did, the other did also. In school they were always in the same class, where they were equally proficient.

They began to realize that if they were ever to make for themselves separate and independent careers they must choose different professions and each must go his own way. Therefore when Leopold chose to follow medicine and went to Heidelberg, Julius decided to take up chemistry and for this purpose entered the University of Berlin.

Julius began his studies at Berlin in 1886; his professors were Tiemann, Hofmann, and Rammelsberg in chemistry and Helmholtz in physics.

His thesis, under Tiemann's direction, entitled, "Ueber die Kondensation der Säureamide und analoger Körper durch Abspaltung von Ammoniak oder dessen Derivaten," was completed in 1889 and led to the granting of the Ph.D. degree. Later Stieglitz went from Berlin to Göttingen for a short time to work with Victor Meyer. In 1889 he returned to New York. He was now 22 years old and had lived in Germany the previous eight years.

In 1890 Dr. Stieglitz spent a few months at Clark University as a scholar. He was attracted there by John U. Nef, a brilliant young organic chemist and a Harvard graduate who gained his doctorate at Munich with Adolph von Baeyer.

Later in 1890, Stieglitz found a position with Parke, Davis and Company, manufacturers of pharmaceuticals in Detroit, where his work was chiefly in toxicology. His duties centered about the examination of bodies of persons suspected of having been poisoned. His findings, reported to the coroner, often formed when positive the basis of indictments for murder. Since life or death was dependent upon the accuracy of his analyses, the responsibility of his duties weighed heavily upon him and the lugubrious work was painfully distasteful. After two years he resigned and decided to return to academic life as much better suited to his tastes.

He thought he saw his opportunity at the newly revived University of Chicago which was to open October 1, 1892, with William R. Harper as president. Hitherto colleges had started as academies and had grown painfully and slowly. Now it was proposed, with the backing of John D. Rockefeller, to launch a true university. A faculty of outstanding strength had been chosen by Harper, whose ability to judge men was phenomenal.

Nef was called from Clark University to head the department of chemistry. Michelson was in physics, Chamberlin in geology, Donaldson in neurology, Moore in mathematics, Coulter in botany, Whitman in zoology, Loeb in physiology, and Hale in astronomy. What wonder that young Stieglitz should wish to join such a remarkable group of scientists! His letter to Nef applying for an assistantship in chemistry brought the reply that none was available but that if he wished he could come as docent without salary, but with the privilege of giving lectures from which part of the students' registration fees were allowed him in lieu of salary. This opportunity Stieglitz promptly accepted, thanks to the financial help from his father which allowed him to do so.

The work in chemistry at Chicago was started in temporary quarters over a store at 55th Street and Ellis Avenue. A year and three months later, January 1, 1894, Kent Chemical Laboratory, a stately and commodious Gothic structure in Bedford stone was dedicated. In June, 1895, when the writer began his work under Dr. Stieglitz, not more than one third of the building was in use for chemistry. At the start the faculty embraced John U. Nef as professor; Henry N. Stokes and Edward A. Schneider, assistant professors; Massuri Ikuta, assistant; Felix Lengfeld, Julius Stieglitz, docents; later Alexander Smith succeeded Stokes when the latter went to the United States Geological Survey.

The new university under the guidance of the magnetic president Harper developed in a way that even the latter could scarcely have expected although his hopes knew no bounds. And with the rapid, unprecedented growth of the university, the advancement of the youthful docent kept equal pace. The progress of Dr. Stieglitz is marked by the following steps:

1892–93	Docent
1893–94	Assistant
1894–97	Instructor
1897–02	Assistant professor
1902–05	Associate professor
1905–33	Professor
1912–24	Director of University Laboratories
1915–33	Chairman of the Chemistry Department
1933–37	Professor Emeritus

The chairmanship of the department followed the death of Professor Nef.

During this time the home life of Dr. Stieglitz had developed very happily. In 1891 came the long-hoped-for marriage to Fräulein Stieffel, who had remained in Germany up to this time. The ceremony was celebrated at Oak Lawn, Lake George, New York. Julius was now twenty-four years of age. Three children soon arrived, the first died at birth, the others were Hedwig and Edward.

One of the strongest traits possessed by Dr. Stieglitz was his love for children. His solicitous care led to such precautions that the family became known in university circles as the "sterilized Stieglitzes."

I shall never forget an incident that illustrates the point. It happened at a departmental picnic on the shores of Lake Michigan. One of the ladies had washed a lot of fine strawberries, brought by Mrs. Stieglitz, in water dipped from the lake and mentioned the fact to Mrs. Stieglitz. At this that good lady threw up her hands and sighed, "Ach! Du lieber Gott. I had carefully washed them in *distilled* water at home; now the poor children must get along without strawberries." To this the children, now both doctors of medicine, added, "and we kids caught everything that went the rounds!"

The home was at 6026 Kenwood Avenue where the family lived in simple but comfortable style. With advancing rank and prosperity, emphasis was placed on health and education rather than on elegance and entertainment. This continued to be the home of Dr. Stieglitz and family for the rest of his life, thirty-five years.

With his family life so well settled, Stieglitz was now in a position to devote his energies to his academic work. At first this was two-fold: teaching and research. Later he began to take an active part in university affairs, in which he soon became one of the leaders. As his fame spread his advice was sought by numerous organizations beyond the campus.

The activities of Dr. Stieglitz after joining the university can best be treated under four headings: Teaching, Research, Academic Committees, and Extra-mural Activities.

It was as a teacher that Stieglitz was engaged by the university and it was to this task that he gave his sincere attention first. His work was along two distinct lines: Qualitative and Quantitative analyses, and lectures to graduate students on special topics in organic chemistry. These early lecture courses were on Carbohydrates, Complex Nitrogen Derivatives, and Terpenes. Each course consisted of two lectures a week for a "quarter." The lectures were most carefully prepared in written form, then memorized, and finally given without a trace of notes. They were highly prized and well attended by graduate students and were models of conciseness and accuracy. Not a surplus word was used; when the bell signaled the end of the hour, the last word of the argument had usually been given. The lecture was a finished whole and might well have been printed as delivered. Each time they were offered they were revised so as to include the latest published work on the subject. In later years other courses were offered.

As an illustration of the meticulous care used in the preparation of each lecture, one of his assistants recalls having been sent to Dr. Stieglitz' desk to search for a certain paper. In going through the desk the assistant dug up no less than eight different versions of the same lecture all written out in an effort to arrive at an ideal form for delivery.

Almost from the beginning of his work at the university, analytical chemistry was in Stieglitz' charge. By 1895 he was giving lectures on the fundamental principles on which qualitative analysis is based. At every lecture the long table was filled with apparatus used to illustrate the fundamental principles of his subject. The uniform success of these demonstrations and the clarity and simplicity of his arguments aroused great enthusiasm and attracted many advanced students, other than the undergraduates for which they were given. Through these lectures Dr. Stieglitz exercised great influence over the student body, not only those who went on with chemistry, but others who eventually specialized in other fields. These found his point of view an unforgettable inspiration.

In 1911 the two volume work entitled "Qualitative Chemical Analysis" appeared. Its scope is indicated by the sub-title, "With special consideration of the laws of equilibrium and of modern theories of solution." The introductory sentences of the preface clearly state the reason for their publication, "In venturing to add another book on Qualitative Chemical Analysis to the long list of publications on this subject the author has been moved chiefly by the often expressed wish of students and friends to have his lectures on qualitative analysis rendered available for reference and for a wider circle of instruction." Volume I embodies these lectures in the form to which they have been developed in the course of the last sixteen years. The treatment follows the lines first suggested by Ostwald's pioneering work, "Wissenschaftliche Grundlagen der analytischen Chemie." These volumes are too well known to warrant further description of their contents. Mr. Dana H. Ferrin, Vice-President of the Appleton–Century Company, writes "There have been twenty-two printings (of this work) and I estimate that over two hundred universities and colleges in the United States have used these volumes as their class texts." A most illuminating comment comes from Professor Stanley Wilson, Yenching University, Peiping, China, "I think perhaps that those of you who have been so close to him (Julius Stieglitz) all these years may not realize the full measure of his influence as a teacher." Referring to an article in which the writer speaks of Stieglitz' book as revolutionizing the teaching of qualitative analysis in the United States, Wilson wrote: "The text had a far wider influence than this statement would indicate. In my judgment it is practically the only text produced during the past thirty years which has had a really world wide influence upon the teaching of this branch of the subject. When I came to China twenty years ago I found it was employed in nearly all colleges and universities here. In 1923 I visited a considerable number of outstanding educational institutions in Burma and India. Here again I found the text was known everywhere and widely employed. I was quite surprised at the situation in India as the science staffs of these institutions were either British or British trained."

During a period of approximately twenty-five years Dr. Stieglitz carried on correspondence courses in qualitative analysis and in organic chemistry. It seems evident he enjoyed this contact with students.

The incentive which had led Stieglitz to go to Chicago as a docent without salary was that here he hoped to find not only opportunity for research but, what was more important, adequate facilities, and the encouragement and stimulation of colleagues with similar tastes. He keenly appreciated the belief that research must accompany effective teaching and this for him meant investigation of the problems of pure chemistry.

In all his research Stieglitz was most meticulous and thorough. Of his own work, he was always critical; he dealt with opposing views with candor tempered with moderation and justice. No contrary evidence was deemed too trivial to consider. If experimental work was lacking or inadequate he withheld judgment until he or his students could supply it. No point was too small or too difficult to be thoroughly investigated.

The research papers bearing his name number sixty-six; numerous other addresses, reviews, etc., bring the total to one hundred and thirty. These are supplemented by the theses mostly published in whole or in part, of one hundred and eighteen doctors who took their degrees with him. If we add to this number those whose work was interrupted before having attained the doctorate and those who came to work with him after having obtained their degrees elsewhere, the total would not be far from two hundred.

We may classify his work, which was in pure organic chemistry, into a first period of the early nineties followed by a group of five subjects carried on more or less simultaneously throughout his life. These were: molecular rearrangements, catalysis, indicators and theory of color production, stereoisomerism, and the electron theory in organic chemistry. These groups are so related and were so naturally developed one from another that they form a rather closely knitted whole.

The first eight papers covering the work of 1892 to 1895 resulted from a joint undertaking with Dr. Felix Lengfeld (1863–1938). Lengfeld, older by four years than Stieglitz, had gone from the University of California to Johns Hopkins where he made his doctorate in 1888. After two years at the Universities of Zürich, Liège, Munich, and two more in academic work, he, like Stieglitz threw his fortune in with the new and promising university.

The earlier work of Lengfeld and Stieglitz began with the study of the behavior of bromoamides toward sodium methylate. A specific case is that of the reaction between *p*-nitrobenzbromoamide and a solution of $NaOCH_3$ in $HOCH_3$. The product was a urethan, $NO_2C_6H_4NHCO$-OCH_3, formed as a result of a typical rearrangement.

Lengfeld and Stieglitz saw in the urethans, so easily obtained, intermediate products which might lead, through the corresponding isocyanates, to unsymmetrical ureas by the action of ammonia or amines. Hofmann had found that urethans give isocyanates when treated with phosphorus pentoxide. Lengfeld and Stieglitz tried phosphorus pentachloride which they hoped would react at lower temperatures. In this hope they were right; but the reaction went in a different way. The first product of the reaction was unstable and decomposed giving chlorobromoformanilide and ethyl chloride. They concluded that these products had been formed from an unstable intermediate body, $RNHCCl_2OC_2H_5$, and this they considered as the salt of a carbon base. Numerous stable salts of this class, soluble in water and forming double platinum chlorides, were made. In all such salts it appeared that the halogen was attached to carbon. Even nitrates having the NO_3 attached to carbon were obtained.

In the following paper carbodiphenylimide $C_6H_5N{=}C{=}NC_6H_5$ was found to react with alcohol at 200° to form  $C_6H_5NH{-}\underset{OC_2H_5}{\underset{|}{C}}{=}NC_6H_5$, an isourea. The same compound was obtained at temperatures below zero by means of sodium ethylate. The isourea easily forms with dry hydrogen chloride a salt,  $(C_6H_5NH)_2\underset{Cl}{\underset{|}{C}}{-}OC_2H_5$, which decomposes when warmed (60–80°) giving diphenyl urea and ethyl chloride.

Later, Dains, working with Stieglitz, made other isourea ethers and converted them into ureas by these reactions.

Two short papers on thiamines by Lengfeld and Stieglitz report the last joint work of the authors.

There was in these earlier studies some foreshadowing of Stieglitz' later work, particularly that on molecular rearrangements to which he devoted so much time and energy throughout his productive years.

Molecular rearrangements[1] are generally known by the names of their discoverers as the Lossen, Hofmann, Beckmann, or Curtius rearrangements. Porter[1] calls those involving triphenylmethane derivatives Stieglitz rearrangements. In that which follows an attempt will be made to give a brief account of the nature of the problem and Stieglitz' contribution to the subject.

By way of introduction it may be noted that the well-known Hofmann method of converting acid amides into amines affords one of the simplest examples of rearrangements. The bromoamide RCONHBr first formed by the action of a hypobromite on an amide gives with excess alkali first an isocyanate, RNCO, which is hydrolyzed by more alkali to form an amine, RNH_2, and a carbonate.

Similarly, all the rearrangements considered by Stieglitz exhibit the same striking singularity; the radical R originally bound to carbon becomes in the product attached to nitrogen. In these reactions the ordinary laws of substitution no longer hold.

Stieglitz' interest in this subject came about from a deep appreciation of its bearing on the fundamentals of organic chemistry. In an address before the National Academy of Science, December, 1914, he pointed out the importance of rearrangements in the following words: "In most chemical actions taking place at moderate temperatures a change affecting an atom or group of atoms in a molecule leaves the remaining atoms in undisturbed relation one to another. This stability of grouping of atoms led, especially, in the domain of organic chemistry, to the theory of the structure of molecules and underlies our methods for determining structure. Occasionally, however, the study of the products of a reaction shows that a profound rearrangement of the grouping of the atoms in the reacting molecule has taken place. Molecular rearrangements of this kind are of special importance for the reason that their study should shed some light on the forces holding atoms in place in molecular structures."

At the time the lines here quoted were written, Stieglitz' researches on the subject were in their nineteenth year. All rearrangements so far studied seemed to find an explanation under one simple and unique hypothesis, in which it was assumed that a hypothetical body having univalent nitrogen is an intermediate product in each case.

By Stieglitz' hypothesis, the primary action of alkali on benzoic bromoamide is the removal of hydrogen bromide, leaving C_6H_5CO-N. The great reactivity of the assumed univalent nitrogen then causes the observed rearrangement. The product, phenyl isocyanate, C_6H_5NCO, finally hydrolyzes in aqueous alkali solution giving aniline and a carbonate as end-products. Stieglitz tested this view in a wide variety of cases. Only those bodies which can lose constituents and form a hypothetical intermediate containing univalent nitrogen are capable of rearrangement. Similar rearrangements occur when each of the following classes of compounds is treated with the appropriate reagent.

I	Acid bromoamides	RCONHBr
II	Acyloximido acid salts	RC(NOAcyl)ONa
III	Ketoximes	$R_2C(NOH)$
IV	Oximido acid esters	RC(NOH)(OR)
V	Oximido acids	RCO—NOH
VI	Amide oximes	$RC(NOH)NH_2$
VII	Acid azides	$RCN(N_2)$
VIII	Benzylazides	$RCH_2N(N_2)$

One of the strongest points in Stieglitz' theory is that in all cases the reagent that must be used to bring about the rearrangement is one which will combine with the constituents to be removed. In the case of azides since only nitrogen is lost no reagent is needed; heat alone is sufficient to cause the typical reaction.

Stieglitz' original explanation of the Beckmann rearrangement based as it was on the earlier prevailing views of valence could not be more than an approach to the ultimate solution; this he himself realized.

During the following decade the electron theory as proposed by J. J. Thomson had thrown a new light on the whole subject of valence. A number of chemists had begun to apply Thomson's suggestions to organic as well as inorganic problems. In his National Academy address in December in 1914, Stieglitz expresses his theory of rearrangements in terms of the newer views. In a chloroamine the chlorine is the radical of hypochlorous

---

(1) C. W. Porter, "Molecular Rearrangements," Chemical Catalog Co., New York, 1928 and A. H. Blatt, "The Beckmann Rearrangement," *Chemical Reviews*, **12**, 215 (1933), give extended accounts of the subject. Later critical reviews are to be found in the chapters by Hurd and by Wallis in Henry Gilman's "Organic Chemistry," John Wiley and Sons, New York, 1938.

acid. It is an atom of chlorine that has lost an electron, and is therefore electro-positive. In ordinary chlorides the atom of chlorine has gained an electron, becoming the familiar negative chlorine ion.

He illustrated his newer views by means of a reaction studied by Stieglitz and Leech. Triphenylmethyl chloroamine, $(C_6H_5)_3CNHCl$, when treated with sodium hydroxide gives phenylimidobenzophenone, $(C_6H_5)_2CNC_6H_5$, by loss of hydrochloric acid.

The hypothetical intermediate, $(C_6H_5)_3C\text{-}N$, with univalent nitrogen owes its activity to the loss of two electrons required to convert the positive chlorine, Cl^+, into negative chlorine, Cl^-. The intermediate then undergoes rearrangement. Stieglitz then generalizes as follows: "Finally there is a whole group of rearrangements analogous to that of the chloroamines. In each instance one can plainly recognize as the common characteristic of all rearranging compounds that the labile component in the original molecule is an unstable electro-positive radical or atom, which tends to go over into its stable negative form. In every instance, this tendency is found satisfied in the action, and as this involves the absorption of two electrons from neighboring atoms in the original molecule, one must conclude that in all these cases the tendency mentioned and its satisfaction bring about the rearrangement."

With Miss Vosburg and Mrs. Morgan, Stieglitz found, as he expected, that $(C_6H_5)_3CNCH_3Cl$ which contains the very stable NCH_3 group could not be made to rearrange. On the other hand, when the closely analogous hydroxylamine derivative $(C_6H_5)_3CNCH_3OH$ was treated with phosphorus pentachloride, Stieglitz with Leech and with Stagner proved that a normal rearrangement occurs, as shown by the identification of benzophenone and methylaniline after hydrolysis of the products of the reaction. Stieglitz now recognized that this exception to the result expected by his hypothesis established for the first time that substances which could not form simple univalent nitrogen derivatives may rearrange and that Beckmann's postulate of the direct exchange of radicals should be considered.

However, he concluded: "The first result is that the positive group of the hydroxyl amines and of the oximes undoubtedly becomes a negative group in the course of the reaction; it still would be the unstable radical in the original molecule and the satisfaction of its tendency to become negative would still be the prevailing influence in the rearrangement."

The work of Stieglitz on rearrangements represents an enormous effort. He took up a little known subject, developed it in many details, showed its extent and its limitations, and proposed theories for its explanation. The importance of his work had been recognized by his contemporaries as of outstanding significance.

The second of the four major topics of research, catalysis, had its inception soon after Stieglitz began his work at Chicago. It continued to occupy his attention for more than thirty years, although little of significance was added to his views on this subject after 1917. His war time activities together with already heavy academic interests left but little time for this subject.

In a paper in 1893 Lengfeld and Stieglitz discussed briefly the salts of imido esters and concluded with the statement, "The main importance of the subject is in its application to esterification and saponification by halogen acids." They follow this with graphic equations showing the formation of salt-like chlorides of esters as intermediates in their saponification.

The subject was taken up again experimentally by Stieglitz and McCracken in 1899.

In 1904 Stieglitz discussed his theory of catalysis in an address before the International Congress of Arts and Sciences at the St. Louis Exposition. His more mature views, based on further extensive experimental work with Derby, Schlesinger, and others, were set forth in numerous papers in 1908 to 1913.

According to classical theory, catalytic action can only be studied in reactions that conform to three fundamental principles: (1) Acceleration is proportional to the concentration of the catalytic agent. (2) The catalytic agent acts simply by its presence and does not form a compound with any of the components of the reaction. (3) The condition of equilibrium in a reversible reaction is not measurably changed by the catalytic agent. Stieglitz proposed to set aside these principles and consider the fact of acceleration as the true criterion for catalysis. He returned to the hypothesis that, in the catalysis of esters, the acid forms a salt with the ester, which acts as a weak base. He further supposed that the speed of the ensuing catalysis depends on the concentration of the salt so formed and proposed to subject the question to a quantitative examination from the standpoint of the laws of equilibrium and reaction velocity.

Since simple esters, although they are theoretically weak bases, are far too weak to allow direct measurement of their affinity constants, Stieglitz turned to the imido esters as bases whose ionization constants could be measured. The imido esters proved to be much weaker bases than ammonia, but somewhat stronger than aniline.

The imido esters react catalytically at measurable speeds with acids forming ammonia (or its salts) and simple acid esters. As a result of extensive studies with Derby, McCracken, and Schlesinger, Stieglitz concluded that the positive ion of the imido ester salt is the active substance and that the accelerating action of the acid is due to the formation of larger reacting masses of the active ion from the scarcely ionized, weak base.

To arrive at this result other possibilities such as the activity of the free base or of the total imido ester were taken into account by mathematical methods and shown not to be valid. But the so-called "Salt effect" was noted here, just as in catalysis of acid esters, sugar inversion, etc., and its effect, which is proportional to the hydrogen ion concentration, was deducted in reaching the conclusion that it is the positive ion of the imido ester salt that reacts with water.

In the work with McCracken nine imido esters were studied and a further interesting relationship was noted. The affinity constants of the imido esters as measured by Stieglitz and Derby were not only much smaller than that of ammonia but in general the smaller the constant the faster the decomposition with water took place.

Although the action of water on an imido ester when catalyzed by an alkali yields an alcohol and a nitrile instead of ammonia and an acid ester, as when an acid is a catalyst, Stieglitz showed that the speed of reaction is in accord with his theory. In this case it is the negative ion formed by the imido ester and alkali whose active mass determines the speed of catalysis.

Stieglitz now concluded that the three tenets of the classical theory of catalytic action are practically true only for limiting cases where the proportion of salt formed is negligible. None of the three is absolutely true under any conditions. When the amount of salt formation becomes measurable they need not hold even approximately. It was therefore concluded that acceleration due to an increase in the active mass of a reacting component is the only fundamental fact common to all catalytic reactions.

At the time of his first papers on catalysis, 1904–1907, his brilliant attempt to use the imido esters as a basis of a quantitative analysis of the true factors of hydrogen and hydroxyl ion catalysis made a great impression. However, the work was done before the newer applications of thermodynamics to the study of solutions. In these he did not participate.

The incentive for the papers on indicators seems to have been found when Stieglitz reviewed H. C. Jones' book, "Physical Chemistry," in 1902. In the chapter on indicators color change was explained by Jones according to one part of Ostwald's theory. This, it will be recalled, assumed that phenolphthalein, for example, is a very weak acid which is therefore un-ionized as long as the solution remains even faintly acid. But at the point where a minute excess of alkali prevails, the indicator is converted into its ionized salt. According to Ostwald, the change of color is explained by assuming that the un-ionized phenolphthalein is colorless whereas its negative ion is red.

This very simple explanation seemed so convincing that it was pretty generally accepted, especially as so many other physico-chemical facts had found their elucidation in the magic theory of ionization. Textbooks of physical chemistry all presented the view of Ostwald without reference to other possible explanations.

Stieglitz, whose familiarity with analytical as well as organic chemistry enabled him to see clearly the inadequacy of the theory of Ostwald respecting change of color, presented briefly in this review the contrary evidence from the standpoint of the organic chemist. A year later he elaborated these views into a critical paper on the theory of indicators.

After readily endorsing Ostwald's views of the cause of sensitivity as being due to the weak acidic or weak basic character of an indicator, he called attention to the fact that ten years earlier Bernthsen had given an explanation of the color change that greatly appealed to organic chemists. According to this view the change of color is due to a change of constitution of the indicator brought about by the excess of alkali or acid, the subsequent ionization being merely incidental.

The free (colorless) phenolphthalein is pictured as a lactone, without a chromophoric group

I $\underbracket{\mathrm{OCOC_6H_4C}}\mathrm{(C_6H_4OH)_2}$

while the red salt has the chromophoric form

II 
$$\mathrm{NaOCOC_6H_4}\left\langle\begin{matrix}\mathrm{C_6H_4OH}\\ \mathrm{C_6H_4{=}O}\end{matrix}\right.$$

The solid (and therefore un-ionized) silver salt, is also intensely colored. It undoubtedly has a quinoid form like II. This view is further supported by the work of Nietzki and Bruckhardt, who made colorless esters having lactoid forms corresponding to I and colored (un-ionizable) esters of quinoid form II.

Stieglitz pointed out similar relations for the para rosaniline dyes which contain the chromophoric quinoid grouping, whereas the free base is a colorless carbinol. When dyes in general are converted by reduction into leuco forms, the change of color is concomitant with similar changes of structure.

The work of Hantzsch is cited as showing that the change of colorless organic compounds (pseudo acids) into deeply colored salts is always accompanied by a change in the structure of the molecule as illustrated by the case of nitrolic acid. The regeneration of the free (colorless) form of the pseudo acid often takes place quite slowly.

Stieglitz points out that to be useful as an indicator the reversible color change must be a rapid one.

The behavior of indicators like litmus or methyl orange, which show one color in acid solution and another in alkaline, is explained quite simply by the same theory.

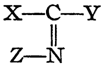
The great merit of Stieglitz' work on indicators lies in the fact that he, more than any other, was instrumental in showing the insufficiency of Ostwald's ionization theory, and in leading chemists to the acceptance of the sounder view based on facts and theories of organic chemistry.

The work on indicators led Stieglitz to propose in an address before the National Academy of Science and the Franklin Institute a highly suggestive theory of color production.

Even if the seat of color in dyes is ascribed to certain rather definite arrangements of atoms in the molecule, there still remains to be explained why such an arrangement causes the light absorption that produces the complementary color in the compound, and why if such atomic groupings are absent the compound is colorless.

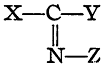
Stieglitz showed that all dyes which easily can be reduced to colorless leuco compounds are oxidizing agents. The leuco bodies are reducing agents which readily are reconverted again into dyes. Stieglitz believed it is the vibration of these mobile but restrained electrons of the dyes that causes the light absorption which results in color.

In his researches on the stereoisomerism of nitrogen compounds, Stieglitz worked with a number of assistants and students, including, Earle, Hale, Eckstein, Hilpert, Peterson, Raiford, and others. In the course of this work a new class of nitrogen stereoisomers was sought for and found. A dozen years earlier Hantzsch and Werner had suggested that the isomerism of the benzil oximes of Victor Meyer was to be likened to that in the case of derivatives of ethylene. Accordingly, we would have the two forms:



$$\begin{matrix}\mathrm{X{-}C{-}Y}\\ \Vert\\ \mathrm{Z{-}N}\end{matrix}$$

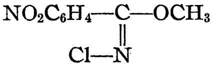
and



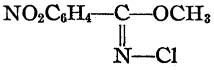
$$\begin{matrix}\mathrm{X{-}C{-}Y}\\ \Vert\\ \mathrm{N{-}Z}\end{matrix}$$

cis and *trans* forms containing doubly bound carbon and nitrogen.

Hitherto all efforts to produce unquestioned nitrogen stereoisomers among bodies other than oximes and hydrazones, where Z is an atom or a simple radical, had been in vain. Stieglitz and Earle had sought such bodies in connection with studies on the rearrangement of halogen amides like $\mathrm{RC({=}NCl)OCH_3}$. This search was at last rewarded when they succeeded in making two methyl chloroimido-*m*-nitrobenzoates



$$\begin{matrix}\mathrm{NO_2C_6H_4{-}C{-}OCH_3}\\ \Vert\\ \mathrm{Cl{-}N}\end{matrix}$$



$$\begin{matrix}\mathrm{NO_2C_6H_4{-}C{-}OCH_3}\\ \Vert\\ \mathrm{N{-}Cl}\end{matrix}$$

A little later Stieglitz and Hale made the analogous pair of ethyl esters. Hilpert made three and Peterson made several others. It was shown conclusively that each of a given pair of substances has identical composition, molecular weight, and structural arrangement, excepting of course in the orientation of the nitrogen–chlorine groups. Each isomer maintains its identity under physical conditions, such as solution, melting, and even volatilization in vacuum.

The only means found to convert the isomers, each into an equilibrium mixture of the two, was the action of chlorine gas on the fused substance. Although the stereoisomers have different solubilities and melting points, their complete individuality was established. Like acid chloroamides these bodies react with hydrochloric acid to form salts of imido esters and free chlorine.

This record of achievement in research marks Stieglitz as one of the strong men of his time. In addition to splendid teaching and high class research, he carried on other activities of great importance both to his university and to the nation.

It was no part of Stieglitz' philosophy that teaching, research, and the writing of textbooks should constitute all of one's duties as professor. His horizon had a much wider scope and not many years had passed before he took an active part in faculty matters. His thorough investigation of the questions involved, his logical and forceful method of presentation of their significance, and his fairness to both sides soon were recognized.

He became a key man whose advice on university affairs was eagerly sought; his was the guiding influence in many committees. I will mention only two instances of the many where his services were of great value; and, in later years, there was scarcely an important question about which he was not consulted.

Of his many memorable achievements, one was that concerned with the conflict between science and the classics. In the early nineties Chicago in common with most other colleges still adhered to a rigid requirement in the classics as a prerequisite for the bachelor's degree even for science students. This inheritance from medieval times was becoming very irksome to the students in Physical and Biological sciences. The preceding twenty years had witnessed amazing and unprecedented developments in Natural Philosophy which had now become a group of experimental sciences with seemingly unlimited possibilities. To be required to thumb through musty tomes of Latin and Greek when so much of greater interest and practical value was at hand seemed, to science students, a sacrilegious waste of time. The battle for the removal of this restriction waxed long and hard; Stieglitz was the leader for the cohorts of science.

In the department of Chemistry at Chicago, Stieglitz' students commemorated the ultimate triumph of the science group by presenting him with a parchment scroll expressing their gratitude for his untiring efforts in their behalf; the names of many who have since risen to prominence are appended.

For one without special training in the subject, Stieglitz was outstanding among his colleagues for having a remarkable knowledge of medicine. This interest arose in early life and doubtless would have led him into that profession but for reasons already mentioned. Perhaps, also, the facts that Mrs. Stieglitz was afflicted with asthma for long years, and that their first child had died at birth and the other two passed through numerous contagious ailments had much to do with the strengthening of this interest.

It seems natural then that in 1901 when President Harper in his desire for a medical school at Chicago began to strive for a union with Rush Medical College as a means to this end, Stieglitz should find a place on the committee of which the late Dr. H. H. Donaldson was chairman.

With only $50,000 in sight, Harper proposed to begin in a modest way by transferring to the university campus the work of the two preclinical years. After a memorable conference of President Harper with the combined committee of the two institutions, in which ways and means were thoroughly discussed, Stieglitz asked Dr. Ingals, treasurer of Rush, the critical question he long had had in mind; that was, whether the tuition fees of the transferred students would revert to the university. When Ingals replied in the affirmative, Stieglitz saw at once that with this additional income the union so greatly desired by the University could be safely made with the $50,000 available. Harper was equally quick to grasp the situation and, in his characteristic fashion, changed the subject immediately and quickly brought the conference to a close. On the way out he said privately to Stieglitz, "Mr. Stieglitz, let me have your budget by next Saturday morning."

Stieglitz had already worked out the details, but to avoid any serious blunders he and Dr. Donaldson made a hurried visit to four leading eastern medical schools prospectuses of which they had studied. They returned convinced that with the laboratories and staffs at the University, together with the modest sum the President had mentioned as being in sight, they could offer facilities equal or superior to those of the schools they had visited.

The union of Rush and the University was soon consummated and proved successful from the start. The hitherto nearly empty Hull laboratories were filled with medical students. The departments of anatomy, physiology, pathology, physiological chemistry, and bacteriology became realities instead of mere names, and suddenly took on new life.

The union with Rush was looked upon by Stieglitz as a vital transfusion of blood into all science departments. He was justly proud of the part he had played in helping to lay the foundation of a great medical institution now a part of the University.

After the premedical courses had been brought to the university the deanship for the new division was offered to Dr. Stieglitz by President Harper. The former with characteristic farsightedness begged to decline the honor and pointed out to the President that he considered it a better policy to put a Rush medical professor in the deanship.

Stieglitz' close association with physicians and surgeons during the period of negotiations with Rush Medical College led to lifelong friendships with many leading medical men. This was the beginning of his affiliation with the American Medical Association that lasted officially two decades, but actually existed throughout his lifetime. In 1905, he became vice-chairman of the powerful Council of Pharmacy and Chemistry, a responsibility he held until 1924. A record for the year 1920 shows Stieglitz' name on five of the fourteen committees of the Council.

Dr. Leech, present secretary of the Council, commenting on Stieglitz' services to the American Medical Society says: "It is proof of his fine judgment and parliamentary ability to note that the rules are essentially the same today as thirty-two years ago. He took great interest in seeing that every safeguard was put in the rules for impartiality of decisions.

"In his capacity as vice-chairman of the Council, Stieglitz exerted a powerful influence on its action during the nineteen years of his tenure of office."

The summer of 1914 marked the beginning of the most critical period for chemistry in America. The British blockade that quickly followed the beginning of the World War shut off importation from Germany and thus soon produced a dearth of the previously imported fine chemicals so necessary for medicine and industry. The situation threatened speedy disaster. In the decade that followed Stieglitz played a conspicuous part among the army of loyal chemists whose efforts proved so successful in this emergency.

On January 1, 1917, Dr. Stieglitz became president of the American Chemical Society. The war was now in the middle of its third year. Three and a half months later America joined the cause of the Allies. As never before, war had developed into a conflict of chemists. Few officers of our society faced graver tasks than did Stieglitz and none deserves greater credit than he for his unselfish services in aiding in the stupendous developments that finally brought relief to medicine and industry and chemical independence to America. His notable success was due not only to his sound and extensive knowledge of organic chemistry, to his love of the science and art of medicine, to his deep interest in synthetic drugs, as evinced by his long service on the Council of Pharmacy and Chemistry of the American Medical Association; but, in no small measure, to his subsequent election or appointment to leading positions in organizations where his opportunities for acquiring information about existing conditions were unexcelled.

On February, 1917, he was appointed Chairman of the Committee on Synthetic Drugs of the National Research Council which committee was the scientific adviser of the Government, and which had been organized in the foregoing year under the authority of the National Academy of Sciences. He also held a semi-official position as adviser to the Federal Trade Commission.

In 1918, he became president of the Chicago Institute of Medicine, an organization having for its object the promotion of medicine through scientific research. At the same time he accepted an appointment in the United States Public Health Service as Special Expert in Arsenicals.

The Chemical Foundation was incorporated in February, 1918; the following month Mr. Francis Garvin became its president and Dr. Stieglitz its Chemical Adviser. In 1920 he was chosen Consultant for Chemical Warfare Service by General Amos A. Fries. During this period he also maintained his position as Director of the Department of Chemistry at the University of Chicago.

Thus his facilities for acquiring accurate information regarding the chemical situation in America were unexcelled, and his prestige assured him a sympathetic hearing among those in authority whenever his advice was offered.

For months the lamentably insufficient supply of synthetic drugs had been an acute problem. Such drugs were formerly imported from Germany almost exclusively. Their number had been much greater than necessary. Many of them had been introduced merely for commercial reasons. Through his various medical connections Stieglitz was able to ascertain that most of these could be dispensed with if but a very small number of the most reliable ones were made available. Only four or five were indispensable and for several reasons it seemed desirable to give these substances new, American names. Arsphenamine was the name coined by Stieglitz for the drug called Salvarsan by the Germans. It is the "606" of Ehrlich and is the recognized cure of syphilis, a disease with which ten million Americans were said to be afflicted.

Barbital (formerly called Veronal) was the most widely used and reliable hypnotic. Procaine (formerly called Novacaine) was the most useful of all local anesthetics. Lack of it necessitated the so-called "Bulgarian operations," those made without anesthesia. Cincophen (Atophan) was the most efficient drug in the treatment of gout and rheumatism. Phenobarbital (luminal) a sedative and hypnotic, was a specific drug for the prevention of the seizures of epilepsy. Physicians and hospitals were literally begging for this drug for two years before it was made in America.

As a member of the Committee on Synthetic Drugs, it was the duty of Stieglitz to see that the public received supplies of these indispensable drugs as quickly as possible. To this end he either induced or encouraged certain reliable pharmaceutical manufacturers to take up their production. He gave them chemical advice and aided them in obtaining the supplies of auxiliary chemicals that were required, as, for example, hydrosulfite, needed to make arsphenamine and bromine, used in the synthesis of procaine.

As Adviser to the Federal Trade Commission, his trying duty was to decide to which manufacturers licenses were to be issued, for the production of each drug.

When, in 1918, it became known to the Federal Health Service that some domestic supplies of arsphenamine were causing serious trouble in the treatment of army cases, Stieglitz, as Special Expert in arsenicals, rendered much valuable service.

Speaking of the Public Health Service, Dr. George W. McCoy, chief of its Hygienic Laboratory, says, "We were urgently in need of the very best advice available anywhere with respect to the standardization as to quality and safety of the preparation of the arsphenamine group. Professor Stieglitz gave unstintedly of his time and effort. It was always a source of great comfort to know that we were proceeding in accordance with the advice and suggestions of Professor Stieglitz."

In his capacity as Professor of Chemistry of the University, Stieglitz and his students conducted important researches on arsphenamine in the course of which it appeared to his satisfaction that the specifications given in the patent were not sufficient to guide a trained chemist to the preparation of a safe product. The additional steps which he employed were highly necessary. His investigations on Phenobarbital, so long in demand by physicians, led to work by Stieglitz and Mary M. Rising that resulted in the finding of improved methods for its preparation through substitution of methyl esters, which are solids easily purified by recrystallization, for the liquid ethyl esters used originally.

It was Stieglitz more than any other chemist who stressed the close genetic relationship between the three great classes of organic substances: dyes, war chemicals, and medicinals. To these, of course, may be added photographic chemicals. In all his efforts to keep this connection to the forefront he clearly saw that an ultimate solution could only be reached through the establishment in this country of a great dye industry. The dye "intermediates" are just those chemicals which form the starting material for explosives, war gases, synthetic drugs, and photographic chemicals. For economic reasons all must go together. The works and equipment for the manufacture of one class of products serves with little modification for all. It was through his connection with the Chemical Foundation that his greatest efforts on this subject were made. In the record of the trial of this organization, Stieglitz' achievements are recorded in much detail.

It will be remembered that this was the celebrated case in which the Government tried to set aside as illegal the purchase of over four thousand German patents covering dyes and related substances and their subsequent license to American firms. The Chemical Foundation had acquired title to the patents through their purchase for $250,000 from the Alien Property Custodian.

The trial occurred in Wilmington, Delaware, in December, 1923, before the Honorable Hugh M. Morris, United States District Judge. In the course of the trial Stieglitz gave valuable testimony in support of the contention of the defendant (C. F.) that a complete domestic dye industry is the logical and only practical defense against a recurrence of the perilous situation in which the country was placed at the outbreak of the World War.

He showed clearly to the satisfaction of the court how and why an adequate supply of dye intermediates would provide those chemicals indispensable for the manufacture, not only of the dyes themselves but also of explosives, war gases, medicinals, photographic, and other fine chemicals. The climax of Stieglitz' testimony, at least for the non-technical audience, was reached when by permission of the court he illustrated his point by an actual demonstration in which he showed that a given intermediate might serve for the preparation of a dye, a medicinal, or a war gas. He placed a few drops of aniline in each of three test-tubes: in the first he produced the dye, mauve, by oxidation of the crude aniline with a drop or two of ferric chloride. In the second tube he converted the aniline into the popular sedative, acetanilide ("aspirin"), by the action of acetyl chloride. To the aniline in the third tube he added alcoholic potash and a drop of chloroform. The nauseating phenyl isocyanate formed was convincing as a war gas.

Referring to Stieglitz' testimony in this suit, Dr. Charles L. Parsons writes: "I remember how completely he confounded the opposition who thought they were going to make a point by asking him as to the fees he drew from the Chemical Foundation by quietly stating that he never went into court except in the public interest and consequently never accepted any fee therefor. The statement was extremely affective in the outcome of the trial, which was won by the Chemical Foundation."

Dr. Stieglitz was editor of and contributor to the well known book, "Chemistry and Medicine," a most interesting and informing document. This contribution of forty-three leading scientists was sponsored by the Chemical Foundation and widely distributed, gratis, by Mr. Garvan as a memorial to his daughter, Patricia, who died in childhood.

His services as Adviser to the Chemical Foundation are thus described in a letter by Mr. William Buffum, treasurer and general manager of the organization, "His council was often sought and freely given. He was always very coöperative in assisting us to solve our general and specific problems. It can undoubtedly be said that Dr. Stieglitz was the foremost exponent for American chemotherapeutic research. He was one of Mr. Garvan's and my closest friends." As concrete evidence of his friendship and admiration, Mr. Garvan created the Stieglitz Foundation which was put at the disposal of Dr. Stieglitz for research on problems in the field of Chemistry as applied to medicine.

In accord with university regulations Stieglitz' retirement took place in September, 1933, at the age of sixty-five. This change in official status did not prevent his retention of his rooms at Jones Chemical Laboratory, the splendid new home of the department given by George Herbert Jones, where, as emeritus professor, he continued to give advice on departmental matters whenever requested to do so. His students were so loath to give him up that they raised a special fund which permitted him to continue his lectures and direct research.

Although he had numerous attractive opportunities he had steadfastly refused to act as a consulting chemist for industry during his professorship. It was only after his retirement that he made his first and only connection of this kind, a "half-time" position on the staff of Universal Oil Products Company. Here he was associated with the able organic chemists Egloff, Ipatieff, and others.

Many additional honors came to Professor Stieglitz. Several honor societies elected him to membership: the National Academy of Sciences, the American Philosophical Society, and the American Academy of Arts and Sciences. The Society of Sigma Xi elected him national president in 1917. In 1920 he was the presiding officer of the Chicago Chapter of the same society. He was a member of the Société Chimique de France, the Washington Academy of Sciences, and the American Association for the Advancement of Science, of which he was vice-president in 1916.

For the years 1912–1919 he was an associate editor of THIS JOURNAL.

Stieglitz was a charter member of the Chaos Club, an informal group whose personnel is chosen from eminent scientists in and about Chicago.

In 1909 Clark University conferred upon him the honorary Doctor of Science degree and in 1916 he received the honorary degree of Doctor of Chemistry from the University of Pittsburgh. In 1923 he was the recipient of the Willard Gibbs medal.

Many institutions honored him with special lectureships. He was Lecturer at the Exposition of Arts and Sciences at St. Louis in 1904; he held the Hitchcock Lectureship at the University of California in 1909 and later in 1915. Stanford University honored him with a lectureship in 1921 and he also held the Dohme lectureship at The Johns Hopkins University in 1924, the Fenton lectureship at the University of Buffalo in 1933, and in 1936 he delivered the Edgar F. Smith Memorial Lecture at the University of Pennsylvania.

He was a trustee for International Critical Tables, as representative of the American Chemical Society, and contributed materially to its ultimate successful publication. He was a member of the International Commission for the Annual Tables of Constants 1915–1921. For approximately a quarter of a century, he was a member of the advisory council of the Sprague Institute in Chicago.

The bust of Dr. Stieglitz that has occupied a pedestal in the entrance hall of Jones Chemical Laboratory, along with those of Dr. Nef and Dr. Alexander Smith, was the gift of his admiring students and other friends. It stands as a lasting memorial of the esteem in which he was held by those who knew him best.

The personal life of Professor Stieglitz has been sketched up to the time he joined the University of Chicago. In the years that followed he and Mrs. Stieglitz with their two children continued a happy and uneventful home life. Both children passed through the University and Rush Medical College, and subsequently established homes for themselves. Both are actively engaged in the practice of Medicine. The elder, Hedwig, is the wife of Dr. Hugh Kuhn (M.D.) of Hammond, Indiana. The younger, Edward J., in addition to his practice is also Associate Clinical Professor at Rush Medical College.

After having been afflicted with asthma for many years, Mrs. Anna Stieglitz died on December 25, 1932.

Following his great loss, Dr. Stieglitz tried to live alone in the old home. His friends were delighted when he married his former student and colleague, Dr. Mary Meda Rising, August 30, 1934.

Dr. Rising is the daugher of Roland S. and Meda (Menardi) Rising who now reside in Hollywood, California. Mr. Rising is a retired banker; Mary Rising was born in Ainsworth, Nebraska, in 1889. After graduation from Mt. Holyoke College in 1912, where she was a student under Professor Emma P. Carr, she went to the University of Chicago for graduate work in chemistry. There she received her doctorate degree in 1922 and from that time to the date of her marriage Dr. Rising was a member of the Department of Chemistry where she was Associate Professor at the time of her marriage. She then gave up her professorship to become Research Associate.

A few years prior to her marriage, Dr. Rising had adopted a baby daughter, Kate. It is not strange that after the marriage, little Kate was soon so firmly established in the affection of Dr. Stieglitz that he too adopted her. Professor Stieglitz often spoke feelingly of his fondness for children. A typical remark was "Babies, I love them. If I could, I would like to have them in the house all the time!" With his three grand-children, two sons of Mrs. Kuhn and the daughter of Edward, his desires seem to have been realized. The home, thus newly established, provided those things which for him were so necessary for life and productive work.

In spite of a most strenuous and time-consuming schedule, Stieglitz found some time for diversions. In his younger days, tennis and billiards were favorites. Later their place was substituted by golf. Stieglitz never played bridge; once when the subject was brought up, Stieglitz remarked, "I hate cards, that is, except poker; that's not cards but a play of human nature."

A hobby in which he attained results of high artistic merits was photography. This was the field in which his elder brother, Alfred, had reached world-wide distinction. Much time was spent at this diversion and many splendid prints attest his skill.

Dr. Stieglitz' love for music inspired him to maintain his practice on the cello throughout his life. He was very fond of opera, which he patronized as often as time and finances permitted; his favorite was Tristan and Isolde. Of composers, Mozart, Beethoven, Bach, Schubert, and Wagner interested him most. In later years he found great pleasure in the radio, which brought to him both opera and symphony.

Up to the time of his last illness, Stieglitz had enjoyed consistent good health; on but very few occasions were his regular duties interrupted by illness.

In the summer of 1936 he suffered a heart attack which caused Mrs. Stieglitz to be summoned home from California. From this illness he recovered quickly. The following Thanksgiving Day he had a more severe attack. This was followed by pneumonia, from which he rallied after some weeks. The end came suddenly on January 10, 1937, due to coronary thrombosis.

This account would be incomplete without further comment on the remarkable character of the man whose career was thus brought to a close.

To the countless thousands who knew him only by his published works Julius Stieglitz was a chemist of high attainments. To the smaller favored number whose acquaintance was more intimate, his friends, colleagues, and students, he was a unique and highly gifted personality.

His life work formed an exceptionally consistent whole in full accord with his oft-expressed formula of a complete academic career. His activities were apportioned with rare idealism between teaching, research, university administration, and public service. To have made a success in one or two of these lines of endeavor would have assured him a lasting remembrance. His pre-eminence in all four is a symbol of his versatility and stamps him as one of the outstanding men of his time.

Although Dr. Stieglitz' solicitous care for the welfare of his family was at all times uppermost in his mind, his personal interests were always subordinated in favor of the attainment of his ideals. As an example of this it is related on excellent authority that he once refused a position as chemist in a major industry at $50,000 a year.

It was a rare trait of Stieglitz' character that in the accomplishment of a desired end he did not merely lend his support to the movement. It was his custom to work out in complete detail a plan by which the project could be carried out. Thanks to his prodigious and accurate memory he could take a conflicting mass of details, sift them, discard the irrelevant, and weave the sound arguments into a convincing whole. His erstwhile opponents were wont to give way with the remark, "What's the use; Stieglitz is too logical."

Perhaps it was in his relations with his students that his memory is most highly cherished. His popularity as a teacher is attested by the significant fact that in all the University, the number of students who made their doctorate with him was greater than with any other professor. Among this number, 118, are many men and women who have achieved a national reputation. Among those whose life's work is complete and who were most widely known are Dr. Otto Folin, Professor of Biological Chemistry, Harvard Medical School, and Dr. Edwin E. Slosson, author of "Creative Chemistry" and founder of Science News Service. Numerous others occupy high places in the field of pure and applied Chemistry.

The problems he set for his research students were always well thought out in advance, never too difficult or impossible. In the laboratory his attitude was dignified and formal, but quiet and kindly, never seemingly hurried, but never wasting time or words, never neglecting students but always keeping before them the highest ideals. A typical remark, "I think the compound can exist, Mr. X. In a week you should have at least ten grams of it," was taken by the student as an order that he exerted himself to the utmost to fulfill, although its accomplishment won only the equally mild, but greatly valued, approval, "Very good, Mr. X."

Excepting during the earliest years at Chicago, Dr. Stieglitz rarely carried out his researches with his own hands. Nevertheless he was always critical of apparatus and technique. Often when he was forced to disapprove, his criticism was couched in so humorous a vein as only to spur the man to greater efforts toward improvement. A beginner at research had set up a piece of apparatus that differed greatly from that described in the reference given. On seeing it Dr. Stieglitz remarked, "That is not the apparatus used by ......, Mr. Y." When the student excused the fault as due to his scanty knowledge of German, Dr. Stieglitz left without a word;

a minute later he returned, placed on the desk the volume in question, opened to the page showing a figure of the apparatus, saying, "The picture is not in German, Mr. Y."

On another occasion when a student in qualitative analysis explained that he was evaporating a solution of ammonia to concentrate it, Stieglitz' only comment was, "Go right ahead, Mr. Z."

To his students Dr. Stieglitz always lent his helpful sympathy when other resources failed. He was ever ready and willing to listen to their problems and was most happy when he was able to work out a satisfactory solution of their difficulties. With students, as with others, he had a great reputation for fair dealing. In many cases the advice was more personal, extending as his daugher (Dr. Hedwig Stieglitz Kuhn, M.D.) humorously avers, "To every subject from the proper selection of the bride's silver to the choice of an obstetrician."

Always overworked, with his time sorely crowded, it is not strange that those who came to his room unannounced to speak on trivial matters often mistook a brusque dismissal for surliness. This was only apparent and not intended. Until late in life he had no secretary who could protect him from thoughtless intrusions.

On his part Dr. Stieglitz was always considerate of the time of others. For years the writer's laboratory was directly across the hall from his. He very rarely came informally to discuss matters, instead it was his custom to place handwritten notes in my box.

The esteem in which Dr. Stieglitz was held by his contemporaries is amply attested by the many positions of honor and responsibility to which he was called. Little can now be added to his fame by the laudation of his biographer. To employ a favorite maxim of Dr. Stieglitz: "Let the work show its worth by itself." The work of Julius Stieglitz is his memorial; a fitting testimony to a splendid career. In this work he realized his highest ideal: a life devoted to the advancement of science and the promotion of human welfare.

The Separation of Primary Active Amyl Alcohol from Fusel Oil by Distillation

BY FRANK C. WHITMORE AND J. HARRIS OLEWINE

Fusel oil, regardless of its origin, generally consists of primary active amyl alcohol $CH_3CH_2CH(CH_3)CH_2OH$, and isoamyl alcohol $(CH_3)_2CHCH_2CH_2OH$. These two alcohols, boiling at 128° and 130.5°, respectively, had never before been separated effectively by distillation alone.

Klages and Sautter[1] obtained active amyl alcohol in 42–61% purity by distillation of fusel oil from beet sugar molasses. Votocek and Vesely[2] isolated the active alcohol in only 46% purity by the distillation of fusel oil obtained from molasses. Since the completion of the present study (1936), Brauns has reported such a successful separation.[3] In this paper, the fractionation of fusel oil to give primary active amyl alcohol of approximately 95% purity, is described. The separation necessitated the use of very efficient columns.[4,5]

Experimental

The fusel oil used was a refined product[6] obtained in the fermentation of cane molasses, $\alpha^{33}\text{D}$ −0.69°. Prior to fractionation, it was dried at 0° for forty-eight hours with anhydrous sodium sulfate.

Preliminary Fractionation.—In a series of trial fractionations, two packed columns of metal construction were used. One column was 27 feet (7.9 meters) long and 3 inches (7.6 cm.) in diameter with a capacity of 13 gallons (49 liters), the other column was 52 feet (15.4 meters) long and $^3/_4$ inch (1.9 cm.) in diameter with a capacity of 1.5 gallons (5.7 liters). The construction and operation of these columns already has been described in detail.[4] In one preliminary fractionation, 40 liters of the refined fusel oil was first distilled in the 27-foot (7.9-m.) column and the best intermediate fractions therefrom were then twice redistilled in the 52-foot (15.4-m.) column. Approximately 0.6 liter of primary active amyl alcohol was obtained, b. p. 128° (760 mm.), $n^{20}\text{D}$ 1.4111, having an average observed rotation of $\alpha^{33}\text{D}$ −4.27° in a 1-dm. tube. The maximum rotation included in this average value was −4.34°, specific rotation $[\alpha]^{33}\text{D}$ −5.32°. Based on −5.9° as the specific rotation of pure primary active amyl alcohol, the alcohol thus obtained was approximately 90% pure.

Isolation of Primary Active Amyl Alcohol.—The design and efficiency of the distillation equipment used in this fractionation had been described previously.[5] The column was of nickel construction with a height of packed section of 38 feet (11.4 meters) and having a distilling capacity of 12 liters. When tested with *n*-heptane and methylcyclohexane and operating at a velocity of 3.4 liters per hour at the top of the tower, the column had the equivalent of 101 theoretical plates.

Four fractionations were made using a total of 35.2 liters of fusel oil. The following describes a typical run. A charge of 10 liters of fusel oil was refluxed for twelve hours to bring the column to equilibrium, after which the distillate was collected at a rate of approx. 70 cc. per hour during a period of continuous operation for eight and one-half days. This rate enabled an average reflux ratio of 30:1 to be maintained and to give at 760 mm.: Fractions 1–13, 1310 cc., b. p. (Cottrell) 107.8–117.4°, $n^{20}\text{D}$ 1.3835–1.4000; 14–17, 450 cc., 119.6–128.7°, 1.4025–1.4102, obsd. rotation (1-dm. tube) $\alpha^{27}\text{D}$ −0.72 to −3.81°; 18–42, 3300 cc., 129.3–130.8°, 1.4101–1.4069, −3.49 to 0.00°; 43–62, 3973 cc., 130.8–131°, 1.4069; residue, 725 cc.

The cuts of the four fractionations having the highest concentration of active alcohol were combined (8209 cc.) and refractionated through the nickel column during seven days to give: Fractions 1–7, 625 cc., b. p. 125.1–127.9° (760 mm.), $n^{20}\text{D}$ 1.4003–1.4110, $\alpha^{28}\text{D}$ −0.41 to −4.90; 8–22, 1310 cc., 127.7–128.5°, 1.4110, −4.91 to −4.93°,

d^{28}_4 0.8169–0.8137; 23–34, 1465 cc., 128.5–129.8°, 1.4110–1.4103, −4.92 to −4.12°, 0.8137-0.8130; 35–44, 1210 cc., 129.7–131.0°, 1.4097–1.4070, −3.55 to −0.70°, 0.8130.

Fractions 8–34 are primary active amyl alcohol of high rotatory power. The maximum observed rotation for the best fraction was $\alpha^{28}\text{D}$ −4.93°; specific rotation $[\alpha]^{28}\text{D}$ −6.04°. The constants (average) of the primary active amyl alcohol are: b. p. 128–129° (760 mm.), $n^{20}\text{D}$ 1.4109, d^{20}_4 0.8189, $d^{27.5}_4$ (calcd.) 0.813, $\alpha^{27.5}\text{D}$ −4.77°, $[\alpha]^{27.5}\text{D}$ −5.86° (1-dm. tube). The rotation of an aliquot sample was kindly checked by Levene,[7] who reports $\alpha^{25}_{5875.6}$ −9.186 ± 0.003° (2-dm. tube), and Wallis,[8] who reports $\alpha^{24.5}_{5893}$ −4.52° (1-dm. tube).

Summary

Primary active amyl alcohol having a high optical purity can be separated from fusel oil by a laboratory distillation process. The physical constants are reported.

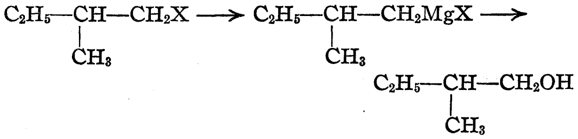
The Primary Active Amyl Halides

BY FRANK C. WHITMORE AND J. HARRIS OLEWINE

The separation of approximately 95% pure primary active amyl alcohol by fractionation of fusel oil has been described in the preceding paper.[1] Disagreement concerning the optical purity of the halides prepared from this alcohol exists in the literature.[2] In the present work, the preparation and properties of the active halides are reported. The chief objective of the study was the determination of the amount of racemization on conversion to the Grignard reagent and then to the alcohol.



$$\underset{\substack{|\\ CH_3}}{C_2H_5\text{—}CH\text{—}CH_2X} \longrightarrow \underset{\substack{|\\ CH_3}}{C_2H_5\text{—}CH\text{—}CH_2MgX} \longrightarrow \underset{\substack{|\\ CH_3}}{C_2H_5\text{—}CH\text{—}CH_2OH}$$

The action of thionyl chloride on primary active amyl alcohol in pyridine gave the corresponding chloride in 77% yield, specific rotation $[\alpha]^{28.5}\text{D}$ +1.66°. Treatment of the alcohol with phosphorus tribromide produced the active halide in 29% yield, $[\alpha]^{29}\text{D}$ +3.75°. These values agree closely with those of Brauns[2] but are lower than those of Marckwald.[3] The iodide, $[\alpha]^{28}\text{D}$ +4.84°, was prepared in 17.5% yield by conversion of the alcohol to the benzoate and treatment with magnesium iodide. The low value for the rotation indicated racemization.

Conversion of the chloride and bromide to the Grignard reagents, and treatment with oxygen regenerated the active amyl alcohol with a total racemization not greater than 10% for the four reactions. Similar treatment of the iodide gave no active amyl alcohol. This reaction will be investigated further.

Experimental

Preparation of Primary Active Amyl Chloride.—The method of Clark and Streight[4] was used in a series of one mole preparations. Addition of 2 moles of thionyl chloride to a solution of one mole of primary active amyl alcohol in one mole of dry pyridine gave the crude chloride. Purification in the usual fashion and fractionation with an efficient column, 75 × 2 cm.,[5] packed with 4-mm. single-turn glass helices,[6] gave a 77% yield of primary active amyl chloride, b. p. (Cottrell) 50.5–51° (140 mm.), $n^{20}\text{D}$ 1.4125, d^{20}_4 0.8852, $[\alpha]^{28.5}\text{D}$ +1.66°.

Preparation of Primary Active Amyl Bromide.—The method of Jones[2] was used. The crude product from the addition of 0.37 mole of phosphorus tribromide to one mole of primary active amyl alcohol at 5–15° was purified and fractionated to give a 29% yield of active amyl bromide, b. p. 69.6° (140 mm.), $n^{20}\text{D}$ 1.4450, d^{20}_4 1.2239, $[\alpha]^{29}\text{D}$ +3.75°.

Preparation of Primary Active Amyl Iodide.—The halide was prepared by the action of magnesium iodide on active amyl benzoate.[7] Treatment of 1.5 moles of primary active amyl alcohol with 2 moles of benzoyl chloride gave an 80% yield of the benzoate, b. p. (Cottrell) 140.2° (20 mm.), $n^{20}\text{D}$ 1.4948, d^{20}_4 0.9913, $\alpha^{28}\text{D}$ +6.09° (1-dm. tube). Magnesium iodide was prepared from magnesium and iodine in dry ether. Refluxing of a solution of 1.5 moles of

magnesium iodide and one mole of the ester in 500 cc. of ether for two weeks gave 126.5 g. of crude iodide and much resin formation. Fractionation of the crude product gave 17.5% of primary active amyl iodide, b. p. (Cottrell) 47.1° (20 mm.), $n^{20}D$ 1.4969, $d^{20}{}_4$ 1.5227, $[\alpha]^{28}D$ +4.84°.

Regeneration of Primary Active Amyl Alcohol from the Corresponding Chloride and Bromide.—The primary active amyl chloride and bromide were converted into the Grignard compounds in 83 and 76% yields, respectively. Treatment of the Grignard compounds with oxygen at 0° and decomposition of the complex with water regenerated the primary active amyl alcohol. A comparison of the constants for the regenerated alcohol with those of the original alcohol is given.

A similar attempt to regenerate the active alcohol from primary active amyl iodide failed.

Summary

1. The preparation and physical constants of the primary active amyl chloride, bromide and iodide are reported.

2. Primary active amyl alcohol can be regenerated from the corresponding chloride or bromide by conversion to the Grignard compound and treatment with oxygen. The iodide cannot be used for the conversion.

3. The total racemization in the steps alcohol → bromide or chloride → Grignard reagent → alcohol is not over 10%.

The Nonanes. 2-Methyloctane, 3-Ethylheptane, 2,3-Dimethylheptane and 2,2,4,4-Tetramethylpentane[1]

BY FRANK C. WHITMORE AND HARRIET A. SOUTHGATE

The present work was undertaken because of the interest in this Laboratory in petroleum hydrocarbons, in rearrangements in the aliphatic series, in the limitations of typical aliphatic reactions and in the relation of structure to physical properties of aliphatic compounds.

Theoretically, thirty-five structurally isomeric nonanes are possible. Twelve were known when the present work was started, namely, *n*-nonane, the three monomethyloctanes, 2,4-, 2,5-, 2,6- and 3,3-dimethylheptanes, 4-ethylheptane, 2,3,5- and 2,2,5-trimethylhexanes, and 3,3-diethylpentane. The scattered and incomplete data on the physical properties of these eleven nonanes indicate that regularities exist similar to those found in the hexanes, heptanes and octanes.

Three new nonanes, 3-ethylheptane, 2,3-dimethylheptane and the most highly branched nonane, 2,2,4,4-tetramethylpentane, have been synthesized in the present study. Since the data on 2-methyloctane are meager,[2] this compound also was prepared.

The 2,2,4,4-tetramethylpentane was obtained in poor yield from 2,2,4-trimethyl-4-bromopentane or the corresponding chloride with dimethylzinc. The main course of the latter reaction involved the removal of halogen acid to form the known diisobutylenes. This agrees with results obtained by S. N. Wrenn of this Laboratory on the action of a variety of alkaline agents with these halides. The other three nonanes were obtained by dehydration of the tertiary alcohols, 2-methyl-2-octanol, 3-ethyl-3-heptanol, and 2,3-dimethyl-3-heptanol by Hibbert's[3] iodine method and hydrogenating the olefin mixtures at high pressure using a nickel catalyst supported on alumina.

The reactions involved in these syntheses are not ones which are accompanied by rearrange-

ments. The physical constants recorded for the four nonanes indicate a high degree of purity. It is interesting that the most highly branched nonane boils lower than *n*-octane.

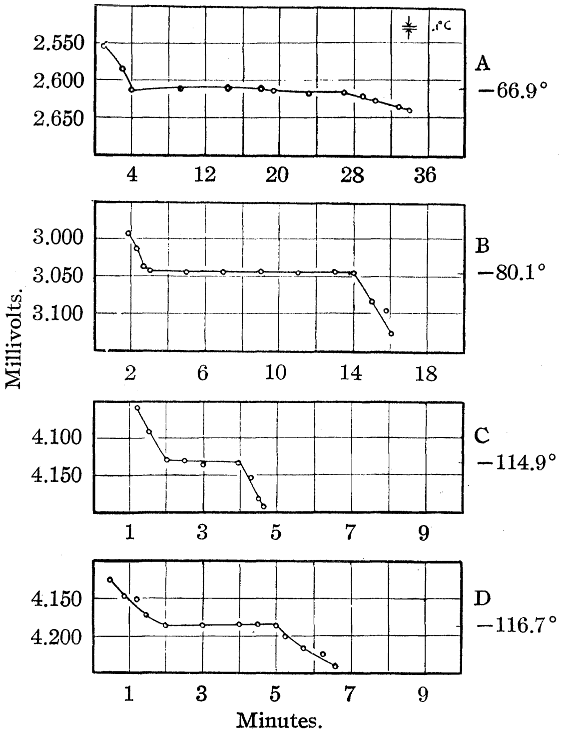

Fig. 1.—A. Freezing curve of 2,2,4,4,-tetramethylpentane: cooling medium, carbon dioxide + acetone; B, C, D. Freezing curves of 2-methyloctane, 3-methylheptane, and 2,3-dimethylheptane: cooling medium, liquid air.

Experimental

Dimethylhexylcarbinol.—Methyl hexyl ketone, b. p. 169.9–171.5° (735 mm.), n^{20}D 1.4150, was prepared in 26–32% yield by dehydrogenation with a copper catalyst of capryl alcohol supplied by the Röhm and Haas Company of Philadelphia. It was treated in 2-mole lots with methylmagnesium chloride solution in the usual way. The product was fractionated under reduced pressure through a 43 × 1.4 cm. column of the usual type used in this Laboratory. The dimethylhexylcarbinol, b. p. 82–85° (20 mm.), n^{20}D 1.427, was obtained in 85% yield.

Methylisopropyl-*n*-butylcarbinol.—Methyl isopropyl ketone, b. p. 93–95° (732 mm.), prepared from *t*-amyl alcohol[4] supplied by the Sharples Solvents Corporation of Philadelphia was treated in 3-mole lots with *n*-butylmagnesium bromide as usual. The methylisopropyl-*n*-butylcarbinol, b. p. 75–78° (16 mm.), n^{20}D 1.4355, was obtained in 65% yield.

Diethyl-*n*-butylcarbinol.—Diethylcarbinol, b. p. 113–118° (732 mm.), was oxidized by chromic acid mixture to diethyl ketone, b. p. 102–105°, in 65% yield. Diethyl ketone in a 4-mole lot was treated as usual with *n*-butylmagnesium bromide. The yield of diethyl-*n*-butylcarbinol, b. p. 95–97° (36 mm.), was 67%.

Dehydration of the Carbinols.—This was done by refluxing with a trace of iodine. The olefins were dried with anhydrous copper sulfate, refluxed over sodium and fractionated. Dehydration of 260 g. of 2-methyl-2-octanol gave 165 g. of olefins, b. p. 144.5–146° (722 mm.), n^{20}D 1.4223; 360 g. of 3-ethyl-3-heptanol gave 242 g. of olefins b. p. 137.5° (734 mm.), 1.4261; 319 g. of 2,3-dimethyl-3-heptanol gave 181 g., b. p. 135–140° (735 mm.), 1.4237–1.4252. Hydrogenation using a nickel catalyst on activated alumina and hydrogen under pressure gave the corresponding hydrocarbons in 98–100% yield.

2,2,4,4-Tetramethylpentane.—Dimethylzinc was prepared in 82–100% yields in lots up to 4 moles.[5] 2,2,4-Trimethyl-4-bromopentane, b. p. 75° (36 mm.), n^{20}D 1.455, was prepared by saturating a diisobutylene fraction of n^{20}D 1.4085 with dry hydrogen bromide at 15°.[6] Removal of excess hydrogen bromide was found to be essential. This was done by cooling the mixture and applying reduced pressure and by passing carbon dioxide through the mixture. The corresponding chloride has been obtained by heating diisobutylene with fuming hydrochloric acid in sealed tubes at 105°[7] and by simply saturating diisobutylene with hydrogen chloride at 15°. The 2,2,4-trimethyl-4-chloropentane, b. p. 53° (29 mm.), n^{20}D 1.431 was obtained in 75% yield.

Dimethylzinc was treated in an atmosphere of carbon dioxide with 2,2,4-trimethyl-4-chloropentane or the corresponding bromide. The chloro compound gave better results. During ten hours 408 g. (2.8 moles) of the chloride was added to a stirred solution of 147 g. (1.55 moles titrated) of dimethylzinc in 150 cc. of dry tetralin in a 3-necked flask provided with a dropping funnel, condenser, and mercury-seal stirrer. The temperature was maintained at 40°. Precipitation started almost immediately and rendered stirring difficult. After standing overnight the mixture was acidified with hydrochloric acid. The organic layer was washed with sodium bicarbonate solution and dried with 10 g. of calcium chloride. Fractionation through the 43 × 1.4 cm. column yielded mainly diisobutylenes formed by the removal of hydrochloric acid from the chloride, a small amount of higher polyisobutylenes and a yield of 18% (average of many runs) of the crude 2,2,4,4-tetramethylpentane, b. p. 120–125° (730 mm.), n^{20}D 1.408.

Purification of the Nonanes.—Each of the four nonanes was shaken with successive one-tenth volume portions of concentrated sulfuric acid until a fresh portion showed no color. All acid was removed by washing with sodium bicarbonate solution and then with water. After drying over calcium chloride the product was fractionated.

Measurement of Physical Properties.—A Valentine No. 451 refractometer was used for determining the refractive indices. The temperature was controlled to 0.1°.

Boiling points were measured with a Cottrell type boiling point apparatus. The temperature was read by means of a copper–copel thermocouple checked against a

Bureau of Standards couple and also checked at the boiling points of *n*-hexane, *n*-heptane, water, 2,2,4-trimethylpentane, naphthalene and toluene. Boiling points recorded represent the boiling point when 50% of the sample had been removed.

The freezing points were determined with samples of about 20 cc. of the nonane placed in a glass-jacketed test-tube which was lowered into a Dewar flask containing a mixture of carbon dioxide snow and acetone or liquid air. The sample was stirred vigorously and the temperature determined every twenty to thirty seconds by means of a chromel–copel thermocouple[8] and a Leeds Northrup Portable, Double Range Potentiometer. The cooling curves are given in Fig. 1.

Densities and viscosities were determined by W. A. Herbst of this Laboratory.

Summary

2-Methyloctane and three new nonanes, 2,3-dimethylheptane, 3-ethyloctane and 2,2,4,4-tetramethylpentane have been prepared.

Boiling point, index of refraction, density, freezing curves and viscosity have been determined for the four nonanes.

A New Synthesis of Tertiary Hydrocarbons

BY FRANK C. WHITMORE AND H. PHILIP OREM

The general method of preparation of saturated aliphatic hydrocarbons involves the hydrogenation of an olefin formed by dehydration of the corresponding alcohol or by removal of halogen acid from the alkyl halide.[1] Other methods, such as the hydrolysis of the Grignard reagent and the reduction of the halide with "nascent" hydrogen[2] have been used.

Levene[3] prepared hexadecane from cetyl iodide by adding zinc dust to the iodide and passing in dry hydrogen chloride with heating for several hours. In the present study, a modification of this method has been applied to tertiary iodides. Five tertiary aliphatic hydrocarbons have been prepared from their corresponding tertiary alcohols by the modified method. This offers a new and simple method of preparing branched-chain hydrocarbons from tertiary alcohols.

Experimental

Preparation of the Alcohols.—Four of the alcohols were prepared from Grignard reagent and ketone; the other from Grignard reagent and acid chloride.

Preparation and Purification of the Hydrocarbons.—The hydrocarbons were prepared by treating the tertiary alcohols with dry hydrogen iodide[4] until one and one-half times the theoretical quantity of hydrogen iodide had been added. Then zinc dust (Baker C. P. 95%) was added in small quantities until reaction ceased. The mixture was then stirred and dry hydrogen chloride was passed in with the addition of more zinc until four times the theoretical quantity was added. The flask was heated to 70–80° with stirring and the addition of hydrogen chloride for approximately ten hours for each half mole of alcohol used. Water was then added slowly to give equal volumes of water and reaction product in the flask. The hydrocarbon was steam distilled and separated from the water layer.

The hydrocarbon was purified by washing with 70% (by weight) sulfuric acid until only a pale yellow color remained, then with 85% sulfuric acid, and finally with concentrated sulfuric acid until little color appeared upon adding fresh acid. The product was then washed once

with water, twice with 25% sodium hydroxide solution, and dried over sodium. It was carefully fractionated[5] from sodium–potassium alloy, washed with concentrated sulfuric acid, water, 25% sodium hydroxide, dried over sodium, and refractionated from sodium–potassium alloy to give a constant index material that gave no halide test with copper wire and no olefin test with bromine in carbon tetrachloride.

Summary

A new synthesis of tertiary hydrocarbons has been described, and applied to five aliphatic hydro carbons.

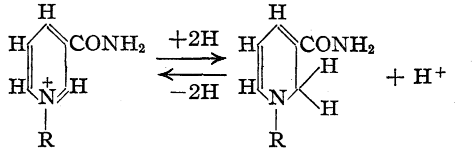
Hydrogenation of Vitamin B_1 and Other Quaternary Thiazoles[1]

BY FRITZ LIPMANN AND GERTY PERLMANN

Dehydrogenation of various substrates in the cell is effected by quaternary pyridine compounds—nicotinic acid derivatives[2,3]—acting as hydrogen-transporting systems between the respective substrates and other hydrogen carriers.[2,4] The catalytic action of these pyridinium compounds is due to alternate hydrogenation and dehydrogenation at the double bond adjoining the quaternary nitrogen.



(1)

The action of vitamin B_1 (which hereafter in this paper will be referred to as "thiamin") as codehydrase for pyruvic acid dehydrogenation was made highly probable by the work of Peters and co-workers[5] with avitaminotic tissues (see also Lipmann[6]). Using the pyruvic acid dehydrogenase of *Bacterium Delbrückii*, the codehydrase function of thiamin—as thiamin pyrophosphate, Lohmann's cocarboxylase[7]—could be shown definitely.[8]

The presence of a quaternary thiazole in thiamin,[9] the well-known similarity between thiazoles and pyridines together with the codehydrase function of thiamin suggested a similar mode of action for the pyridine and thiazole codehydrases.

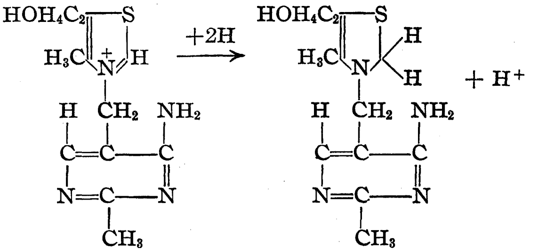
[9] R. R. Williams and A. E. Ruehle, THIS JOURNAL, **57**, 1856 (1935).

In a previous short communication[10] the dehydrogenation of thiamin with sodium hyposulfite ($Na_2S_2O_4$) was described. The reaction was followed by the use of Warburg's manometric method,[11,12] which measures bicarbonate decomposition due to oxidation of neutral hyposulfite to acid sulfite ($Na_2S_2O_4 + R + 2NaHCO_3 = 2Na_2SO_3 + H_2R + 2CO_2$). It was found that for each mole of thiamin approximately 3 moles of bicarbonate was decomposed. In accordance with the findings of Warburg[2b] and Karrer[3] with the quaternary pyridines (equation 1), the appearance of one extra equivalent of acid was interpreted as being due to the change from strong to weak basicity on reduction. This led to the conclusion that the hydrogenation of thiamin takes place at the double bond adjoining the quaternary nitrogen in the thiazole part of the molecule



(2)

This interpretation is supported by the recent findings of Erlenmeyer[13] that thiazole-5-carboxylic ester methiodide is hydrogenated with hyposulfite in exactly the same manner as the corresponding pyridine compound, both yielding one extra equivalent of acid on reduction.

The results mentioned above made it desirable to study the hydrogenation of thiamin and other quaternary thiazoles more in detail.

Throughout the work, the hydrogenation with hyposulfite was measured by the manometric method of Warburg.[11,12] Hydrogenation with platinum black and hydrogen was measured in Warburg manometers. The platinum black was prepared according to the directions of Willstätter and Waldschmidt-Leitz.[14]

For all the experiments carried out with thiamin, the synthetic product of the I. G. Farbenindustrie was used, for a large gift of which we are greatly indebted to the staff of the I. G. Farbenindustrie.

The Hydrogenation of the "Cleavage Products."—To exclude the possibility that hydrogenation takes place upon the pyrimidine part, the split products obtained by the sulfite cleavage of Williams[15] were tried separately. As shown by Williams, thiamin is split into pyrimidine-sulfonic acid and thiazole by the action of acid sulfite

$$C_{12}H_{16}N_4OS + H_2SO_3 \longrightarrow C_6H_9N_3SO_3 + C_6H_9NOS$$

Thereby the quaternary thiazole is converted into a tertiary. The methiodide of the thiazole part was prepared according to Buchman, Williams and Keresztesy.[16]

Hydrogenation with Hyposulfite.—The results of the manometric measurements are assembled in Table I.

TABLE I

HYDROGENATION OF THE "CLEAVAGE PRODUCTS" WITH HYPOSULFITE: MANOMETRIC MEASUREMENTS

No.	Substance	Moles CO_2	Atoms hydrogen	Extra acid
1	Pyrimidine sulfonic acid	0	0	..
2	Thiazole part (tertiary)	0	0	..
3	Thiazole part (quaternary)	3.1	2	1.1
4	Thiamin	2.75	2	0.75

It appears from the table that none of the split products (Nos. 1 and 2) reacts with hyposulfite but that the thiazole methiodide (No. 3) reacts in the same manner as thiamin (No. 4), but more slowly (see last column and Fig. 1). In both

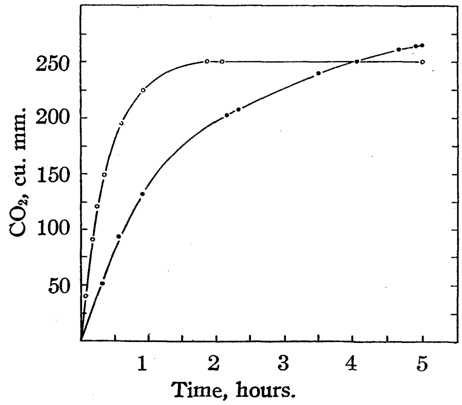


Fig. 1.—Manometric experiment with 0.405 × 10^{-2} millimole of thiamin (upper curve) and 0.383 × 10^{-2} millimole of 4-methyl-5-hydroxyethylthiazole methiodide (lower curve); temperature 30°.

cases nearly one equivalent of extra acid appears on reduction. Since the pyrimidine part does not and the thiazole part, when quaternary, does, react as the whole, evidence is thus obtained that the hydrogenation of thiamin with hyposulfite takes place in the thiazole part of the molecule.

Hydrogenation with Platinum Black–Hydrogen.—Though only the hydrogenation with hyposulfite can be taken as significant as a model reaction, reduction with Pt–H_2 was also measured for comparison. The results are assembled in Table II. As mentioned in the first publication,[9] thiamin absorbs nearly one mole of hydrogen (Nos. 7 and 8). The reactivity of the pyrimidine part depends on *p*H (or buffer system). In borate at *p*H 10.5 a very sluggish absorption takes place (No. 1). In phosphate at *p*H 8 approximately two moles of hydrogen were taken up at a medium rate. The thiazole part (tertiary) absorbs virtually no hydrogen (No. 3). The quaternary thiazole absorbs a total of two moles. The absorption curve shows a break after one mole is taken up (No. 4 a and b). Besides, two other quaternary thiazoles were tried: 4-methyl-5-carboxylic ester thiazole methiodide and 4-methylthiazole methiodide, both prepared according to Clarke and Gurin.[17] The ester thiazole, like thiamin, takes up approximately one mole at a rapid rate, the methylthiazole takes approximately two moles; the first at a rapid, the second at a slower, rate.

TABLE II

HYDROGENATION OF THE "CLEAVAGE PRODUCTS" AND QUATERNARY THIAZOLES WITH PLATINUM BLACK AND HYDROGEN

No.		Substance	*p*H	Moles H_2	Time, hours
1		Pyrimidine sulfonic acid	10.5	0.12	4
2		Pyrimidine sulfonic acid	8	1.88	20
3		Thiazole part tertiary	10.5	0.1	4
4	a	Thiazole part quaternary	8	1.0	1.5
	b			1.97	20
5		Thiamin	8	0.92	4
6		Thiamin	10.5	1.07	8
7		4-Methyl-5-carboxylic ester thiazole methiodide	8	1.2	18
8		4-Methylthiazole methiodide	8	1.8	18

The reactivity of the second double bond in quaternary thiazoles depends apparently to a large extent on the nature of the substituents. When reacting, it always went more slowly than the first. It is to be noted that the pyrimidine-sulfonic acid is hydrogenated with Pt–H_2. That the one mole of hydrogen taken up by the thiamin goes to the same place as on hydrogenation with hyposulfite seems quite probable, since it was found that with Pt–H_2 also one mole of acid appears on reduction (by titration of a larger sample before and after reduction, in Na_2HPO_4 with thymolphthalein as indicator).

The Colored Intermediate Hydrogenation Product.—It was observed that a transient yellowish-green color appears on addition of hyposulfite to neutral thiamin solutions.[18] Experiments with various thiazoles (see next paragraph) have shown that the greenish colored intermediate appears generally on hydrogenation of quaternary thiazoles with hyposulfite. In the special cases, the intensity of the color depends on the rate of reaction. With the fast-reacting ester thiazole (Table III, No. 3) a bright color appears in very dilute solution; with a slow reacting substance as 4-methyl-5-ethoxythiazole methiodide only concentrated solutions give a coloration. To compare the described phenomenon with the corresponding one found by Karrer and Benz[19] and Adler, Hellström and von Euler[20] with quaternary pyridines and cozymase, nicotinic acid amide ethiodide[21] was prepared. The course of events is exactly the same with the two classes of compounds. With the pyridines the color is more orange.

On reduction of thiamin with zinc and normal hydrochloric acid, a very similar transient color appears. After the disappearence of the color vigorous hydrogen sulfide formation sets in, indicating that here hydrogenation is followed by profound degradation.

The most obvious explanation for the transient coloration, proposed already for the pyridines,[19] is that hydrogenation occurs in two steps.[22] The half reduced colored compound, of a semiquinone type, is decolorized by further reduction. As the two-step oxidation or reduction is very common with the oxido–reduction catalysts of the cell (flavin, pyocyanine, pyridine coferments, etc.), it seems of importance that it occurs also with thiamin.

The Hydrogenation of Various Quaternary Thiazoles with Hyposulfite.—We have studied the reaction with 4-methyl-5-carboxylic acid

ethyl ester methiodide, a compound similar to that studied by Erlenmeyer.[13] From the ester the corresponding acid amide was prepared, following a procedure used by Karrer[3] to prepare nicotinic acid amide. The similarity of constitution of the two acid amides made the study of this thiazole interesting. Benzothiazole methiodide was prepared according to Möhlau and Krohn.[23] This substance has been studied by Mills and co-workers.[24] Their work, to be discussed later, made the inclusion of it desirable.

In Table III all our manometric experiments with quaternary thiazoles are summarized. For comparison the nicotinic acid amide ethiodide is included. In all the cases approximately one mole of extra acid appears in addition to the two moles originating from the transfer of two hydrogens. The rate of reaction (see last column) is greatest for derivatives of the acid, nearly approaching that of the pyridine compound. It is intermediate with thiamin and slowest with the methiodide of the cleavage product.

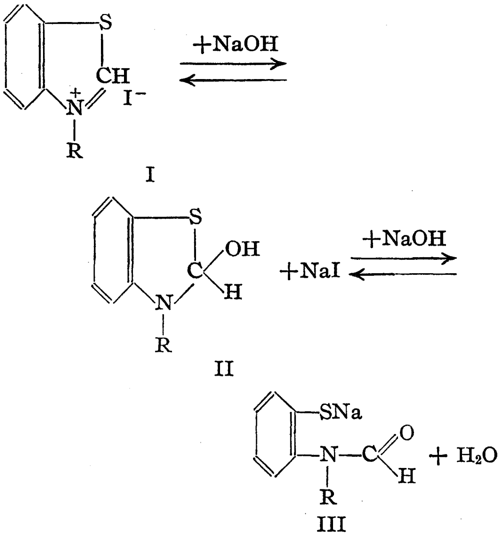
TABLE III

HYDROGENATION OF QUATERNARY THIAZOLES WITH HYPOSULFITE: MANOMETRIC MEASUREMENTS

No.	Substance	Moles CO_2	Atoms H	Extra acid	50% Reduction time, min.
1	Nicotinic acid amide ethiodide	3.1	2	1.1	1.5
2	Thiamin	2.8	2	0.8	15
3	4-Methyl-5-ethoxy thiazole methiodide	3.1	2	1.1	57
4	4-Methyl-5-carboxylic acid ethyl ester thiazole methiodide	2.9	2	0.9	3
5	4-Methyl-5-carboxylic acid amide thiazole methiodide	2.88	2	0.88	5

The behavior of benzothiazole methiodide was somewhat different. Mills and co-workers have described the reduction of this compound with zinc and hydrochloric acid. The α-dihydrobenzothiazole, a water-insoluble substance of characteristic odor, was isolated in good yield. They described also the reversion of the dihydrothiazole to thiazole methiodide by oxidation with iodine in alcoholic solution.

When benzothiazole methiodide, freshly dissolved in bicarbonate, is treated at once with hyposulfite, we found that the bright greenish color of the intermediate appeared, the solution became cloudy and a characteristic odor, the same as on reduction with Zn–HCl, developed. The experiment showed that benzothiazole methiodide is reduced by hyposulfite in the same manner as other quaternary thiazoles. Therefore, it was surprising to find that the manometric experiment did not show any reaction, when carried out in the usual manner—that is to dissolve the thiazole in bicarbonate, equilibrate the vessel in the thermostat and to tip the hyposulfite into the solution. The explanation is found in the fact that benzothiazole methiodide reacts rapidly with bicarbonate. In about fifteen minutes at 30° two moles of bicarbonate was decomposed. It is known from the work of Mills and of Williams that by the action of strong alkali the pseudobase is formed first and then the thiazole ring is opened in the following manner



(3)

Mills called attention to the strong acidity of the thiophenol derived from benzothiazole. It must be an appreciably stronger acid than carbonic acid. Therefore in bicarbonate at the end of the reaction practically only molecule III is present in the solution. Molecule I, which reacts with hyposulfite, has disappeared.

The amide reacts similarly, but only incompletely. The equilibrium can be driven back in the direction of molecule I by saturation with carbon dioxide. Therefore the manometric experiment with the amide was carried out with carbon dioxide in the gas phase. The other thiazoles did not decompose bicarbonate.

The Question of Reversibility. Discussion

At an early stage of this investigation, attempts were made to isolate the hydrogenated thiamin,

---

[23] R. Möhlau and C. W. Krohn, *Ber.*, **21**, 59 (1888).

[24] W. H. Mills, L. M. Clark and J. A. Aeschlimann, *J. Chem. Soc.*, **123**, 2353 (1923).

but met with great difficulties, which it has not been possible to overcome up to now. On extraction of the more or less alkaline solutions with chloroform or ether, the greater part of the products of reaction remained always in the water phase. The brownish oily residue from chloroform or ether was obviously inhomogeneous. Furthermore, it was not possible to reoxidize the product of reduction to thiochrom with ferricyanide and alkali. Only a comparatively feeble blue fluorescence appeared. Therefore it was not surprising to find that the biological activity was lost after hydrogenation.

A similar behavior was found with the ester thiazole and the acid amide thiazole methiodides. The latter substance required attention because the work of Karrer[25] showed that the acid amide group has a stabilizing effect on the equally unstable dihydropyridines. The only thiazole which yielded with hyposulfite a stable hydrogenated product, was benzothiazole. The identity of this product with benzodihydrothiazole obtained on reduction with Zn–HCl by Mills and co-workers, though still to be established, can scarcely be doubted. With this compound the reversibility of dehydrogenation had been shown before. As our experience makes it quite probable that the primary process of reduction is the same in all cases, it might be concluded that, primarily a reversible hydrogenation product, the 2-dihydrothiazole is always formed which subsequently undergoes irreversible rearrangements.

If the codehydrase action of thiamin or, better, thiamin pyrophosphate should—as was suggested in the beginning of this paper—be due to a reversible hydrogenation of the thiazole, the hydrogenated thiamin must be stabilized in the enzyme (codehydrase–protein compound). This could possibly be effected by the combination with the specific protein. It has been described elsewhere[8] and has been confirmed recently[26] that in pyruvic acid dehydrogenase the codehydrase is strongly bound to the protein and most probably does not dissociate in the cell. Thus the thiamin enzyme differs from the pyridine enzymes, in which the pyridine–protein dissociates easily.

We wish to thank Dr. Albert Fischer, Director of this Laboratory, for the kind support he has given to the above work. We also wish to express our gratitude to Dr. Stig Veibel for his help in obtaining materials for the preparation of some of the compounds used.

Experimental

4-Methyl-5-carboxylic Acid Amide Thiazole Methiodide.—One and one-half ml. of 4-methyl-5-carboxylic ester thiazole[17] was dissolved in 3 ml. of methanol and saturated with ammonia at −18°. The mixture was heated in a bomb tube for twelve hours to 150°. On cooling crystals separated from the methanolic solution. The methanol and ammonia were distilled off. From the brownish, mostly crystalline residue, the amide was extracted by boiling three times with benzene. The substance crystallized from the benzene in only slightly discolored crystals, yield 0.75 g. *Anal.* Calcd. for $C_5H_6N_2OS$: N, 19.67. Found: N (Dumas), 18.81. Without further purification the product was treated with methyl iodide. It was dissolved in 2 ml. of absolute alcohol mixed with 7 ml. of methyl iodide and boiled gently on the reflux condenser for twelve hours. After removal of the methyl iodide, the methiodide was crystallized twice from absolute alcohol.

Anal. Calcd. for $C_6H_9N_2OSI$: N, 9.84. Found: N (Dumas), 9.73.

4-Methyl-5-carboxylic Acid Ethyl Ester Thiazole Methiodide.—The ester was mixed with an excess of methyl iodide and warmed in a sealed tube to 40° for twenty-four hours. A brown oil separated on the surface. After removal of the methyl iodide, the solid, partly crystalline residue was dissolved in absolute alcohol. On careful addition of ether, the methiodide crystallized in large light yellow needles, m. p. 140°.

Summary

The dehydrogenation of vitamin B_1 (thiamin) and other quaternary thiazoles is studied in connection with the codehydrase function of thiamin.

Quantitative Measurement of the Ultraviolet Activation of Sterols. I. Ergosterol

BY ROBERT S. HARRIS, JOHN W. M. BUNKER AND L. MALCOLM MOSHER

Ten years ago Kon, Daniels and Steenbock[1] reported that the ergs of radiant energy necessary to form from ergosterol an amount of vitamin D sufficient to demonstrate a deposition of calcium in the bones of rachitic rats was constant (700–1000 ergs) for mercury lines 2560, 2652, 2804 and 2937 Å.

Another paper, that by Marshall and Knudson,[2] reported that the rate of production of vitamin D is directly proportional to the number of light quanta absorbed by ergosterol and is independent of the wave length. They also stated that one quantum produced an average of 0.3 molecule of vitamin D.

A more recent publication[3] has reported that one International Unit of vitamin D was synthesized from ergosterol by 900 ergs of ultraviolet energy and that lines 249, 254, 265, 275, 280, 297 and 303 mμ were equally effective on a quantum basis. These results have created confusion, since they indicate that the photochemical conversion of ergosterol into vitamin D by various frequencies is dependent upon (1) the ergs of radiant energy irrespective of wave length (in the active region), (2) the quanta of energy irrespective of wave length and (3) equal ergs and equal quanta for the various wave lengths. Since ergs and quanta do not have a constant relation as wave lengths are varied, there is some obvious discrepancy.

The study which is being reported at this time was undertaken to determine more accurately the antirachitic effectiveness of the various lines in the mercury arc spectrum, and to determine the efficiency of the photochemical reaction in which ergosterol is converted into its antirachitically active isomer vitamin D (vitamin D_2 or calciferol). In this study 600 rachitic rats were used with a double quartz monochromator in a study of the active ultraviolet lines.

Procedure.—In this study we used the five active lines[4] of the mercury arc spectrum. The quantum–erg relationship of these lines is as follows.

Å.	Ergs/quantum
3025	6.50×10^{-12}
2967	6.62×10^{-12}
2804	7.01×10^{-12}
2652	7.41×10^{-12}
2537	7.74×10^{-12}

Irradiation Procedure.—In all experiments a cylindrical quartz vessel (27 mm. diameter, 152 mm. long) with flat ends was filled to capacity (approximately 80 cc.) with a 0.1% solution of ergosterol (du Pont) in C. P. anhydrous ethyl ether. This cell was mounted against the exit slit of a Bausch and Lomb quartz monochromator[4] (type no. 33-86-05) with prisms 8 × 8 cm. in such a way that the incident energy entered the front face of the vessel and passed into the ergosterol solution along the axis of the vessel.

By the use of photographic paper and malachite green leucocyanide reagent,[5] it was shown with all wave lengths studied that the energy was all absorbed in passing through the ergosterol solution.

These experiments were designed to compare the relative ability, on a quantum basis, of the different lines to activate ergosterol. Exposure times were calculated so that in a given experiment the ergosterol solution was exposed to the same number of quanta. Because of variations in the energy emission of the mercury arc the exposure times were different for each line. The emission from this lamp was measured from time to time during the course of the investigation.

To ensure the greatest accuracy the time was varied until an exposure would produce an amount of vitamin which, when fed to eight standard rachitic rats (Steenbock diet 2965), would produce a Steenbock unit of healing. Concurrent assays were run with USP Reference Oil so that in all cases a conversion into USP or International Units was possible.

The amount of energy entering the quartz cell was determined with the thermopile–galvanometer (type HS, Leeds and Northrup), using a Bureau of Standards K-4 lamp as a reference. The vertical six-inch (15 cm.) Uviarc was housed in a white transite box with an open window. The lamp was placed in the principal optical axis of the monochromator, at a distance of 13 cm. from its front face. The lamp was operated at 170–174 v. and 4.0–4.5 amp. The voltage was controlled by a photoelectrically operated voltage regulator (Stockbarger, to be published).

Following exposure the ergosterol solution was run into 20.0 g. of pure olive oil, three rinsings with anhydrous ether were added to the oil. The ether was removed from the oil under carbon dioxide by vacuum and the oil solution of irradiated ergosterol then thoroughly incorporated into 360 g. of Steenbock diet 2965. The mixture was divided into eight portions of 45 g. each and fed to eight

rachitic rats. Additional 2965 diet was placed in the cages of the animals when this special mixture had been consumed. The animals were killed at the end of ten days, their leg bones X-rayed and line tested so that the degree of healing could be calibrated. In all cases, Wistar strain albino rats were placed in individual cages and given the rachitogenic diet when twenty-eight days old. They were fed the irradiated ergosterol supplement after twenty to twenty-four days on the diet.

Results

Early in the research it was found that the efficiency of our irradiation procedure was better than that reported by Marshall and Knudson,[2] for 11.6 × 10^{13} quanta in our hands produced more than one USP unit of vitamin D. In six successive stages the irradiation time was decreased until it was established that 7.5 × 10^{13} quanta produced a unit of rachitic healing.

Space does not permit a presentation of the data in full. A total of sixteen complete experiments has been run with each active mercury line, the last ten of which are summarized in Table I.

Table I

Quantum Efficiency of Activation of Ergosterol in Ether

Number of Runs	Number of Animals	Lambda in Å.	Energy received in Ergs/sec.	Energy received in Quanta	Average healing
10	77	2537	81.1	7.5 × 10^{13}	2.26
10	77	2652	86.2	7.5 × 10^{13}	2.39
10	78	2804	48.5	7.5 × 10^{13}	2.58
10	78	2967	60.3	7.5 × 10^{13}	2.20
10	78	3025	120.9	7.5 × 10^{13}	2.46
10	74	USP Reference Oil			2.33

Discussion

The arithmetical values of healing displayed in Table I show a variation between 2.20 and 2.58 for the averages of recorded response to administration of ergosterol activated by monochromatic ultraviolet of various wave lengths. The interpretation of these mathematical differences is complicated by the fact that there is no evidence that the scale of healing (1+ to 4+) represents corresponding linear variations in physiological response. The intent of the experimental work was to produce a degree of healing as nearly identical as possible with that induced by measured dosages of USP Reference Oil in the neighborhood of 2.0. Individual animal variations in response are compensated to some degree by employing groups of at least eight animals for each feeding level.

The mathematical symbols used to represent observational data in the bioassay for vitamin D are in general recognized to be approximations rather than precise values. Differences in such values, to be significant, must be greater than those which can be computed mathematically as significant upon a purely statistical basis. This defect in the assay procedure is universal and is not peculiar to the experiments reported herein. We believe that the results herein reported comprise a minimum of probable error for such work.

Considering the results for the several wave lengths on the basis of the averages for eighty animals and comparing them with the value 2.33 which is the average for control animals fed USP Reference Oil concurrently, we are of the opinion that no significant differences have been demonstrated in the quantum efficiency of the several active wave lengths of ultraviolet in the photochemical activation of ergosterol.

Upon examining the original data from another point of view, namely, by groups of eight animals, and having regard for the slight changes in severity of experimental rickets, one is impressed with a tendency for more effective activation by the mercury line 2804, and whether or not it be coincidence that this line is one that shows maximum absorption by ergosterol or whether it be an indication of correlation between absorption and activatability only further work, with probably greater refinements than are now known to us, can definitely demonstrate.

Conclusion

1. The photochemical activation of ergosterol in ether by monochromatic ultraviolet light of 2537, 2652, 2804, 2967 or 3025 Å. is substantially uniform per quantum of energy applied.

Aqueous Solubilities of Some Isomeric Heptanols

BY P. M. GINNINGS AND MARY HAUSER

Aqueous solubilities of the pentanols[1] and some hexanols[2] have been determined in previous investigations. This is a similar investigation of nine heptanols that seemed of greatest interest. These nine include the seven tertiary and the two secondary isomers of most compact structure. Apparently the solubility of only one heptanol has been determined precisely. Butler[3] using an interferometric method found a value of 0.180 weight per cent. at 25° for normal heptanol.

The results of our determinations, which are given in the table, seem to be in accord with the theory outlined in previous investigations. As in the lower alcohols, the seven tertiary isomers are more soluble than the two secondary isomers of most compact structure, and increase of temperature is always accompanied by a decrease in solubility. Six of the seven tertiary heptanols can be considered as being derived from the six secondary hexanols by addition of a methyl group to the alpha carbon atom. It is noteworthy that the *relative* solubilities of the resulting six heptanols remain in the same order as in the hexanols. In the case of compound no. 1, the measurement of the solubility at the usual temperatures of the others was prevented by separation of the solid phase of the crystalline hydrate of the alcohol. However, determination of the solubility of the next alcohol (no. 2) at 40° also supplied a definite basis for comparison with the rest of the isomers. The importance of the compact molecule is easily noticed by a comparison of the solubilities of compounds nos. 1 and 2, where the former has a much more compact molecule than the latter. In the case of the two secondary isomers (nos. 8 and 9), the asymmetrical molecule containing the tertiary butyl group seems to dominate slightly the symmetrical molecule of no. 9.

Experimental

All compounds were prepared by some modification of the Grignard reaction with the usual procedure and purified by careful fractionation through a 1-meter column with a reflux ratio of about 10:1. Usually calcium oxide was also used in the distillation. The following specific reagents were used: no. 1 from *t*-butylmagnesium chloride and acetone; no. 2 from ethylmagnesium bromide and ethyl propionate; no. 3 from ethylmagnesium bromide and *i*-propyl methyl ketone; no. 4 from *s*-butylmagnesium bromide and acetone; no. 5 from *i*-butylmagnesium bromide and acetone; no. 6 from *n*-propylmagnesium bromide and methyl ethyl ketone; no. 7 from *n*-butylmagnesium bromide and acetone; no. 8 from *t*-butylmagnesium chloride and propionaldehyde; no. 9 from *i*-propylmagnesium chloride and *i*-butyraldehyde.

The procedure used for the measurement of the solubilities was essentially identical with that used in the work on

pentanols and hexanols. If details are desired, reference should be made to the article on pentanols. The results seem reliable to better than 0.1 weight per cent. and the authors feel that the validity of the results will approach this limit.

Summary

Aqueous solubilities of eight isomeric heptanols have been determined for 20, 25 and 30° and one for 40°. The seven tertiary isomers are more soluble than the two most compact secondary isomers. Maximum solubility is obtained by having the hydroxyl group as close as possible to the center of a compact tertiary molecule. Solubility of the isomers decreases as the temperature increases from 20 to 30°.

The Densities of Aqueous Solutions of Urea at 25 and 30° and the Apparent Molal Volume of Urea[1]

BY FRANK T. GUCKER, JR., FRED W. GAGE AND CHARLES E. MOSER

Introduction

In 1929 Masson[2] showed that the apparent molal volume of an electrolyte is a linear function of the square root of the concentration, while that of a weak electrolyte or a non-electrolyte is a linear function of a higher power of the concentration. The relationship for electrolytes has been confirmed by numerous investigators. In reviewing this and other properties of electrolytic solutions, one of us[3] pointed out that the data of Perman and Urry[4] for the apparent molal volumes and compressibilities of sucrose and of urea also might be represented as linear functions of the square root of the concentration. Redlich and Klinger[5] subsequently proved from more accurate density data that the change of the apparent molal volume of sucrose was much more nearly linear with the first power than with the square root of the concentration. We then found that the data of Perman and Urry could be represented equally well by either plot, within the limit of 0.1% to which their data were tabulated. The present work was undertaken to determine the apparent molal volumes of urea in aqueous solutions with high enough precision to determine whether it was also a linear function of the concentration—like sucrose.

Experimental Methods.—In order to attain an accuracy of a few parts per million (p. p. m.) the densities were measured differentially, using three pycnometers of about 60-ml. capacity. Two of them were filled with solution and the third with water. After all three had come to equilibrium in a thermostat and the volumes were adjusted in the capillaries, the pycnometers containing solution were weighed successively against the water-filled tare. Such a differential arrangement minimizes errors due to changes in the temperature of the thermostat, and also decreases the errors due to adsorption of moisture on the surface of the pycnometers and the correction required in reducing the weights to the vacuum standard.

In adjusting the pycnometers, they were placed in a thermostat holding 36 liters of water. The bottom and sides of the thermostat were protected by a 5-cm. layer of magnesia insulation and the top was covered with a wooden lid, in the center of which was a glass panel, through which the capillaries of the pycnometers were read.

The thermostat was equipped with an adequate stirrer and heated by means of three coils of bare nichrome wire connected to the lighting circuit through a thyratron relay. During the first series of measurements (made by F. W. G.) the relay was actuated by a large ether-filled regulator with mercury contact, which kept the temperature constant to ±0.002° under most conditions and to ±0.005° at all times. The temperature throughout the bath was found to be uniform to 0.001°. These temperatures were measured with a calibrated Beckmann thermometer. During the second series of measurements (made by C. E. M.) the regulator consisted of a pair of 100-ohm nickel resistance thermometers, connected in opposite arms of a Wheatstone bridge, equipped with a sensitive galvanometer. The light from the galvanometer mirror actuated a photoelectric cell which controlled the relay. This system gave more rapid response and kept the temperature constant to ±0.0004°, as measured by a platinum resistance thermometer. This regulator has the added advantage of great flexibility and instant response at any desired temperature.

The pycnometers were constructed of Pyrex glass, which has the advantage of chemical inertness but the disadvantage of changing volume appreciably with time. The body of each pycnometer was made from 2-cm. tubing bent into a U which was 6 cm. in total width and about 13 cm. high.

---

[1] Part of this paper was presented before the Symposium on "The Electrochemistry of Solutions" held by the Division of Physical and Analytical Chemistry at the Kansas City meeting of The American Chemical Society, April, 1936.

[2] Masson, *Phil. Mag.*, [7] **8**, 218 (1929).

Heavy capillary tubes of 0.4–mm. bore, sealed to the tops of the U, extended vertically for 2 cm. and then were bent at right angles. Each horizontal section was 6 cm. in length and its end was covered with a ground glass cap to minimize evaporation. The end of one was drawn down to a bore of about 0.1 mm., while the central portion of the other was graduated with 20 clearly-etched lines about 1 mm. apart. This allowed a latitude of about 0.002 ml. in setting the pycnometer. If a single mark were used, the volume would have to be set to 0.00006 ml. in order to give a sensitivity of 1 p. p. m.

Before the graduated capillaries were sealed into place, each was tested by measuring the length of a short mercury thread in different positions. When it was found to be uniform,[6] it was calibrated by measuring the length of a mercury thread which nearly filled the graduated section and then weighing the mercury. The volume per graduation was 0.00012 ml. in pycnometers 1 and 3, and 0.00013 ml. in number 2. An error of 0.5 mm. in reading the capillary therefore would only make an error of 1 p. p. m.

The volume of each pycnometer was determined by filling it with distilled water to some point on the graduated capillary and weighing the water it contained. The volume from the constricted end to the *first* mark on the graduated arm was then found by subtracting the volume of water in the graduated arm. The pycnometers were standardized at 25° and then at 30° in the summer of 1936. Two standardizations were carried out at each temperature, agreeing on the average to 12 p. p. m. No regular change in volume was observed during the few weeks in which the work was done. However, when the second series of measurements were made, starting in December, 1937, a decrease of 0.114% was found in the volume of pycnometer 2 and a decrease of 0.115% in 1 and 3. This evidently was due to the contracting of the pycnometers on aging, although they were annealed when they were made.

The weights used in this investigation were standardized to 0.01 mg. by the well-known method of Richards[7] as modified by Weatherill to employ transposition. They were checked from time to time and found consistent to a few hundredths of a milligram. The weighings in the first series of experiments were made on a good analytical balance of the required sensitivity. Those in the second series were made on a semi-micro balance with a notched beam graduated in hundredths of a milligram and with magnetic damping which decreased the time required to determine the balance point. In the second series, all weighings were made by transposition, to eliminate the effect of a difference of about 0.01% in the length of the balance arms.

Throughout this work, all weighings were reduced to the vacuum standard. The density of the brass weights was taken as 8.4, the figure given by the manufacturer. Calculations showed that an error of 10% in this value would not affect the results by 1 p. p. m. The density of 2.25 for Pyrex, given in the "International Critical Tables,"[8] was used in calculating the vacuum corrections for the pycnometers in the first series of experiments. Later, direct weighings in air and in water gave the value 2.234 which was used in the second series. The density of solid urea was taken as 1.335[9] at 20°. At the end of this work we found the value 1.329 at 25° as described in a later paragraph. Both these differences are negligible in calculating vacuum corrections. The atmospheric pressure was read on a mercurial barometer, corrected for temperature and the local value of the gravitational acceleration. The relative humidity was read on a hair hygrometer. The density of the air was calculated from these values, the room temperature and corresponding aqueous tension, by the formula given in the "International Critical Tables."[10]

Materials and Solutions.—The urea used in this work was prepared by crystallizing the commercial C. P. product twice from water, draining the crystals centrifugally and drying the product *in vacuo* at 50–60°, as described in a previous paper.[11] After use in the pycnometers, the solution was evaporated at 50° until crystallization began, then poured into an equal volume of redistilled ethanol held in an ice-bath at 0°. The urea precipitated in this way was collected on a sintered glass crucible and dried as before. Since urea is fairly soluble in 50% alcohol the filtrate was evaporated further and a second batch of crystals was reclaimed.

The water used in this work was redistilled from alkaline permanganate and had a specific conductance of about 1.5×10^{-6} mhos. It was always deaerated immediately before use by means of a water aspirator.

The solutions were made up determinate from the dry urea and this water. The urea was weighed into a 500-ml. flask to which the desired amount of water was added. After the solution was mixed thoroughly and brought up to room temperature, it was weighed and the amount of water found by difference. The solutions more concentrated than 4 molar required special treatment to prevent the appearance of small air bubbles which coalesced very slowly in the viscous medium. It was necessary to apply the full suction of the water aspirator, or the partial suction of a Hyvac pump, and to shake the flask at intervals for about a half hour in order to deaerate the solution completely. The final weighing was not made until this process was complete.

The pycnometers were cleaned with sulfuric acid and dichromate solution, rinsed with distilled water and dried with a current of filtered air. One of the capillary tubes was then connected, by means of a piece of gum-rubber tubing, to a glass tube extending through a rubber stopper into the suction flask containing the solution. The solution was forced into the pycnometer by air pressure from a rubber aspirator bulb connected to the side-arm of the flask. In some of the most concentrated solutions, a small amount of insoluble matter was removed by connecting a platinum sponge filter to the end of the glass tube through which the solution was forced.

After the pycnometers had come to equilibrium in the water-bath, the liquid menisci were adjusted as usual with a thin V-shaped piece of filter paper. When the meniscus remained stationary for five minutes, its position was read

[a] In this table and the next, c is the concentration of solute in moles per liter; d, the density of the solution in g. per ml.; and Δd, the observed density minus that calculated from the equation. The density of pure water is taken from the "I. C. T.," Vol. III, p. 25.

and recorded. All three pycnometers were then removed from the water-bath, rinsed with distilled water, wiped with a lintless towel and hung in the balance room. After a period of thirty or forty-five minutes, the weighings were made.

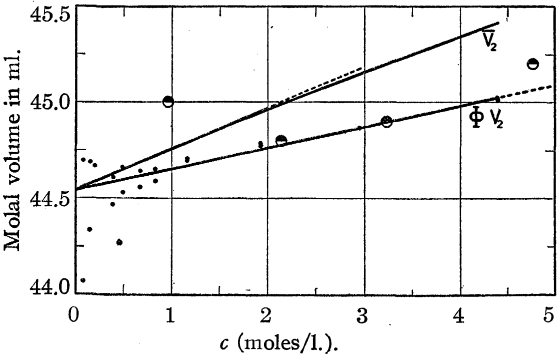

Fig. 1.—Apparent and partial molal volumes of urea at 30°: ●, this investigation; ⊖, Perman and Urry.

Experimental Results.—We originally planned a series of experiments over the whole concentration range at 25°. After the first six of these were made (by F. W. G.), hot weather necessitated a change to 30°. The series at 25° was completed later (by C. E. M.). The experimental results, numbered chronologically, are collected in Tables I and II, which include all the experiments except those affected by some known error. Duplicate experiments were always made, but in seven cases minor accidents prevented the completion of one of the pair. From the densities, the apparent molal volumes were calculated by the equation

$$\Phi V_2 = \frac{1000}{c}\left(\frac{d_1 - d}{d_1}\right) + \frac{M_2}{d_1} \qquad (1)$$

where c is the concentration in moles per liter, d_1 and d the densities of water and of solution, and M_2 the molecular weight of urea (60.058). A plot of the apparent molal volume at 30° (Fig. 1) showed that within experimental error it is a linear function of c up to the highest concentration studied. The best straight line representing the experimental values was found by the method of least squares, weighting each point according to its probable accuracy, measured by $(d - d_1)$. It was found to be

$$\Phi V_2 = 44.546 + 0.1087c$$

Substituting this value in equation (1) gives for the density the equation

$$d = 0.995673 + 0.015705c - 1.082 \times 10^{-4} c^2$$

Values calculated from this equation were compared with the experimental results and the differences, as shown in Table I, average ±29 p. p. m.

The partial molal volumes of solvent ($\bar{V}_1$) and solute ($\bar{V}_2$) are defined as

$$\bar{V}_1 = \left(\frac{\partial V}{\partial n_1}\right)_{n_2,\,T} \text{ etc.}$$

where V is the volume occupied by n_1 moles of solvent and n_2 of solute. These values were calculated from the apparent molal volume of the solute by the equations[12]

$$\bar{V}_1 = \frac{1000\,\bar{V}_1^\circ}{1000 + c^2\dfrac{\partial \Phi V_2}{\partial c}} \qquad (2)$$

$$\bar{V}_2 = \Phi V_2 + \left[\frac{1000 - c\Phi V_2}{1000 + c^2\dfrac{\partial \Phi V_2}{\partial c}}\right] c\,\frac{\partial \Phi V_2}{\partial c} \qquad (3)$$

These values are also collected in Table I and $\bar{V}_2$ is plotted in Fig. 1. It starts with twice the slope of the ΦV_2 curve and is practically linear to 1 molar, above which it increases somewhat less rapidly, as shown.

In Table II are given the results of the more complete series at 25°, which extends nearly to the saturated solution. Here also the apparent molal volume of urea may be represented as a linear function of c to a concentration of 3 molar by the equation

$$\Phi V_2 = 44.224 + 0.1319c$$

which was fitted to these data by the method of least squares. The corresponding equation for the density

$$d = 0.997074 + 0.015964c - 1.315 \times 10^{-4}c^2$$

reproduces the experimental values with an average deviation of ±5 p. p. m.

In more concentrated solutions, the increase is less rapid, as shown in Fig. 2. The whole series

---

[12] The first is analogous to that derived by Gibson, *J. Phys. Chem.*, **38**, 320 (1934), and listed as equation (6). The second was derived by Geffcken, *Z. physik. Chem.*, **A155**, 1 (1931), and used by Gucker, *J. Phys. Chem.*, **38**, 311 (1934).

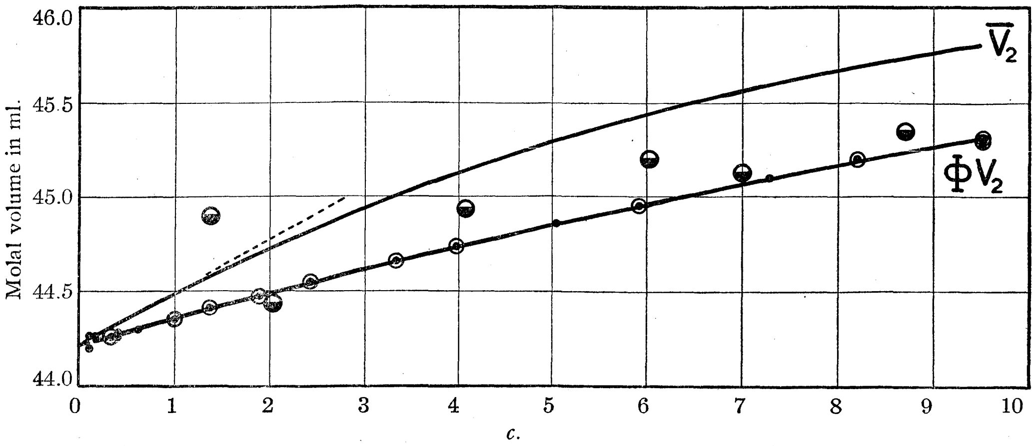

Fig. 2.—Apparent and partial molal volumes of urea at 25°: ● and ○, our data; ◒, Dunstan and Mussell.

lies along a smooth curve which is represented very satisfactorily by the second order equation

$$\Phi V_2 = 44.218 + 0.13999c - 0.002601c^2$$

The corresponding expression for the density is

$$d = 0.997074 + 0.0159686c - 1.3958 \times 10^{-4}c^2 + 2.593 \times 10^{-6}c^3$$

The experimental results agree with the values calculated from this equation with an average deviation of only ±7 p. p. m. up to 7 molar and ±26 p. p. m. over the whole range. The values of $\overline{V}_1$ and $\overline{V}_2$ were calculated as before and are included in Table II.

One other interesting experimental value was the density of solid urea, from which its molal volume in the solid state could be calculated. The value of 1.335 for the density at 20° which is tabulated in the "International Critical Tables"[9] apparently was determined by Mez.[13] It is frequently quoted in the literature. We were surprised to find, however, that another volume of the same Tables[14] listed, among "values reliable to four decimals or values over a temperature range," the figures of 1.3190 and 1.3617 determined by Dewar[15] at 17 and −188°, respectively. Assuming linear expansion, this would give the value 1.3184 at 20°, which is 1.2% lower than the value of Mez. Further search also disclosed the values of 1.333 and 1.323 found by Schröder[16] by the displacement of benzene and olive oil, respectively. No statement of the temperature was found, but it was probably 18 or 20°. Because of the diversity of these results, we measured the density at 25° in a specific gravity bottle with a ground plug. As the displacing liquid we used *n*-heptane, in which urea was found to be insoluble. The urea was powdered and dried as before and the liquid level was adjusted in the same thermostat. Five experiments were made. One of these was discarded because, for an unknown reason, the weight of the bottle increased upon standing on the balance pan. The other results were 1.3308, 1.3286, 1.3284 and 1.3279. We therefore took as a reliable average of our results the value 1.329 g./ml. at 25°. Correcting the other values to 25° we find that our results are half-way between those of Schröder and Mez, and about 1% higher than those of Dewar, as the following comparison shows:

Dewar (corr.)	1.317
Schröder (corr.)	1.327
This investigation	1.329
Mez (corr.)	1.334

Discussion

These measurements show conclusively that the apparent molal volume of urea is a linear function of the first power of the volume concentration from 0.1 to about 3 molar. This is demonstrated in Fig. 3, where the results for 25° are plotted against c along the upper line and against $c^{1/2}$ in the lower curve. The same conclusion follows from the results at 30°, although the experimental uncertainty is somewhat greater. Our results at 25° show a maximum difference from those of Dunstan and Mussell[17] of −0.6% and an average of −0.2%. Since their results are only given to 0.1%, this agreement is quite satisfactory. Our results at 30° agree with those of Perman and

Urry[4] within the accuracy of 0.1% with which they were tabulated. Four of their values, covering the range of our results, are plotted in Fig. 1, and six of the eight data of Dunstan and Mussell in Fig. 2. One of the others fell above and the second below the range of our figure. The large scattering emphasizes the difficulty of determining the true function of the concentration from them. Taking our value of the density of the solid, we find that its molal volume is 45.19 ml. at 25°. This differs very little from the volume in solution. In fact, it is the same as the apparent molal volume in a 6.5 molar solution or the partial molal volume in a 3.5 molar solution. Urea therefore is very nearly a perfect solute and does not cause the large electrostriction typical of electrolytes and of polar non-electrolytes,[18] nor does its apparent molal volume change so much with concentration. The increase from 0 to 1 molar solution is only about 4% of that of a typical 1-1 electrolyte.

Since the apparent molal compressibility[19] is the pressure derivative of the apparent molal volume

$$\Phi K_2 = -\left(\frac{\partial \Phi V_2}{\partial P}\right)_T$$

we would expect it to be the same function of the concentration as the apparent molal volume. A review of the literature did not disclose enough accurate data to prove this point, but we may reasonably assume that accurate compressibility measurements would show that the apparent molal compressibility of urea is also a linear function of c rather than $c^{1/2}$ as we first thought.[3]

In the case of electrolytes, the apparent molal heat capacity was found to parallel the volume properties.[3] The same is true of sucrose,[20] but the case of urea is different, since the apparent molal heat capacity[11] does not change in a simple manner with either c or $c^{1/2}$.

Added in Proof.—Recently we have found an article by Skarre, Demidenko and Brodskiĭ,[21] on the densities and apparent molal volumes of urea at 25° from 0.003 to 1.3 molar. They employed the differential flask method which Washburn[22] and his collaborators used to determine the density of heavy water, and consider their results accurate to 1 p. p. m. Their ten results from 0.003 to 0.09 molar differ on the average by only ±1.3 p. p. m. from the densities calculated from our equation, using the 1936 value of the molecular weight (60.047) which they apparently employed. Their results at the four higher concentrations show increasingly negative deviations of 16, 26, 66 and 102 p. p. m. for which we have no explanation.

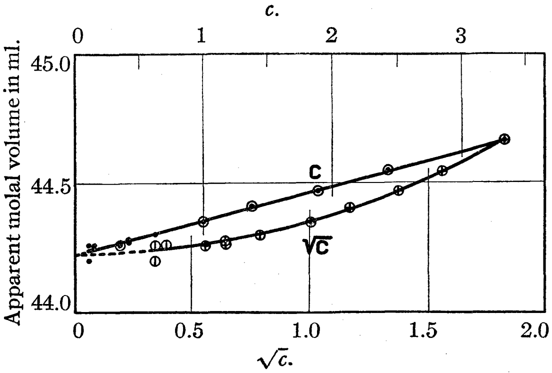

Fig. 3.—Comparison of abscissas for urea at 25°.

They plotted their results against $c^{1/2}$ and found a nearly linear relationship from 1.3 down to 0.05 molar. At greater dilution, their results fell *below* the line, and they hesitated to extrapolate to infinite dilution. However, their values of the apparent molal volume, tabulated to 0.001 ml., are accurate only to 0.1 ml. at 0.1 molar and 1 ml. at 0.004 molar. The average deviation in density is only 1 p. p. m., which seems to us to be within their probable experimental error. Their range of concentrations was not great enough to allow a satisfactory comparison of the $c^{1/2}$ and c plot, although they state that unpublished work by Dikowa in their laboratory indicates an upward concavity in the $c^{1/2}$ plot such as we have found.

Acknowledgments.—It is a pleasure to acknowledge our indebtedness to Dr. Ralph K. Day of the Corning Glass Works for supplying us with the capillary tubing used in our pycnometers; to Paul Kleppisch who, working on an N. Y. A. grant, purified the urea for these measurements; and to Nicholas Boukidis, also an N. Y. A. assistant, who helped in the construction of the thermostat.

Summary

Using a differential pycnometer method, we have measured the densities of aqueous solutions of urea from 0.1 to 4 molar at 30° and from 0.1 to 9.5 molar at 25°.

The apparent molal volume of urea is a linear

function of the volume concentration, *c*, over the whole range at 30° and up to 3 molar at 25°. Urea therefore behaves like sucrose and not like typical electrolytes, the apparent molal volumes of which increase linearly with $c^{1/2}$. The experimental results and the partial molal volumes of urea and water are tabulated. Equations giving the apparent molal volume and density as functions of concentration are also included.

The density of solid urea is found to be 1.329 g./ml. at 25° and its molal volume 45.19 ml.

Kinetics of Neutralization of Pseudo Acids in H_2O and D_2O

BY SAMUEL H. MARON[1] AND VICTOR K. LA MER

In this paper are reported kinetic measurements by a conductance method on the neutralization at 0 and 5° of nitromethane, nitroethane, and nitroisopropane by hydroxyl and deuteroxyl ions.

The familiar protolytic processes of ionization and neutralization of acids are in most cases not amenable to kinetic study for they proceed, if not instantaneously, at least with velocities too high to measure. In the class of substances designated as pseudo acids, however, ionization and neutralization proceed at a much slower rate, and in certain cases can be followed kinetically.

This difference in rates of protolytic transfer has been employed by Hantzsch[2] to define a pseudo acid as a substance whose salt formation is a function of time, as against the acid whose neutralization is essentially instantaneous. He states, further, that "if the salt formation is a function of the time, then it is evidence that the molecule undergoes a change in the salt formation process; it is also evidence for the fact that the undissociated substance and its ions are constitutionally different."

As a class, the primary and secondary nitroparaffins have long been recognized as pseudo acids. Ley and Hantzsch[3] have postulated that the primary and rate determining step in the neutralization of a nitroparaffin by a base is the isomerization of the nitro to the aci form, with subsequent rapid neutralization of the latter, *i. e.*

$$RCH_2NO_2 + B \xrightarrow[k_1]{} RCH{=}NOOH + B \xrightarrow[k_2]{} RCH{=}NOO^- + BH^+ \quad (1)$$

and $k_1 << k_2$. In this mechanism the sequence of transformations is nitroparaffin → undissociated aci acid → aci ion. However, Pedersen[4] has shown that this view is inconsistent with present ideas of acid–base catalysis as outlined by Brönsted.[5] The isomerization of a nitroparaffin must be considered a prototropic process, and as such it cannot take place spontaneously, but must involve the intermediary of an acid or basic catalyst. In conformity with this view he actually found the isomerization of nitromethane to the aci form to be a reaction subject to general base catalysis.[4] He consequently postulated as the mechanism of neutralization

$$RCH_2NO_2 + B \xrightarrow[k']{} RCH^-{\cdot}NO_2 + BH^+ \xrightarrow[k']{} RCH{=}NO_2^- + BH^+ \quad (2)$$

i. e., the nitro form donates a proton to the base, and the residue is converted rapidly by an electron shift to the ion. Thus $k_1' << k_2'$, and is rate determining. The aci ion may associate under the proper conditions, to form the aci acid. In this scheme the sequence is nitroparaffin → aci ion → aci acid.

Pedersen's formulation of the mechanism of isomerization of the nitroparaffins has been accepted by Junell,[6] Wynne-Jones,[7] and Reitz,[8] and will be employed to explain the results of this paper.

Following Hantzsch and Veit's[9] orienting semiquantitative conductivity measurements, Junell[6] studied in H_2O at 0° the neutralization by sodium hydroxide of nitromethane, nitroethane, nitropropane, and nitroisopropane by a modification of

the bromination method. Wynne-Jones, on the other hand, employing a conductance method, studied the neutralization of nitroethane by Ba$(OH)_2$ and $Ba(OD)_2$ at 0° in both light and heavy water.

A reinvestigation of the problem by the conductance method has been undertaken in order: (a) to confirm, refine, and extend Wynne-Jones' measurements, which in heavy water were restricted to a single experiment employing a very small volume of solvent; (b) to ascertain whether the bromination method gives a true measure of the rate of isomerization; (c) to determine the effect of substitution of alkyl groups in the molecule on prototropic rates in light and heavy water; (d) and to determine the rates of proton and deuteron transfer, and their temperature coefficients.

Experimental

Of the two methods available for following the rates of neutralization of nitroparaffins, conductance is more direct, avoids analytical determinations, and is free of the assumptions of the bromination method. The conductance method depends on the fact that as neutralization proceeds in an equivalent mixture of nitroparaffin and hydroxide, the highly mobile hydroxyl ions are removed, to be replaced by the considerably slower anions of the aci acid formed. Consequently the resistance of the solution increases with time from an initial value, R_0, to a final limiting value R_∞, due to the salt of the aci acid. The concentrations and velocity constants can be calculated in terms of the measured resistances.

Apparatus.—The bridge employed for measuring resistances was composed of a 1000-cycle microphone hummer, tuned Brown headphones, two variable, 10,000-ohm standard resistance boxes, and an L & N Student Type slide wire. This form of slide wire was preferred to the more accurate Kohlrausch type because balancing and reading could be accomplished with greater speed—an important consideration with the very fast reactions studied.

Four cells differing in size and shape of both cell and electrodes were employed. One was of the Henry type, one of the Freas type, while two were of special design. The latter had a total capacity of 20–25 ml., but required only 2–3 ml. of liquid to cover the electrodes. In these cells measurements could be made with small or large quantities of material; dilutions or additions of reagent could be made with ease. All the runs in D_2O were made in these special cells.

The electrodes were in all cases platinized. No catalytic effect due to the electrodes was observed.

One thermostat consisted of a 12-liter Dewar vessel of large opening, and filled with distilled water and crushed ice. Once charged, and with only occasional manual stirring, the temperature could be kept constant for twenty-four hours. For the experiments at 5° a large capacity water thermostat was operated in conjunction with a refrigerating unit, and regulated to ±0.005°.

Chemicals.—The nitromethane and nitroethane were Eastman products, and were purified by repeated fractional distillation. For nitromethane only the fraction boiling at 100.0° at 741.5 mm. was retained, while for nitroethane the fraction boiling at 112.5–113.0° at 739.3 mm. was used.

Nitroisopropane was prepared from purified isopropyl iodide and freshly prepared silver nitrite according to the directions of Kohler.[10] The fraction boiling between 119–120° was collected. Since the product was found to contain nitrous acid, it was treated with urea, dried with calcium sulfate and calcium chloride, and distilled twice under vacuum. The final product was a very mobile, colorless liquid, with a characteristic odor.

The distilled H_2O had a specific conductance of about 1×10^{-6} mhos. The D_2O, obtained from Hydro Norsk, was purified by molecular distillation under high vacuum twice from alkaline permanganate, and once without any addition. After use the D_2O was freed from organic matter by heating to 60–70° with alkaline permanganate and then distilling several times molecularly *in vacuo*. Water of satisfactory purity could be obtained in this manner without difficulty. Density measurements were made with a 10-ml. pycnometer.

The $Ba(OH)_2$ solution was prepared by dissolving C. P. $Ba(OH)_2 \cdot 8H_2O$, peroxide free, in distilled water. Carbonate was removed by filtration in a closed system through a sintered glass funnel. The $Ba(OD)_2$ was prepared in the same manner by dissolving anhydrous C. P. $Ba(OH)_2$, peroxide free, in D_2O, and removing the carbonate by filtration through a micro, all-glass funnel.

The H_2SO_4 was prepared by diluting concentrated C. P. acid with distilled water. The D_2SO_4 was prepared from thrice recrystallized pyrosulfuric acid and D_2O. The recrystallization was accomplished by melting the solid, and allowing part to crystallize.

Both acid and alkali were standardized by titration and on several occasions also gravimetrically as barium sulfate. The $Ba(OH)_2$ and $Ba(OD)_2$ were approximately 0.17 *N*, the acid solutions 0.3 *N*.

Procedure.—Since it is difficult to weigh into a cell 1–4 mg. of a volatile liquid with the desired accuracy, stock solutions, 0.04–0.06 *N* in nitroparaffin, were prepared in both light and heavy water. No decomposition in these solutions could be detected after several weeks at 0°.

A definite quantity of solution of the nitroparaffin in H_2O (or D_2O) was pipetted into a cell, water added in quantity sufficient to give the desired initial concentration, and the cell placed in the thermostat. The total volumes ranged from 2.4 to 7 cc. for the D_2O and from 5 to 18 cc. for H_2O. To initiate reaction an equivalent quantity of Ba$(OH)_2$ [or $Ba(OD)_2$], precooled to the same temperature, was delivered into the cell with a hypodermic syringe; a stop watch was started simultaneously.

Since the reactions are very rapid, and the quantity of reagent to be added in each case was small, 0.15–1.60 cc., it was especially important to deliver the reagent rapidly, with accuracy, and at the same time produce thorough mixing. A set of hypodermic syringes, ranging in capacity from 0.25–2.00 cc., was found to be highly satisfactory

---

(10) Kohler, THIS JOURNAL, 38, 898 (1916).

after calibration.[11] When provided with rustless steel or platinum needles these syringes deliver their charge in one to three seconds with a force sufficient to stir the contents of the cell thoroughly. This stirring was supplemented in the initial stages of a run by manual shaking of the cell to eliminate any possibility of concentration differences in the solution.

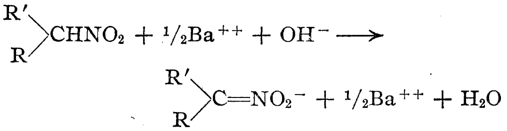
Resistance readings were taken within ten to thirty seconds after the addition of hydroxide. For nitromethane and for nitroethane at 5°, readings were taken at ten-second intervals for the first few minutes, and less frequently thereafter; for nitroisopropane, and for nitroethane at 0°, readings were made at fifteen-second intervals or less frequently, as the occasion demanded. In practically all cases the reaction was followed considerably past the point of half neutralization.

In many of the runs after completion of neutralization the nitroparaffin was regenerated from its barium salt by the addition of an equivalent quantity of sulfuric acid which precipitated the barium and liberated the aci acid. The isomerization of the aci acid to the nitro form is also a time reaction, subject to general acid catalysis.[6b,c] The kinetics of this reaction will be reported in another paper.

Once the nitro form of the pseudo acid had been regenerated, barium hydroxide in equivalent quantity was again added, and the whole sequence of measurements repeated. Thus the reproducibility of the rate and the reversibility of the isomerization process could be established.

Results of Measurements

The neutralization of a primary or secondary nitroparaffin by $Ba(OH)_2$ proceeds according to the equation



$$\begin{matrix}R'\\R\end{matrix}\!\!>\!CHNO_2 + {}^1/_2Ba^{++} + OH^- \longrightarrow \begin{matrix}R'\\R\end{matrix}\!\!>\!C{=}NO_2^- + {}^1/_2Ba^{++} + H_2O \quad (3)$$

where R and R′ are either a hydrogen atom or an alkyl group. The rate of reaction follows the equations

$$dx/dt = k_2\left(\begin{matrix}R'\\R\end{matrix}\!\!>\!CHNO_2\right)(OH^-) \qquad (4a)$$

$$= k_2\,(a - x)^2 \qquad (4b)$$

In terms of resistances it can be shown that Eq. (4b) on integration takes the form

$$k_2 = \frac{1}{at}\left[\frac{R - R_0}{R_\infty - R}\right]\frac{R_\infty}{R_0} \qquad (5)$$

where a is the initial concentration of nitroparaffin (and hydroxyl ion), R_0 the initial resistance, R_∞ the final, and R the resistance at time t.[12]

R and R_∞ in (5) can be measured directly, but R_0 must be obtained by extrapolation of the R values to zero time. For rapid reactions, like those of nitromethane and nitroethane, where the resistance increases rapidly with time in the initial stages, it is practically impossible to make such an extrapolation with any certainty or accuracy. Equation (5) can be rearranged to

$$t(R_\infty - R) = \left[\frac{R_\infty}{ak_2R_0}\right]R - \frac{R_\infty}{ak_2} \qquad (6)$$

Since for any one experiment the variables are only t and R, a plot of $t(R_\infty - R)$ *vs.* R should be a straight line with slope given by

$$\text{slope} = R_\infty/ak_2R_0 \qquad (7)$$

and y-intercept, b

$$b = -R_\infty/ak_2 \qquad (8)$$

From the latter k_2 follows as

$$k_2 = -R_\infty/ab \qquad (9)$$

This method of evaluating k_2 was found to be satisfactory, and eliminated the uncertainty in the determination of R_0.

In Fig. 1 are shown plots of $t(R_\infty - R)$ *vs.* R for nitroethane and nitroisopropane in H_2O and in D_2O. The linear character of the plot furnishes evidence of the fidelity with which equation (6), and hence equation (4), reproduces the data in a given experiment.

The results obtained with nitromethane, nitroethane, and nitroisopropane in both light and heavy water are summarized in Tables I, II and III. The A runs refer to the first neutralization of the nitroparaffin; the B runs are those made with nitroparaffin which had been neutralized, reconverted to the nitro form, and again neutralized. Because of its high rate, the neutralization of nitromethane was measured only at 0° in light water. Nitroethane has been studied at both 0 and 5° in light water and at 5° in heavy water. Only once were we fortunate in maintaining supercooling to obtain a measurement at 0° in heavy water; in five subsequent attempts the supercooled D_2O solutions froze and made rate measure-

[11] The syringes, manufactured by Becton, Dickinson & Co., Rutherford, N. J., were of the Tuberculin or Precision type. The 0.25-cc., the 0.50-cc., and the 1.00-cc. syringes were subdivided into 0.01 cc., and could be estimated further to 0.001, 0.002, and 0.003 cc., respectively. The 2.00-cc. syringe was subdivided into 0.05 cc. and could be read easily to 0.01 cc.

[12] Wynne-Jones[7] gives this equation without proof. We find that in order to derive this expression it is necessary to assume that the *specific* conductances of the ionic species present in solution are additive and that they vary linearly with concentration.

ments impossible at that temperature. Consequently nitroisopropane has been studied at 0 and 5° in light water, and only at 5° in D_2O.

Attention should be directed to the B runs in Table II. The results of these runs are evidence that the barium salt of nitroethane is stable, and that it can be reconverted *completely* to the nitro form by the addition of an equivalent quantity of sulfuric acid. The same can be said for Run 44-B in Table I. Although the result deviates from the mean, still it must be considered as satisfactory evidence, if the uncertainties of reagent addition, barium sulfate precipitation, and the high rate of the reaction be recognized.

No B runs could be made with nitroisopropane. Although the barium salt was stable, the free acid, liberated on addition of an equivalent quantity of sulfuric acid, decomposed partially to yield a

	5	3.36 ± .01	..	..

product or products other than the nitro form. In this respect Junell's[6c] (p. 110) experience is in accord with our own.

The nitroethane measurements in D_2O merit further explanation. Wynne-Jones[7] first called attention to the fact that it should be possible to study the kinetics of exchange of the H for D atoms on the carbon adjacent to the nitro group in nitroethane by the following series of reactions carried out in D_2O

$$CH_3CH_2NO_2 + OD^- \xrightarrow{k_1} CH_3CH{=}NO_2^- + HOD \tag{10a}$$

$$CH_3CH{=}NO_2^- + D_3O^+ \longrightarrow CH_3CHDNO_2 + D_2O \tag{10b}$$

$$CH_3CHDNO_2 + OD^- \xrightarrow{k_2} CH_3CD{=}NO_2^- + HOD \tag{11a}$$

$$CH_3CD{=}NO_2^- + D_3O^+ \longrightarrow CH_3CD_2NO_2 + D_2O \tag{11b}$$

$$CH_3CD_2NO_2 + OD^- \xrightarrow{k_3} CH_3CD{=}NO_2^- + D_2O \tag{12a}$$

The idea in this sequence of reactions is to remove the protons one at a time with OD^- and introduce deuterons instead of protons with D_3O^+, until finally only D atoms are attached to the alpha carbon. Further neutralization should involve the transfer of a deuteron to the OD^- ion (12a). By this simple artifice it should be possible to measure both the rate of proton transfer (10a) and deuteron transfer (12a) to the same ion, OD^-, in the same solvent D_2O. Reaction (11a) would proceed only as written if the rate of proton removal is considerably greater than that of the deuteron from CH_3CHDNO_2.

One such sequence of measurements with nitroethane was carried out by Wynne-Jones at 0°. We have repeated these experiments at both 0 and 5°. In Table II the constants designated first stage refer to reaction (10a), while those marked second stage refer to reaction (11a). Stage three, corresponding to (12a), could not be measured for reasons to be given below.

Comparison of Results with Previous Measurements

In Table IV are summarized all the known rate constants for the neutralization of nitroparaffins in light water. Inspection of these data shows that Wynne-Jones' result for nitroethane at 0° is in very good agreement with our value of 39.11. On the other hand, Junell's constants, obtained by a bromination method, are in every case *lower* than those of this paper.

The conductance method measures directly the rate of removal of hydroxyl ions from solution. Since the latter are removed in the reactions under discussion by taking on a proton from the substrate, we conclude that we are measuring directly the rate of proton transfer to hydroxyl ions. In the bromination method, however, the rate of proton transfer is arrived at indirectly through two fundamental assumptions. As used by Junell, the procedure consisted in neutralizing a nitroparaffin with sodium hydroxide up to a certain point, and then suddenly adding a large excess of strongly acid solution of bromine. The assumptions were (1) that the acid would neutralize the alkali and thus stop the reaction, and (2) that the bromine would react very rapidly with the aci acid present. From the quantity of bromine consumed the extent of neutralization at the time of addition of bromine could then be calculated.

Nothing definite can be said about the second of these assumptions. It is known that bromine is absorbed very rapidly by the aci form of a nitroparaffin, but just how rapidly is still an open question. To the first assumption, however, two serious objections can be raised. First, Nef[13] has shown that in the presence of excess mineral acid the aci salts are unstable and decompose to give various products. Secondly, Junell[14] has shown that in the presence of H_3O^+ the anions of the aci-paraffins isomerize rapidly to the nitro-forms.

(13) Nef, *Ann.*, **280**, 263-291 (1894).

(14) Refs. 6b; 6c, p. 79.

He has shown, further, that the reaction anion + acid is subject to general acid catalysis. We may expect that even with a very rapid bromination rate, an appreciable back reaction may set in on addition of a large excess of mineral acid, converting some aci to nitro-form before bromination is completed. The two factors mentioned should operate to give *low* results for the concentration of aci form, and hence for k_2. The error should be especially large with nitromethane, where the rate constant for the back reaction is known to be large, and smaller for the other nitro-paraffins under discussion.

This is actually the case, as may be seen from Table IV. The divergence between the rate constants of this paper and Junell's is 28% for nitromethane, about 10% for nitroethane, and about 7% for nitroisopropane.

It should be mentioned that Junell, in some preliminary experiments, tried out his method on nitroethane and found the error involved in the concentration determinations to be 0.5–4%, depending on the dexterity of operation. The error in the determination of the nitromethane concentrations would then be expected to be even larger, leading to greater error in the constants for nitromethane. These facts substantiate the above analysis of the bromination procedure.

In view of these considerations we consider the results of conductance to be more accurate and reliable than those obtained by the bromination method.

Table V gives a summary and comparison of the kinetic constants obtained in D_2O. The agreement between Wynne-Jones' value at 0° for the first stage and that of this paper is fair, but there is no agreement at all for the second. Wynne-Jones' $k_2 = 36$ is altogether too high in view of the constants measured at both 0 and 5°. For the third stage Wynne-Jones reported a rather unsatisfactory constant varying from 6 to 15. We have found that no satisfactory constants for this stage can be obtained because the $CH_3CD{=}NOO^-$ ion, although stable in the salt, is more sensitive to acid than the corresponding $CH_3CH{=}NOO^-$ ion, and undergoes some decomposition on addition of D_2SO_4. In the light of Nef's[13] work the decomposition product may be expected to be CH_3CDO. A test with 2,4-dinitrophenylhydrazine gave a positive reaction. This finding renders Wynne-Jones' measurement of the third stage too questionable to have any meaning in the calculation of ratio of proton to deuteron transfer.

TABLE V

COMPARISON OF RESULTS FOR NITROETHANE IN D_2O

First stage	0	55.6	60
	5	81.33 ± 0.49	..
Second stage	0	20.7	36
	5	29.54 ± .16	..
Third stage	0	No result	6–15

Discussion

The rate of proton donation by a nitroparaffin to a base depends greatly on the nature of the atoms or groups attached to the α-carbon. An inspection of Table IV shows that the rate of neutralization is highest for nitromethane and least for nitroisopropane, *i. e.*, the greater the number of hydrogen atoms attached to the α-carbon the greater the rate of proton donation to a base. As the hydrogens are progressively replaced by alkyl groups, the rate decreases rapidly. Apparently the length of the substituent alkyl group is of relatively minor importance, since the rates of neutralization of nitroethane and *n*-nitropropane are not very different. On the other hand, the number of alkyl substituents is of importance, as is evidenced by the very large decrease in rate constants when two hydrogen atoms are replaced by methyl groups in nitroisopropane.

Qualitatively these observations are in accord with the "inductive effect" ascribed to methyl groups in particular and to alkyl groups in general. An alkyl group is considered to be more "electron repulsive" than a hydrogen atom. Consequently, on replacement of a hydrogen atom by an alkyl group, the carbon to which the attachment is made becomes more negative by induction, and exercises a greater attraction for the proton. This stronger attraction between hydrogen and carbon should be evidenced by a decrease in rate beyond that expected on purely statistical grounds. Such is actually the case. From Table IV it will be observed that the rate inhibiting effect of various alkyl groups is in the order

$$\begin{matrix}CH_3\\CH_3\end{matrix} > > CH_3CH_2 > CH_3 > H$$

This is the sequence found by Kharasch and Flenner[15] for the order of increasing electron repulsive character of alkyl groups, and is also the order

---

[15] Kharasch and Flenner, THIS JOURNAL, **54**, 674 (1932).

given by Watson[16] for the relative magnitudes of the "inductive effect."

Again, the inductive influence of halogen, which is electron attractive, should be to increase the rate of prototropic change. This is in accord with Junell's measurements[17] which show that the rates of ionization of brominated nitromethane and nitroethane are faster than those of the corresponding unhalogenated nitroparaffins.

Quantitatively, the velocity constants for the neutralization of nitroisopropane, *n*-nitropropane, nitroethane and nitromethane are in the ratio 1:14:18:114, respectively. These figures are not explicable on purely statistical grounds. Again, the effect of the methyl groups is not additive. Although there is about a six-fold decrease in rate on going from nitromethane to nitroethane, the decrease in rate from nitroethane to nitroisopropane is 18-fold. These variations in rate, outside of statistical considerations, can be ascribed only to differences in force of binding of the hydrogen to the carbon produced from compound to compound by the substitution of alkyl groups.

The heavy water experiments add nothing to the above facts. The ratio of the velocity constants of nitroethane to nitroisopropane in D_2O is the same as in H_2O, 18. These experiments do show, however, that the rate of proton transfer from a nitroparaffin to OD^- in D_2O is *faster* than the rate for the transfer of a proton to OH^- in H_2O. The ratio of velocity constants is essentially constant, being 1.42 and 1.39 for nitroethane at 0 and 5° and 1.36 for nitroisopropane at 5°. Such accelerations in reactions involving OH^- and OD^- ions in the two media have been observed in the saponification of ethyl acetate,[18] the hydrolysis of diacetone alcohol,[19] and the hydrolysis of the monochloroacetate ion.[20] The ratios found there were in the order given 1.33, 1.22 (15°) and 1.2 (45°).

Since the substrates in the examples cited were the same in both H_2O and D_2O, the differences in rate in the two media may be ascribed to solvent effect and to differences in the OH^- and OD^- ions. It is doubtful whether the solvent alone would account for a 40% acceleration in rate observed here. These experiments indicate that the OD^- ion is a stronger base than the OH^- ion, and by virtue of its greater basicity accelerates the rate of proton removal from the substrate.

The ratios of the rates of proton to deuteron transfer could not be determined by the method suggested by Wynne-Jones. Nor do the results for the first and second stages for nitroethane in D_2O support Wynne-Jones' contention that the rate of removal of a proton from $CH_3CH_2NO_2$ is essentially twice that from CH_3CHDNO_2. This factor of two was explained on statistical grounds by the decrease in number of mobile protons present from two to one. His conclusion was based on a value of $k_2 = 36$ for the second stage, a value we believe to be considerably in error. The results of this paper show that the ratio of constants in the first and second neutralization stages is 2.7. There is no evidence for a simple quantitative statistical connection between rate constants and number of prototropic hydrogens in the molecule.

The rate constants reported in Tables II and III can be expressed as functions of the temperature by the equations

(a) Nitroethane in H_2O

$$\log_{10}k = -\frac{2640.5}{T} + 11.261$$

(b) Nitroethane in D_2O, first stage

$$\log_{10}k = -\frac{2513.7}{T} + 10.949$$

(c) Nitroethane in D_2O, second stage

$$\log_{10}k = -\frac{2341.0}{T} + 9.888$$

(d) Nitroisopropane in H_2O

$$\log_{10}k = -\frac{3163.0}{T} + 11.899$$

The units are equivalents per liter and minutes.

Columns (4) and (5) of Table VI summarize the energies of activation and the constant B in the Arrhenius equation: $\log_{10}k = B - (\Delta E^*/2.303RT$. All the reactions proceed with energies of activation somewhat lower than are usually encountered (*ca.* 20,000 cal.). The considerably lower rate for nitroisopropane in H_2O as compared with nitroethane in the same solvent is partially explicable by the difference of 2400 cal. in the energies of activation. The increase in rate of neutralization of nitroethane in D_2O over that in H_2O may be accounted for by the decrease in energy of activation of 600 cal. although this difference would call for a larger increase in rate than has been observed. However, no explanation can be advanced on this basis for the rate observed in the second stage for nitroethane in

Nitroethane	H_2O	0.1738	12,100	11.26	1.70	− 9.58	−3.26	−14.99
Nitroethane								
First stage	D_2O	.1655	11,500	10.95	1.83	− 9.12	−3.59	−16.41
Second stage	D_2O	.1541	10,700	9.89	1.40	− 8.49	−4.65	−21.25
Nitroisopropane	H_2O	.2082	14,500	11.90	0.42	−11.48	−2.64	−12.06

D_2O. Although the energy of activation is lower than that for the first stage by about 800 calories the rate observed is also lower, though the exact opposite would be expected. The difficulty can be resolved by ascribing a part of the difference in rates observed to differences in entropy of activation of the reactions in question. The magnitude and variations in the B constant show that the entropy terms are appreciable.

According to the transition state theory of reaction velocity[21]

$$k = \frac{RT}{Nh} e^{-\Delta S^*/R} e^{-\Delta E^*/RT} \qquad (13)$$

or

$$\log_{10}k = \log_{10}\frac{RT}{Nh} + \frac{\Delta S^*}{2.303R} - \frac{\Delta E^*}{2.303RT} \qquad (14)$$

where R/N and h are the Boltzmann and Planck constants, respectively, and ΔS^* is the entropy of activation for all degrees of freedom.[22] By comparison with the Arrhenius equation

$$B = \log_{10}\frac{RT}{Nh} + \frac{\Delta S^*}{2.303R} \qquad (15)$$

Since ΔE^* was taken as constant for 0 and 5° in the calculation of B, ΔS^* values were calculated for the average temperature of 2.5°. At this temperature ΔS^* is given by

$$\frac{\Delta S^*}{2.303R} = B - \log_{10}\frac{RT}{Nh} = B - 14.54 \qquad (16)$$

when the time is expressed in minutes. The values are tabulated in columns (8) and (9) of Table VI, and show large negative values for the entropy of activation.

Columns (7) and (8) give the activation energy and activation entropy contributions to the logarithm of the velocity constant at 2.5° shown in column (6). The entropy contributions are in every case large fractions of the energy contributions. Comparison of nitroethane and nitroisopropane in H_2O shows that the decrease in rate observed for nitroisopropane is due primarily to increase in activation energy,[23] although an increase in the activation entropy of about three units mitigates the decrease in rate constants. On the other hand, the increase in rate in D_2O over that in H_2O for nitroethane is due to the fact that although the entropy decreases, the simultaneous decrease in the energy of activation outweighs the effect of the entropy, thus leading to a higher rate of reaction. For the second stage, however, just the reverse is true. Here the decrease in entropy of activation outweighs considerably the decrease in the activation energy, and consequently the rate constants *decrease* although from a consideration of activation energies alone they should increase.

Summary

1. The rates of neutralization of nitromethane, nitroethane, and nitroisopropane by OH^- ion in H_2O and by OD^- ion in D_2O have been studied by a conductance method. Measurements are given for nitromethane at 0° in H_2O and for nitroethane and nitroisopropane at 0 and 5° in both H_2O and D_2O.

2. The rate constants for these prototropic reactions in H_2O decrease as we pass from nitromethane to nitroethane, to nitroisopropane. A qualitative explanation of this change in rate with substitution is given in terms of the "inductive effect" of alkyl groups.

3. The rates for nitroethane and nitroisopropane are 40% faster in D_2O than in H_2O at the same temperature.

4. The results of this paper have been compared with previous measurements in the light of

[22] La Mer and Liotta, THIS JOURNAL, **60**, 1967 (1938); La Mer, *J. Franklin Inst.*, **225**, 709 (1938). See p. 729 for a more detailed discussion of difference between the entropy of activation as defined by Eyring (ΔS^*) and as defined by La Mer ($\Delta S_{\text{act.}}$) in *J. Chem. Phys.*, **1**, 289 (1933).

[23] By the term "increase in activation entropy" on passing from nitroethane to nitroisopropane we refer to the algebraic increase in the entropy of the activation process: $S^* = -15$ to 12 E. U. respectively. This means that the latter complex is more probable, *i. e.*, more states, in the statistical sense, exist for the isopropane than for the ethane complex. On the other hand the energy differences for the activation process represented by $\Delta E^*/2.3RT$ are higher for the former, namely, 11.48 and 9.58. Hence the rate of reaction is slower for nitroisopropane.

the methods employed. A critical discussion of the bromination method is given, and certain errors pointed out.

5. Wynne-Jones' attempt to determine the ratio of proton to deuteron transfer by progressive exchange of H for D in nitroparaffins is inapplicable to nitroethane and nitroisopropane because of the instability of the substrate at certain stages in the process.

6. Equations for rate constants as functions of temperature are given, and energies and entropies of activation calculated. It is shown that the differences in rates observed cannot be explained in terms of changes in the activation energy alone; the differences in the observed rates are caused by an interplay of variations in both energy and entropy of activation.

Reactions of Trialkyl Phosphates, Alkyl Acetates, and Tertiary Butyl Hypochlorite in the Friedel–Crafts Syntheses[1]

BY NATHAN BERMAN AND ALEXANDER LOWY

The synthesis of alkylated substances by means of the Friedel–Crafts reaction has been extended widely from the original use of alkyl chlorides with aromatic hydrocarbons. An important advance in the alkylation reaction was the application of esters to the synthesis. Among the esters used were: alkyl borates, alkyl acetates, alkyl formates, *n*-butyl oxalate, tetraethyl silicate, and diethyl carbonate. The trialkyl phosphates gave phenol ethers with phenol.

The purpose of this investigation was to observe whether the use of esters might be extended to the alkyl esters of phosphoric acid, acetic acid, and tertiary butyl hypochlorite. These substances proved to be efficient alkylating agents. The conditions which influenced the yield of alkylated benzenes were observed, such as concentration of reagents, duration of heating, and reaction time.

Experimental

The apparatus employed for the alkylations was the usual one-liter three-necked Pyrex flask, into one neck of which extended a dropping funnel and thermometer. The central neck was fitted with a glass stopper and mercury seal, through which extended a motor-driven glass stirrer. The third neck was connected to a modified Hopkins-type reflux condenser. Fractionations were conducted with a seventeen-inch (43-cm.) Vigreux column, which was wrapped in asbestos paper.

The aluminum chloride used throughout was of 99.5% purity. The benzene was dried over sodium and distilled at 80–81°. The various esters were purified by distillation or by vacuum distillation before use.

Typical Experiment. Triethyl Phosphate.—Benzene (435 g.) was stirred with 68.5 g. (0.515 mole) of aluminum chloride in the Pyrex flask, surrounded by an ice-water bath; 25 g. (0.137 mole) of triethyl phosphate was added dropwise through a separatory funnel over a two-hour period. The mixture was then stirred for eight hours at room temperature (20–25°). Throughout this time there was a vigorous evolution of hydrogen chloride. The mixture was poured over cracked ice and allowed to hydrolyze overnight. The benzene layer was washed with aqueous sodium bicarbonate and water, dried over calcium chloride, filtered, and fractionally distilled. There was obtained 27 g. of ethylbenzene boiling at 134–137°; n^{20}_D 1.4951. There was also obtained 8 g. of a higher boiling fraction.

Preparation of Triisopropyl Phosphate.—The procedure analogous to that described in "Organic Syntheses" for the preparation of *n*-butyl phosphate[2] was followed. In the four-necked flask fitted with (a) a mercury-sealed stirrer, (b) a Hopkins-Cole type condenser, (c) a thermometer, and (d) a separatory funnel, there was mixed three moles (180 g.) of isopropyl alcohol with 3.3 moles of pyridine and 275 ml. of benzene as solvent. This mixture was stirred and cooled in an ice-salt bath to −5°. Through the separatory funnel, 153 g. of phosphorus oxychloride was added dropwise over six hours at such a rate that the temperature never exceeded 10°. The mixture was refluxed for two hours at 80°; 500 ml. of water was added to dissolve the pyridine hydrochloride; the benzene layer was washed with 100 ml. of water and dried over anhydrous sodium sulfate. On vacuum distillation, 100 g. of triisopropyl phosphate was collected, which represents a 44.7% yield. Its boiling point was 122–125°, at 15–16 mm. pressure.

The accompanying Table I gives the results of the experiments conducted with the various esters as alkylating agents. The experimental procedure was analogous to that followed in the experiment with triethyl phosphate, except as indicated below.

I. Alkylating agent = triethyl phosphate (b. p. 96–101° at 3–5 mm.). Product = ethylbenzene (b. p. 134–137°; n^{20}_D 1.4951).

[a] No mercury. [b] Amount of mercury unknown. [c] 10 g. of mercury.

In the experiments conducted with *s*-butyl acetate, the 19-g. high boiling fraction (experiment V-A) showed the usual effect of a high concentration of aluminum chloride. The molar ratio of aluminum chloride to ester of approximately one to one (experiment V-B) was more favorable to the production of *s*-butylbenzene. Experiment V-C showed that the relatively small amount of aluminum chloride did not promote the reaction, from which it was assumed that the aluminum chloride plays an integral part in the reaction, and its role is not purely catalytic.

The formula given to methyl amyl acetate by the Carbon and Carbide Co. was: $CH_3COOCH(CH_3)CH_2CH(CH_3)_2$(2,4-dimethylbutyl acetate). It has been established that under the conditions of the experiments mercury is a necessary catalyst for the alkylation of benzene with methyl amyl acetate. The physical constants of the alkylated benzene were: b. p. 195–200°; $n^{15}D$ 1.4930; d = 0.866 (15°), which corresponds with β-methyl-δ-phenylpentane (b. p. 197°; $n^{15}D$ 1.4876; d 0.863 (15°)).

t-Butyl hypochlorite was supplied by the Pennsylvania Salt Manufacturing Co. The question was considered as to whether it would condense the alkyl or alkoxy group on to benzene. Under the conditions of experiment VII-B, aluminum chloride was found to be a necessary catalyst for the alkylation of benzene by tertiary butyl hypochlorite. Since no ether but *t*-butylbenzene was obtained exclusively, it was apparent that the alkyl–oxygen bond in the hypochlorite was split in the reaction.

Aluminum Chloride with Isopropyl Acetate.—For the elucidation of the mechanism of these syntheses, it is important to determine the behavior of the esters when treated with aluminum chloride. In the following experiment an attempt was made to isolate any isopropyl chloride which might be evolved in the reaction of isopropyl acetate with aluminum chloride. Twenty-five grams of isopropyl acetate was added dropwise to 71.8 g. of aluminum chloride at 15° in the reaction flask. The mixture was stirred for five and one-half hours at 15° and then for two hours at 50°. Some reaction was apparent due to the mixture becoming thick and dark with an evolution of hydrogen chloride. No isopropyl chloride (b. p. 39°) was obtained.

Under the conditions of the experiment, any alkyl halide which might be formed could react further at once and hence was not isolated.

Summary

1. It has been shown that the trialkylphosphates (ethyl, isopropyl and butyl), the alkyl acetates (isopropyl, *s*-butyl, and methyl amyl) and *t*-butyl hypochlorite will condense with benzene in the presence of aluminum chloride to give the corresponding alkylated benzene. These reactions may be summarized by the equations

$$(RO)_3PO + 3C_6H_6 + AlCl_3 \longrightarrow 3RC_6H_5 + AlPO_4 + 3HCl$$

$$CH_3COOR + C_6H_6 + AlCl_3 \longrightarrow RC_6H_5 + HCl + CH_3COOAlCl_2$$[3]

$$t\text{-}C_4H_9OCl + C_6H_6 + (AlCl_3) \longrightarrow t\text{-}C_4H_9C_6H_5 + HOCl$$

2. The preparation of triisopropyl phosphate has been described.

Hexamethylethane and Tetraalkylmethanes

BY RUSSELL E. MARKER AND THOMAS S. OAKWOOD

Because of the difficulty of preparing hexamethylethane and other tetraalkyl substituted methanes in quantity by following the methods given in the recent literature,[1] a practical method has been developed whereby a tertiary halide may be condensed with an alkylmagnesium halide giving yields of 11 to 20% of the desired hydrocarbon. This condensation has been brought about by the addition of cuprous iodide to a mixture of the straight chain Grignard reagent and a tertiary halide. This method also may be applied to the condensation of a branched chain Grignard reagent with a tertiary halide as shown in the case of hexamethylethane, obtaining a yield of better than 16% in a preparation of 1120 g.

Two series of hydrocarbons were prepared, the 2,2-dimethyl compounds from tertiary butyl chloride and RMgBr, and the 3,3-dimethyl compounds from tertiary amyl chloride and RMgBr. If the physical properties of each of these two series of hydrocarbons are arranged in order of increasing molecular weights, not only is there a regular increase in boiling points, but the refractive indices and densities exhibit the same regular increase in value for each series of similar hydrocarbons. The results obtained are summarized in Table I.

TABLE I

	Yield, %	B. p. (760 mm.) °C.	$n^{20}D$	d^{20}_4
2,2-Dimethylbutane	11	49.6	1.3709	0.6491
2,2-Dimethylpentane	21	79.0	1.3825	.6739
2,2-Dimethylhexane	14	106.2	1.3942	.6934
2,2-Dimethylheptane	17	130.4	1.4035	.7105
3,3-Dimethylpentane	22	86.0	1.3911	.6937
3,3-Dimethylhexane	17	112.0	1.4008	.7107
3,3-Dimethylheptane	16	137.2	1.4087	.7254
3,3-Dimethyloctane	11	161.2	1.4165	.7390

Experimental

As the preparations of the hydrocarbons were essentially the same, the details will be given only for 2,2-dimethylbutane and hexamethylethane. The remainder were made by the condensation of the suitable straight chain alkylmagnesium bromide with tertiary butyl chloride or tertiary amyl chloride in the presence of cuprous iodide. Their properties and yields from ten mole runs of Grignard reagents are given in the table.

2,2-Dimethylbutane.—The Grignard reagent was made from 144 g. of magnesium with 1200 cc. of dry ether and 654 g. of ethyl bromide. The flask was cooled in ice and 400 g. of tertiary butyl chloride added with stirring. This was followed by 20 g. of cuprous iodide. The mixture stood overnight, during which time it solidified to a hard cake. This was decomposed by water and dilute acid. The ether extract was dried over solid potassium carbonate and fractionated. The crude hydrocarbon was shaken twice with cold concentrated sulfuric acid, followed by water, then sodium carbonate solution and finally dried over sodium sulfate. It was then refluxed for six hours with sodium–potassium alloy and again treated with sulfuric acid.

Hexamethylethane.—To 6 moles of tertiary butylmagnesium chloride in 2 liters of dry ether with rapid stirring was added a mixture of one-half mole of tertiary butyl iodide and five and one-half moles of tertiary butyl chloride. Much gas came off. Twenty grams of cuprous chloride was then added in 2-g. quantities. The reaction mixture heated up considerably, giving off gas and soon formed a hard cake. After standing overnight it was heated on a steam-bath until no more ether distilled. Dilute acid was then dropped slowly into the flask, the ether and hydrocarbon distilling off during decomposition. After the solid had dissolved, the residue was steam distilled. The hydrocarbons then were separated roughly by distillation, obtaining a product boiling at 104–106°. This crystallized in the receiver. This product was then crystallized from ether at −50° and redistilled from sodium taking a fraction boiling at 105–106° at 735 mm. This product although not of extreme purity melted above 99° and the crystals were dry; yield, 1120 g. from 60 moles of *t*-butylmagnesium chloride.

Summary

A practical method is given for the preparation of hexamethylethane and other hydrocarbons containing a tertiary group by condensation of an alkyl Grignard reagent with a tertiary halide by means of cuprous iodide.

Chemical Studies of Certain Pathogenic Fungi. I. The Lipids of *Blastomyces dermatiditis*[1]

BY ROBERT L. PECK AND CHARLES R. HAUSER

This series of investigations has been undertaken with the purpose of studying the constituents of certain pathogenic fungi with the hope that more light may be thrown on the chemical nature of the factors responsible for their pathogenicity. Data on nonpathogenic fungi are available to afford comparisons.

In this paper are presented the results obtained from a study of the lipid fraction of *Blastomyces dermatiditis*. No previous chemical study of the lipid fraction of *Blastomyces dermatiditis* in the yeast-like form could be found in the literature. The present investigation is concerned with the isolation and identification of the constituents of the lipids extracted from this organism by a mixture of alcohol and ether and by chloroform. The isolation and purification of the fractions were in general carried out according to the methods developed by Anderson.[2] In all operations involving unsaturated lipids, an atmosphere of nitrogen or carbon dioxide was maintained as far as possible. All solvents were purified and freshly distilled before use. During extractions and concentrations special precautions were taken in order to avoid contamination of the fungus lipids with extraneous fatty materials.

In Table I are given the percentages of lipids extracted from the cells. Table II gives the proportions of the phosphatide and the acetone-soluble fractions. In order to form an idea as to the precision of our methods of extraction and estimation, two small batches of organisms were grown and extracted for one month with a mixture of alcohol and ether. The extracts and washings were worked up as described in the experimental part. The results are given in Tables I and II, batches III and IV. These results indicate that the methods of extraction and of separation of the phosphatide and acetone-soluble fractions are reproducible within about five per cent.

TABLE I

PERCENTAGES OF LIPIDS EXTRACTED FROM *Blastomyces dermatiditis*

Batch and wt., g.		Lipids extracted Alc.-ether	CHCl$_3$	Total
I	Grams	81.7	4.6	86.3
818.5[a]	Extd., %[b]	9.0	0.5	9.5

62.7[a]	Extd., %[b]	8.9		8.9
IV	Grams	5.6		5.6
60.4[a]	Extd., %[b]	8.5		8.5

[a] Weight of extracted cells after drying *in vacuo*. [b] Per cent. of weight of dried extracted cells plus weight of total extracted lipids.

TABLE II

PROPORTIONS OF THE PHOSPHATIDE AND ACETONE-SOLUBLE FRACTIONS OF *Blastomyces dermatiditis*

Batch		Phosphatide	Acetone soluble
I	Grams	21.0	65.3
	% of whole cell[a]	2.3	7.2
	% of lipids[b]	24.3	75.7
II	Grams	1.7	18.8
	% of whole cell[a]	0.7	8.2
	% of lipids[b]	8.2	91.8
III	Grams	2.1	4.0
	% of whole cell[a]	3.0	5.9
	% of lipids[b]	34.1	65.9
IV	Grams	1.9	3.7
	% of whole cell[a]	2.9	5.6
	% of lipids[b]	34.3	65.7

[a] The whole cell weight is assumed as that of the dried extracted cells plus extracted lipids.

[b] The lipids are the ether-soluble lipids extracted as in our experiments.

Batch I was grown on a medium[3] containing a small amount of blood. Batches II, III, and IV were grown on the same medium without blood. It can be seen from Table II that the composition of the lipids of batch I is essentially the same as that of batches III and IV; hence it would appear that the presence of blood in the medium does not greatly influence the lipid composition.

Batch II was left for two weeks in a preliminary killing solution of 1% aqueous phenol before ex-

---

(1) *Blastomyces dermatiditis* [Gilchrist and Stokes (1898)] a yeast-like organism when grown at 37°, is the etiological agent of the human disease, blastomycosis. The disease may be either a skin infection or a fatal generalized condition. See Martin and Smith, *Am. Rev. T. B.*, in press.

(2) Anderson, *J. Biol. Chem.*, **74**, 525 (1927), and later papers.

(3) This medium was developed by Dr. Wm. H. Kelly of the Department of Medicine, Duke University. It consists of 10 g. of dextrose, 10 g. of peptone, 15 g. of agar-agar, 3 g. of beef extract, 0.5 g. of sodium chloride, and 1000 g. of distilled water. To this is added 20 cc. of laked blood (one part blood to three parts distilled water).

traction of the lipids, whereas the other batches were placed in alcohol and ether immediately after removal from the culture. It is evident from Table II that immediate extraction of the living organisms with alcohol and ether yields much more phosphatide than similar extraction of the organisms after allowing them to stand with aqueous phenol. It should be observed, however, that the total fat remains about the same in the two methods.

In Table III the data on the phosphatide fraction are presented. It can be seen that, although grown and extracted under somewhat different conditions, batches I and II yielded phosphatides of essentially the same composition. The phosphatide fraction is presumably a mixture containing substances resembling lecithin and cephalin. The nitrogen–phosphorus ratio is 1:1. On hydrolysis with aqueous sulfuric acid, glycerophosphoric acid, choline, ethanolamine and fatty acids were obtained. The first three compounds were isolated and identified. Evidence has been obtained which indicates that the following fatty acids were present: palmitic, stearic, oleic, and linoleic acids. It should be mentioned also that a small amount of carbohydrate was obtained on saponification of the phosphatide.

Tables IV and V give the data on the acetone-soluble fats. The acetone-soluble fraction obtained from batch I was qualitatively the same as from batch II, but certain quantitative differences appear; these are probably due to the differences in treatment of the cells before extraction. The acetone-soluble fraction appears to be a mixture containing free fatty acids and sterols. On saponification it gave glycerol, ergosterol, and palmitic, oleic and linoleic acids. These compounds were isolated and identified. Stearic acid was probably also present.

TABLE III

PERCENTAGE COMPOSITION OF PHOSPHATIDE FRACTIONS

	Blastomyces dermatiditis Batch I	*Blastomyces dermatiditis* Batch II	Tubercle bacilli[a]
Water soluble	32	32	34
Ether soluble	68	68	64.2
Unsaponifiable	3	3	1.8

[b] See Anderson, *Physiol. Rev.*, **12**, 166 (1932).

TABLE V

PERCENTAGE COMPOSITION OF THE ACETONE-SOLUBLE FATS

	Blastomyces dermatiditis Batch I	*Blastomyces dermatiditis* Batch II	Tubercle bacilli[c]
Unsaponifiable matter	8.0	15.4	10.3
Water soluble	4.0	4.8	6.3
Fatty acids	88.0	79.8	83.3
Solid acids (satd.)	14.5	11.9	30.3
Liquid acids	73.5	67.9	50.6
Iodine no.	116	126	31
Liquid saturated acids	0	0	38.0
Oleic acid[a]	55.0	37.7	10.6
Linoleic acid[a]	18.5	30.2	?
Palmitic acid[b]	9.7		30.3
Stearic acid[b]	4.8		Traces
Sterols[d]	4	6	0

[a] Calculated from the weight and iodine number of the unsaturated acid. [b] Calculated from weight and mean molecular weight of the saturated acids. [c] See ref. 4. [d] Colorimetric analysis.

In a later paper the lipids of *Blastomyces dermatiditis*, together with those of another pathogenic fungus, *Monilia albicans*, will be compared with the lipids of certain non-pathogenic fungi.

In this paper it seemed of interest to compare the lipids of *Blastomyces dermatiditis* with those of the tubercle bacillus,[4] since the clinical picture of the disease caused by the fungus resembles in certain respects that caused by the bacillus,

---

(4) R. J. Anderson, *Physiol. Rev.*, **12**, 166 (1932).

Data on the lipids of both organisms are listed in Tables III, IV and V.

It can be seen from Tables III and V that, while the lipids of *Blastomyces dermatiditis* and of tubercle bacilli have a number of similarities, certain striking differences appear. In the fungus are found a higher percentage of unsaturated acids and a lower percentage of saturated acids than are found in the tubercle bacillus, but, more significant, the latter organism contains a considerable amount of liquid saturated fatty acid, which appears to be entirely absent in the fungus. The phosphatide of the fungus (Table III) contains two nitrogenous constituents which apparently are not found in the tubercle bacillus, and the nitrogen–phosphorus ratio is different in the two organisms. Sterols (ergosterol) are present in the acetone-soluble fraction of the fungus (Table V) but this constituent apparently is not found in the tubercle bacillus. It is of interest that carbohydrates are present in the phosphatides of both organisms.

Experimental

Materials.—The culture medium was prepared from bacto-peptone, bacto-dextrose, and agar–agar purchased from Difco Laboratories, Detroit, Michigan, and beef extract from Armour and Company, reagent quality sodium chloride, and distilled water. In the media for batch I, laked sheep blood (one part blood to three parts distilled water) was used; no blood was in the media for batches II, III and IV. The medium was placed in liter prescription bottles which were then plugged with cotton and gauze and sterilized. The cultures were always checked for contamination; only pure cultures were used for the experiments.

Ether was dried over sodium; acetone and chloroform were dried over drierite. These were freshly distilled before use. Alcohol was freshly distilled from potassium hydroxide.

Growth and Extraction.—A virulent strain of *Blastomyces dermatiditis* (Strain F-2) was grown[5] for seven days on the solid media at 37° in the dark. The organisms (in the case of batches I, III, and IV) were washed from the media with 95% alcohol, collected in 5-gallon (19 liters) bottles, an equal volume of ether was added and the bottles were stoppered with corks covered with tin-foil and stored for one month at room temperature in the dark. They were shaken occasionally with a rotary motion. Control experiments have shown that no appreciable amounts of lipids were extracted from the media or the stoppers under the conditions used in this work. The cells were filtered off, washed with alcohol and ether, and reëxtracted for two weeks with a mixture of equal parts of alcohol and ether. After filtration and washing, the cells finally were extracted with chloroform for one month. The cells were filtered off, washed with chloroform, and dried *in vacuo* giving a cream-colored powder.

Batch II was washed from the culture with aqueous 1% phenol and allowed to stand under this solution for two weeks. The cells were then filtered off and placed in a mixture of equal volume of alcohol and ether. The procedure from this point was the same as in the extraction of the other batches.

Concentration of Extracts.—The alcohol–ether extracts and washings were concentrated under reduced pressure in an all-glass apparatus to a small volume. The resulting aqueous emulsion was thoroughly extracted with ether. The residual aqueous solution was treated as described in the next section. The ether extract, after drying over sodium sulfate, yielded on evaporation a clear red-brown oil (batch I, 81.7 g.; batch II, 18.9 g.). White crystals (batch I, 2.12 g.) appeared in this oil on standing overnight. These were separated and identified as ergosterol as described below.

The chloroform extract and washings, on concentration under reduced pressure, yielded a dark brown oil (batch I, 4.6 g.; batch II, 1.6 g.). This was similar to the alcohol–ether soluble material and was therefore combined with it.

The Residual Aqueous Solution.—The aqueous solution, remaining after the ether extraction of the lipids described in the previous section, was concentrated to small volume and treated with two volumes of 95% alcohol. A crude polysaccharide (batch I, 1.5 g.) was precipitated. The purified polysaccharide possessed biological activity and will be reported at another time. From the sirup obtained by concentrating the supernatant solution and washings, mannitol (batch I, 1.0 g.) melting at 164–165° was obtained. This was proved by the mixed melting point method, and by the preparation of the hexaacetate, melting at 121°, and of mannitol tribenzal[6] melting at 218–220°.

Separation of the Phosphatide and Acetone-Soluble Fractions.—On addition of acetone to the brown oil which formed the combined lipids, the phosphatide separated as a sticky brown residue on the bottom of the flask. This fraction was purified by repeated precipitation from ether solution by means of acetone. The phosphatide (batch I, 19.5 g., batch II, 1.5 g.) was a buff-colored hygroscopic powder. The acetone solutions and washing from the separation and purification of the phosphatide (about four liters) were concentrated under reduced pressure to a volume of approximately 300 cc. To this solution was added a small amount of saturated alcoholic strontium chloride. After standing overnight in the refrigerator, a further small amount of phosphatide had separated (batch I, 1.5 g., batch II, 0.2 g.).

The supernatant solution and washings from the separation of the phosphatide fraction yielded on concentration a clear red oil (batch I, 65.3 g., batch II, 18.8 g.). It contained only traces of phosphorus and nitrogen. This fraction was designated the acetone-soluble fat.

The Phosphatide Fraction.—The phosphatide, obtained as a pale buff-colored powder, softened at 100°, was fully liquid at 125°, and began to decompose at about 130°. It formed emulsions with water. The phosphorus–nitrogen ratio was 1–1.

Micro-Anal. Found: P, 3.89; N, 1.78.

---

[5] The organisms were grown in the laboratories of the Department of Medicine, Duke University, by one of us (R. L. P.).

[6] Preus, Peterson and Fred, *J. Biol. Chem.*, **97**, 483 (1932).

Hydrolysis was carried out by refluxing the phosphatide with 5% aqueous sulfuric acid for eight hours. After extraction of the fatty acids with ether, the water solution was freed quantitatively from sulfuric acid with barium hydroxide. The water-soluble constituents were separated essentially as described by Newman and Anderson[7] and by Peterson and co-workers.[8] Barium glycerophosphate was isolated as a white powder and was purified by means of its lead salt. This was decomposed with hydrogen sulfide, reconverted to the barium salt and dried in air.

Micro-Anal. Calcd. for $C_3H_7O_6PBa \cdot 2H_2O$: Ba, 39.99; P, 9.03. Found: Ba, 39.48; P, 8.91.

Choline was isolated as the chloroplatinate, melting point 235–236° with decomposition.

Micro-Anal. Calcd. for $(C_5H_{14}ON)_2PtCl_6$: Pt, 31.68. Found: Pt, 31.57.

Ethanolamine was isolated as the picrolonate, melting point 224–226° with decomposition.

Micro-Anal. Calcd. for $C_{12}H_{15}O_6N_5$: N, 21.55. Found: N, 21.30.

The residual sirup from the water-soluble fraction gave a positive acrolein test and a positive Molisch test. A small amount of a sticky residue appeared on the walls of the flask when a sample of the phosphatide was hydrolyzed with alcoholic potassium hydroxide. This was soluble in water and gave a positive Molisch test for carbohydrate. The small amount of this substance obtained has prevented further study at present.

The fatty acids made up 65% of the phosphatide. They were separated in the case of batch I by means of the lead salt treatment into 12.4% solid and 52.6% liquid acids. The solid acids were a white crystalline mass melting at 54–55° and having a mean molecular weight of 266. On the assumption that the mixture of solid acids consisted only of palmitic and stearic acids, the relative proportions of each may be calculated from the neutral equivalent and the weight of the mixed acids. This would indicate a mixture composed of about two-thirds palmitic and one-third stearic acid. A sample of the liquid acids was reduced with hydrogen and platinum oxide.[9] On treatment of the reduced acids by the lead salt method, a very small amount of liquid acid was obtained, but this was shown to be unsaturated. No liquid saturated acids were found. The solid reduced acid, crystallized once from alcohol, was a white crystalline mass, melting at 70–71°. Admixture with pure stearic acid (m. p. 70–71°) did not lower the melting point. The neutral equivalent was 284.8. This shows that the reduced acid was stearic acid (neut. equiv. 284.3).

Micro-Anal. Calcd. for $C_{18}H_{36}O_2$: C, 75.95; H, 12.76. Found: C, 76.14; H, 12.79.

On bromination of the unsaturated acids only a trace of petroleum ether insoluble acids was obtained. The main product was a brown oil, probably dibromostearic acid.

Micro-Anal. Calcd. for $C_{18}H_{34}Br_2O_2$: Br, 36.15. Found: Br, 37.20.

The iodine number (96) and the amount of stearic acid isolated on reduction indicate that the liquid acids consisted mainly of oleic acid with a small amount of linoleic acid.

Analysis of the Acetone Soluble Fat.—This fraction was a red-brown oil containing only traces of phosphorus and nitrogen. It possessed a peculiar musty smell. Some of its constants are given in Table III.

The oil (batch I, 33.7 g.; batch II, 15.1 g.) was saponified by refluxing with 4% alcoholic potassium hydroxide for eight hours. After most of the alcohol was distilled off, the soap solution was diluted with water and the unsaponifiable material thoroughly extracted with ether. The remaining solution was resaponified for three hours and again extracted with ether. The soap solution was then acidified with hydrochloric acid and the crude fatty acids were extracted with ether. The aqueous acid solution was concentrated to dryness under reduced pressure and extracted with alcohol–ether solution (1:1). This extract was concentrated to a sirup. The sirup was extracted with warm absolute alcohol. The alcohol extract was evaporated, yielding a pale brown sirup. The sirup, which was evidently crude glycerol, gave a positive acrolein test. A sample was benzoylated, giving a very small yield of a crystalline derivative melting at 75–76°. This melting point was not lowered by admixture with glycerol tribenzoate (m. p. 76°). The presence of glycerol is thus established.

The unsaponifiable material was a brown semi-solid mass (batch I, 8%; batch II, 15.4% of the acetone-soluble fat). Since a colorimetric determination indicated that about one-half of this unsaponifiable material consisted of sterols, it was recrystallized from a mixture of alcohol and benzene (2:1). The white crystals obtained melted at 158–160° and were identified as ergosterol by the mixed melting point method and by conversion to the acetate. The latter melted at 169–171° and when mixed with the acetate from authentic ergosterol showed no depression. The ergosterol mentioned under the heading "Concentration of Extracts" was identified in the same manner.

The fatty acids were separated by the lead salt method into solid and liquid acids. The crude solid acids melted at 55–56° and gave a neutral equivalent of 266. They were thus similar to the crude solid acids of the phosphatide fraction. The methyl esters of a portion of the solid acids were prepared and fractionally distilled under 0.5 mm. pressure. The top fraction was saponified and the free acid was isolated. After repeated crystallization from methyl alcohol and acetone, an acid melting at 62–63° was isolated. This was proved to be palmitic acid by the mixed melting point method and by analysis.

Micro-Anal. Calcd. for $C_{16}H_{32}O_2$: C, 74.91; H, 12.58. Found: C, 75.27; H, 12.59.

A sample (2.408 g.) of the liquid acids in alcohol solution was reduced catalytically with hydrogen and platinum oxide. The reduced acids, a semi-crystalline buff-colored mass, were separated by means of the lead salt treatment into a main fraction of white crystals and a very small amount of liquid acid. The recovery was 95% (2.291 g.). Since the small amount of liquid acid was shown to be unsaturated, it appears that no liquid saturated acids were present. The solid crystalline acid melted at 69.5–70.5°

and had a neutral equivalent of 283.8. Its melting point showed no depression on mixing with pure stearic acid (m. p. 70–71°, neut. equiv. 284.3); hence the reduced acid was stearic acid.

Anal. Calcd. for $C_{18}H_{36}O_2$: C, 75.95; H, 12.76. Found: C, 76.19; H, 12.82.

Oxidation of a small amount of the liquid acids with alkaline permanganate[10] yielded a mixture of dihydroxy- and tetrahydroxystearic acids. The dihydroxystearic acid was extracted from the crude mixed acids with chloroform. After crystallization from alcohol it melted at 129–130°. No depression was observed in the melting point on admixture with authentic 9,10-dihydroxystearic acid.

Anal. Calcd. for $C_{18}H_{36}O_4$: C, 68.26; H, 11.47. Found: C, 67.99; H, 11.48.

The acid insoluble in chloroform was crystallized from alcohol and melted at 171–172°. A mixed melting point with authentic tetrahydroxystearic acid showed no depression and established the substance as tetrahydroxystearic acid.

Anal. Calcd. for $C_{18}H_{36}O_6$: C, 61.99; H, 10.42. Found: C, 62.29; H, 10.21.

Another sample of the unsaturated acids was brominated in cold light petroleum ether. The precipitate which formed was crystallized from petroleum ether yielding a white crystalline acid melting at 113–114°. It was proved by the mixed melting point method to be tetrabromostearic acid.

Anal. Calcd. for $C_{18}H_{32}O_2Br_4$: Br, 53.29. Found: Br, 53.01.

The substance remaining in the petroleum ether after removal of the tetrabromostearic acid was a light brown oil. It was probably dibromostearic acid.

Anal. Calcd. for $C_{18}H_{34}O_2Br_2$: Br, 36.15. Found: Br, 38.21.

The above data show the presence in the acetone-soluble fat of both oleic and linoleic acids. Since no substance insoluble in ethyl ether was found on bromination, it appears that no higher unsaturated acids were present.

Acknowledgment.—This work was supported in part by grants from the Duke University Research Council. The expense of growing the fungi was also in part defrayed by a grant from the John and Mary R. Markle Foundation.

Summary

1. The chemical composition of the lipids of the pathogenic fungus, *Blastomyces dermatiditis*, has been determined. The lipids make up about eight to ten per cent. of the weight of the whole dried cells.

2. The lipids were separated into approximately one-third phosphatide and two-thirds acetone-soluble fat.

3. The phosphatide on hydrolysis with aqueous sulfuric acid gave glycerophosphoric acid, choline, ethanolamine, and fatty acids. These substances were isolated and the first three identified. The fatty acids probably consisted of palmitic, stearic, oleic and linoleic acids. A small amount of carbohydrate was obtained on saponification.

4. The acetone soluble fat gave on saponification glycerol, ergosterol, and palmitic, oleic and linoleic acids. These were isolated and identified. Stearic acid probably was present also.

5. These results are compared with the data on tubercle bacilli and certain striking differences noted.

The Reversibility of the Reaction between Triglycerides and Glycerol

BY HARLAND H. YOUNG, JR., AND HOWARD C. BLACK

The fact that triglycerides react with glycerol at high temperatures has been known for several years. The products obtained by such a reaction have been described in the literature[1] and more recently have become of commercial importance as emulsifying agents for water-in-oil emulsions. Many of the products reported have been prepared from natural fats and oils and necessarily have been complex mixtures. The designation of these as mixtures of mono- and diglycerides has been based upon saponification numbers, acetyl values and their marked solubility in the lower alcohols.[1a,c] Grün[1b] reported the formation of di- and triglycerides when monoglycerides were heated but did not identify the products completely. Fischer[2] prepared α-dibenzoylglycerol by the vacuum distillation of α-monobenzoylglycerol. More recently Hurd[3] has described the formation of glycerol triphenyl-

methyl di- and triethers by heating the α-monoether to 190 and 260°, respectively.

This research has resulted from the observation that commercial monoglycerides, as prepared from natural fats and glycerol, do not hydrolyze when deodorized with steam at high temperatures and reduced pressures, but lose glycerol and are converted into the original fat. In the present investigation, pure synthetic triglycerides have been treated with glycerol in the presence of catalysts. The reaction products have been separated and identified. Their behavior during vacuum distillation with and without the aid of steam has been studied.

Experimental

α-Monoglycerides.—Monolaurin, monopalmitin and monostearin were prepared by Fischer's method as described by King and co-workers.[4] In the purification of these compounds by numerous crystallizations, it was noted that rate of crystallization is an important factor in obtaining the high melting points reported by King. Saponification values were used as the best criterion of purity.

Triglycerides.—Trilaurin, tripalmitin and tristearin were prepared by the action of a slight excess of the fatty acid chlorides on anhydrous glycerol in the presence of quinoline or pyridine. This procedure is a modification of that described by King.[4] After one crystallization from ether and two from an alcohol–chloroform mixture (70:30 by volume) the white crystalline compounds melted sharply and had the theoretical saponification values.

Ethylene Dipalmitate.—Three and one-tenth grams (0.05 mole) of redistilled ethylene glycol and 16 g. of quinoline were placed in a glass-stoppered bottle and cooled in an ice-bath. Twenty-eight g. (0.10 mole) of palmityl chloride was added and the mixture shaken vigorously until it set to a hard mass. After standing at room temperature for two or three days, the product was taken up in 1200 cc. of ether and 400 cc. of 0.5 *N* sulfuric acid. Successive washings with additional 0.5 *N* sulfuric acid, 10% sodium bicarbonate and water removed most of the impurities. After drying over anhydrous sodium sulfate, the ether solution was allowed to stand at −26°. Light yellow plates separated which were redissolved in 500 cc. of ether, decolorized with carbon and recrystallized at −26°: yield 20.0 g.; m. p. 68.7–68.9°. This compound, as prepared in another way, has a reported m. p. of 68.7°.[5]

Reaction of Triglycerides with Glycerol.—The reaction between trilaurin and glycerol is described as typical of the procedure. Ten grams of glycerol, 10 g. of trilaurin and 0.2 g. of trisodium phosphate were refluxed for fifteen minutes at the boiling point of glycerol under anhydrous conditions in an atmosphere of nitrogen. One layer formed after five minutes of boiling. After the flask had cooled, some of the excess glycerol was held in solution in the solid fatty layer, but 4 g. of it separated into a clear liquid lower layer. The solid product was dissolved in 100 cc. of anhydrous ether, leaving behind all of the excess glycerol, most of the catalyst and a trace of soap. The ether solution was dried over anhydrous sodium sulfate, decolorized with carbon and crystallized at −26°. The gummy precipitate was recrystallized from 150 cc. of ether and then from 50 cc. of alcohol at −26°: yield 3 g.; m. p. 60.5–61.0°; sap. value 204.2, calcd. for monolaurin, 204.6; mixed m. p. with monolaurin was 60.5–61.0°. With no alkaline catalyst thirty minutes boiling was necessary for the formation of one layer and only 1.0 g. of pure monolaurin was isolated. A small quantity of another compound was separated from the uncatalyzed reaction mixture. This melted at 54.5–55.0°; reported melting point for α,α′-dilaurin 56.6°.[4] The amount obtained was insufficient for saponification value determination. When 0.2 g. of sodium carbonate was used as a catalyst, 0.5 g. of crystalline material was separated: m. p. 54.5–55.0°; sap. value 236.4, calcd. for dilaurin, 245.8.

Ten grams of tripalmitin treated in the same way gave 1.0 g. of crystals: m. p. 75.0–75.5°; mixed m. p. with pure monopalmitin 75.0–75.5°; sap. value 171.0, calcd. 169.8. With no alkaline catalyst, a five-hour boiling period failed to cause the formation of one layer and no crystalline product could be isolated. The amorphous nature of many of these products is probably due to the formation of polyglycerol ethers and their esters.

In the case of tristearin 0.5 g. of crystals melting at 79.5–80.0° was isolated when trisodium phosphate was used as catalyst: mixed m. p. with pure monostearin 79.5–80.0°; sap. value 156.0, calcd. 156.6.

Several recrystallizations were required in the isolation of pure reaction products from the reësterification of tripalmitin and tristearin. The low yields of pure monoglycerides obtained are not indicative of the completeness of the reaction. In every case, the saponification value of the reaction mixture, after complete removal of excess glycerol, was only slightly above the calculated value for the pure compound. The loss occurred in the several crystallizations necessary for the removal of last traces of di- and triglycerides.

Decomposition of α-Monoglycerides when Heated in Vacuo.—The distillation of α-monopalmitin is described as typical of this procedure. Five grams of monopalmitin was distilled at 0.5 mm. With an oil-bath temperature of 200°, material was distilled at 189–190°. Distillation stopped after half the material came over. Nothing more distilled even by raising the temperature to 225°. The non-volatile residue, when purified by successive crystallization from alcohol–chloroform mixtures, was tripalmitin and melted at 63.5–64.0°. The distillate was extracted with ether to separate the fatty material from glycerol. Seven-tenths gram of material was isolated from the distillate melting at 74.0–75.0°; mixed m. p. with pure monopalmitin 74.0–75.0°.

Similar treatment of α-monolaurin resulted in the distillation of a large portion of the monolaurin unchanged, b. p. 171–172° (0.5 mm.). A very small amount of glycerol was found in the distillate. The residue in the flask was purified and yielded 0.5 g. of trilaurin. α-Monostearin was transformed into tristearin with only a trace of the

[5] Rutan and Roebuck, *Trans. Roy. Soc. Canada*, [3] **9**, June (1915).

monoglyceride distilling unchanged at 184–86 (0.3 mm.). An appreciable quantity of glycerol which distilled with the trace of fatty material made isolation of the small amount of monoglyceride impossible.

Reaction of Ethylene Dipalmitate with Ethylene Glycol.—Ten grams of ethylene glycol (redistilled and dry) was refluxed at its boiling point with 10 g. of ethylene dipalmitate and 0.2 g. of anhydrous trisodium phosphate. The reaction proceeded for fifteen minutes, one layer being formed after ten minutes of boiling. The esters were separated from excess ethylene glycol by means of dry ether extraction. Impure crystals were obtained by holding the ether solution at −26°. These, after being filtered, were dissolved in 250 cc. of hot alcohol. As the solution cooled to room temperature, crystals of unreacted dipalmitate separated, m. p. 68.6–68.9°; yield 2 g. The mother liquor, when cooled to 2°, yielded 5 g. of β-hydroxyethyl palmitate, m. p. 51.2–51.5°. Rutan and Roebuck[5] reported the melting point of β-hydroxyethyl palmitate and ethylene dipalmitate as 51.5 and 68.7°, respectively. This method for the preparation of the monoester is an improvement over earlier methods. With no alkaline catalyst the interesterification did not take place during three hours of refluxing at the boiling point of ethylene glycol.

Decomposition of β-Hydroxyethyl Palmitate when Heated in Vacuo.—Five grams of the palmitate was distilled as described previously for the α-monoglycerides. About half the material distilled at 155–160 (2 mm.). From the residue there was separated 1.5 g. of pure ethylene dipalmitate, m. p. 68.5–68.9°. The distillate was separated and purified by fractional crystallization from alcohol. A trace of the crude dipalmitate, melting at 66–67°, separated at room temperature. The mother liquor at 2° yielded 1.5 g. of pure β-hydroxyethyl palmitate, m. p. 51.5–52.0°.

Steam Distillation of α-Monoglycerides in Vacuo.—The distillation procedure already described was repeated with a rapid current of steam being used. A vacuum of 2 mm. was maintained. The same general reaction was obtained in every case; *i. e.*, some of the monoglyceride and glycerol distilled, the triglyceride remaining in the residue. At no time was there found more than minute traces of free fatty acid in the distillates from the steam distillation. This is noteworthy because much steam was used, and during the removal of glycerol and the transformation to triglyceride one might expect any free acyl groups to react with the steam as rapidly as with monoglyceride. In the presence of steam, decomposition of mixed monoglycerides, as prepared from natural fats, to triglycerides and glycerol takes place at a much lower temperature (140°) than under the condition of ordinary vacuum distillation (170°).

Discussion

The reaction between triglycerides and glycerol is reversible. The reaction between the higher diesters of ethylene glycol and the glycol is also reversible. Alkaline catalysts promote the formation of the monoesters but seem to have no accelerating effect upon their decomposition during vacuum distillation with or without steam. Temperatures required for formation of mono- from polyesters are appreciably higher than for the reverse decomposition. The catalytic effect of the alkaline salts used may be due either to the alkalies themselves or to the soaps formed during the reaction. Approximately 90–95% of the alkaline salt catalysts are recovered when anhydrous reactants are used, but small traces of soap are always found in the reaction mixture.

Summary

1. The products obtained by the interaction of triglycerides with glycerol have been isolated in pure state. These products are chiefly α-monoglycerides.

2. There has been effected the reverse of this reaction, namely, the formation of triglycerides from the mono- or diglycerides by distillation *in vacuo* with or without steam.

3. A new method of preparation for β-hydroxyethyl palmitate has been described as well as a method for its separation from ethylene dipalmitate.

Some Derivatives of *s*-Triethylbenzene

BY WINTHROP B. DILLINGHAM[1] AND E. EMMET REID

Mesitylene has been investigated thoroughly but its homolog, *s*-triethylbenzene, is comparatively little known; figures for its boiling point range from 200 to 220°. As the polyethylbenzenes are now readily available it seemed that this, the most abundant of the triethylbenzenes, merited further study.

Klages and Lickroth[2] found that *s*-triethylbenzene can be separated conveniently from its isomers by taking advantage of the facts that it is more difficult to sulfonate than its isomers and its sulfonic acid is hydrolyzed more readily. We have verified their observations and used their method for obtaining *s*-triethylbenzene from the proper fraction of the ethylation mixture.

The *s*-triethylbenzene used boiled at 211.2° at 760 mm. and had density 0.8772 0°/4° and 0.8568 25°/4°. The properties and analyses of the derivatives are given in Table I.

[a] Since our work was done v. Auwers and Mauss, *Ann.*, **460**, 240 (1928), made this phenol by the reduction of 2,6-diethyl-4-acetylphenol and gave its b. p. as 244–246°.

Experimental

Into 200 g. (2.5 moles) of benzene and 50 g. of aluminum chloride 205 g. (7.4 moles) of ethylene was passed with stirring at 10,000 r. p. m. The temperature was about 60° at the start and was raised gradually to 85°. The absorption was slow at first but rose to 2500 cc. per minute. The products from several runs were fractionated and the fractions 190–230° united and refractionated. The triethylbenzene fraction was stirred for three hours at 60–70° with 2 parts of concentrated sulfuric acid. On cooling the mixture separated into 3 layers, the upper of which proved to be the desired *s*-triethylbenzene. The mixture of sulfonic acids was hydrolyzed by Armstrong's method.[3] At 110–125° the *s*-triethylbenzene was set free, while the liberation of the 1,2,4- did not occur until 160–175° was reached. The *s*-triethyl thus obtained was identical in all respects with the unsulfonated hydrocarbon above. This was proved by completely sulfonating a portion with 6 parts of sulfuric acid and converting the product into the amide which melted at 117–119°.[4]

It was nitrated with a mixture of 2 parts fuming to 3 concd. nitric acid at 25 to 30° for two hours which converts about half to the mononitro with a negligible amount of the dinitro which is obtained by stronger treatment. One part of the nitro derivative, 1 of water, and 3 of iron filings with a trace of acetic acid on the steam-bath for six hours gave the amino derivative which was purified by precipitation from benzene solution by hydrogen chloride. The acetyl and benzoyl derivatives were prepared by usual methods. The thiocarbanilide was prepared by adding 40% caustic soda solution to a cooled solution of the amine in carbon disulfide. The phenol was obtained through the diazo and methylated with dimethyl sulfate. The iodo derivative was made by the diazo. Its properties checked the data of Klages. It was converted into dichloride but this could not be isolated. The nitrile was obtained by the diazo reaction. The diazonium chloride was coupled with β-naphthol which gave a red azo dye.

Summary

A number of derivatives of *s*-triethylbenzene have been prepared and their properties determined.

A Spectrophotometric Study of Certain Neutralization Indicators[1]

BY W. B. FORTUNE WITH M. G. MELLON

Various organic compounds have been used extensively as indicators in neutralimetry and for the colorimetric determination of the *p*H value of solutions. While the general nature of the absorption spectra of solutions of such indicators has been known for years, few reliable spectrophotometric data on the transmittancy curves at different *p*H values have been reported until recently.[2] The present availability of objective photoelectric spectrophotometers has led the authors to check some of the earlier data obtained with subjective visual instruments. In addition to the simple systems studied by other workers, the present work includes certain modified and mixed indicators used in titrimetry.

Experimental Work

Apparatus.—All measurements of transmittancies were made on a photoelectric spectrophotometer[3] with cells 1.000 cm. thick and a spectral band 10 mμ wide. The data were secured within fifteen minutes of the time the solutions were prepared, the transmittancy–wave length curves being recorded by the instrument.

Tristimulus values were obtained with a calculator[4] using 10 selected ordinates, a procedure shown to give a precision of 0.2%. The values are based on the I. C. I. illuminant C.

Solutions.—The indicator solutions were prepared by dissolving the purest obtainable commercial reagents in doubly distilled water, or ethanol, if necessary. Dilutions were made from the stock solutions to give the concentrations listed in Table I.

Clark and Lubs' buffer solutions were prepared,[5] with *p*H values ranging from 2.2 to 6.8 at intervals of 0.2 *p*H unit. The salts were recrystallized three times, and the solutions were checked with a glass electrode. An antiseptic was added to prevent the growth of mold.

In preparing a solution for measurement exactly 0.3750 ml. of the indicator solution was transferred to a 25-ml. volumetric flask by means of a micro-buret, buffer solution was added to the mark and the system was mixed. Specifications are given below for the solutions prepared to represent colorless end-points with modified indicators.

TABLE I

SYSTEMS STUDIED

Indicator	Concentration, g./l.	Solvent
Brom cresol green	0.4000	Water
Ethyl orange	.4000	Water
Methyl orange	.4000	Water
Methyl red	.4000	50% ethanol
p-Methyl red	.4000	Water
Propyl red	.4000	50% ethanol
Methyl red	.2000	50% ethanol
Brom cresol green	.2000	
Methyl orange	.0400	Water
Brom cresol green	.2000	
Methyl orange	.4000	50% ethanol
Xylene cyanole FF	.5600	
Methyl red	.2500	95% ethanol
Methylene blue	.1750	

Data and Discussion.—The indicators studied are of three general types, simple, modified and mixed. The various indicators in each group are discussed under the respective group headings.

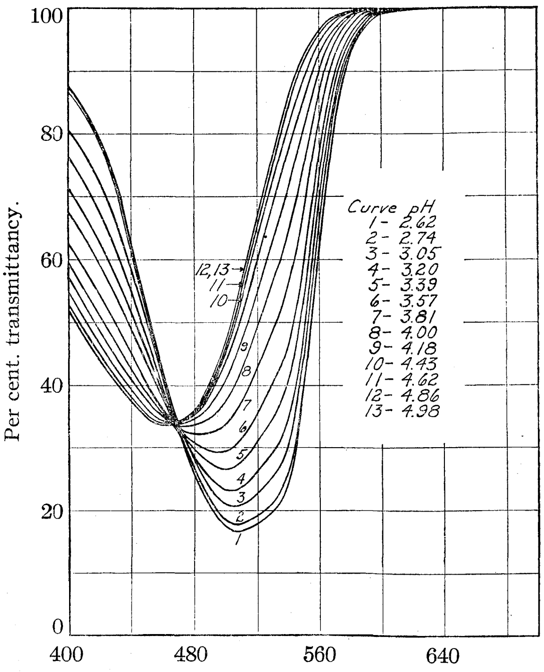

Fig. 1.—Spectral transmission curves for methyl orange solutions at different *p*H values: one cm. cell thickness and 0.375 ml. of a solution containing 0.4 g./l. diluted to 25 ml.

a. Simple Indicators.—The transmittancy curves for methyl orange are shown in Fig. 1. These exhibit a fixed isobestic point at 469 mμ,

[4] Swank and Mellon, *J. Optical Soc. Am.*, **27**, 414 (1937).

[5] Clark, "Determination of Hydrogen Ions," Williams and Wilkins Co., Baltimore, Md., 1928, p. 200.

together with a consistent change in intensity of absorption with increase of pH. The absorption band of this indicator, an azo compound, shows a definite shift of the wave length of the peak of the band through the transformation range. At pH 2.62 the peak is located at 507 mμ; with increase of pH the shift of the band is toward the blue, the peak being located at 472 mμ at pH 4.0. The shift of the peak follows approximately a hyperbolic spiral.

Ethyl orange, another azo compound, gave curves resembling those for methyl orange but bearing a mirror image relationship to them with respect to the relative heights of the absorption bands for the acidic and the basic forms of the indicator. In the curves for each of the two indicators a weak secondary band shows the same shift as the primary.

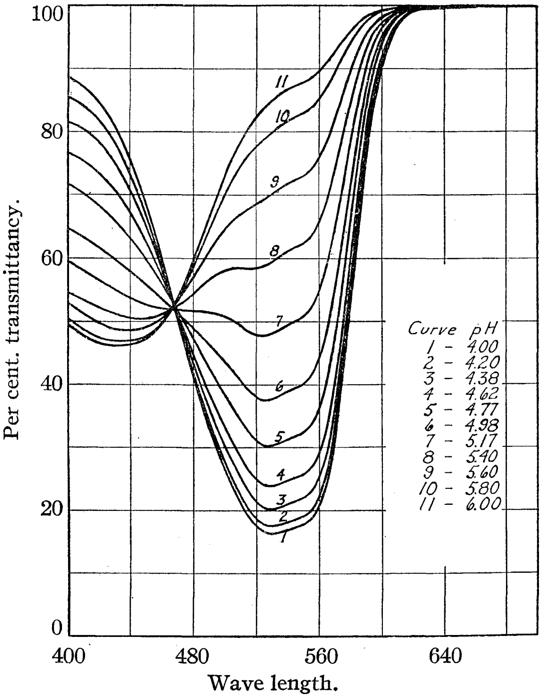

Fig. 2.—Spectral transmission curves for methyl red solutions at different pH values: one cm. cell thickness and 0.375 ml. of a solution containing 0.4 g./l. diluted to 25 ml.

The curves for methyl red are shown in Fig. 2. Although some earlier data[2] (p. 588) indicate that the peak of the absorption band apparently does not change in wave length through the transformation range, these curves, like those for methyl orange, show a shift toward the violet with increase in pH. The small secondary band shows a similar, but less obvious, shift.

Measurements on tropaeoline 00 gave results very similar to those for other azo indicators, the shift of the peak of the absorption band with change of pH being evident.

Unsuccessful attempts were made to secure curves for several other azo compounds. Solutions containing propyl red faded as much as 50% within two minutes after preparation. Paramethyl red precipitated from the buffer solution so rapidly that reliable curves were not obtainable. Dimethylaminoazobenzene gave reproducible curves on the acidic side of the transition point of the indicator; on the basic side fading occurred to the extent of more than 1% per minute. The curves for the acidic side showed a shift of the peak of the absorption band similar to that obtained for the other azo indicators studied.

Figure 3 shows the curves for brom cresol green, a sulfonphthalein type indicator. This is an example wherein the peak of the absorption band, at 615 mμ, does not change in wave length with change of pH of the solution. A good isobestic point is shown for this indicator also.

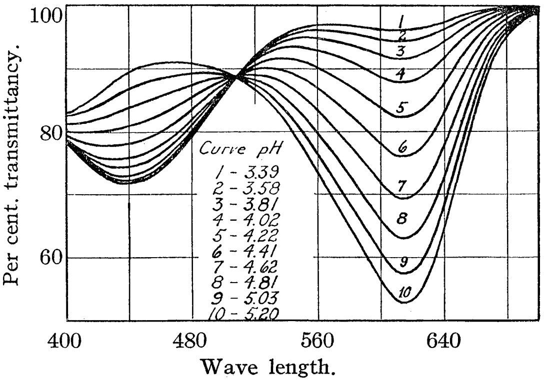

Fig. 3.—Spectral transmission curves for brom cresol green solutions at different pH values: one cm. cell thickness and 0.375 ml. of a solution containing 0.4 g./l. diluted to 25 ml.

Reference to Figs. 1 to 3 shows that a shift in the peak of the band is to be expected unless the slope of the top curve is nearly zero at the wave length of the minimum point of absorption for the bottom curve. Intermediate curves represent mixtures of the acidic and basic color forms of the indicator. The direction of the shift depends upon the slope of the top curve, that for methyl orange being toward the violet. In Fig. 3 the top curve for the primary band is nearly flat at 615 mμ while that for the secondary band at 436 mμ has considerable slope.

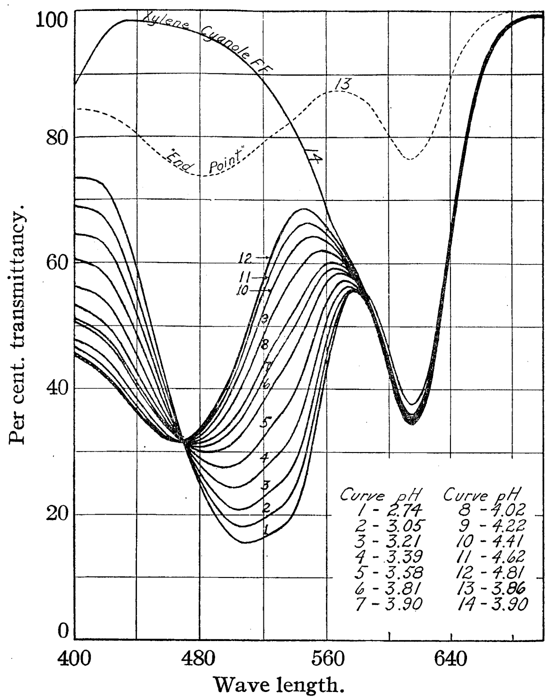

Fig. 4.—Spectral transmission curves for modified methyl orange at different *p*H values and the modifying agent at one value: one cm. cell thickness and 0.375 ml. of a solution containing 0.4 g./l. of methyl orange + 0.56 g./l. of xylene cyanole FF diluted to 25 ml. For the end-point curve 0.100 ml. of the indicator solution was diluted to 25 ml.

b. Modified Indicators.—A study was made of xylene cyanole FF and of methylene blue, modifying agents for methyl orange and methyl red, respectively. A curve for one concentration of each reagent is shown in Figs. 4 and 5. The curves do not show a shift in wave length of the peak with change of *p*H above 3.2. These curves represent the same concentration of modifying agent as that in the modified indicator discussed below.

Figure 4 shows the curves for methyl orange modified with xylene cyanole FF. The indicator was prepared according to the directions of Hickman and Linstead.[6] The characteristic shifting of the peak of the methyl orange absorption band is shown here, as with the simple indicator; also a definite isobestic point is exhibited with the modified indicator.

Curves for methyl red, modified with methylene blue, are given in Fig. 5. The solution was prepared according to recommendations of Johnson and Green.[7]

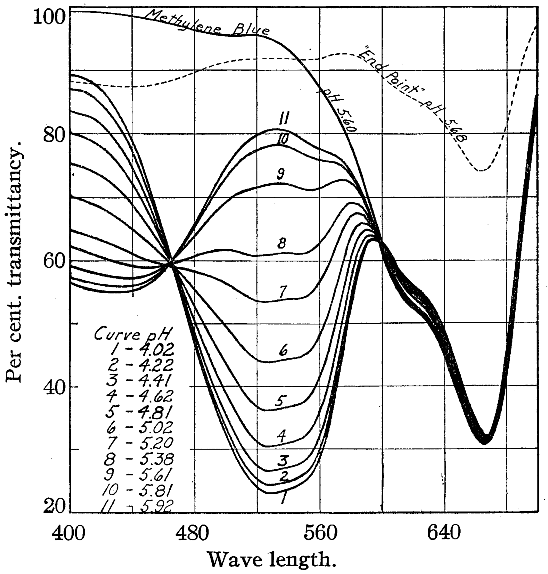

Fig. 5.—Spectral transmission curves for modified methyl red at different *p*H values and the modifying agent at one value: one cm. cell thickness and 0.375 ml. of a solution containing 0.25 g./l. of methyl red + 0.175 g./l. of methylene blue diluted to 25 ml. For the end-point curve 0.100 ml. of the indicator solution was diluted to 25 ml.

Curves for the colorless end-points obtainable in titrations using modified methyl orange or methyl red also are shown in Figs. 4 and 5. In each case 0.1000 ml. of the indicator solution (Table I) was diluted with a buffer to make 25 ml. of solution. This corresponds to about two drops of the stock solution in 125 ml. of solution to be titrated. Other concentrations gave similar curves.

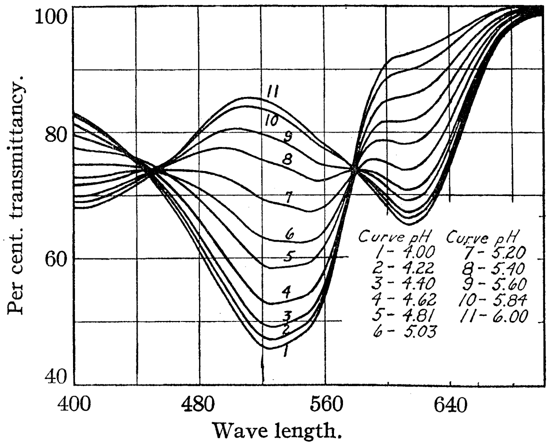

Fig. 6.—Spectral transmission curves for the mixed indicator methyl red + brom cresol green at different *p*H values: one cm. cell thickness and 0.375 ml. of a solution containing 0.2 g./l. of methyl red + 0.2 g./l. of brom cresol green diluted to 25 ml.

Colorless mod. M. red	(5-)	30.8	32.0	37.2	515	95.0	1.9

[a] Figure curve number.

[b] Dominant wave length of the complementary.

c. **Mixed Indicators.**—Since many mixtures of indicators, the individual compounds of which have contrasting hues, have been proposed, representative examples were studied. The results for one of them are included here.

Selected curves for the mixture proposed by Hähnel,[8] consisting of equal parts of methyl red and brom cresol green, are shown in Fig. 6. A definite isobestic point is exhibited at 580 mμ, and a diffuse crossing at 450 mμ.

Color specifications were determined for selected curves for each indicator. Values for one curve on the acidic side and one on the basic side of the indicator are presented in Table II.

Recently De Almeida[9] suggested the use of a graph coördinating dominant wave length with *p*H as a means of determining the *p*H of solutions. In the present work the dominant wave length of representative curves of several indicators was plotted against the *p*H of the solution, but the results have little practical value for indicators whose dominant wave length falls in the purple on one side of the transformation range. Since the dominant wave length of a purple is specified as that of its complementary, the curve consists of two widely separated parts—one for the true dominant wave lengths and one for the complementaries. With sulfonphthalein indicators which show no purple characteristics, the method may be used with some degree of accuracy. Relative brightness also was plotted against the *p*H of the solution, but the resulting curve seemed to have little practical value.

Summary

A spectrophotometric study has been made covering the transformation range of various simple, modified and mixed neutralization indicators. The spectral transmittancy curves show the characteristics of the absorption bands in the visual region at different *p*H values. Colorimetric specifications are included for selected curves for several indicators.

The Conductance of Dilute Solutions of Alkali Iodides in Dimethylamine[1]

BY ELIJAH SWIFT, JR.

While solutions of electrolytes in solvents of low dielectric constant exhibit many of the properties of aqueous solutions, there are differences in these properties which have not been investigated fully because of the experimental difficulties involved. Kraus and Fuoss[1a] have shown that for mixtures of dioxane and water, as well as for other systems, as the dielectric constant of the mixture is lowered, the shape of the conductance–concentration curve for any salt changes continuously. These curves can be accounted for quantitatively on the basis of a combination of ion association and interionic attraction.

It was the purpose of this investigation to extend the generality of this theory by using salts with ions which are comparatively small. Since the particular salts chosen have small ions, they should be only very feebly dissociated in dimethylamine ($D = 3.3$). By comparing the members of a series of salts, such as the alkali iodides, it should be possible to decide whether there may be any solvation of these small ions by a solvent of low dielectric constant with an "unshared electron-pair."

The solvent used, dimethylamine, has been shown to be extremely useful in precise thermodynamic studies of alkali metal amalgams by means of concentration cells.[2,3] In the course of this investigation it was found that while sodium and lithium iodides are extremely soluble and form low-conducting solutions, potassium and cesium iodides (and probably rubidium iodide by inference) are too insoluble to be of use without highly refined methods of potential measurement, or concentration cells of extremely low cell constant. The specific resistance of a saturated solution of potassium iodide at 25° is approximately 7×10^6 ohms, and that of cesium iodide about 4×10^7 ohms,[4] while a specific resistance of 10^4 is readily obtained with either sodium or lithium iodide. This latter is a convenient value for these thermodynamic studies.

Experimental

Dimethylamine was prepared from dimethylamine hydrochloride obtained from the Eastman Kodak Company, dried over activated alumina and desiccated by dissolving sodium fluorenone in it.[5] It was then twice distilled in vacuum to remove the last traces of dissolved gases and high boiling impurities, and was thereafter kept in sealed Pyrex containers out of contact with air at all times.

The salts were Mallinckrodt Reagent grade chemicals, fused in a platinum boat at a pressure of less than 10^{-4} mm. The solutions were made up in a closed system without exposing the fused salts to the atmosphere.[3] The concentrations of the original solutions were found by measuring the volume of solution in a special sealed pycnometer before running it into the conductance cell. The amount of dissolved salt was measured after the completion of each series of measurements. The cells used have been described by Bent and Keevil,[6] and were designed so that a series of successive quantitative dilutions could be made on the original solution in the cell without opening the sealed system.

When calculating the equivalent conductances of the solutions which were measured at 0°, it was assumed that the molar concentration was the same as at 25°. This is, of course, not strictly true, due to a change in the density of the solution, but makes too small a difference to be of importance here. No correction was made for the change in cell constant with temperature.

The resistances were measured with a Leeds and Northrup student type bridge with parallel capacitances, using a Shallcross variable resistance box, reading up to 1 megohm, as an auxiliary resistance. The resistances and the slide wire were calibrated carefully, and no error as great as 0.1% was found. However, vaporization of the solvent out of the conductance cell during measurements, cumulative errors in concentration, and the large temperature coefficient of conductance contributed to cut down the accuracy of the measurements to 2–5%, a somewhat greater error being made in the most dilute solutions. The resistances measured ranged from 7.0 ohms to 1 megohm.

To see whether the precision of the resistance measurements in cells of as low cell constant as this could be bettered, which would be worth while in other solvents where errors could be better controlled, the measurements on lithium iodide were made with a bridge of the type described by Jones and Josephs.[7] Readings were usually made at 1000 and 2000 cycles, and a frequency correction applied to obtain the true resistances.

In order to apply the frequency correction, it was necessary to know whether the difference in the reactance at the two frequencies was due to a capacitance in the cell or

in the resistance, or a combination of the two. Measurements were made at one particular concentration, using four different frequencies. Applying the equation suggested by Jones and Josephs[8] and neglecting the higher terms, good agreement was found among the calculated resistances.

TABLE I

$$R_{\text{true}} = R_{\text{meas.}}(1 - R^2_{\text{measd.}}W^2C^2 + \ldots)$$

Frequency	$R_{\text{measd.}}$	$R_{\text{calcd.}}$

5.64×10^{-6}	2.31	4.91
1.05×10^{-6}	5.63	18.32

An attempt was made to use d. c. in order to carry the measurements to lower concentrations, but this was not successful due to a small variable potential in the cell which could not be balanced out or removed by short circuiting.

It was unnecessary to correct for the conductance of the solvent, which has been found[2] to be about 3×10^{-12}, far too low to affect these measurements.

Results and Discussions

It is evident from examination of the figure that these systems are in accord with the Kraus and Fuoss theory, qualitatively at least. Both lithium iodide and sodium iodide exhibit minima in their conductance–concentration curves in the neighborhood of 0.005 *M*, and it is probable that potassium iodide would also if it were more soluble. Kraus and Fuoss[1a] state that, except for viscosity effects, the forms of conductance–concentration curves are dependent almost exclusively on the dielectric constant. If we compare the results of these measurements in dimethylamine ($D = 3.3$) with theirs in a dioxane–water mixture of $D = 3.5$, it is seen that for tetraisoamylammonium nitrate the minimum falls at almost exactly the same concentration. The minimum is also at this concentration for the same salt in a mixture of dioxane and ethylene dichloride ($D = 3.1$). It might be expected that the alkali iodides, having so much smaller ionic radii than tetraisoamylammonium nitrate, would show a stronger tendency to form triple ions, and that the minimum would occur at a lower concentration. It is evident, however, that the ionic size has little effect on the position of the minimum even in the extreme case of these small ions. This fact has been discussed by Kraus and Fuoss,[10] who have shown that, from a theoretical standpoint, the dielectric constant is the controlling factor in the position of the minimum, and that the ionic radius has little effect.

Below the minima the curves for all three salts show a slope of $-1/2$ within the limits of experimental error, corresponding to the association of two ions to form an ion-pair. It was not found possible to calculate Λ_0 and the dissociation constants of these equilibria, since the curves show no downward deviations from linearity in the low concentration region. However, we may estimate these constants by means of Walden's rule, using data obtained for aqueous solutions, but due to lack of necessary data on viscosities, it is

[8] Grinnell Jones and R. C. Josephs, THIS JOURNAL, **50**, 1076 (1928).

[9] See, for example, Grinnell Jones and collaborators, *ibid.*, **56**, 602 (1934); **58**, 2561 (1936); **59**, 731 (1937).

[10] R. M. Fuoss and C. A. Kraus, *ibid.*, 55, 2387 (1933).

somewhat difficult to apply it in this case. If we assume the value of the viscosity of dimethylamine at 25° to be 0.002, as compared with water at 18° = 0.01, the three values of Λ_0 are as follows: LiI = 500, NaI = 550, KI = 650. Rough calculations of the dissociation constants from the data of this paper give for LiI, $K = 2.5 \times 10^{-10}$, for KI, $K = 1 \times 10^{-10}$ and for NaI, $K = 4 \times 10^{-11}$. These values are of course only approximate, but are probably correct within a factor of ten and, relative to each other, this discrepancy is doubtless even smaller. The degree of dissociation at the minimum is only about 10^{-4}, and the single ion concentration must be at least as low as 5×10^{-7}, which is an upper limit because of a considerable formation of triple ions.

Although the ionic diameters of the three positive ions in the crystalline state increase from lithium to potassium, the conductances at any given concentration do not occur in that order. We would expect that since the potassium ion is larger than the sodium ion, the conductance curve of its iodide would be lower than that of the sodium iodide because of its lower mobility. That this is not the case is probably because of the greater dissociation of the potassium salt due to its greater diameter. It is evident that the increase in dissociation is of more importance than the decrease in mobility, a fact that might be anticipated since the relationship between the dissociation and the ionic diameter is exponential in nature[11] and the mobility decreases only as the square of the ionic diameter.

On the other hand, these facts might be interpreted as showing that the sodium ion is solvated and hence has a lower mobility, as is the case in liquid ammonia solutions. If the sodium ion is solvated and hence low-conducting, the lithium ion should be even more so. That this is not true may be seen by comparison of these curves with that for lithium iodide which lies above them. It is highly probable that the difference in conductivity between the sodium and the lithium salts is not due to a difference in mobility, which would hardly amount to a factor of 3–4. Therefore we are led to the conclusion that the lithium salt is more highly dissociated due to solvation, which increases the size of the lithium ion greatly. This is in accordance with the fact that this solvent is a strong base; that is, it solvates a proton very readily.

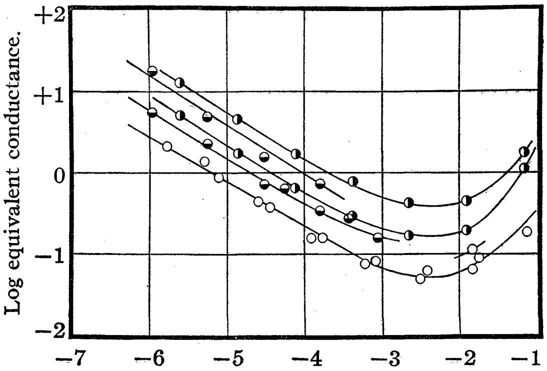

Fig. 1.—◑, LiI; ○, NaI; ◒, KI. The measurements at 0° lie *above* those at 25° in every case.

Additional evidence for an enhanced size of the lithium ion comes from consideration of the temperature coefficients of the resistance. These temperature coefficients are very large and positive; that is, the resistance is smaller at the lower temperature. This is the reverse of what is observed in aqueous solutions, but has often been observed in solutions of low dielectric constant. According to Coolidge and Bent,[12] since the process of separating two ions in solution requires work, the heat content of the system is increased thereby. During ionization, however, the molecules of the solvent are subjected to an electrostatic field which tends to orient them. This involves an entropy change which decreases the heat content of the system. ΔH (ionization) = ΔF (separation of ions, positive) + $T\Delta S$ (orientation, negative). Since the conductivity is greater at the lower temperature, it is evident that the dissociation is greater there and since K_{d}. is larger at the lower temperature, ΔH must be negative. Therefore for these systems the energy involved in the orientation of the solvent is greater than the work of separation of the two ions. Unfortunately there are no viscosity data available for dimethylamine except at the temperature of boiling ammonia,[13] and so it is impossible to calculate the values of ΔH and ΔS for these solutions. However, we can compare the three salts without knowing the absolute values. In Table V below, *r* represents the temperature coefficient of the resistance, written as $(R_{25} \times R_0)/R_{25}$.

In this table it is seen that the temperature coefficients fall in the order sodium iodide,

1×10^{-6}	.69	......	..	2×10^{-6}	.61

potassium iodide, lithium iodide, with lithium iodide having the largest coefficient. This in turn means that ΔH for lithium iodide has the largest negative value, indicating either that the entropy of orientation of the solvent is greater for this ion or that the free energy of ionization is smaller. Bent and Keevil[6] point out from their somewhat meager data on ether solutions that while ΔF varies somewhat with the distance of closest approach of the ions, the entropy change is relatively constant. If this is generally true, then the variation in ΔH is due to a difference in ΔF, rather than ΔS. Since the free energy of ionization decreases with increasing ion size, that is, larger salts are more easily ionized, it follows that the lithium ion has the largest ionic radius with the potassium ion next, as deduced previously. This again probably means that the lithium ion is solvated.

In a recent article,[14] Kelso and Felsing have reported finding negative partial molal volumes for lithium chloride in methylamine solutions. This probably indicates some solvation of this salt, while sodium nitrate has a positive partial molal volume, and probably is not solvated. These findings are in accord with the results of this research in a very similar solvent, and throw some light on the mechanism of the ionization process in solution. Since only an extremely small fraction of the lithium salt present is in the form of single ions in a solution of ordinary concentration such as those measured by Kelso and Felsing, the large negative partial molal volume observed must be caused by the ions in combination, rather than those existing as single ions. If these negative partial molal volumes are to be interpreted as indicating solvation, then the ions in the ion pairs are solvated and the greater dissociation of the lithium salt is due to the greater separation of the ions in the ion-pairs, resulting in a weakening of the coulombic force between them.

The author wishes to thank Professors H. E. Bent and Grinnell Jones for many suggestions and helpful criticisms.

Summary

1. The conductances of dilute solutions of sodium, potassium and lithium iodides in dimethylamine have been measured.

2. The results are qualitatively in accord with the Kraus and Fuoss theory.

3. It was found that the lithium ion is probably solvated by dimethylamine.

Stable Sulfur Dithiocyanate

By P. A. Bond and G. A. Weaver, Jr.

In 1926, while investigating the solubilities of inorganic salts in sulfur monochloride, Baker[1] found that the thiocyanates of barium and potassium formed orange-red precipitates which were amorphous, insoluble in the strongest alkali, and stable in all except the most powerful oxidizing acids. Since the determination of the exact nature of this product did not come within the scope of the thesis, the reaction was not investigated further at that time. It seemed probable, however, that the orange-red powder belonged to the general class of "pseudo thiocyanates," upon which considerable research has been carried out.

In 1922, Lecher and Goebel[2] prepared the compound sulfur monothiocyanate, $S_2(SCN)_2$, by treating a mercuric thiocyanate in carbon disulfide with sulfur monochloride. The entire experiment was carried out at low temperatures in an apparatus described as being "practically completely protected from air."

Also, Lecher and Whittwer[3] prepared sulfur dithiocyanate, $S(SCN)_2$, by treating the free

(2) Lecher and Goebel, *Ber.*, **55**, 1483–1495 (1922).

(3) Lecher and Whittwer, *ibid.*, **55**, 1481–1482 (1922).

thiocyanate, $(SCN)_2$, formed by the action of bromine on thiocyanates, with diethyl ether and dry hydrogen sulfide. Sulfur dithiocyanate was described as pearly yellow crystals which darkened upon standing, decomposed into an orange-red smoke at the temperature of the water-bath, and decomposed less rapidly in water or in alcohol.

Since Baker's product was prepared at reasonably high temperatures, it did not seem possible that the product could be sulfur monothiocyanate, which has a melting point of −3.3°; neither did the appearance of it correspond to the sulfur dithiocyanate of Lecher and Whittwer—although, as will be seen, its formula shows it to be sulfur dithiocyanate, $S(SCN)_2$, or some isomer.

Baker's work was repeated and somewhat extended to include the thiocyanates of mercury and ammonium. (Pure salts dried at 110° and purified sulfur monochloride were used.) The product formed by the reaction of each of these, as well as by the thiocyanates of potassium and barium, upon sulfur monochloride was identical in each case. The orange-red precipitate was purified by extracting three times with carbon disulfide, then by boiling with distilled water until the filtrate gave no tests for either the chloride or the metallic ions, and finally by extracting once again with carbon disulfide. Qualitative tests established the presence of only sulfur, nitrogen, and carbon.

Sulfur was determined by oxidation with nitric acid and precipitation as barium sulfate. Kjeldahl determinations were made for the nitrogen content. Carbon was determined as carbon dioxide by combustion in the presence of copper oxide, lead chromate, and potassium dichromate. From these analyses, as shown in Table I, the purified reaction product was found to be sulfur dithiocyanate, $S(SCN)_2$, or some polymerized form. On account of its insolubility, the molecular weight was not determined.

TABLE I

Element	% found in prepared samples		% calcd. for $S(SCN)_2$
S	64.81	64.88	64.91
N	18.98	19.01	18.90
C	16.22	16.29	16.19

The fundamental reaction between any metallic thiocyanate and sulfur monochloride, at high temperatures, appears to be

$$2MeSCN + S_2Cl_2 \longrightarrow 2MeCl + S(SCN)_2 + S$$

During the reaction, however, there was a considerable quantity of gas evolved which is not accounted for in the reaction as written. The gas, collected over mercury, is colorless and hydrolyzes in the air or in water, in which it is very soluble. It does not condense at room temperatures as would be expected were it a vaporized sulfur chloride, nor is it cyanogen.

Because the product differed in physical aspects from the sulfur dithiocyanate of Lecher and Whittwer, their preparation was repeated and the occurrence of pearly yellow crystals was verified. This crystalline form was found to change completely in approximately forty-eight hours to the orange-red form. When this was purified and analyzed, the results (as shown in Table II) were identical with those obtained by our reaction. Since Lecher and Whittwer found the crystalline form to have this composition also, it would appear that the change is a molecular rearrangement rather than a decomposition.

TABLE II

Element	% found in the purified product after rearrangement		% calcd. for $S(SCN)_2$
S	64.73	64.77	64.91
N	19.08	19.00	18.90
C	16.17	16.30	16.19

The stability of the final product, with respect to the high temperatures required for its decomposition, 500–600°, and its general insolubility taken in connection with its intense color, indicate the possibility of its use as a pigment.

Summary

1. Sulfur dithiocyanate, $S(SCN)_2$, has been prepared, at moderately high temperatures, by the action of pure sulfur monochloride upon metallic thiocyanates.

2. This compound is identical with the *final* product which Lecher and Whittwer obtained by the action of bromine and hydrogen sulfide upon thiocyanates.

3. It does not correspond to the sulfur monothiocyanate, $S_2(SCN)_2$, prepared by Lecher and Goebel by the action of sulfur monochloride upon thiocyanates in carbon disulfide solution at low temperatures.

Specific Gravities of Pure and Mixed Salt Solutions in the Temperature Range 0 to 25°[1]

BY RAYMOND W. BREMNER, THOMAS G. THOMPSON AND CLINTON L. UTTERBACK

In this paper are presented specific gravity data for aqueous solutions. The solutions are those of some of the various salts occurring in sea water. The concentrations of the binary solutions were in the same ratios that occur in the ocean waters.

Method of Procedure and Apparatus

Using the Archimedes principle, the weight of a given volume of solution was compared with that of an equal volume of pure water, the density of which was accurately known.[2] This method is more rapid than the pycnometer method and, with the refinements used, is capable of great precision.

A cylindrical glass bulb weighted with mercury and suspended by means of a piece of fine platinized platinum wire, was weighed when immersed in water and also in the solutions. For this purpose, the water and the solutions were contained in a cylindrical copper tank of suitable design, which was suspended in a water-bath. The temperature fluctuation in the water-bath varied from 0.01° at 0° to 0.002° at 25°. The weighings were made to 0.1 mg.

Check determinations were made with two different glass bulbs and two cylindrical copper tanks, using duplicate solutions. The approximate volumes of the bulbs were 250 and 260 ml., respectively. With the copper tank in position in the water-bath and the glass bulb suitably suspended in the solution at the desired temperature, consecutive weighings of the bulb were made at five-minute intervals until the change in weight during a five-minute interval was not greater than 0.1 mg. Observations were made in this way at 0, 5, 10, 15, 20, and 25°, respectively.

Immediately after making each observation, the weight of the support for the bulb was determined. The change in the buoyancy of the solution on the portion of the support immersed was negligibly small over the temperature range.

Solutions Measured

Materials.—Very pure potassium chloride and sodium chloride were prepared by well-known methods.[3] Purified magnesium sulfate was heated in air at 360° for sixteen hours. It was cooled in a vacuum desiccator charged with anhydrous magnesium perchlorate. It was then weighed in contact with dried air in a tared ground glass-stoppered weighing bottle.[4,5] The water used was similar to the equilibrium water described by Washburn.[6] The solutions were prepared according to the composition of sea water as reported by Thompson.[7]

The ions of the salts comprising the major constituents of sea water are chloride, sulfate, sodium, magnesium, calcium, and potassium. The ratio of the number of milligram atoms of any one of these to that of any other is a constant.[8] The concentrations of the elements comprising these ions for a sea water having a chlorinity of 19.00‰[9] are as follows:

	Mg. at./kg. of sea water
Chlorine	535.0
Sodium	454.0
Magnesium	52.30
Sulfur (sulfate)	27.63
Potassium	9.6

The solutions were prepared by taking a fixed mass of pure water, 1 kg., to which were added the various salts in the proper concentrations. It should be noted that this method differs from that in which the number of grams of salt per kilogram of solution is considered.

The constituents used were salts that are comparatively easy to purify and handle quantitatively in the dry condition. The sodium and potassium ions were introduced as chlorides, the sulfate and magnesium ions as magnesium sulfate.

TABLE I

SHOWING THE WEIGHT OF SALT ADDED TO 1 KG. OF WATER

Approximate chlorinity	19‰	14‰	8‰	4‰
	Sodium Chloride Solutions

$MgSO_4$, g.	3.41678	2.49969	1.41629	0.704166

Sodium chloride was present in all of the solutions containing two salts. In preparing such solutions the approximate amount of a stock solution of the salt, other than sodium chloride, required to prepare about a liter of the desired solution was weighed accurately in a ground glass-stoppered flask. From this, the required weight of

sodium chloride and of the desired solution was calculated. The calculated amount of dry sodium chloride was weighed out and added to the solution in the flask, which was then made up to the calculated weight by the addition of equilibrium water. All weights were corrected to vacuum for the purpose of computation and to the conditions pertaining in the laboratory for the purpose of weighing. The apparatus used for weighing has been described.[10] The solutions, as well as the equilibrium water used in their preparation, were kept in well seasoned and steamed Pyrex ground glass-stoppered bottles.

Experimental Results

The specific gravities of each of the following solutions were measured at 0, 5, 10, 15, 20, and 25°: sodium chloride, potassium chloride, magnesium sulfate, sodium chloride plus potassium chloride, and sodium chloride plus magnesium sulfate. Each of these was found by direct comparison with one of the values for water given in the "International Critical Tables." The experimentally determined data are accurate to five decimal places, the sixth being a close estimate in most cases. Duplicate values usually agreed exactly to five decimal places. A total of 120 determinations was made.

The specific gravities of the solutions were computed by the usual method. The volume of the bulb, its weight *in vacuo*, and its weight immersed in the solution at each temperature were redetermined several different times during the work, but no appreciable departure from the original values was observed.

The equation proposed by Root,[11] contains

$$D = D_0 + pN + qN^{3/2}$$

two constants p and q which are different for each type of solution and at each temperature. These constants were evaluated by the method of least squares at each of the six temperatures for each type of solution measured, and their values are listed in Table II. D and N are density and normality, respectively. Normalities were computed from the data in Table I, using the 1936 atomic weights.

After p and q were obtained for a particular type of solution, the specific gravities were calculated for the concentrations at which measurements were made and for concentrations at which specific gravity data were found in the "International Critical Tables."

Table III is illustrative of the agreement between the observed and calculated values for two mixed solutions at two of the temperatures.

The agreement between the calculated and observed values, not given in Table III, is also in every instance within 5 in the sixth decimal place. Thus the equation proposed by Root is shown to reproduce the experimental results within the limit of experimental error in the case of mixed salt solutions as well as pure salt solutions in all the concentrations and at all the temperatures measured.

The most exact applicable data found in the "International Critical Tables" are for potassium chloride at 20°. They are reported to eight decimal places. These data and the values calculated from the constants given in Table II are consistent within the limits of experimental error.

Specific gravity values for sodium chloride solutions at 0, 10 and 25° are reported in the "International Critical Tables" to five decimal places. Using the concentrations listed and the above constants, these specific gravities were calculated by means of the equation proposed by Root. The deviations of the calculated values from those given in the "International Critical Tables" range from 0.00002 to 0.00023. These deviations are large considering that the data are reported to five decimal places. They are all negative but are considerably larger at 25 and 0° than they are at 10°. In some instances they increase with concentration while in others they decrease. It is evident that the "International Critical Tables" data for sodium chloride do not conform to the Root equation as well as those for potassium chloride.

Summary

1. The specific gravities of various solutions of salts occurring in sea water have been measured at 5° intervals from 0 to 25° inclusive.

2. The solutions were prepared to contain the pure and mixed salts in concentrations covering the range found in nature.

3. The specific gravity measurements, which are accurate to five decimal places and closely estimated to the sixth, were made by the method of weighing a weighted glass bulb suspended in the solutions.

4. Some of the data on the specific gravity of sodium chloride solutions reported to five decimal places in the "International Critical Tables" can be represented by the equation proposed by Root to only four decimal places. Certain more accurate data on potassium chloride solutions have been shown to be entirely consistent with the data reported in this paper.

5. The equation proposed by Root has been shown to reproduce the experimental results, within the limits of experimental error, at each of the six temperatures used. It applies equally well to solutions containing one solute and to those containing sodium chloride plus potassium chloride and sodium chloride plus magnesium sulfate. The constants for this equation have been calculated at six temperatures for each of the five types of solutions studied.

The Infrared Absorption Spectra of Some Sugars and Furans

BY LEWIS H. ROGERS AND DUDLEY WILLIAMS

In a previous paper,[1] the authors reported a study of the infrared absorption spectrum of Vitamin C. At that time a band was observed at 4 μ which, it was suggested, may have arisen from the lactone linkage. Additional studies on similar compounds are reported in this paper.

The infrared absorption spectra between 2 and 12 μ have been mapped for the following furans: furfural, tetrahydrofurfuryl alcohol, furfuryl alcohol and hydrofuramide. Spectra between 3 and 12 μ have been studied for the following sugars: *d*- and *l*-arabinose, *d*-lyxose, *l*-xylose, *d*-galactose, *d*-mannose, levulose and dextrose. Several studies of the Raman spectra of the furans have been reported,[2] while Coblentz[3] studied the infrared spectra of levulose and dextrose in approximately the same region as that studied here.

The spectrometer and experimental details have been described elsewhere;[1] the only change which has been made consists of the addition of a current amplifier employing two photocells. With the furans, rock salt absorption cells were used, which were of approximately 0.05 mm. thickness. The liquid furans were introduced directly into the cells; hydrofuramide, however, was melted onto the rock salt plates. The data are corrected for the absorption of the rock salt. The furans were contributed by the Quaker Oats Company.

Saturated water solutions of the sugars were used and fluorite cells of approximately 0.02 mm. thickness, together with a comparison cell of fluorite containing water. The sugars were obtained from Eastman Kodak Co.

In Fig. 1 are presented the transmission curves for the furans. Table I summarizes these data. In Table II, data are given on the sugars.

Discussion

The furans show considerable similarity in their absorption spectra in the region studied. In Fig. 1, it will be noted that the bands which occur in the 3–3.5 μ region are more pronounced in the alcohols than in the other two furans, a result which is to be expected, since no OH groups appear in furfural and hydrofuramide. From 5.6 to 6.6 μ there are several bands which arise from C═O, C═C or C═N. Tetrahydrofurfuryl alcohol, which contains none of these groups, exhibits no distinct bands in this region. Furfural contains a band at 5.9 μ which is characteristic of the C═O linkage. Again, in the 10 to 11 μ region, a band known to arise from the C—C linkage is found in all the furans.

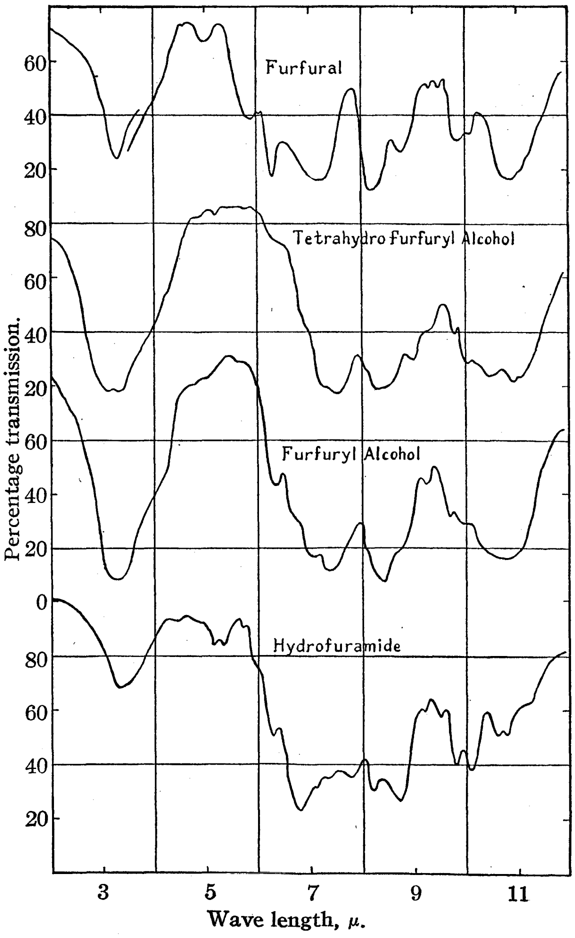

Fig. 1.

It will be seen that at 4 μ no band was observed in any of the furans. This would seem to indicate that the band observed at this wave length in Vitamin C was not due to a vibration involving the lactone linkage, as was previously suggested.[1]

2080		1890	
1750	ν(C=O)	1350	δ(CH$_2$)
1590		1100	
1350	δ(CH$_2$)		
1100			

In column 4 of Table I are given some of the Raman frequencies reported by Catlin and Wilhelm.[2] The agreement in the case of furfural is good with the exception of the 3030 cm.$^{-1}$ frequency. This discrepancy is to be expected, since the high frequency OH vibration is active in the infrared, but is inactive in the Raman effect. On account of the low resolution obtainable in the 3 μ region with a rock salt prism the C–H and O–H bands could not be separated. The other frequencies reported here are apparently not active in the Raman effect. Similarly, certain Raman frequencies do not appear in the infrared.

The data in Table II for the eight sugars studied are strikingly similar for each compound. Charlton, Haworth and Peat[4] have discussed the possibility of a lactone linkage occurring in some of these sugars; since no band was observed at 4 μ in these materials, there is no evidence indicating that a lactone linkage gives rise to a band at this point.

The data in Table II for dextrose are in partial agreement with Coblentz' data,[3] since he reported a broad absorption maximum between 3 and 4 μ and another maximum at 4.8 μ. Beyond 7 μ, however, Coblentz was unable to detect any transmission. In the present study, thinner

---

[4] W. Charlton, W. N. Haworth and S. Peat, *J. Chem. Soc.*, 89–101 (1926).

cells permitted the extension of the data to longer wave lengths. Also, it should be noted that Coblentz made his measurements with melted samples while in the present study sugar solutions were used. Furthermore, small bands were found at 6.0 μ and 6.3 μ which were not reported by Coblentz. In the case of levulose, agreement between Coblentz' data and those reported here is still less satisfactory. There is agreement on the 3.3 μ band, but Coblentz reports a band at 5.85 μ which is not noted here, and another at 5.3 μ reported here is not shown by Coblentz. Again, thinner cells permitted the extension of this study to longer wave lengths.

The effect of the solvent on the absorption of the sugars is very slight; also, no variation of the spectra of the solutions with time was detected.

Summary

The infrared absorption spectra for four furan derivatives, four pentoses and four hexoses between 2 and 12 μ have been mapped and the results compared with Raman and infrared data from other sources. Several bands were common to all the furans. Data on sugar solutions are in fair agreement with earlier results obtained in studies of melted compounds. No pronounced differences occurred between the spectra of any of the sugars studied.

The Dihydroabietic Acids from So-called Pyroabietic Acids

BY E. E. FLECK AND S. PALKIN

In a previous paper it has been shown that so-called "α-pyroabietic acid" prepared from *l*-abietic acid by the catalytic method, was a mixture of dehydro-, dihydro- and tetrahydroabietic acids.[1] It was pointed out, however, with regard to the *di*hydro acid ($[\alpha]^{20}\text{D}$ $-3°$) isolated, that while the combustion data were in good agreement with those calculated for the dihydro compound, the rotation did not conform to that indicated by the Biot relationship[2] in that the latter pointed to a dihydroabietic acid of high positive rotation.

This compound ($[\alpha]^{20}\text{D}$ $+108°$) has now been isolated by first removing the tetrahydroabietic acid as the insoluble ammonium salt and then the dehydroabietic acid as the crystalline methyl ester. The non-crystalline residue of methyl esters was saponified with 10% *n*-butyl alcoholic potassium hydroxide to obtain the new dihydroabietic acid.

Another dihydroabietic acid ($[\alpha]^{20}\text{D}$ $+ 9.0°$, m. p. 193–194°) from α-pyroabietic acid mixture prepared by heat, without catalyst has been reported recently by Ruzicka *et al.*[3]

Further work on the previously reported dihydro compound ($[\alpha]^{20}\text{D}$ $-3°$, m. p. 130–131°), which was isolated by partial sulfonation of the non-crystalline portion of the mixed methyl esters and subsequent hydrolysis of the unsulfonated part, has now been found to be a lactone, as it took up no alkali on direct titration. This lactone was found to be identical with that reported by Hasselstrom, *et al.*,[4] who also obtained it as a sulfonation by-product, and with that reported earlier by Ruzicka, *et al.*,[5] who prepared it by the action of hydrobromic acid on dihydroabietic acid.

By treatment with butyl alcoholic potassium hydroxide, the lactone yielded hydroxytetrahydroabietic acid, m. p. 164–165°, identical with that reported by the above authors.

Experimental Part

Fifty grams of *l*-abietic acid was converted into "pyroabietic" acid mixture at 225° as previously described.[1] The yield was 47 g. of a product that melted at 166–168° and showed $[\alpha]^{20}\text{D}$ $+62°$ in absolute alcohol. This mixture was dissolved in 180 cc. of alcohol and 425 cc. of 0.4 *N* ammonium hydroxide. On standing overnight at room temperature fine needles separated which consisted chiefly of tetrahydroabietic acid. These were removed by filtration. A second and third crop of crystals was obtained from the mother liquor at intervals of several days. The crystalline ammonium salts were recrystallized and the mother liquors were united with the original filtrate. The combined mother liquors were evaporated to dryness on the

steam-bath. The residue was taken up in ether and shaken, first with dilute hydrochloric acid, and then with water. The ether was distilled and the residue (19.5 g.) was esterified with diazomethane in the usual manner.

The solvents were removed under reduced pressure and the residue was taken up in methyl alcohol. The solution was cooled to 0° and water was added until the solution became cloudy. On standing several days at 0° the crystalline methyl ether of dehydroabietic acid was deposited. By addition of more water to the filtrate a semi-crystalline deposit was obtained. The supernatant liquid was decanted and the methyl alcohol distilled under reduced pressure.

Nine grams of the resulting oil was refluxed for three hours with 90 cc. of *n*-butyl alcohol and 9 g. of potassium hydroxide. The butyl alcohol was removed by steam distillation. When the residue was cooled an amorphous potassium salt separated. Ether was added to the mixture and the aqueous layer was removed. This aqueous layer did not contain an appreciable amount of potassium salt of dihydroabietic acid. The ether solution was then shaken out with 0.25 *N* sodium hydroxide. The aqueous extract was shaken twice with fresh ether and then the dihydroabietic acid was isolated by addition of dilute hydrochloric acid, extraction with ether and evaporation of the solvent.

Eight grams of this light yellow product was dissolved in 35 cc. of alcohol and 50 cc. of 0.4 *N* ammonium hydroxide. On standing overnight 1.3 g. of stout prisms separated. The free acid was liberated as outlined above and the residue was recrystallized from alcohol. The final product melted at 174–176° and gave a yellow color with tetranitromethane: $[\alpha]^{20}\text{D}$ +108°; *c*, 2.043% in absolute alcohol.

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.88; H, 10.60; neut. equiv., 304.3. Found: C, 78.70, 79.00; H, 10.55, 10.32; neut. equiv., 310.

52.1 mg. of substance was dissolved in 10 cc. of alcohol and directly titrated with 0.1 *N* sodium hydroxide against phenolphthalein: neutralization equivalent, 310; calcd., 304.3.

Hydroxytetrahydroabietic Acid.—A solution of 50 mg. of the lactone in 10 cc. of 10% *n*-butyl alcoholic potassium hydroxide was refluxed for five hours. The butyl alcohol was removed by steam distillation, the aqueous solution diluted with water and extracted three times with ether to remove any neutral material. The aqueous solution was then made acid to litmus and neutral to congo red by addition of dilute acetic acid. The crystalline precipitate which separated was extracted with ether, the ether solution washed with water and the solvent evaporated. The residue after recrystallization from dilute methyl alcohol had a melting point of 164–165°.

Anal. Calcd. for $C_{20}H_{34}O_3$: C, 74.47; H, 10.63. Found: C, 74.25; H, 10.88.

Summary

A dihydroabietic acid of high positive rotation has been isolated from so-called "α-pyroabietic acid" prepared by the catalytic method.

Another compound of the same elemental composition, previously thought to be a dihydro compound, was found to be a lactone.

Vinyl Halide Polysulfones. Peracetic Acid as a Catalyst for the Reaction between Sulfur Dioxide and Olefins[1]

BY C. S. MARVEL AND F. J. GLAVIS

Polysulfones have been obtained from many common olefins and olefin derivatives and sulfur dioxide by using various organic peroxides to catalyze the reaction. However, up to this time no descriptions of the polysulfones prepared from vinyl chloride and vinyl bromide have appeared. Solonina[2] and Staudinger and Ritzenthaler[3] report failures to obtain the addition reaction between vinyl chloride and sulfur dioxide. Recently Frey, Fitch and Snow[4] intimate that the reaction occurs readily although they do not give the details of the preparation or a complete description of the product.

We have found that vinyl chloride and vinyl bromide will combine with sulfur dioxide to give polysulfones which have two vinyl units for each sulfur dioxide unit. In this respect they differ from all other olefins, olefin derivatives, or acetylenes which have been examined previously.

The addition reaction appears to require an especially effective catalyst and in our early experiments could only be brought about in the presence of an unusually "active" sample of paraldehyde which contained peroxides.

A closer examination of the paraldehyde samples which were tried as catalysts showed that the ones which would cause the reaction to run smoothly not only contained peroxides but also were strongly acidic and showed absorption

in the ultraviolet at 2400 Å. Other samples of paraldehyde which did not show all of these properties were relatively non-effective as catalysts. This combination of properties suggested to us that the active constituent in the aged paraldehyde was peracetic acid.

A sample of peracetic acid in acetic anhydride was prepared by the method of Böeseken, Cohen and Kip[5] and without attempting to purify it was tested as a catalyst for the vinyl chloride–sulfur dioxide reaction. The reaction took place quickly and gave a good yield of polymer. This result is especially significant as it is now possible to bring about the addition reaction with a catalyst which can be prepared readily whereas previously it was necessary to examine many samples of paraldehyde before finding one that was effective.

Peracetic acid also proved to be an effective catalyst to bring about the addition of sulfur dioxide to allyl chloride as well as for the simple olefins and acetylenes which have been reported in earlier papers[1] as condensing when active paraldehyde was used as a catalyst. However, no polysulfones could be obtained from allyl bromide, 1,2,3-trichlorobutene or 1-bromoheptene.

Several structural formulas seem quite possible for the vinyl chloride polysulfone but as yet it is impossible to decide which one is correct. The polymer is a white, amorphous, insoluble, high-melting compound. On heating it loses sulfur dioxide. When treated with liquid ammonia it is not degraded to a cyclic disulfone as are most of the polysulfones from the other olefins[1] which have been studied. Vinyl chloride polysulfone reacts with liquid ammonia to produce a nitrogen-containing polymer with the approximate composition $[(CH_2CHNH_3Cl)_2SO_2]_x$. Aniline also reacts with vinyl chloride polysulfone to yield a product which contains nitrogen. Treating the polysulfone with hot aqueous sodium hydroxide solution removes about one-third of the chlorine as hydrogen chloride, leaving a black insoluble polymer. Boiling the polysulfone with 7% sodium hydroxide and distilling with steam at the same time, causes the polymer to darken instantaneously and gives a distillate which contains very small quantities of an aldehyde. A 2,4-dinitrophenylhydrazone of this aldehyde melting at 127–129° has been isolated and analyzed. The analysis indicates that this derivative has one C_3H_5 unit for each dinitrophenylhydrazone residue. The product is apparently not the 2,4-dinitrophenylhydrazone of acetone (m. p. 128°).[6]

Further work must be done to characterize this compound and to establish the way in which the two vinyl chloride units are combined with one sulfur dioxide unit in the polymer. It should be mentioned that vinyl bromide polysulfone gives essentially the same reactions as the chloride in all cases which have been examined.

Some copolymers of vinyl chloride, 1-pentene and sulfur dioxide have been obtained using ascaridole as a catalyst although ascaridole will not cause vinyl chloride and sulfur dioxide to combine in a reasonable time. Benzoyl peroxide did not bring about the formation of a copolymer. Analysis of this copolymer indicated that the ratio of constituents may be one mole of vinyl chloride to one mole of 1-pentene to two moles of sulfur dioxide. A copolymer prepared from a mixture of vinyl chloride and phenylacetylene with sulfur dioxide seemed to have these constituents present in the ratio of two moles to one mole to two moles, respectively.

Some rather rough freezing point determinations of solutions of styrene, 1-pentene, 10-hendecenoic acid and vinyl chloride in liquid sulfur dioxide showed that there was apparently no compound formation in the absence of a catalyst in the first three cases. Styrene and sulfur dioxide mixtures showed a eutectic at 27 mole per cent. of styrene, and 10-hendecenoic acid and sulfur dioxide mixtures showed a eutectic at 4 mole per cent. of the acid. 1-Pentene and sulfur dioxide mixtures gave a complex melting point curve similar to that observed by Seyer and Hugget[7] in their careful study of the system 1-hexadecene–sulfur dioxide. On the other hand, vinyl chloride and sulfur dioxide mixtures showed eutectics at 37 mole per cent. of vinyl chloride and 98 mole per cent. of vinyl chloride and a peak indicating compound formation at approximately 40 mole per cent. of vinyl chloride. While it is impossible to relate this compound to the composition of the polysulfone which is obtained in the presence of a catalyst, it is of interest that only in the case of vinyl chloride was compound formation noted in the solution, and this is the only olefin derivative to combine in a two to one ratio with sulfur dioxide to yield a polysulfone.

Experimental Part

Vinyl Chloride Polysulfone.—To a mixture of equal volumes of liquid vinyl chloride and liquid sulfur dioxide was added about a half volume of active paraldehyde and one-fifth volume of 95% ethanol. The ice-cold mixture was sealed in a pressure bottle and allowed to warm to room temperature. The reaction apparently was complete in one hour and longer standing did not increase the yield. The polymer separated as an insoluble powder as it formed. The reaction flask was cooled and opened and the contents were poured into ether. The polymer was isolated by filtration and was purified by repeated washing with alcohol. Unless the product was washed thoroughly it would turn dark on standing. The dark material had very nearly the same analysis as the white product. The yields varied with the effectiveness of the catalyst from about 5 to 30%. The reaction goes so quickly that practically the same yields are obtained by running the reaction in an open vessel. Addition of larger amounts of catalyst did not increase the yield, but when the reaction was carried out under conditions which permitted recovery of the unused vinyl chloride, it was found that the recovered material gave as good results as the original material when a fresh charge of catalyst was added.

When ascaridole and benzoyl peroxide were tried as catalysts for the addition reaction, no polysulfone was obtained in six hours. Over a longer period some dark colored material was obtained from reaction mixtures containing ascaridole. With benzoyl peroxide no product was obtained even after twenty-four hours. When 15 cc. of the solution of peracetic acid prepared from 97.3 g. of acetic anhydride, 20 g. of 30% hydrogen peroxide and 1 g. of *p*-toluenesulfonic acid[5] was used as a catalyst the polymer formed in 30% yields within one-half hour.

The polysulfone was a white amorphous powder. It darkened at 135–140° and melted at 250–275°. It was insoluble in common organic solvents except dioxane in which it was very slightly soluble.

Anal. Calcd. for $(C_4H_6Cl_2SO_2)_x$: C, 25.40; H, 3.17; S, 16.93; Cl, 37.57. Found: C, 26.42; H, 3.67; S, 17.62, 16.83, 16.53; Cl, 38.19.

Vinyl Bromide Polysulfone.—Using 10 cc. of liquid sulfur dioxide, 10 cc. of liquid vinyl bromide, 5 cc. of active paraldehyde and 2 cc. of 95% ethanol there was obtained 1–2.5 g. of polysulfone. It was isolated and purified as described for the chlorine analog. The product melted with decomposition at 200–225°.

Anal. Calcd. for $(C_4H_6Br_2SO_2)_x$: S, 11.51; Br, 57.55. Found: S, 10.92; Br, 54.13.

Reactions of Vinyl Chloride Polysulfone

With Liquid Ammonia.—When 1 g. of vinyl chloride polysulfone was dissolved in 100 cc. of liquid ammonia a deep blue solution formed. Evaporation of the ammonia left 0.5 g. of dark colored residue insoluble in organic solvents and acetic acid.

Anal. Calcd. for $(C_4H_{12}Cl_2N_2SO_2)_x$: C, 21.52; H, 5.38; S, 14.38; N, 12.55. Found: C, 23.19, 22.50; H, 6.09, 7.39; S, 13.32, 15.79, 15.42, 13.55, 15.32; N, 12.46.

With Aniline.—One gram of the polysulfone was dissolved in 25 cc. of aniline and the solution allowed to stand at room temperature for fifteen hours. Most of the aniline was removed by distillation under reduced pressure. When about 5 cc. of solution remained, the residue was poured into 100 cc. of 95% ethanol. The precipitate was collected on a filter and washed with ethanol. The residue weighed about 1 g.

Anal. Calcd. for $(C_{10}H_{12}NClSO_2)_n$: C, 48.9; H, 4.9; S, 13.1; Cl, 14.5. Found: C, 51.3; H, 5.5; S, 13.4; Cl, 14.0.

Action of Heat.—A weighed sample of vinyl chloride polysulfone was placed in 75 cc. of dioxane. A stream of air purified by leading it through an "ascarite" tube was led through the apparatus and then through standard potassium dichromate solution. The dioxane was heated to boiling for various lengths of time with different samples and the amount of sulfur dioxide liberated was determined by titration of the standard dichromate solution. In three hours using about 0.1 g. of polysulfone about 75–85% of the calculated amount of sulfur dioxide was given off. With five hours of heating the sulfur dioxide evolved amounted to 97%.

With Alkali.—When a weighed sample of polysulfone (about 0.1 g.) was suspended in standard sodium hydroxide solution and heated to boiling the mixture turned black. After six hours this mixture was acidified and titrated for chloride ion, and it was found that about one-third of the chlorine in the polymer had been removed. A reaction mixture which was refluxed for twenty-four hours gave the same result.

A mixture of 2 g. of the polymer with 75 cc. of 7% aqueous sodium hydroxide solution was distilled with steam. The distillate was collected in a solution of 2,4-dinitrophenylhydrazine. The distillate gave a positive test with fuchsin aldehyde reagent. A small amount of 2,4-dinitrophenylhydrazone was obtained. It melted at 127–129° after recrystallization from alcohol.

Anal. Found: C, 45.19; H, 3.85; N, 23.21, 23.35.

This product gave a depression in melting point when mixed with the 2,4-dinitrophenylhydrazone of acetone (m. p. 128°). While the analysis checks for $[(C_3H_5)(NNHC_6H_3(NO_2)_2)]_x$ it has not been identified further.

Vinyl Bromide Polysulfone and Liquid Ammonia.—This reaction was carried out exactly as described for the chloride analog. The product was analyzed for sulfur.

Anal. Calcd. for $(C_4H_{12}Br_2N_2SO_2)_x$: S, 10.25. Found: S, 9.25.

Freezing Point–Composition Diagrams of Solutions of Olefins in Liquid Sulfur Dioxide.—Freezing point curves were taken on solutions of styrene, 10-hendecenoic acid, 1-pentene and vinyl chloride in liquid sulfur dioxide. The olefin was introduced into a weighed glass tube and the amount thus introduced determined by weight difference. Liquid sulfur dioxide was then added and the tube weighed again. Temperature measurements were made by means of a copper–constantan thermocouple with the reference end held at 0° by an ice–water mixture. These measurements are not considered to be of great accuracy but do give some evidence of the nature of the mixtures. The freezing point–composition curves are given in Figs. 1–4.

Vinyl Chloride–1-Pentene–Sulfur Dioxide Copolymer.—An equimolecular mixture of vinyl chloride and 1-pentene

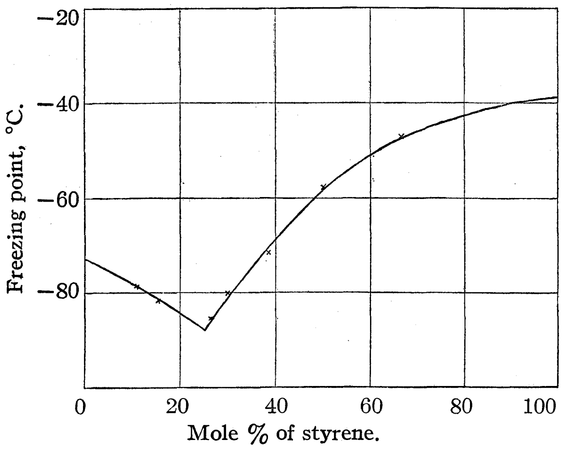

Fig. 1.—Sulfur dioxide–styrene freezing point–composition diagram.

was treated with an equal volume of liquid sulfur dioxide, catalyst and 95% ethanol and placed in a pressure bottle. The usual reaction mixture consisting of 10 parts of olefin, 10 parts of sulfur dioxide, $^1/_2$ part of catalyst and 2 parts of ethanol was used. Two catalysts, ascaridole and a mixture of ascaridole and active paraldehyde, were used without significant change in yield or properties of the product. The yield was about 50% of a polymer which melted with decomposition at 200–225°. The polymer was insoluble in common organic solvents.

Anal. Calcd. for $[C_5H_{10}C_2H_3Cl(SO_2)_2]_x$: S, 24.6; for $(C_5H_{10}SO_2)_x$: S, 23.88; for $(C_2H_3ClSO_2)_x$: S, 25.29. Found: S, 24.57, 24.07.

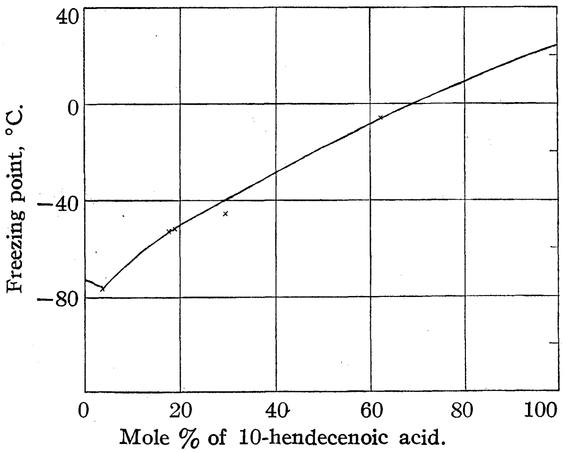

Fig. 2.—Sulfur dioxide–10-hendecenoic acid freezing point–composition diagram.

Vinyl Chloride–Phenylacetylene–Sulfur Dioxide Copolymer.—Two mixtures of vinyl chloride and phenylacetylene were treated with sulfur dioxide in the presence of ascaridole and alcohol in the usual ratios. Ten cubic centimeters of a mixture containing 13 moles of vinyl chloride for 5 moles of phenylacetylene gave 5.5 g. of a polymer which melted with decomposition at 280–285°.

Anal. Calcd. for $[(CH_2{=}CHCl)_2(C_6H_5C{\equiv}CH)(SO_2)_2]_x$: S, 18.03. Found: S, 17.97.

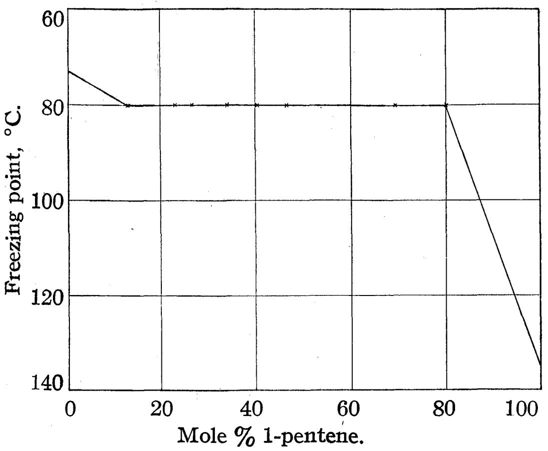

Fig. 3.—Sulfur dioxide–1-pentene freezing point–composition diagram.

Ten cubic centimeters of a mixture containing 8 moles of vinyl chloride for 5 moles of phenylacetylene gave 4 g. of polymer which melted with decomposition at 285–290°.

Anal. Found: S, 18.47.

Both polymers were insoluble in common organic solvents.

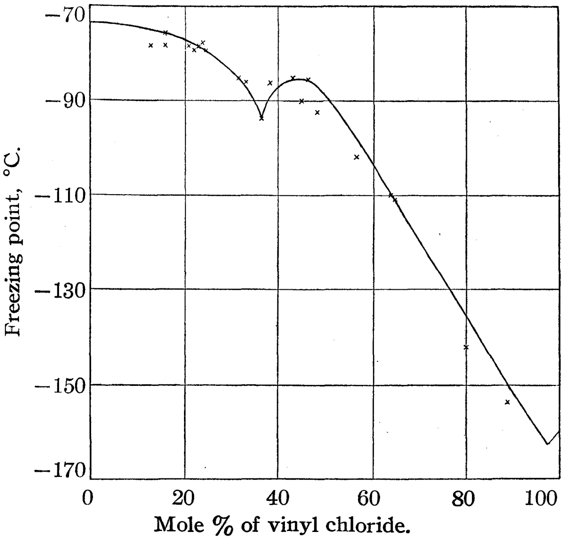

Fig. 4.—Sulfur dioxide–vinyl chloride freezing point–composition diagram.

Allyl Chloride Polysulfone.[4]—From 15 cc. of allyl chloride, 10 cc. of sulfur dioxide, 2 cc. of ethanol and 5 cc. of active paraldehyde, 2.5 g. of polymer was obtained in one hour. The polymer was slightly soluble in acetone and dioxane but insoluble in other common solvents. It melted at 185–215° and decomposed at 225–275°. Peracetic acid solution was equally effective as a catalyst for this preparation.

Anal. Calcd. for $(C_3H_4ClSO_2)_x$: S, 22.93. Found: S, 22.55.

Summary

1. The catalytic activity which certain samples

of aged paraldehyde have shown in promoting the reaction between olefins and sulfur dioxide can be obtained by use of peracetic acid solutions.

2. Vinyl chloride and vinyl bromide combine with sulfur dioxide in the presence of active paraldehyde or peracetic acid to give a polymer of the composition $[(CH_2{=}CHX)_2SO_2]_n$, rather than the usual one to one type of polymer. A preliminary study of the reaction of the vinyl halide polymer has not indicated its structural unit.

3. Freezing point–composition curves for solutions of styrene, 1-pentene and 10-hendecenoic acid in liquid sulfur dioxide offer no evidence of compound formation. But vinyl chloride and liquid sulfur dioxide form a compound containing approximately 40 mole per cent. of vinyl chloride.

Electronegativities of Highly Branched Aliphatic Groups

BY FRANK C. WHITMORE AND HERBERT BERNSTEIN

Since the well-known Kharasch table of relative electronegativities of univalent organic groups consists chiefly of aromatic groups,[1] we decided to place in the table some of the highly branched aliphatic groups available in this Laboratory. Following the method of Kharasch, the mixed dialkyl mercury compounds were treated with alcoholic hydrogen chloride.

$$R{-}Hg{-}R' + HCl \longrightarrow RHgCl + R'H$$

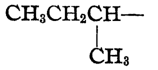
This result would place R′ above R in relative electronegativity. Of the fifteen mixed dialkyl mercury compounds used in the present study, four gave mixtures of R′HgCl and RHgCl. The groups involved in these cases are thus indistinguishable by Kharasch's method. With ten of the other compounds a clear distinction in the relative electronegativity of the groups was obtained.

The results are given in Tables I and II.

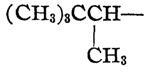
TABLE I

ORDER OF DECREASING ELECTRONEGATIVITY

Phenyl
Methyl
Ethyl
n-Propyl
$\left\{\begin{array}{l}n\text{-Butyl, }(CH_3)_3CCH_2CH_2{-}\\ n\text{-Hexyl, }(CH_3)_3CCH_2CH_2CH_2{-}\end{array}\right.$



$CH_3CH_2CH(CH_3){-}$



$(CH_3)_3CCH(CH_3){-}$

……

Benzyl
$(CH_3)_3C{-}$, $(CH_3)_3CCH_2{-}$

Groups on the same line or bracketed are not distinguishable by this method. The dotted line above the benzyl group indicates that its relation to the groups immediately above it has not been determined experimentally.

The most interesting feature of this table is the position held by the *t*-butyl and neopentyl groups. Both are less electronegative than the benzyl, which, according to Kharasch, is less electronegative than any alkyl group which he tested. Furthermore, their electronegativities approximate each other. This corresponds to the inertness of *t*-butyl chloride and neopentyl chloride in certain metathetical reactions.[2]

Also of interest is the relationship between the pinacolyl and the secondary butyl groups. The *n*-hexyl and *n*-butyl groups have the same relative electronegativity. However, the pinacolyl, a group very susceptible to rearrangement,[3] is distinctly less electronegative than the secondary butyl group.

Experimental

Neopentyl chloride was prepared by the chlorination of neopentane.[2]

1-Chloro-3,3-dimethylbutane was prepared by slowly adding 29.8 g. (0.25 mole) of thionyl chloride to a solution of 21.7 g. (0.21 mole) of neopentylcarbinol in 19.7 g. (0.25 mole) of pyridine cooled on an ice-bath. A thick white solid formed. When the addition was complete, the ice-bath was removed and the temperature of the flask raised. Decomposition of the solid occurred between 94–133°. The residue was added to a mixture of 45 g. of ice and 30 g. of concentrated hydrochloric acid, the organic layer was separated from the aqueous layer and the latter was extracted with ether. Upon distillation, 15.5 g. of

material (n^{20}_D 1.4161) boiling at 115° resulted. A small portion of the neohexyl chloride was converted to the Grignard reagent, the latter oxidized and the α-naphthylurethan prepared, m. p. and mixed m. p. with the α-naphthylurethan of neopentylcarbinol, 83°.

Pinacolyl chloride (2-chloro-3,3-dimethylbutane) resulted from the chlorination of neohexane.[4] 1-Bromo-4,4-dimethylpentane was made by the addition of hydrogen bromide to neopentylethylene under oxidizing conditions.[5]

Preparation of Alkyl Mercuric Chlorides.—The method used was essentially that of Marvel, Gauerke and Hill,[6] excess mercuric chloride reacting with a Grignard reagent. If the initial halide was a bromide, 70% alcohol and an equimolar quantity of silver chloride were added to the reaction mixture and the whole refluxed for five hours.

t-Butylmercuric chloride could not be recrystallized by the conventional methods, since it decomposed readily. Acetone was added to the reaction mixture at room temperature. After filtration water was added until the solution became cloudy. Enough acetone was added to clarify the solution. The acetone was then evaporated under vacuum at room temperature. The *t*-butylmercuric chloride precipitated out in long needles, m. p. 122–123° (dec.).

Analyses for mercury on the new alkylmercuric chlorides prepared were conducted by the method of Sobatzki.[7] The iodine solution was standardized against purified neopentylmercuric chloride.

TABLE III

n-Octyl, $CH_3(CH_2)_7$—	115–115.5	57.8	57.4

Preparation and Reactions of Dialkyl Mercury.—Neopentyl mercury *n*-butyl will serve as a typical example. *n*-Butylmagnesium bromide was prepared from 2.7 g. (0.02 mole) of *n*-butyl bromide and 0.48 g. (0.02 mole) of magnesium, and 3 g. (0.01 mole) of neopentylmercuric chloride was added to the Grignard reagent in small portions. The reaction was instantaneous and vigorous. The flask was surrounded by an ice-bath and the excess Grignard reagent was decomposed using 8 cc. of 0.5% sulfuric acid solution. The ether layer was decanted, shaken with 7 g. of anhydrous sodium sulfate and separated. The ether was then removed under vacuum at room temperature. The residue was divided into two portions.

To one portion of the dialkyl mercury was added 4 cc. of saturated alcoholic hydrogen chloride. After warming the flask for a minute the reaction proceeded vigorously. A portion of the resulting mixture was dried on a watch glass at 90–100°. No recrystallization was attempted, since this would change the ratio if two alkylmercuric chlorides had formed. Melting points and mixed melting points were taken (Table II).

To the second portion of the dialkyl mercury was added saturated alcoholic mercuric chloride until no more precipitate formed. The reaction was instantaneous. Neopentylmercuric chloride and *n*-butylmercuric chloride were isolated from the reaction products by fractional crystallization in aqueous alcohol, the latter precipitating first.

When the mixed dialkyl mercury compounds were treated with mercuric chloride and the products crystallized from aqueous alcohol, the following observations were made: if one of the alkyls is neopentyl the other alkylmercuric chloride separates first; if only one alkyl is normal its alkylmercuric chloride is least soluble; higher normal alkylmercuric chlorides show decreased solubility; in the case of related groups like the neohexyl and neoheptyl, the alkylmercuric chlorides could not be separated by crystallization.

Summary

1. Fifteen mixed dialkyl mercury compounds containing branched-chain groups have been treated with hydrogen chloride, the resulting alkylmercuric chlorides indicating the relative electronegativities. The *t*-butyl and neopentyl groups are the least electronegative, while the neohexyl

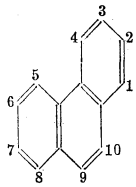
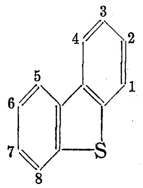
Isosteric Compounds. I. Acyl Derivatives of Dibenzothiophene

BY ALFRED BURGER, WILLIAM B. WARTMAN, JR., AND ROBERT E. LUTZ

The similarity between the physical characteristics of benzene and thiophene and their corresponding derivatives, and the agreement in the physiological behavior of certain of these compounds[1] have been subject to frequent speculation. In 1933 Erlenmeyer[2] advanced the theory that divalent sulfur contains a shell of orbit electrons similar to that of the group or "pseudoatom,"—CH=CH—, and that this similarity in electronic structure known as isosterism,[3] accounted for the formation of mixed crystals and the many like physical properties of the two series. In a few cases, isosteric compounds are interchangeable in serological reactions and cannot be differentiated by the precipitin reaction.[2a]

The present paper is the first in a series of studies on the physical and pharmacological changes effected by introducing a thiophene nucleus into condensed ring systems in place of an aromatic nucleus. The first case under investigation is dibenzothiophene (I) which may be regarded as a pseudophenanthrene. Amino alcohols derived from dibenzothiophene, characterized by the groups —CHOHCH$_2$NR$_2$ and CHOHCH$_2$CH$_2$NR$_2$, may be expected to resemble the corresponding alkamines of the phenanthrene series in analgesic action.[4] Their similarity to the corresponding alkamines derived from dibenzofuran[5] and carbazole[6] should be less marked, since oxygen and the imino group are not isosteric with the —CH=CH— group.





I

The preparation of acetyldibenzothiophenes as starting materials for the proposed dibenzothienyl alkamines is described in this communication. The direct introduction of the acetyl group by the Friedel–Crafts reaction was chosen as a suitable approach. The only ketone derived from dibenzothiophene known heretofore is stearoyl dibenzothiophene, prepared by the Friedel–Crafts reaction in boiling carbon disulfide.[7] No proof for the position of the stearoyl group has been offered, but the group is presumed to have entered position 3 which is known to be preferred in nitration, sulfonation, and halogenation.[8]

Friedel–Crafts reaction on dibenzothiophene with acetyl chloride at low temperature yielded a difficultly separable mixture of methyl ketones, from which one (II), melting at 111–112°, was separated by laborious fractional crystallization and was the major product. An isomeric monoketone, melting at 128–129°, was isolated in small amounts during this procedure. The structure of the major constituent of this mixture, 3-acetyldibenzothiophene (II), was proved by Beckmann rearrangement of its oxime. The resulting acetaminodibenzothiophene and the amine obtained from it by hydrolysis were

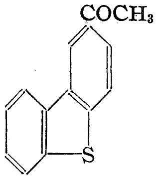
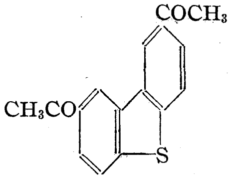
identical with 3-acetamino- and 3-aminodibenzothiophene, respectively, which had been prepared from 3-nitrodibenzothiophene.[8c]



II



III

When the Friedel–Crafts reaction was carried out in boiling carbon disulfide, the main reaction product was a diacetyldibenzothiophene. One of the acetyl groups must be attached in position 3, because the compound was formed in excellent yield by the action of acetyl chloride and aluminum chloride in boiling carbon disulfide on 3-acetyldibenzothiophene (II). The position of the second acetyl group was demonstrated when the dioxime was rearranged to 3,6-diacetaminodibenzothiophene, which on hydrolysis yielded 3,6-diaminodibenzothiophene.[8a] Our diketone must be therefore 3,6-diacetyldibenzothiophene (III).

The good yield of III obtained by drastic acetylation of dibenzothiophene and 3-acetyldibenzothiophene, respectively, suggests that the first acetyl group enters position 3 largely, and therefore II must be the chief product in the mixture of monoketones.

Experiments are under way to make more practicable the direct synthesis of dibenzothiophene ketones for preparative purposes. We are also studying the introduction of the succinoyl group. The mono- and disuccinoyl derivatives are expected to yield naphthobenzo- and dinaphthothiophenes, respectively, by the usual reactions. These compounds may exhibit carcinogenic properties similar to those of the analogous benzanthracenes and benzphenanthrene.

Experimental

Dibenzothiophene.—The dibenzothiophene used was prepared by heating diphenyl with sulfur in the presence of anhydrous aluminum chloride.[9]

Acetylation of Dibenzothiophene.—The action of acetyl chloride and anhydrous aluminum chloride on dibenzothiophene under widely varying conditions was investigated in a series of nine experiments. Carbon disulfide, nitrobenzene, tetrachloroethane, and a mixture of the latter two were employed as solvents, the reaction temperature ranging from 0 to 55°. The aluminum chloride was added to the mixture of dibenzothiophene and acetyl chloride in preference to the reverse order of addition to avoid a side reaction of the aluminum chloride with the starting material. Mixtures of methyl ketones were obtained in all cases, and only two of the experiments yielding the best results are described here.

3-Acetyldibenzothiophene.—A solution of 145 g. of aluminum chloride in 400 ml. of dry nitrobenzene was added dropwise to a well-stirred, ice-cold mixture of 95 g. of dibenzothiophene, 48 ml. of acetyl chloride, and 500 ml. of dry tetrachloroethane over a period of one hour. The mixture was stirred at 0° for two hours and allowed to stand at this temperature for twelve days. It was decomposed by pouring onto ice and hydrochloric acid. The solvent was removed by steam distillation, the brown oily residue was dissolved in benzene, the solution was filtered, and the benzene was evaporated. The crude reaction product obtained from three combined runs totalling initially 265 g. of dibenzothiophene was combined and distilled under reduced pressure, using an oil pump. The distillate was redistilled, and three fractions were collected. Treatment of the partly crystalline main fraction with methanol yielded crystals melting at 85–100°. Crystallization from benzene–petroleum ether, and purification through the semicarbazone which was hydrolyzed easily by the action of boiling dilute hydrochloric acid, failed to improve the melting point. At this stage, the yield of the purified mixture of monoketones was approximately 50%. The mixture was boiled out with two portions of 400 ml. of ether each for one half hour; the sparingly soluble portion was collected and recrystallized from methanol. Twenty grams of 3-acetyldibenzothiophene was thus obtained in colorless plates; m. p. 111–112°.

Anal. Calcd. for $C_{14}H_{10}OS$: C, 74.31; H, 4.46. Found: C, 74.10; H, 4.69.

3-Acetyldibenzothiophene semicarbazone was prepared by boiling the alcoholic solution of the ketone with a concentrated aqueous solution of the calculated amounts of semicarbazide hydrochloride and sodium acetate for ten minutes. It crystallized from ethanol as slightly yellow plates; m. p. 234–235° (dec.).

Anal. Calcd. for $C_{15}H_{13}N_3OS$: C, 63.58; H, 4.62. Found: C, 63.49; H, 5.01.

The oxime was formed by boiling 1.5 g. of 3-acetyldibenzothiophene, 1 g. of hydroxylamine hydrochloride, and 3.7 g. of barium carbonate in 75 ml. of ethanol under reflux for four hours. The barium salts were filtered, the alcoholic filtrate was concentrated and the oxime allowed to crystallize. Recrystallization from ethanol yielded colorless needles; m. p. 161–164°.

Anal. Calcd. for $C_{14}H_{11}NOS$: N, 5.81. Found: N, 5.86.

?-Acetyldibenzothiophene.—The ether extracts of the less soluble 3-isomer deposited on cooling 1 g. of a more soluble ketone as rhombic prisms. It was recrystallized from methanol; m. p. 129–130°.

Anal. Calcd. for $C_{14}H_{10}OS$: C, 74.31; H, 4.46. Found: C, 74.29; H, 5.06.

The semicarbazone formed much slower than that of the isomeric 3-acetyldibenzothiophene. It was necessary to

boil the mixture for thirty minutes. It crystallized as slightly yellow plates; m. p. 302–304° (dec.).

Anal. Calcd. for $C_{15}H_{13}N_3OS$: N, 14.83. Found: N, 14.81.

Beckmann Rearrangement of 3-Acetyldibenzothiophene Oxime.—Dry hydrogen chloride was passed into a solution of 1 g. of 3-acetyldibenzothiophene oxime in 4 ml. of glacial acetic acid and 2 ml. of acetic anhydride for one hour, and the mixture was allowed to stand for twenty hours. Water was added; the crystals which had formed were filtered and recrystallized from methanol. The substance appeared as colorless needles; m. p. 181–183°.

Anal. Calcd. for $C_{14}H_{11}NOS$: C, 69.68; H, 4.60. Found: C, 69.86; H, 5.02.

A mixture melting point with 3-acetaminodibenzothiophene of the same melting point, obtained by acetylation of 3-aminodibenzothiophene with acetic anhydride in pyridine solution, showed no depression.

Hydrolysis of 3-Acetaminodibenzothiophene.—A mixture of 0.3 g. of 3-acetaminodibenzothiophene, 1.5 ml. of glacial acetic acid, and 1.5 ml. of 6 *N* hydrochloric acid was boiled under reflux for one hour. On cooling, the amine hydrochloride separated out. It was converted to the base by treatment with dilute sodium hydroxide solution, and the amine was recrystallized from alcohol. It appeared as colorless needles, m. p. 131–133°.

A mixture melting point with 3-aminodibenzothiophene of the same melting point, prepared by reduction of 3-nitrodibenzothiophene[8c] with stannous chloride and hydrochloric acid in ethanol solution showed no depression.

3,6-Diacetyldibenzothiophene.—Anhydrous aluminum chloride (3.7 g.) was added to a solution of 5 g. of dibenzothiophene and 2.1 ml. of acetyl chloride in 75 ml. of dry carbon disulfide at 10° with vigorous stirring over a period of thirty minutes. The mixture was stirred for forty-five minutes, and then boiled under reflux for five hours. It was poured onto ice and hydrochloric acid, the solvent was driven off with steam, and the brown oily residue was extracted into chloroform. The solution was evaporated, and the crystalline residue was extracted with cold benzene. The insoluble portion was recrystallized from ethanol and obtained as colorless needles; m. p. 208–209°; yield, 1.4 g.

Anal. Calcd. for $C_{16}H_{12}O_2S$: C, 71.62; H, 4.51. Found: C, 71.02; H, 4.94.

The portion soluble in benzene also contained ketones as shown by its conversion into a mixture of semicarbazones. Hydrolysis of these semicarbazones yielded a mixture of ketones, m. p. 85–100°.

3,6-Diacetyldibenzothiophene was formed in 90% yield when a solution of 1 g. of 3-acetyldibenzothiophene and 1 ml. of acetyl chloride in 20 ml. of dry carbon disulfide was treated with 1 g. of aluminum chloride, and the mixture was boiled under reflux for six hours and worked up as described above.

3,6-Diacetyldibenzothiophene Dioxime.—A mixture of 1 g. of diacetyldibenzothiophene, 1 g. of hydroxylamine hydrochloride, 3 g. of sodium acetate, and 50 ml. of ethanol was boiled under reflux for seven hours. A precipitate formed and was filtered and washed with alcohol and water. Recrystallization from ethanol yielded colorless crystals; m. p. 272–274° (dec.); yield, 1 g.

Anal. Calcd. for $C_{16}H_{14}N_2O_2S$: N, 9.38. Found: N, 8.99.

Beckmann Rearrangement of 3,6-Diacetyldibenzothiophene Dioxime.—A solution of 1 g. of the dioxime in 6 ml. of glacial acetic acid and 3 ml. of acetic anhydride was saturated with dry hydrogen chloride and allowed to stand for sixteen hours. The diacetamino compound separated out. Water was added and the product was filtered and purified by sublimation in a high vacuum and crystallization from methanol. It appeared as colorless crystals, melting at 253–255°. Courtot and Pomonis[8a] describe 3,6-diacetaminodibenzothiophene as brown crystals, m. p. 237–239° (dec.).

The diacetamino product was hydrolyzed in the same manner as the 3-acetamino compound described above. 3,6-Diaminodibenzothiophene appeared as grayish needles, m. p. 178° (dec.). This is in good agreement with the data of the French authors. However, our product could be purified by sublimation in a high vacuum and recrystallization from ethanol. It appeared then as colorless needles, m. p. 193–194° (dec.).

Summary

A Friedel–Crafts reaction with acetyl chloride on dibenzothiophene at low temperatures yields a mixture of methyl ketones from which two isomeric monoketones have been isolated. One of these ketones has been shown to be 3-acetyldibenzothiophene by degradation to 3-aminodibenzothiophene. At higher temperatures, the reaction furnishes mainly 3,6-diacetyldibenzothiophene, which could be converted to 3,6-diaminodibenzothiophene.

Substitution Reactions of Dehydroabietic Acid

BY LOUIS F. FIESER AND WILLIAM P. CAMPBELL[1]

In our paper[2,3] reporting the first preparation of the partially aromatic dehydroabietic acid, obtained from abietic acid by hydroxylation with selenium dioxide and dehydration, we advanced the hypothesis that the so-called pyroabietic acids of the literature are not isomerization products of abietic acid but mixtures of hydro and dehydro acids resulting from the disproportionation of the doubly unsaturated acid. This conception of the pyro acids, based at the time merely on the recognition that the substances contain dehydroabietic acid, as revealed in Pd-treated acid by spectroscopic data and nitration and in heat-treated acid by nitration, was promptly established by Fleck and Palkin,[4] who obtained the first conclusive evidence of disproportionation. From their Pd-treated pyroabietic acid,[5] these investigators succeeded in isolating pure dehydroabietic acid, identical with our material, a tetrahydro acid, and a substance having the composition of a dihydro acid and later identified[6] as an isomeric (known) lactone; in the recent work[6] another dihydro acid was isolated. Littmann[7] also isolated dehydroabietic acid from Pd-treated material and obtained evidence of the presence of a tetrahydride, and Ruzicka and co-workers[8] have reported experiments showing that Pd-treated and heat-treated acids are mixtures. Although heat-treated acids have been characterized less extensively than material prepared by the method of Fleck and Palkin,[5] evidence is available showing that disproportionation also occurs on heating. Hasselstrom and co-workers,[9] in an investigation of the action of sulfuric acid on a heat-treated pyro acid, obtained a crystalline sulfonic acid having the composition of a dehydroabietic acid derivative, and isolated a lactone known to be an isomerization product of a dihydroabietic acid. This is the lactone which Fleck and Palkin[6] subsequently isolated from Pd-treated acid. Ruzicka and co-workers[8] fractionated a heat-treated acid and isolated another dihydro acid and a substance corresponding in properties and spectrum to our dehydroabietic acid.

It is evident that the acid mixtures obtained by heating abietic acid either alone or with a dehydrogenation catalyst constitute a potential and abundant source of dehydroabietic acid. Since the method of preparing the pure acid previously described[2] does not provide a ready means of obtaining the acid in quantity, as required for our projected research,[2] we investigated this possible source. Probably the material richest in dehydroabietic acid is that prepared

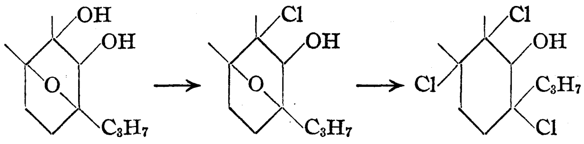
[3] The position regarding the structures suggested in this paper[2] for abietic acid and levopimaric acid is not altered by recent work from other laboratories. The new degradation of levopimaric reported by Wienhaus and Sandermann, *Ber.*, **71**, 1094 (1938), can be explained just as well with our formula (Δ: 7, 8; 14, 13) as with that employed for illustration by these authors (Δ: 5, 6; 7, 8), the reaction of their dihydroxy oxide with hydrogen chloride at 0° being represented as follows



The ready cleavage of the oxide bridge without disturbance of the acetylatable hydroxyl group is indeed better understandable on the assumption that the bridge is linked at each end in a tertiary rather than secondary condition. The degradations of Steele's "abietic acid" and of levopimaric acid by Ruzicka and Sternbach, *Helv. Chim. Acta*, **21**, 565 (1938), and by Ruzicka, Bacon, Lukes and Rose, *ibid.*, **21**, 583 (1938), can be interpreted, as these investigators show, with the formulas suggested. Ruzicka and Sternbach raise an interesting question concerning the validity of the evidence of conjugation in abietic acid furnished by our observation that the compound enters into the diazo coupling reaction but accept the view that conjugation is indicated by the absorption maximum. They point out, however, that some of their degradation products obtained in small amounts from the Steele acid mixture may have arisen from companion substances and not from the conjugated acid responsible for the selective absorption. This does not alter conclusions based upon results obtained with suitably purified (Palkin) abietic acid. Raudnitz, Lederer and Kahn, *Ber.*, **71**, 1273 (1938), have expressed the view that even this acid may not be homogeneous, their evidence being that purified acid and Steele acid were both found to give about 3% of acetone on prolonged treatment with ozone. Since Ruzicka, Meyer and Pfeiffer, *Helv. Chim. Acta*, **8**, 637 (1924), found that Steele acid yields isobutyric acid on ozonization as in the permanganate oxidation, it appears that ozone is capable of breaking the carbon chain as well as adding to the double bonds. The isolation of a small amount of acetone therefore seems of questionable significance. While Schultz, *Bull. inst. pin*, **38**, 25 (1938), regards the isolation of oxalic acid in good yield on oxidation of abietic acid with permanganate as an argument for the Δ: 13, 5; 6, 7-structure, this seems to us less convincing than the evidence against such a formulation, particularly since oxalic acid may arise from various parts of the molecule.

according to Fleck and Palkin[5] by heating pure abietic acid with palladium charcoal at a high temperature (250°), but there are difficulties in the way of effecting a practical recovery of pure acid by fractionation as acid or ester. We investigated the sulfonation of this pyro acid and found that sulfodehydroabietic acid can be obtained easily from this source in 61–63% yield, the non-aromatic hydro compounds and companion substances being left completely in the water-insoluble residue. It was next found that the sulfonic acid group can be removed smoothly by acid hydrolysis at 135° to give, after a single crystallization, dehydroabietic acid of perhaps slightly higher purity than that obtained from hydroxyabietic acid. The entire process is rapid, and the over-all yield of pure material from abietic acid is 42–43%.

Our purified sulfodehydroabietic acid melts with decomposition at about 248°, depending upon the manner of heating, and the analytical data correspond most closely with the formula for a hemihydrate. Hasselstrom and McPherson,[9b] on the other hand, obtained a trihydrate, m. p. 224° (uncorr.) dec., and Fanica,[10] who probably had the same sulfonic acid in hand, reports the m. p. 214° (uncorr.), dec. The free acid does not appear suitable for identification or determination of the empirical formula, but Hasselstrom and McPherson[9b] found that the diesters and the diamide fulfil these purposes, and they showed that the acid indeed belongs to the dehydro series. Our sample of the sharply melting dimethyl ester, prepared with diazomethane, corresponded exactly with theirs and analyses of this derivative and of the *p*-toluidine salt confirmed their conclusion. We can also supply the further evidence that the acid is a derivative, specifically, of the known[2] partially aromatic dehydroabietic acid, for we obtained the same acid, identified as the diester, from the pure dehydro acid as from pyro acid, and converted it into the dehydro acid as described above.

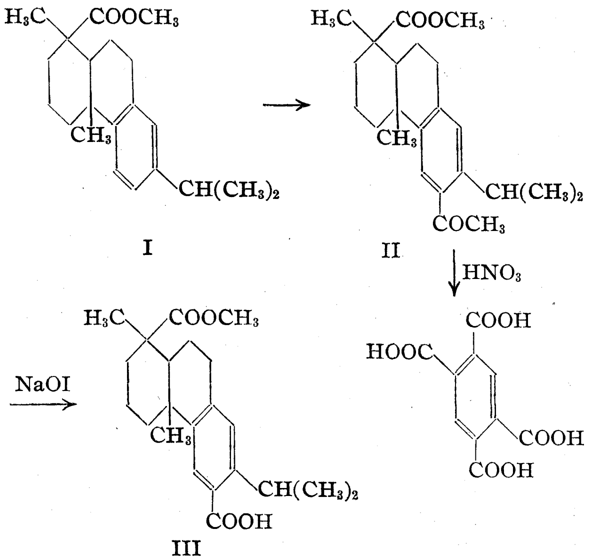
Attempts to convert sulfodehydroabietic acid into the corresponding phenol were unsuccessful. The acid is resistant to the action of alkali until a critical temperature is reached at about 300°, and at this temperature complex changes occur. The fusion was conducted in an autoclave in an atmosphere of nitrogen to avoid oxidation, but the product was found to be a mixture of at least four substances. The top fraction gave a nicely crystalline substance (A) of constant melting point (196.5–197.5°), but analyses indicated the presence of 2.5 atoms of oxygen and the substance yielded two distinctly different anilides. One of these (m. p. 257°) corresponded in composition to the anilide of an acid $C_{19}H_{24}O_3$ or $C_{20}H_{26-28}O_3$. The substance evidently contains one oxygen atom beyond that coming from the carboxyl group and may be the anilide of the desired hydroxydehydroabietic acid, $C_{20}H_{28}O_3$. The analyses of the second anilide agree best with the formula $C_{19}H_{22}O_2$ for the acid; this would be dehydroabietic acid less one molecule each of methane and hydrogen (naphthalene nucleus?). The more soluble fraction from the alkali fusion yielded only crystallizates of varying melting point, and one of these (B, composition: $C_{19}H_{26}O_2$) gave two constantly melting products on reaction of the acid chloride with aniline. One of these corresponds to the anilide of an acid $C_{19}H_{26}O_2$ (compare dehydroabietic acid: $C_{20}H_{28}O_2$). The anilides are resistant to hydrolysis, and the corresponding acids were not isolated. The results show only that the alkali fusion of the sulfonic acid is accompanied by extensive side reactions involving considerable alteration of the original structure. The phenolic hydroxyl group, if produced, is largely lost, and the molecule seems to suffer dehydration, dehydrogenation, or loss of a carbon atom in the alkali melt. Since substance A, which appears to be a molecular aggregate, was found to yield retene in 68% yield on dehydrogenation with palladium catalyst, it is probable that the carbon atom lost is that of the angular methyl group at C_{12}. With the realization that a phenolic derivative is at least not easily obtainable in quantity from this source, a further study of the fusion was not pursued.

Nitration of sulfodehydroabietic acid with mixed acid at a low temperature gave dinitrodehydroabietic acid, identical with that obtained directly from the dehydro acid.[2] A mononitro compound has not been obtainable in either reaction, even under very gentle conditions, and the smooth introduction of two nitro groups must mean that they enter meta positions. Since the only such positions available are 6 and 8, the dinitro compound very probably is the 6,8-derivative, as previously formulated.[2]

Having been unable to establish the point of attack in monosubstitution from a study of the

---

(10) Fanica, *Bull. inst. pin*, **44**, 151 (1933).



sulfonic acid, we investigated the Friedel and Crafts condensation of methyl dehydroabietate with acetyl chloride in nitrobenzene solution. This gave in good yield a beautifully crystalline and sharply melting monoacetyl derivative (II) which was characterized as the oxime and which yielded a crystalline acid on saponification. The structure was established by oxidation with dilute nitric acid, which gave a substance identified as pyromellitic acid. This proves that the acetyl group occupies the 6-position (II). Oxidation with hypoiodite in dioxane–alkali, following the procedure of Fuson and Tullock's[11] haloform test as used by Adelson and Bogert[12] for a similar oxidation of 6-acetylretene, gave methyl 6-carboxydehydroabietate, III. These and other substitution products are being investigated further.

Experimental Part[13]

Sulfodehydroabietic Acid.—One gram of the pyroabietic acid mixture of Fleck and Palkin[5] was sulfonated at −5° by a procedure similar to that of Fanica[10] and described in more detail below. The crystalline material separating from the filtered aqueous solution was crystallized once from glacial acetic acid, giving 0.76 g. (60%) of the sulfonic acid, m. p. 230° dec. After a second crystallization from this solvent the material was taken up in hot water and a small amount of insoluble resin was removed with Norite before crystallization. A further crystallization from glacial acetic acid gave very fine silky needles which when dried at 110° and 15 mm. over phosphorus pentoxide had the m. p. 247–248° dec., the temperature of decomposition varying considerably with the initial temperature of the bath and the rate of heating; $[\alpha]^{25}_{D}$ +72.4° (2.5% in alcohol[14]).

Anal. Calcd. for $C_{20}H_{28}O_5S \cdot {}^1/_2H_2O$: C, 61.68; H, 7.50; S, 8.22; neut. equiv., 195. Found: C, 61.03; H, 7.65; S, 7.85; neut. equiv., 194.

p-Toluidine Salt.—One-half gram of crude sulfonic acid, m. p. 230° dec., was dissolved in 20 cc. of water and the solution was freed from a trace of resin with Norite and treated with 0.18 g. of p-toluidine, brought into solution in 4 cc. of water with the use of the required amount of acetic acid. The mixture was heated to boiling and enough acetic acid was added to dissolve the gelatinous precipitate which initially separated. On cooling there was obtained 0.48 g. of crystalline salt, m. p. 271° dec. Recrystallization from alcohol gave fine silky needles of the same m. p.; $[\alpha]^{25}_{D}$ +57° (1.3% in alcohol).

Anal. Calcd. for $C_{27}H_{37}O_5SN$: N, 2.87. Found: N, 3.19.

Dimethyl Ester.—On adding excess diazomethane solution to a suspension of 0.5 g. of the pure sulfonic acid in ether the material rapidly dissolved, and after evaporating the filtered solution 0.34 g. of fine needles separated on cooling, m. p. 175–176°, $[\alpha]^{25}_{D}$ +76.2° (0.5% in alcohol). Further crystallization did not change the melting point.

Anal. Calcd. for $C_{22}H_{32}O_5S$: C, 64.69; H, 7.88. Found: C, 64.79; H, 8.06.

Sulfonation of Pure Dehydroabietic Acid.—A 0.5-g. sample of the dehydro acid prepared from hydroxyabietic acid[2] was sulfonated as before and the product crystallized once from glacial acetic acid. The yield of material, m. p. 230° dec., was 0.48 g. (73%). Esterified with diazomethane, 0.2 g. of this acid gave 0.15 g. of the dimethyl ester, m. p. 175–176°, and this did not depress the m. p. of the above sample.

Nitration of the Sulfonic Acid.—A solution of 0.6 g. of the sulfonic acid in 2.5 cc. of concentrated sulfuric acid was stirred in a salt–ice bath and treated with 0.1 cc. of concentrated nitric acid. After fifteen minutes the solution was poured into 300–400 cc. of water, giving a gelatinous precipitate containing a considerable amount of unchanged sulfonic acid. On bringing this into solution by heating there remained a small amount of water-insoluble precipitate. This was collected, washed well with water, and treated with excess diazomethane in ether. Crystallization of the product from hexane gave shiny, flat plates, m. p. 188–188.5°. A mixed melting point determination established the identity of this substance with methyl dinitrodehydroabietate[2] (m. p. 189–189.5°).

A mononitro derivative could not be obtained on nitration with mixed acids or in acetic acid solution.

Preparation of Pure Dehydroabietic Acid.—Pure abietic acid (47.5 g.) of the quality previously specified[2] was heated with palladium catalyst at 250° according to Fleck and Palkin[5] and the acidic product was extracted from an ethereal solution with 1% sodium hydroxide, precipitated with dilute acid, and crystallized once from aqueous alcohol, giving 38.5–40.5 g. (81–86%) of pyro acid. This acid (38.5–40.5 g.) was powdered and added rather rapidly (about ten minutes) with mechanical stirring to 200 cc. of concentrated sulfuric acid, keeping the tempera-

[14] 95% Ethyl alcohol.

ture at −8 to −4°. After forty-five minutes the mixture was poured into 800 cc. of ice and water and the precipitated sulfonic acid was collected and washed with cold water until the wash water became cloudy on mixing with the mother liquor. Crystallization from water at this point was unsatisfactory, for the resin present formed an emulsion which could not be filtered, and the moist product was therefore crystallized from glacial acetic acid (about 200 cc.), giving 27.5 g. of satisfactory acid. The mother liquor was concentrated to a volume of about 50 cc. and poured into 800 cc. of water; some resin was removed by filtering through glass wool, and the sulfonic acid was precipitated by the addition of 200 cc. of concentrated hydrochloric acid and crystallized from glacial acetic acid, giving 3.6 g. of product. The total yield of material, m. p. 230°, dec., was 30.5–31 g. (61–63%).

A suspension of 31 g. of the powdered sulfonic acid in a mixture of 750 cc. of concentrated sulfuric acid and 1000 cc. of water was refluxed for ten hours, the temperature of the liquid being about 135°. The appearance of the suspended solid changes considerably during the heating and the progress of the hydrolysis is followed readily. After cooling, the solid was collected and washed with hot water. A solution of the dried material (19.1 g.) in 200 cc. of alcohol was clarified with a little Norite and water was added at the boiling point to incipient turbidity. On slow cooling there was obtained 17.3 g. (71%) of crystalline dehydroabietic acid, m. p. 173–173.5°,[15] $[\alpha]^{25}_D$ +62° (2.3% in alcohol[16]). The mother liquor and washings were combined and treated with 400 cc. of concentrated hydrochloric acid, and after standing overnight at 5° the crystalline sulfonic acid which separated was collected and dried; weight 5 g. Based on the amount of sulfonic acid consumed, the yield of dehydroabietic acid in the hydrolysis is 84% of the theoretical amount and the overall yield from abietic acid averaged 42–43%.

The melting point is slightly higher and sharper than observed with samples prepared by the earlier method. A further indication of the purity of the acid is that esterification with diazomethane gave an ester which crystallized at once and melted at 61–62.5° without further purification. For the pure ester Fleck and Palkin[4] give the m. p. 62–63°.

Alkali Fusion of the Sulfonic Acid.—In trial fusions carried out in the open at atmospheric pressure there was so much oxidation and decomposition that in subsequent experiments the fusion was run in an autoclave in an atmosphere of nitrogen. The acid was recovered entirely unchanged after heating with 25% potassium hydroxide solution under nitrogen at 280–285°, whether the heating was continued for fifteen minutes or for ten hours; fusion occurred, however, when the temperature was raised to 300°.

After heating 10.5 g. of sulfonic acid with 45 g. of potassium hydroxide and 90 cc. of water under nitrogen in an autoclave at 300° (thermocouple) for one hour, a solid layer separated on top of the aqueous solution on cooling. The solid was dissolved in water, acidified, and the precipitate washed, dried, and taken into ether. After filtering and concentrating, the ether was displaced by hexane, and on cooling 0.85 g. of solid, m. p. 183–187°, separated. The material in the mother liquor was distilled at 3 mm., and crystallization of the distillate from hexane gave a further batch of the above high-melting solid. The combined solid was distilled at 3 mm. and on crystallization from ether–hexane gave 0.75 g. of colorless prisms, m. p. 193–194.5°. The substance is moderately soluble in ether or methanol and slightly soluble in hexane. Repeated crystallization from methanol gave material melting constantly at 196.5–197.5° (Product A).

Anal. Found: C, 78.45, 78.77; H, 8.15, 8.28; neut. equiv., 301; mol. weight (Rast), 291.

An empirical formula calculated from the analytical data would contain 2.5 atoms of oxygen, which indicates that the material is a mixture or a molecular aggregate. The same substance was obtained on fusing the dimethyl ester of the sulfonic acid under similar conditions. The substance is slowly attacked by alkaline or neutral permanganate. Dehydrogenation by heating 0.4 g. of material, m. p. 194–195°, with 0.1 g. of 10% palladium charcoal under nitrogen at 290–300° for three hours gave, after extraction of the product and crystallization from methanol, 0.21 g. (68%) of retene, m. p. 99–99.5°. Treatment with sulfur at 300° also yielded retene.

No constantly melting substance could be isolated from the mother liquors remaining after removal of the high-melting product. The material is very soluble in all organic solvents. One fraction, m. p. 159.5–160.5°, had the neutralization equivalent 310; another, m. p. 167–169° (Product B), from a fusion of the dimethyl ester, gave the values: C, 79.45; H, 9.13. This corresponds to $C_{19}H_{26}O_2$ (Calcd.: C, 79.68; H, 9.15), and the result shows at least that no phenolic hydroxyl group is present.

Anilides from Fusion Product A.—One gram of material (m. p. 194–195°) was warmed on the steam-bath with 0.7 g. of phosphorus pentachloride, then stirred with 2.5 cc. of aniline, and the product washed in ether with water, acid and alkali. On concentrating the dried solution, a 0.32-g. crop of crystals, m. p. 250–255°, was obtained, and the mother liquor material on crystallization from methanol gave 0.38 g. of crystals, m. p. 110°. The higher melting anilide on crystallization from acetone gave diamond shaped leaves melting constantly at 255.5–257°. It is slightly soluble in ether and moderately soluble in acetone or methanol.

		C	H	N

	$C_{26}H_{33}O_2N$:	79.77	8.50	3.58
	Found:	80.29	8.06	3.78

The lower melting anilide, after removal of the less soluble product by partial solution in ether, was crystallized from methanol to the constant m. p. 114–114.5° (fine needles).

Anal. Calcd. for $C_{25}H_{27}ON$: C, 84.00; H, 7.61; N, 3.92. Found: C, 84.10; H, 7.81; N, 4.30.

---

[15] Ruzicka and co-workers[8] comment on their observation that a sample of dehydroabietic acid prepared from the purified ester did not show a sharp melting point, as reported in our first description of the compound. We have obtained sharply melting samples by both the previous and present method of preparation on numerous occasions, and Fleck and Palkin's[4] sample of acid from the pure ester melted over a 1°-range.

[16] In stating that we did not specify the solvent used in determining the rotation, Ruzicka and co-workers[8] evidently overlooked Note 45 of our paper.

Anilides from Fusion Product B.—Material melting at 165° gave a mixture of anilides from which the following seemingly homogeneous products were isolated: fine needles from aqueous acetone, m. p. 214–215°; long flat needles from methanol, m. p. 147.5–148°. The second substance was analyzed as follows:

Anal. Calcd. for $C_{25}H_{31}ON$: C, 83.07; H, 8.63; N, 3.87. Found: C, 83.31; H, 8.87; N, 3.89.

Attempts to hydrolyze various samples of anilides were unsuccessful. The trials included treatment with boiling 10% butyl alcoholic potassium hydroxide (unattacked), aqueous alkali and ethylene glycol at 150° (unattacked), and sodium ethylate at 180° (acidic gum).

Methyl 6-Acetyldehydroabietate.—A solution of 9.4 g. of methyl dehydroabietate and 2.3 cc. of acetyl chloride in 50 cc. of nitrobenzene was stirred at 0–5° and treated with 8.25 g. of aluminum chloride. After this had gone into solution the mixture was allowed to stand for thirty-six hours at 5° and then poured onto ice and 20 cc. of concentrated hydrochloric acid and steam distilled. The residue, which solidified on cooling, was taken up in ether and after washing with aqueous bicarbonate the solution was dried over sodium sulfate and treated with Darco 6–60, which removed practically all of the color. After concentration the solution deposited in three crops 6.6 g. of long, heavy transparent prisms, often 2–3 mm. thick. On working the mother liquor as described below there was obtained 0.4 g. more of the prisms (pure); total yield of prisms, 66%. The acetyl compound was purified by crystallization from ether (prisms) and aqueous acetone (flat needles of the same m. p.) and melted sharply at 133.5–134°, $[\alpha]^{25}D$ +56° (0.9% in alcohol).

Anal. Calcd. for $C_{23}H_{32}O_3$: C, 77.47; H, 9.03. Found: C, 77.49, 77.14; H, 8.84, 9.00.

For proof of structure 0.5 g. of the 6-acetyl compound was heated in a sealed tube with 1 cc. of concentrated nitric acid and 2 cc. of water at 190° for thirteen hours, and for twelve hours longer after adding 1 cc. of fresh acid. Evaporation of the clear solution to dryness gave a white solid which was stirred and washed with fuming nitric acid and sublimed at 250° (20 mm.) to yield pyromellitic anhydride, m. p. and mixed m. p. with an authentic sample, 282–285°.

The oxime was prepared by refluxing for one hour a mixture of 0.25 g. of the 6-acetyl compound, 0.5 g. of hydroxylamine hydrochloride, 0.7 g. of potassium acetate, 3 cc. of water, and 10 cc. of alcohol. The product was thrown out with water and crystallized from ether–petroleum ether to give needles, m. p. 151.5–152°; yield, 0.2 g. (77%); $[\alpha]^{25}D$ +83° (1.6% in alcohol). Using pyridine in place of potassium acetate solution the yield was 90%.

Anal. Calcd. for $C_{23}H_{33}O_3N$: N, 3.77. Found: N, 3.94.

From the ethereal mother liquor of the Friedel and Crafts reaction product there was obtained what appears to be a different crystalline modification of the 6-acetyl ester. After removal of the 6.6 g. of prisms, the solution on concentration deposited a crystallizate consisting largely of needles, which when crystallized twice from ether–petroleum ether gave 0.45 g. of fine needles, m. p. 117–119°. The remaining ethereal mother liquor when concentrated and treated with petroleum ether then gave crops consisting chiefly of the higher melting prisms, mixed with some needles, and purification by mechanical separation and crystallization gave 0.4 g. of pure prisms. After two recrystallizations of the more soluble, low melting material (0.45 g.) from ether–hexane, the substance was obtained as fine needles melting sharply at 119.5–120° (0.35 g.); $[\alpha]^{25}D$ +58 (0.7% in alcohol).

Anal. Calcd. for $C_{23}H_{32}O_3$: C, 77.47; H, 9.03. Found: C, 77.48, 77.11; H, 8.57, 9.13.

Mixtures of this substance with the prism form melted at intermediate temperatures. The oxime, prepared as above from 0.1 g. of needles, melted at 150–150.5° and did not depress the m. p. of the other sample. A 0.1-g. sample of needles was oxidized as above but using only one charge of acid (seventeen hours) and the reaction product treated with excess diazomethane. The resulting ester when crystallized twice from methanol melted at 141–142°, with some previous softening, and a mixture of this with authentic pyromellitic acid tetramethyl ester, m. p. 142.5–143.5° (sharp) melted at 141–143°. The structure therefore is that of methyl 6-acetyldehydroabietate, and since the rotation, as tested on small samples, is practically the same for the needles as for the prisms, stereoisomerism is unlikely. Consequently, although an interconversion was not observed, it is believed that the two substances are different modifications of the same chemical individual.

6-Acetyl Dehydroabietic Acid.—One-half gram of the acetyl ester was refluxed for three hours with 15 cc. of alcohol containing 1 g. of potassium hydroxide. A small amount of white solid precipitated on adding water and was removed by filtration (plates from ether–petroleum ether, m. p. 117–117.5°). The alkaline filtrate was acidified and the precipitate dried in ether and crystallized from ether–petroleum ether (20–40°), giving fine, silky needles, m. p. 174.5–175° (0.2 g.); $[\alpha]^{25}D$ +74° (1% in alcohol).

Anal. Calcd. for $C_{22}H_{30}O_3$: C, 77.14; H, 8.82; neut. equiv., 342. Found: C, 76.89; H, 9.05; neut. equiv., 344.

Methyl 6-Carboxydehydroabietate.—Iodine–potassium iodide solution was added to a solution of 2.5 g. of methyl 6-acetyldehydroabietate in 100 cc. of dioxane and 20 cc. of 10% sodium hydroxide solution until the color persisted for two minutes at 60° after a fresh addition. The solution was diluted with 600 cc. of water, filtered from iodoform, treated with a little bisulfite and acidified. The gummy yellow precipitate was extracted from ether into 1% alkali, and the substance then separated on acidification as a white solid. One crystallization from hexane gave 0.4 g. of material, m. p. 165–180°, and on three crystallizations from acetone the compound formed fine, silky needles melting constantly at 190–191.5°; $[\alpha]^{25}D$ +74° (0.9% in alcohol).

Anal. Calcd. for $C_{22}H_{30}O_4$: C, 73.69; H, 8.44; neut. equiv., 358. Found: C, 73.38; H, 8.50; neut. equiv. (40-mg. sample), 344.

Summary

Pure dehydroabietic acid may be obtained readily in quantity by sulfonating the palladium-

treated pyroabietic acid of Fleck and Palkin and hydrolyzing the crystalline sulfonic acid. Fusion of the sulfonic acid with alkali results in extensive alteration of the molecule and under the conditions studied gives a mixture of several products.

Methyl dehydroabietate reacts smoothly with acetyl chloride in nitrobenzene solution in the presence of aluminum chloride and gives a sharply melting product characterized as the 6-acetyl derivative. This was hydrolyzed to the free acid and oxidized with hypohalite to methyl 6-carboxydehydroabietate.

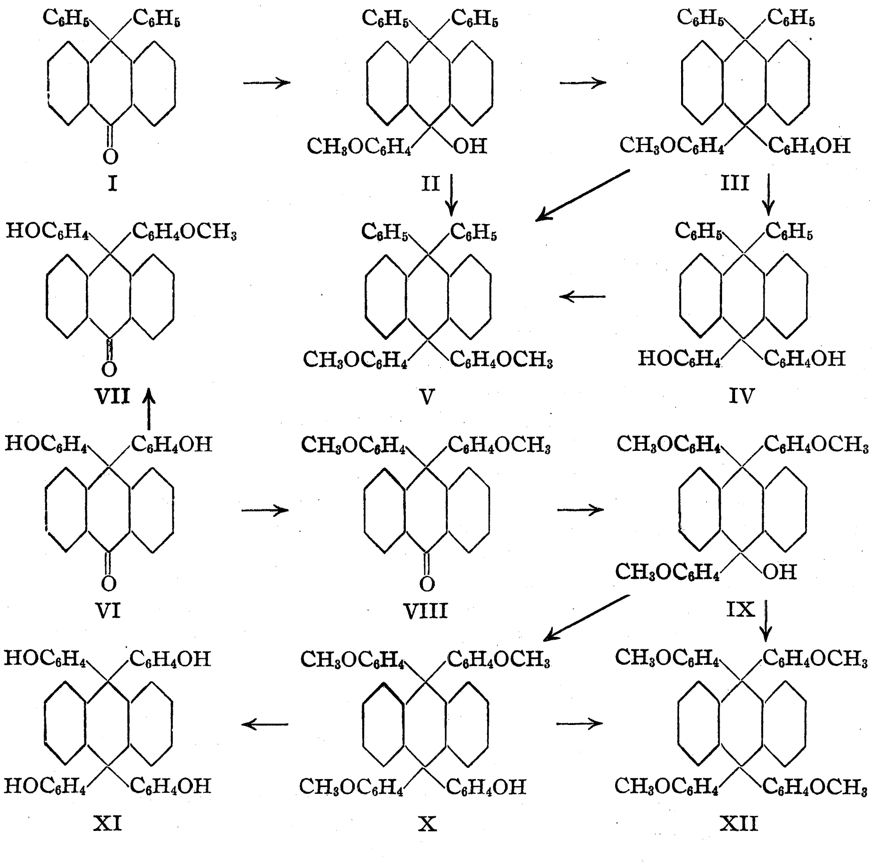
Hydroxy- and Methoxyphenyldihydroanthracenes

BY F. F. BLICKE AND R. A. PATELSKI[1]

Very few substitution products of 9,10-dihydroanthracene are known in which aryl groups occupy *meso* positions and it seems that hydroxyaryl derivatives such as 9,9,10-tri- and 9,9,10,10-tetra-(*p*-hydroxyphenyl)-9,10-dihydroanthracene, compounds in which we were especially interested, have never been prepared.



Since the carbonyl group in a 9,9-diarylanthrone-10 reacts toward an arylmagnesium halide in the characteristic manner, it was possible to convert the carbonyl compound into a tertiary carbinol which represents a 9,9,10-triaryl-10-hydroxy-9,10-dihydroanthracene. The hydroxyl group of the latter proved to be especially reactive toward phenol and anisole in the presence of a small amount of sulfuric acid, hence the hydroxyl group could be replaced by the hydroxyphenyl and anisyl nuclei and in this way a tetraaryl-9,10-dihydroanthracene could be obtained. Demethylation, in the case of the anisyl compounds, yielded the desired hydroxy derivatives.

It has been found that 9,9-diphenylanthrone-10 (I) reacts with *p*-anisylmagnesium iodide to yield 9,9-diphenyl-10-hydroxy-10-(*p*-anisyl)-9,10-dihydroanthracene (II); this product was converted readily into its carbinol methyl ether by methyl alcohol and hydrogen chloride. Compound II condensed with phenol, in the presence of a small amount of sulfuric acid, to yield 9,9-diphenyl-10-(*p*-hydroxyphenyl)-10-(*p*-anisyl)-9,10-dihydroanthracene (III), and with anisole to produce 9,9-diphenyl-10,10-di-(*p*-anisyl)-9,10-dihydroanthracene (V). Compound V was obtained also by methylation of compounds III and IV. By demethylation of the last named

---

[1] Monsanto-Pfizer Research Associate.

substance (III) there was produced 9,9-diphenyl-10,10-di-(*p*-hydroxyphenyl)-9,10-dihydroanthracene (IV).

9,9-Di-(*p*-hydroxyphenyl)-anthrone-10 (VI) was converted by methyl sulfate into its monomethyl ether, 9-(*p*-hydroxyphenyl)-9-(*p*-anisyl)-anthrone-10 (VII), or into its dimethyl ether, 9,9-di-(*p*-anisyl)-anthrone-10 (VIII). Furthermore, the monomethyl ether (VII) was prepared by condensation of 9-hydroxy-9-(*p*-anisyl)-anthrone-10 with phenol in the presence of sulfuric acid.

Compound VIII reacted with *p*-anisylmagnesium iodide to form 9,9,10-tri-(*p*-anisyl)-10-hydroxy-9,10-dihydroanthracene (IX); condensation of the anthracene with phenol yielded 9,9,10-tri-(*p*-anisyl)-10-(*p*-hydroxyphenyl)-9,10-dihydroanthracene (X). Upon demethylation of compound X there was obtained 9,9,10,10-tetra-(*p*-hydroxyphenyl)-9,10-dihydroanthracene (XI).

9,9,10,10-Tetra-(*p*-anisyl)-9,10-dihydroanthracene (XII) was prepared by condensation of compound IX with anisole and by methylation of compound X.

Experimental Part

9,9-Diphenyl-10-hydroxy-10-(*p*-anisyl)-9,10-dihydroanthracene (II).—A solution of 30 g. of 9,9-diphenylanthrone (I)[2] in 100 cc. of dry benzene was added, gradually, to the Grignard reagent prepared from 35.4 g. of *p*-anisylmagnesium iodide, 3.7 g. of magnesium and 100 cc. of ether. The mixture was refluxed for five hours, decomposed with ice and ammonium chloride, the ether–benzene layer separated, filtered, steam distilled and the oily residue covered with methyl alcohol. After three days the product became crystalline; yield 22.5 g.; m. p. 142–144° after recrystallization from a mixture of ether and petroleum ether (30–60°).

Anal. Calcd. for $C_{33}H_{26}O_2$: C, 87.18; H, 5.77. Found: C, 86.88; H, 5.79.

In order to obtain the carbinol methyl ether, a methyl alcohol solution of the anthracene was partially saturated with hydrogen chloride and after one hour the solvent was removed and the ether recrystallized from acetic acid; m. p. 191–193°.

Anal. Calcd. for $C_{34}H_{28}O_2$: C, 87.14; H, 6.03. Found: C, 87.18; H, 6.09.

9,9-Diphenyl-10-(*p*-hydroxyphenyl)-10-(*p*-anisyl)-9,10-dihydroanthracene (III).—A mixture of 20 g. of compound II, 30 g. of phenol and five drops of concd. sulfuric acid was heated on a steam-bath for two hours, the product washed thoroughly with hot water and the colorless crystals recrystallized from methyl alcohol; yield 23 g.; m. p. 250–252°.

Anal. Calcd. for $C_{39}H_{30}O_2$: C, 88.26; H, 5.73. Found: C, 87.96; H, 5.68.

9,9-Diphenyl-10,10-di-(*p*-anisyl)-9,10-dihydroanthracene (V).—This product was obtained when a mixture of 1.0 g. of compound II, 3.0 g. of anisole and one drop of sulfuric acid was heated on a steam-bath for one hour. After recrystallization from acetic acid the colorless material melted at 233–235°.

Anal. Calcd. for $C_{40}H_{32}O_2$: C, 88.19; H, 5.94. Found: C, 88.26; H, 5.92.

In order to prepare compound V by methylation of compound III, 2.0 g. of the latter, 6.0 g. of sodium hydroxide and 30 cc. of 50% alcohol were refluxed and 5 cc. of dimethyl sulfate added gradually. The mixture was heated for one hour. The product obtained weighed 1.9 g. and melted at 233–235° after recrystallization from acetic acid.

9,9-Diphenyl-10,10-di-(*p*-hydroxyphenyl)-9,10-dihydroanthracene (IV).—A solution of 5 g. of compound III, 25 cc. of constant boiling hydrobromic acid and 150 cc. of acetic acid was refluxed for five hours, the precipitated material separated and the solution concentrated, whereupon more material separated; total yield 3.9 g.; m. p. 343–345° after recrystallization from acetic acid.

Anal. Calcd. for $C_{38}H_{28}O_2$: C, 88.33; H, 5.46. Found: C, 88.14; H, 5.52.

The di-3-bromobenzoyl derivative was prepared in the following manner: 2 g. of the anthracene and 5 g. of 3-bromobenzoyl chloride were heated for an hour at 190–200° and the mixture treated with hot alcohol. The ester was recrystallized from ethyl acetate; m. p. 231–233°.

Anal. Calcd. for $C_{52}H_{34}O_4Br_2$: Br, 18.13. Found: Br, 17.92.

The dimethyl ether was obtained when compound IV was methylated with dimethyl sulfate and alkali in dilute alcohol. It proved to be identical with compound V; mixed m. p. 233–235°.

9-(*p*-Hydroxyphenyl)-9-(*p*-anisyl)-anthrone-10 (VII).—A solution of 3.8 g. of 9,9-di-(*p*-hydroxyphenyl)-anthrone-10 (VI)[3] in 50 cc. of 20% sodium hydroxide solution was heated to 80° and treated, gradually, with 10 cc. of dimethyl sulfate. The precipitated product was recrystallized from acetic acid; m. p. 232–233°; yield 2.5 g.

Anal. Calcd. for $C_{27}H_{30}O_3$: C, 82.62; H, 5.14. Found: C, 82.51; H, 5.06.

We also prepared the anthrone by heating a mixture of 10 g. of 9-hydroxy-9-(*p*-anisyl)-anthrone-10 (XIII),[4] 25 g. of phenol and three drops of sulfuric acid for one hour on a steam-bath. The product was washed with hot water and recrystallized from acetic acid; yield 9 g.; mixed m. p. 232–233°.

9,9-Di-(*p*-anisyl)-anthrone-10 (VIII).—A mixture of 7.6 g. of 9,9-di-(*p*-hydroxyphenyl)-anthrone-10, 100 cc. of alcohol and 100 cc. of 10% sodium hydroxide solution was refluxed and 30 cc. of dimethyl sulfate added gradually. It was heated for one hour and the crystalline precipitate recrystallized from acetic acid; m. p. 208–209°.[5]

[5] Scharwin, Naumof and Sandurin [*Ber.*, **37**, 3619 (1904)], who obtained the anthrone by another method, reported 208°.

The anthrone was prepared also by methylation of compound VII according to the procedure just described.

9,9,10-Tri-(*p*-anisyl)-10-hydroxy-9,10-dihydroanthracene (IX).—Sixteen grams of compound VIII, dissolved in 75 cc. of benzene, was added, gradually, to the Grignard reagent obtained from 18.9 g. of *p*-iodoanisole, 2.0 g. of magnesium and 75 cc. of ether. The mixture was refluxed for five hours, decomposed with ice and ammonium chloride, the ether–benzene layer filtered and the solution steam distilled. The crystalline residue was recrystallized from acetic acid; yield 15 g.; m. p. 226–228°.

Anal. Calcd. for $C_{35}H_{30}O_4$: C, 81.64; H, 5.91. Found: C, 81.42; H, 5.89.

The methyl ether was obtained when a methyl alcohol solution of the anthracene was partially saturated with hydrogen chloride; m. p. 205–206° after recrystallization from acetic acid.

Anal. Calcd. for $C_{36}H_{32}O_4$: C, 81.78; H, 6.11. Found: C, 81.52; H, 6.13.

9,9,10-Tri-(*p*-anisyl)-10-(*p*-hydroxyphenyl)-9,10-dihydroanthracene (X).—A mixture of 5 g. of compound IX, 20 g. of phenol and three drops of sulfuric acid was heated on a steam-bath for three hours, the material washed with hot water and recrystallized from acetic acid; yield 5 g.; m. p. 310–312°.

Anal. Calcd. for $C_{41}H_{34}O_4$: C, 83.35; H, 5.81. Found: C, 83.07; H, 5.84.

9,9,10,10-Tetra-(*p*-hydroxyphenyl)-9,10-dihydroanthracene (XI).—Two grams of compound X, 20 cc. of constant boiling hydrobromic acid and 300 cc. of acetic acid were refluxed for five hours. The mixture was concentrated to a volume of about 75 cc. and poured into 200 cc. of water. The precipitated product was recrystallized from dilute alcohol; m. p. 371–374°.[6] The compound dissolves readily in dilute alkali.

Anal. Calcd. for $C_{38}H_{28}O_4$: C, 83.18; H, 5.15. Found: C, 82.92; H, 5.14.

One gram of the anthracene was heated with 5 g. of *m*-bromobenzoyl chloride for one hour at 190–200°. The material was washed with hot alcohol, then dissolved in hot acetic acid. When the solution cooled a small amount of colored by-product precipitated. The filtered solution was diluted with three volumes of methyl alcohol; the colorless precipitate, which was the tetra-*m*-bromobenzoyl derivative, melted at 163–168°.

Anal. Calcd. for $C_{66}H_{40}O_8Br_4$: Br, 24.99. Found: Br, 25.18.

9,9,10,10-Tetra-(*p*-anisyl)-9,10-dihydroanthracene (XII).—A boiling solution, obtained from 1 g. of compound X, 3 g. of sodium hydroxide and 20 cc. of 50% alcohol, was treated, gradually, with 5 cc. of dimethyl sulfate. The mixture was heated for one hour and the product recrystallized from acetic acid; m. p. 329–331°.[6]

Anal. Calcd. for $C_{42}H_{36}O_4$: C, 83.40; H, 6.01. Found: C, 83.38; H, 6.07.

The same anthracene was obtained when 1 g. of compound IX, 3 g. of anisole and one drop of sulfuric acid were heated for one hour on a steam-bath; mixed m. p. 329–331°.

Summary

A number of 9,9,10-tri- and 9,9,10,10-tetraaryldihydroanthracenes have been prepared in which the aryl groups are phenyl, *p*-hydroxyphenyl and *p*-anisyl.

Hydroxy- and Methoxyphenylanthrones. I.

BY F. F. BLICKE AND R. A. PATELSKI[1]

It is well known that interaction between phthalic anhydride and aromatic hydrocarbons or simple substitution products of the latter yields 2-acylbenzoic acids, diarylphthalides and anthraquinones; other products are formed also but their nature is not known.

It seems to us that in the reaction between phthalic anhydride and phenol, hydroxyphenylanthrones, such as 3,9-dihydroxy-9-(*p*-hydroxyphenyl)-anthrone-10, might be formed and that these anthrones, by further reaction with phenol, might be converted into hydroxy derivatives of diphenylanthrones, tri- and tetraphenyldihydroanthracenes. The hydroxyl groups can occupy either ortho or para positions in the phenyl nuclei and either a 1-, 2-, 3- or 4-position in the anthrone or anthracene nucleus. Since only a few representatives of such compounds have been described in the literature we have synthesized a number of them, often by several different procedures, in order to establish their structure definitely.

In many instances the desired substance has been prepared, with the aid of a Grignard reagent, in the form of its methyl ether; the hydroxy compound was then obtained by demethylation However, this procedure was not always successful since, occasionally, demethylation was accompanied by disruption of the molecule; hence

---

[1] Monsanto–Pfizer Research Associate.

it became necessary to search for procedures by means of which the hydroxy compounds could be obtained directly.

Hitherto, we have obtained certain monoarylanthrones by interaction of an anthrone with an arylmagnesium halide,[2,3] by treatment of a diarylphthalin with sulfuric acid[3,4] or thionyl chloride[3] or by the action of phosphorus pentachloride on a diarylphthalide.[4] It should be mentioned that in some cases the action of sulfuric acid on a diarylphthalin yields a diarylbenzofuran or a mixture of a furan and an arylanthrone[2,3,4] (p. 276). In a paper which is to be published soon it will be shown that interaction of a diarylphthalin with zinc chloride yields an arylanthracene; upon oxidation of the latter an arylanthrone is produced.

Diarylanthrones, of the types in which we are interested, have been prepared by oxidation of a diaryldihydroanthracene; the latter were obtained by loss of water from 2-benzyltriphenylcarbinols.[5]

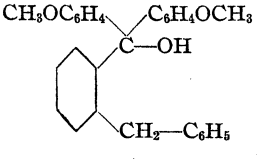
In order to obtain a triaryldihydroanthracene, a diarylanthrone was treated with an arylmagnesium halide.[6]

It was found that a tetra-(*p*-hydroxyphenyl)-dihydroanthracene could be synthesized by demethylation of 9,9,10-tri-(*p*-anisyl)-10-(*p*-hydroxyphenyl)-9,10-dihydroanthracene[6] (p. 2638).

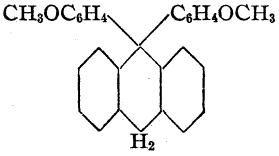
In this paper it has been shown that three different 2-benzyldimethoxytriphenylcarbinols can be converted into 9,9-dianisyl-9,10-dihydroanthracenes by loss of water. Subsequent oxidation and demethylation yielded, in each instance, the desired 9,9-di-(*p*-hydroxyphenyl)-anthrone-10.

It has been found that the ethyl ester of 2-benzylbenzoic acid reacts with two molecular equivalents of 4-anisylmagnesium iodide to yield 2-benzyl-4′,4″-dimethoxytriphenylcarbinol (I); the carbinol was prepared also from 2-(4″-methoxybenzoyl)-diphenylmethane and one molecular equivalent of the Grignard reagent.

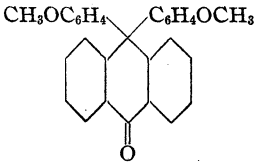
When the carbinol was treated with hydrogen chloride, water was eliminated with the formation of 9,9-di-(*p*-anisyl)-9,10-dihydroanthracene (II). Oxidation of the dihydroanthracene produced 9,9-di-(*p*-anisyl)-anthrone-10 (III) which can be converted into 9,9-di-(*p*-hydroxyphenyl)-anthrone-10 (IV) by demethylation with aluminum chloride. 9,9-Di-(*p*-hydroxyphenyl)-anthrone-10, prepared from anthraquinone, phenol and stannic chloride, according to the method of Scharwin and co-workers,[7] yielded compound III when methylated with dimethyl sulfate.



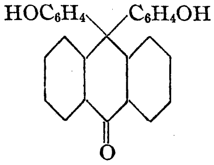
I



II



III



IV

When the ethyl ester of 2-(4′-methoxybenzyl)-benzoic acid was allowed to react with 4-anisylmagnesium iodide there was obtained 2-(4′-methoxybenzyl)-4″,4‴-dimethoxytriphenylcarbinol. This carbinol was converted, by loss of water, into 2-methoxy-9,9-di-(*p*-anisyl)-9,10-dihydroanthracene and the anthracene oxidized to 2-methoxy-9,9-di-(*p*-anisyl)-anthrone-10; upon demethylation 2-hydroxy-9,9-di-(*p*-hydroxyphenyl)-anthrone-10 was formed.

2-(2′-Methoxybenzyl)-4″,4‴-dimethoxytriphenylcarbinol was prepared from the ethyl ester of 2-(2′-methoxybenzyl)-benzoic acid and 4-anisylmagnesium iodide. Ring closure, by elimination of water, produced 4-methoxy-9,9-di-(*p*-anisyl)-9,-10-dihydroanthracene. 4-Methoxy-9,9-di-(*p*-anisyl)-anthrone-10, obtained by oxidation of the anthracene, was demethylated to yield 4-hydroxy-9,9-di-(*p*-hydroxyphenyl)-anthrone-10.

By interaction of ethyl 2-(4′-methoxybenzyl)-benzoate and 2-anisylmagnesium iodide there was obtained 2-(4′-methoxybenzyl)-2″,2‴-dimethoxytriphenylcarbinol which was converted, by ring closure, into 2-methoxy-9,9-di-(*o*-anisyl)-9,10-dihydroanthracene. So far we have been able to obtain the corresponding anthrone only in the form of a gum.

It was thought that 9,9-diarylanthrones might be prepared, easily, by condensation of anisole with a dibromoanthrone such as 3-methoxy-9,9-dibromoanthrone-10. However, we have not been able to effect this condensation. The dibromoanthrone reacts readily with mercury to

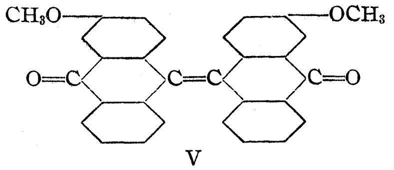
yield 2,2′(or 2,7′)-dimethoxydianthraquinone (V).[8]



V

Experimental Part

9,9-Di-(*p*-anisyl)-9,10-dihydroanthracene (II).—To the Grignard reagent, prepared from 28.7 g. of 4-iodoanisole, 3.0 g. of magnesium, 50 cc. of ether and 50 cc. of benzene, there was added, gradually, a solution of 6 g. of the ether ester of 2-benzylbenzoic acid,[9] dissolved in 25 cc. of benzene. The mixture was refluxed for three hours, decomposed with ice and ammonium chloride, the solvents removed and the product submitted to steam distillation to remove anisole and other by-products. Since the crude, gummy 2-benzyl-4′,4″-dimethoxytriphenylcarbinol could not be obtained in crystalline form it was prepared by a second method.

Four grams of 2-(4″-methoxybenzoyl)-diphenylmethane,[10] dissolved in 40 cc. of benzene, was added, gradually, to the Grignard reagent prepared from 6.1 g. of 4-iodoanisole, 0.64 g. of magnesium, 30 cc. of ether and 30 cc. of benzene. The mixture was refluxed for three hours and treated as described above. In this instance, too, the carbinol was obtained as a gummy product.

The carbinols, obtained by both procedures, were dissolved in acetic acid or alcohol, the solutions partially saturated with hydrogen chloride and the red mixtures heated for three hours on a steam-bath. Upon dilution with water oils were obtained which crystallized after they had been covered with a small amount of acetic acid for twelve hours. After several recrystallizations from methyl alcohol and then from acetic acid the colorless, crystalline products, obtained from both gummy carbinols, melted at 166–167°. This material was 9,9-di-(*p*-anisyl)-9,10-dihydroanthracene.

Anal. Calcd. for $C_{28}H_{24}O_2$: C, 85.67; H, 6.17. Found: C, 85.52; H, 6.20.

9,9-Di-(*p*-anisyl)-anthrone-10 (III).—A mixture of 0.7 g. of 9,9-di-(*p*-anisyl)-9,10-dihydroanthracene, 1.0 g. of sodium dichromate and 15 cc. of acetic acid was heated on a steam-bath for four hours, diluted with water and the precipitated anthrone recrystallized from alcohol and then from acetic acid; m. p. 208–209°. Mixed with a sample of 9,9-di-(*p*-anisyl)-anthrone-10, obtained by methylation[6] (p. 2637) of 9,9-di-(*p*-hydroxyphenyl)-anthrone-10[11] with dimethyl sulfate, the mixture melted at 208–209°.

2-(4′-Methoxybenzyl)-4″,4‴-dimethoxytriphenylcarbinol.—A solution of 20.3 g. of the ethyl ester of 2-(4′-methoxybenzyl)-benzoic acid[2] (p. 1464) in 50 cc. of ether was added to the Grignard reagent obtained from 46.8 g. of 4-iodoanisole, 4.8 g. of magnesium and 120 cc. of ether. The mixture was stirred, refluxed for five hours, decomposed with ice and ammonium chloride and a crystalline, ether-insoluble product removed by filtration. After removal of most of the solvent from the filtrate a crystalline material, the desired carbinol, was obtained; yield 17 g.; m. p. 147–148° after recrystallization from a mixture of benzene and petroleum ether (90–100°).

Anal. Calcd. for $C_{29}H_{28}O_4$: C, 79.05; H, 6.41. Found: C, 78.88; H, 6.46.

2-Methoxy-9,9-di-(*p*-anisyl)-9,10-dihydroanthracene.—A solution of 9.5 g. of the above-mentioned carbinol in 40 cc. of acetic acid was partially saturated with hydrogen chloride and the deep red solution heated on a steam-bath for three hours. The solution then possessed a strong purple fluorescence and, when cooled, deposited the dihydroanthracene in crystalline form; m. p. 167–168° after recrystallization from acetic acid; yield 8.5 g.

Anal. Calcd. for $C_{29}H_{26}O_3$: C, 82.42; H, 6.21. Found: C, 81.92; H, 6.21.

2-Methoxy-9,9-di (*p*-anisyl)-anthrone-10.—A solution of 8 g. of sodium dichromate in 10 cc. of hot water was added to 10 g. of the dihydroanthracene, suspended in 50 cc. of acetic acid, and the mixture heated for three hours on a steam-bath. Upon dilution with water the anthrone was precipitated; yield 8.5 g.; m. p. 183–184°[2] (p. 1464) after recrystallization from acetic acid.

2-Hydroxy-9,9-di-(*p*-hydroxyphenyl)-anthrone-10.—Five grams of anhydrous aluminum chloride was added to a solution of 2 g. of 2-methoxy-9,9-di-(*p*-anisyl)-anthrone-10 in 100 cc. of dry benzene and the mixture refluxed for twenty-four hours on a steam-bath. After treatment with ice and hydrochloric acid the benzene layer was separated, the solvent removed, the residue dissolved in alcohol and the solution decolorized with charcoal. Upon dilution of the solution with water a colorless, crystalline product was obtained which was recrystallized from dilute alcohol; yield 0.9 g.; m. p. 312–314° with decomposition.

Anal. Calcd. for $C_{26}H_{18}O_4$: C, 79.16; H, 4.60. Found: C, 78.98; H, 4.72.

Two grams of the hydroxy-anthrone, dissolved in 50 cc. of hot 10% sodium hydroxide solution was treated gradually with 8 cc. of dimethyl sulfate and the mixture refluxed for three hours. The precipitated material, 2-methoxy-9,9-di-(*p*-anisyl)-anthrone-10, weighed 1.2 g. and melted at 183–184°.

The tri-(3-bromobenzoyl) derivative was obtained when 1.4 g. of the hydroxy-anthrone was heated with 6.5 g. of 3-bromobenzoyl chloride at 140–150° in an oil-bath for two hours. The brown oil was washed thoroughly with 10% sodium hydroxide solution, with water and then with alcohol. The product was covered with ether and, after it had become crystalline, was recrystallized from acetic acid; m. p. 174–176°.

Anal. Calcd. for $C_{47}H_{27}O_7Br_3$: Br, 25.44. Found: Br, 25.12.

Ethyl 2-(2′-Methoxybenzoyl)-benzoate.—A mixture of 90 g. of 2-(2′-methoxybenzoyl)-benzoic acid, 600 cc. of

[8] 1,1′-Dimethoxydianthraquinone has been described by Attree and Perkin [*J. Chem. Soc.*, 163 (1931)] while 3,3′-dimethoxydianthraquinone was prepared by Barnett, Goodway and Savage [*Ber.*, **64**, 2193 (1931)] and by Perkin and Yode [*J. Chem. Soc.*, **127**, 1884 (1925)].

[9] Barnett, Cook and Nixon, *ibid.*, 508 (1927).

[10] Blicke and Swisher, This Journal, **56**, 925 (1934). We found the product melted at 78–79° instead of at 68–70° as reported previously.

[11] See ref. 7. These investigators obtained 9,9-di-(*p*-hydroxyphenyl)-anthrone-10 by demethylation of 9,9-di-(*p*-anisyl)-anthrone-10.

absolute alcohol and 25 cc. of concd. sulfuric acid was refluxed for twenty-four hours, one-third of the alcohol removed by distillation and the residue diluted with two liters of saturated sodium chloride solution. The precipitated oily ester was extracted with ether, the ether extract washed with sodium carbonate solution and then with water. The ether solution was dried with fused sodium sulfate and the solvent removed. The ester boiled at 268–270° under 14 mm. pressure; yield 70 g.

Anal. Calcd. for $C_{17}H_{18}O_3$: C, 75.52; H, 6.72. Found: C, 75.29; H, 6.69.

2 - (2′-Methoxybenzyl)-4″,4‴-dimethoxytriphenylcarbinol.—The Grignard reagent, prepared from 46.8 g. of 4-iodoanisole, 4.8 g. of magnesium and 120 cc. of ether, was stirred and to it there was added, slowly, a solution of 20.3 g. of ethyl 2-(2′-methoxybenzoyl)-benzoate in 50 cc. of ether. The mixture was stirred and refluxed for three hours and then allowed to remain at room temperature for twelve hours. The mixture was decomposed with ice and ammonium chloride. The carbinol was recrystallized from a mixture of benzene and petroleum ether (30–60°); m. p. 139–140°; yield 22.7 g.

Anal. Calcd. for $C_{29}H_{28}O_4$: C, 79.05; H, 6.41. Found: C, 79.11; H, 6.58.

4-Methoxy-9,9-di-(*p*-anisyl)-anthrone-10.—Ten grams of the above mentioned carbinol was dissolved in 50 cc. of acetic acid, the solution partially saturated with hydrogen chloride and the red solution heated for six hours on a steam-bath. The solution, which possessed a strong purple fluorescence, was diluted with water, whereupon a light brown solid, 4-methoxy-9,9-di-(*p*-anisyl)-9,10-dihydroanthracene, precipitated.

A mixture of 10 g. of the dihydroanthracene, 50 cc. of acetic acid, 8 g. of sodium dichromate and 10 cc. of water was heated for three hours on a steam-bath, diluted with four volumes of water and the precipitated, crystalline anthrone recrystallized from acetic acid; m. p. 248–250°.

Anal. Calcd. for $C_{29}H_{24}O_4$: C, 79.78; H, 5.54. Found: C, 79.39; H, 5.52.

4-Hydroxy-9,9-di-(*p*-hydroxyphenyl)-anthrone-10.—Two grams of finely powdered 4-methoxy-9,9-di-(*p*-anisyl)-anthrone-10 and 3 g. of powdered aluminum chloride was heated for one hour at 100–105°, the mixture treated with ice and hydrochloric acid and the gummy product extracted with 10% sodium hydroxide solution. A dark green solid precipitated when the alkaline extract was acidified. The product was dissolved in alcohol and the solution diluted, gradually, with water. A dark brown gum, which precipitated first, was discarded. The light yellow, crystalline precipitate was recrystallized from dilute alcohol; yield 0.8 g.; m. p. 254–256° with decomposition.

Anal. Calcd. for $C_{26}H_{18}O_4$: C, 79.16; H, 4.60. Found: C, 78.89; H, 4.81.

A solution of 0.4 g. of the anthrone in 10 cc. of 10% sodium hydroxide solution was heated to 80° and treated, gradually, with 2 cc. of dimethyl sulfate. The mixture was heated for two hours and the precipitated 4-methoxy-9,9-di-(*p*-anisyl)-anthrone-10 recrystallized from acetic acid; m. p. 247–249°

A mixture of 0.14 g. of the anthrone and 0.65 g. of 3-bromobenzoyl chloride was heated for two hours at 140–150°, the brown oil washed with 5% sodium hydroxide solution and then with water. The product crystallized when rubbed under ether; m. p. 163–165° after recrystallization from acetic acid.

Anal. Calcd. for $C_{47}H_{27}O_7Br_3$: Br, 25.44. Found: Br, 25.01.

2 - (4′-Methoxybenzyl)-2″,2‴-dimethoxytriphenylcarbinol.—Twenty-three grams of ethyl 2-(4′-methoxybenzyl)-benzoate, dissolved in 50 cc. of ether, was added to 2-anisylmagnesium iodide prepared from 50 g. of 2-iodoanisole, 6.7 g. of magnesium and 150 cc. of ether. The mixture was stirred and refluxed for six hours, the crystalline precipitate removed by filtration and decomposed with ice and ammonium chloride. The crystalline product was recrystallized from petroleum ether (90–100°); yield 26 g.; m. p. 129–130°.

Anal. Calcd. for $C_{29}H_{28}O_4$: C, 79.05; H, 6.41. Found: C, 79.19; H, 6.27.

2 - Methoxy-9,9-di-(*o*-anisyl)-9,10-dihydroanthracene.—A solution of 23 g. of the carbinol described above in 75 cc. of acetic acid was partially saturated with hydrogen chloride and heated for five hours on a steam-bath. The solution, which possessed a high purple fluorescence, was diluted with four parts of water and the oily precipitate, which soon crystallized, was recrystallized from methyl alcohol; m. p. 154–155°.

Anal. Calcd. for $C_{29}H_{26}O_3$: C, 82.42; H, 6.21. Found: C, 82.17; H, 6.27.

3-Methoxy-9,9-dibromoanthrone-10.—Sixteen grams of bromine, dissolved in 100 cc. of carbon disulfide, was added to 11.2 g. of 3-methoxyanthrone-10[12] which was dissolved in 400 cc. of carbon disulfide, cooled to −5° and stirred. The mixture was then allowed to remain at room temperature for one hour, diluted with 500 cc. of petroleum ether (30–60°) and the light yellow crystalline precipitate recrystallized from benzene; yield 12 g.; m. p. 175–177° with decomposition.

Anal. Calcd. for $C_{15}H_{10}O_2Br_2$: Br, 41.88. Found: Br, 42.13.

When 3.0 g. of the brominated anthrone was treated with 20 cc. of water 1.8 g. of 2-methoxyanthraquinone was produced; mixed m. p. 195–196°.

2,2′(or 2,7′)-Dimethoxydianthraquinone.—A mixture of 15 g. of the dibromoanthrone, 200 cc. of dry benzene and 5 cc. of mercury was shaken for forty-eight hours, filtered, the benzene removed and the green amorphous solid recrystallized from acetic acid. The yellow crystals melted at 254–256° with decomposition.

Anal. Calcd. for $C_{30}H_{20}O_4$: C, 81.06; H, 4.54; mol. wt., 444. Found: C, 81.14; H, 4.44; mol. wt. (benzene, ebullioscopic procedure), 431.

Summary

A number of new triarylcarbinols, dianisyldihydroanthracenes, dianisylanthrones and di-(*p*-hydroxyphenyl)-anthrones have been described.

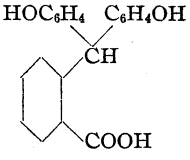
Hydroxy- and Methoxyphenylanthrones. II

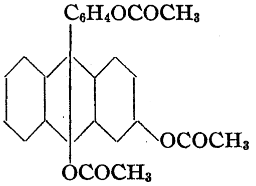
BY F. F. BLICKE AND R. A. PATELSKI[1]

A number of years ago it was stated by Baeyer[2] that phenolphthalin yields 3-hydroxy-9-(4′-hydroxyphenyl)-anthrone-10, or its tautomer, 3,10-dihydroxy-9-(4′-hydroxyphenyl)-anthracene, when treated with sulfuric acid and that the anthrone is converted, by oxidation, into 3,9-di-hydroxy-9-(4′-hydroxyphenyl)-anthrone-10. It has been shown,[3] however, that the two compounds actually obtained by Baeyer were 2,5-di-(*p*-hydroxyphenyl)-3,4-benzofuran and 2-(4″-hydroxybenzoyl)-4′-hydroxybenzophenone.

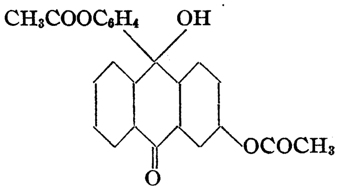
We have found that if phenolphthalin (I), or its diacetyl derivative, is treated with zinc chloride and acetic anhydride, instead of sulfuric acid, there is produced the triacetyl derivative of 3,10-dihydroxy-9-(4′-hydroxyphenyl)-anthracene (II) which, when oxidized, yields the diacetyl derivative of 3,9-dihydroxy-9-(4′-hydroxyphenyl)-anthrone-10 (III).



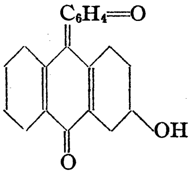
I



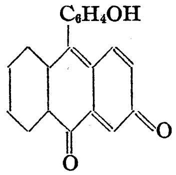
II



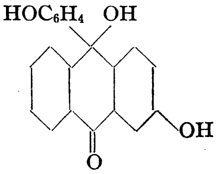
III



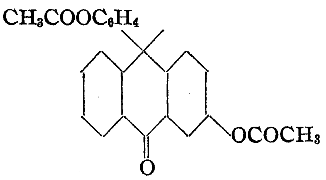
VI



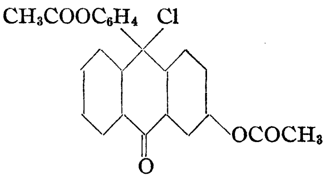
V



IV



VIII



VII

Upon hydrolysis the colorless trihydroxy compound (IV) is obtained. When heated or allowed to come into contact with mineral acids the hydroxy compound is converted into a highly colored fuchsone, either V or VI, or possibly a mixture of the two compounds. The diphenolic ether was obtained upon methylation of the trihydroxy compound (IV).

In order to supply proof of the structure of these compounds the carbinol III was converted into the carbinol chloride, the diacetyl derivative of 3-hydroxy-9-chloro-9-(4′-hydroxyphenyl)-anthrone-10, (VII). A solution of the chloride became deep red instantly when shaken with molecular silver due to the formation of the free radical 3-acetoxy-9-(4′-acetoxyphenyl)-anthronyl-10 (VIII); the red solution decolorized rapidly when exposed to air with the formation of the characteristic peroxide.

2,5-Di-(*p*-anisyl)-3,4-benzofuran (IX) was reduced to 2,5-di-(*p*-anisyl)-2,5-dihydro-3,4-benzofuran (X) with sodium amalgam. Reduction of 2-(4″-methoxybenzoyl)-4′-methoxybenzophenone (XIII) with the same reagent yielded 2-(4″-methoxy-α-hydroxybenzyl)-4′-methoxydiphenylcarbinol (XIV). When treated with zinc chloride in acetic acid solution both X and XIV were converted into 2-methoxy-9-(*p*-anisyl)-anthracene (XI). Upon oxidation the anthracene yielded 2-methoxy-9-hydroxy-9-(*p*-anisyl)-anthrone-10 (XII). The latter condensed with anisole to form 2-methoxy-9,9-di-(*p*-anisyl)-anthrone-10 (XV).

Experimental Part

Triacetyl Derivative of 3,10-Dihydroxy-9-(4′-hydroxyphenyl)-anthracene (II).—Twenty grams of phenolphthalin (I), or an equivalent amount of its diacetyl derivative, and 8 g. of anhydrous zinc chloride, dissolved in 35 cc. of acetic anhydride, were heated on a steam-bath for fifteen minutes and then poured into a mixture of water and ice which contained a small amount of hydrochloric acid. The crystalline product was digested with hot alcohol, filtered and recrystallized from a mixture of benzene and petroleum ether (90–100°); yield 19 g.; m. p. 188–189°.

Anal. Calcd. for $C_{26}H_{20}O_6$: C, 72.87; H, 4.71. Found: C, 73.04; H, 4.88.

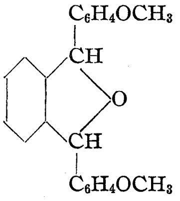
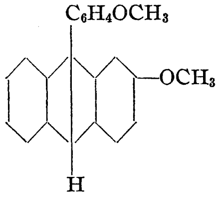
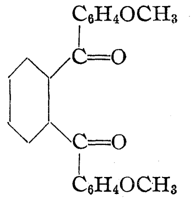
IX



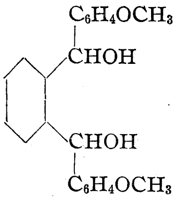
X



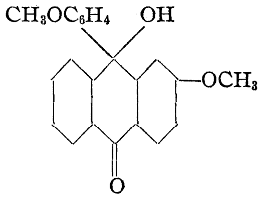
XI



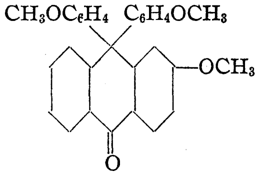
XIII



XIV



XII



XV

The compound exhibits an intense purple fluorescence when dissolved in organic solvents and a red-brown color when moistened with concd. sulfuric acid.

Diacetyl Derivative of 3,9-Dihydroxy-9-(4′-hydroxyphenyl)-anthrone-10 (III).—To 10 g. of the triacetate, dissolved in 50 cc. of acetic acid, there was added 7 g. of sodium dichromate, dissolved in 6 cc. of hot water. The mixture soon began to boil; after it had been heated on a steam-bath for two hours and poured into 500 cc. of water the crystalline product was recrystallized from benzene; yield 8 g.; m. p. 186–187°.

Anal. Calcd. for $C_{24}H_{18}O_6$: C, 71.61; H, 4.51. Found: C, 71.45; H, 4.67.

Solutions of this product in organic solvents do not fluoresce. The material turns purple when treated with concd. sulfuric acid.

3,9 - Dihydroxy-9-(4′-hydroxyphenyl)-anthrone-10 (IV).—A mixture of 5 g. of the diacetate, 20 cc. of 10% sodium hydroxide solution and 5 cc. of alcohol was heated on a steam-bath for five minutes, cooled, diluted with 25 cc. of water and 50 cc. of saturated ammonium chloride solution. The pale pink precipitate was dissolved in cold alcohol, treated with charcoal at room temperature, filtered and the solution diluted with water. After precipitation by water from an alcoholic solution the practically colorless, crystalline product melted at 127–128° with the formation of a deep red liquid. The compound, dried in a desiccator over calcium chloride for two weeks prior to analysis, contained water of crystallization.

Anal. Calcd. for $C_{20}H_{14}O_4 \cdot H_2O$: C, 71.43; H, 4.80. Found: C, 71.41; H, 4.87.

In addition to the development of the deep color, the loss of an amount of water which corresponds closely to that calculated for fuchsone formation demonstrates the conversion of IV into V or VI. Thus, when 0.5219 g. of the colorless anthrone was heated at 130° for twenty-four hours, the deep red sample obtained weighed 0.4669 g.; calcd. wt. 0.4660 g. ($C_{20}H_{14}O_4 \cdot H_2O - 2H_2O$).

The anthrone turns an intense purple when moistened with concd. sulfuric acid or a mixture of acetic and hydrochloric acid. When an acetic acid solution of the anthrone is warmed it turns bright red.

The 3,9-dimethyl ether of the anthrone was obtained when 3.2 g. of the anthrone, dissolved in 35 cc. of 20% sodium hydroxide solution, was treated with 8 cc. of dimethyl sulfate at 80–90°. After recrystallization from alcohol the ether melted at 155–156°.

Anal. Calcd. for $C_{22}H_{18}O_4$: C, 76.27; H, 5.24. Found: C, 76.01; H, 5.42.

The ether is colored an intense blue by concd. sulfuric acid.

Diacetyl Derivative of 3-Hydroxy-9-chloro-9-(4′-hydroxyphenyl)-anthrone-10 (VII).—A hot mixture of 3,9-dihydroxy-9-(4′-hydroxyphenyl)-anthrone-10 diacetate, 75 cc. of benzene and 5 cc. of acetyl chloride was treated with a stream of hydrogen chloride for two hours, the solvent removed under reduced pressure and the oily residue covered with petroleum ether (90–100°). After twelve hours the crystalline material was recrystallized from a mixture of benzene and petroleum ether; m. p. 128–129°.

Anal. Calcd. for $C_{24}H_{17}O_5Cl$: Cl, 8.43. Found: Cl, 8.25.

Peroxide of Free Radical 3-Acetoxy-9-(4′-acetoxyphenyl)-anthronyl-10 (VIII).—A mixture of 1.5 g. of the 9-chloro compound, 15 cc. of benzene and 4 g. of molecular silver was shaken for one hour. An intense red color developed immediately upon the addition of the silver. The mixture was filtered. The filtrate decolorized rapidly upon exposure to air and the peroxide precipitated upon the addition of petroleum ether; m. p. 195–200° with decomposition.

Anal. Calcd. for $C_{48}H_{34}O_{12}$: C, 71.79; H, 4.27. Found: C, 72.09; H, 4.42.

2,5-Di-(*p*-anisyl)-2,5-dihydro-3,4-benzofuran (X).—Ten grams of 2,5-di-(*p*-anisyl)-3,4-benzofuran was suspended in 600 cc. of absolute alcohol and 250 g. of 5% sodium amalgam added in portions. After the initial vigorous reaction had subsided, the mixture was heated for five hours on a steam-bath, filtered while hot and the precipitate of colorless, iridescent crystals recrystallized from alcohol; m. p. 115–116°; yield 7 g. Upon dilution of the mother liquor with water 2 g. more of material was obtained.

Anal. Calcd. for $C_{22}H_{20}O_3$: C, 79.17; H, 6.07. Found: C, 78.92; H, 6.12.

The colorless acetic acid solution becomes green when warmed and exhibits a green fluorescence.

When dissolved in acetic acid and oxidized with sodium dichromate, 2-(4″-methoxybenzoyl)-4′-methoxybenzophenone was produced; it was recrystallized from alcohol; mixed m. p. 157–159°.[4]

---

[4] The same melting point was reported by Blicke and Weinkauff, THIS JOURNAL, 54, 1458 (1932).

2-(4″-Methoxy-α-hydroxybenzyl)-4′-methoxydiphenylcarbinol (XIV).—To 3.5 g. of 2-(4″-methoxybenzoyl)-4′-methoxybenzophenone, dissolved in 150 cc. of absolute alcohol, there was added 100 g. of 5% sodium amalgam. After several hours the reaction mixture was heated on a steam-bath for two hours, filtered while hot and the filtrate concentrated to one-half its original volume. Water was added gradually until the solution became turbid, the solution cooled and the crystalline precipitate recrystallized from alcohol; m. p. 139–140°; yield 2.8 g.

Anal. Calcd. for $C_{22}H_{22}O_4$: C, 75.39; H, 6.33. Found: C, 75.08; H, 6.39.

One and seven-tenths grams of the carbinol, dissolved in 20 cc. of acetic acid, was oxidized to 2-(4″-methoxybenzoyl)-4′-methoxybenzophenone with 2 g. of sodium dichromate, dissolved in 10 cc. of acetic acid; mixed m. p. 157–159°; yield 1.3 g.

2-Methoxy-9-(*p*-anisyl)-anthracene (XI).—To 1.5 g. of anhydrous zinc chloride, dissolved in a mixture of 7.5 cc. of acetic anhydride and 7.5 cc. of acetic acid, there was added 5.0 g. of 2,5-di-(*p*-anisyl)-2,5-dihydro-3,4-benzofuran. The furan dissolved with evolution of heat and the crystalline anthracene soon began to precipitate. After one hour the mixture was diluted with 50 cc. of water and the anthracene recrystallized from acetic acid; yield 3.9 g.; m. p. 177–179°.[5] Solutions of this compound exhibit a blue fluorescence.

Five grams of 2-(4″-methoxy-α-hydroxybenzyl)-4′-methoxydiphenylcarbinol was treated with zinc chloride in the manner described above. After one hour the crystalline anthracene was separated and recrystallized from acetic acid; yield 3.8 g.; m. p. 177–179°.

2-Methoxy-9-hydroxy-9-(*p*-anisyl)-anthrone-10 (XII).—Five grams of 2-methoxy-9-(*p*-anisyl)-anthracene, suspended in 25 cc. of acetic acid, was heated for two hours on a steam-bath with 4 g. of sodium dichromate, dissolved in 4 cc. of hot water. The mixture was diluted with an equal volume of water and the precipitated, crystalline anthrone recrystallized from acetic acid; yield 4.5 g.; m. p. 202–203°.[6]

2-Methoxy-9,9-di-(*p*-anisyl)-anthrone-10 (XV).—Two grams of 9-hydroxy-9-(*p*-anisyl)-anthrone-10, 6.0 g. of anisole and two drops of concd. sulfuric acid were heated for two hours on a steam-bath, the mixture treated with hot alcohol and the crystalline product recrystallized from acetic acid; yield 1.5 g.; m. p. 182–184°.[7]

Summary

It has been shown that a hydroxy- and a methoxyphenylanthrone can be obtained from a phthalin, from a benzofuran and from a benzoylbenzophenone.

A free radical of the anthraquinone type has been described.

The Introduction of Substituted Vinyl Groups. I. Isopropenyl Alkyl Malonic Esters

BY ARTHUR C. COPE AND EVELYN M. HANCOCK

The wide application of the malonic ester synthesis to organic preparations has resulted in the description of a large number of mono- and dialkyl malonic esters, containing both saturated and unsaturated groups. While β,γ-unsaturated (allyl) groups and groups with the double bond further removed from the point of attachment are readily introduced into malonic ester by the ordinary method, α,β-unsaturated (vinyl) groups cannot be introduced directly, because of the inactivity of the vinyl and alkyl substituted vinyl halides. Indirect methods for the introduction of vinyl groups are difficult and give poor yields,[1] and as a result very few vinyl substituted derivatives of malonic ester have been prepared. In this paper a practical method is described for preparing disubstituted malonic esters in which one of the substituent groups is the isopropenyl or 1-methylvinyl ($CH_2{=}C(CH_3)$—) group.

Kon and his associates,[2] in the course of their investigation of three-carbon tautomerism, methylated isopropylidene malonic ester, which forms a sodium derivative through migration of a hydrogen from the γ-carbon atom.

$$(CH_3)_2C{=}C(COOEt)_2 + NaOEt \longrightarrow$$

$$EtOH + \underset{(I)}{[CH_2{=}C(CH_3)C(COOEt)_2]^- Na^+} \xrightarrow{CH_3I}$$

$$CH_2{=}C(CH_3)C(CH_3)(COOEt)_2 + NaI$$

This reaction was employed to prove that the sodium enolate was derived from the isomeric β,γ-unsaturated ester $CH_2{=}C(CH_3)CH(COOEt)_2$, and was not extended as a possible synthetic method. The application of the reaction ap-

peared to be limited, since the methylated ester undergoes alcoholysis readily in the presence of sodium ethoxide with the loss of a carbethoxy group as ethyl carbonate. The conditions of synthesis described by Kon and Speight,[2] therefore, induce alcoholysis, particularly since two treatments with alcoholic sodium ethoxide and methyl iodide were required to complete the methylation. The slow alkylations, to be expected with less active alkylating agents, would allow time for extensive cleavage during the synthesis.

We have found that the sodium enolate (I) can be prepared easily and almost quantitatively by reaction of isopropylidene malonic ester with sodamide, either in liquid ammonia solution or in an inert solvent. The resulting sodium derivative, preferably suspended in an inert solvent, can then be alkylated readily by the ordinary alkylating agents, such as the dialkyl sulfates or alkyl halides. Since the reaction mixtures are free from alcohol, the alkylations are successful even with the less reactive higher alkyl halides, some of which require long refluxing for appreciable reaction. The yields of pure isopropenyl alkyl malonic esters obtained by this method are as high as 90% when the more active alkylating agents are employed. Various primary alkyl groups have been introduced in good yield; the introduction of secondary groups is difficult. In cases in which the alkylation is not complete, the isopropenyl alkyl malonic esters may be purified conveniently by shaking with concentrated aqueous ammonia at room temperature. Like other dialkyl malonic esters, the isopropenyl alkyl derivatives are not affected by this treatment, while isopropylidene malonic ester is converted into acetone and malonamide.[3] The properties of nine isopropenyl alkyl malonic esters, prepared and purified in this manner, are described in the Experimental Part.

The sodium enolate (I) may also be prepared by the reaction of isopropylidene malonic ester with powdered sodium in an inert anhydrous solvent, such as ether or benzene. Unfortunately, a considerable amount of the isopropylidene malonic ester is reduced during the formation of the sodium enolate. Subsequent alkylation, therefore, produces a mixture of isopropenyl and isopropyl alkyl malonic esters which is difficult to separate.

Experimental Part

Ethyl Isopropylidene Malonate.—Improved yields of this ester were obtained by using an excess of acetone in a procedure otherwise similar to that described by Scheiber and Meisel.[4] A mixture of 1 kg. (6.25 moles) of ethyl malonate, 540 g. (9.3 moles) of acetone, 800 g. (7.8 moles) of acetic anhydride and 120 g. of freshly fused zinc chloride was heated under reflux in an oil-bath at 110° for twenty-four hours. The mixture was then cooled, and 800 cc. of benzene added. The nearly black solution was washed with four 500-cc. portions of water. The water washings were extracted with two 100-cc. portions of benzene, which were combined, washed with water and added to the main portion of the benzene solution. The wet benzene was removed by distillation under diminished pressure, and the remainder of the mixture was distilled in vacuum through a Vigreux column. A fore-run of acetic acid and acetic anhydride was collected, followed by 1200 g. of crude ester, b. p. 60–125° (18 mm.). The tarry residue amounted to 50 g. The crude ester was redistilled through an adiabatic, total reflux, variable take-off Fenske type column with a 70 × 1.2 cm. section packed with glass helices. The recovery of ethyl malonate, b. p. 81–83° (9 mm.), plus a small intermediate fraction was 411 g. (41%). A yield of 654 g. (52%) of ethyl isopropylidene malonate, b. p. 111–113° (9 mm.), was obtained, $n^{25}{}_D$ 1.4478, $d^{25}{}_{25}$ 1.0254, M_D calcd. 51.23, obsd. 52.42, exaltation + 1.19.

Alkylations of Ethyl Isopropylidene Malonate

A. Sodamide Procedure.—The ethylation will be described as a typical procedure. All apparatus was dried in an oven at 100 to 150° before use. A 1-liter, three-necked flask was equipped with an inlet tube, mercury-sealed stirrer and a reflux condenser attached to a soda lime tower. The tower was connected to a 3-liter bottle containing 1 liter of water (stirred with another mercury-sealed stirrer), and to the bottle was attached a water trap leading to the sink. Hydrated ferric nitrate (0.3 g.) was placed in the flask, which was then cooled in a dry ice–acetone bath while 300 cc. of anhydrous liquid ammonia was introduced through the inlet tube from an inverted ammonia cylinder. The cooling bath was then removed and 12.65 g. (0.55 mole) of sodium added in small pieces. One piece was added and the solution stirred until the blue color changed to gray, and the remainder added rapidly. Stirring was continued until the solution was gray (ten to thirty minutes), and fifteen minutes longer. All of the sodium should have reacted to form sodamide before the ester is added, since any sodium present will tend to reduce the ester. The solution was again cooled in the dry ice–acetone bath and the ethyl isopropylidene malonate (100 g. or 0.5 mole) added during ten minutes from a separatory funnel (introduced in the neck which originally held the inlet tube). The solution was stirred for ten to thirty minutes and 300 cc. of dry, sulfur-free toluene and 25 cc. of dry ether added. The solution was stirred until most of the ammonia had evaporated (one to two hours). The flask was then placed in an oil-bath which was gradually heated to 110°. During the heating the sodium derivative (I) precipitated as a gray solid and the last traces of the ammonia were distilled out through the reflux condenser

[a] The first three reaction mixtures were neutral after refluxing for the number of hours indicated; the remainder were from 70 to 90% neutralized. [b] We are indebted to Miss Corris Hofmann for these analyses.

with the ether. The oil-bath was removed and 101.6 g. (0.66 mole) of diethyl sulfate added during ten minutes. The oil-bath was then replaced and heated to 135°. After refluxing for one hour the reaction mixture was neutral. It was cooled in ice and washed with two portions of cold water. The washings were extracted with ether, and the ether and toluene distilled off in vacuum. The residue was shaken for twelve hours with 200 cc. of concentrated aqueous ammonia at room temperature. The ester layer was separated and the ammonia solution extracted twice with ether. The ether and ester were washed with water and the product was distilled in vacuum.

Variations of this procedure are less convenient but may be used in some cases. Ether or benzene may be employed as inert solvents. After the sodamide is formed, the inert solvent may be added and the excess ammonia expelled before adding the ester. This procedure is as convenient as that described above if the inert solvent is ether, but the ester reacts slowly with sodamide in benzene or toluene, probably due to the insolubility of both sodamide and the ester enolate. The methylation with dimethyl sulfate proceeds satisfactorily in ether, but the other alkylating agents require temperatures higher than the boiling point of ether for reaction at a satisfactory rate. With the higher alkyl halides, the reaction mixtures never become neutral. It is convenient in such cases to remove 2-cc. aliquots from time to time and determine the percentage reaction by titration with standard acid. If the reaction time is prolonged above that recorded in Table I, the yields are increased slightly in some cases, but in others increased amounts of high boiling material are formed. When the reaction mixtures do not become neutral, they should be neutralized with dilute hydrochloric acid before washing with water. Larger amounts of aqueous ammonia should be used to purify the product in such cases, and the treatment with aqueous ammonia may be prolonged to three or four days. In the alkylations giving poorer yields, it is convenient to distil the crude ester before shaking with ammonia in order to eliminate high boiling material. The esters were redistilled through a Widmer column. The yields of purified products, their physical constants and pertinent data concerning the preparations are recorded in Table I.

B. Sodium Procedure.—One-half mole of sodium was powdered under xylene and rinsed into a 1-liter, three-necked flask with 500 cc. of dry ether. Ethyl isopropylidene malonate (100 g. or 0.5 mole) was added during ten minutes with stirring and cooling in an ice-bath. The solution refluxed during the addition of the ester. The solution was stirred and refluxed for twelve hours, after which the alkylating agent was added and the reaction mixture treated as in part A. Methylation with dimethyl sulfate required two hours, and ethylation with diethyl sulfate twenty-four hours at the boiling point of ether. It is advantageous to replace the ether with benzene or toluene if less active alkylating agents are used. The sodium derivative may be prepared by this method in benzene or toluene, but, whereas in ether the sodium derivative separates as a flour-like solid and all of the sodium eventually reacts, in benzene and toluene stiff gels are formed and mechanical difficulties result.

C. Sodium Ethoxide Procedure.—In the methylation procedure described by Kon and Speight,[2] a large amount of the product is decomposed by alcoholysis, due to the long contact of the alkylated ester with alcoholic sodium ethoxide. The yields are improved if the ethyl isopropylidene malonate is treated once with sodium ethoxide and methyl iodide, and the unalkylated ester removed by shaking with aqueous ammonia as described in part A. Higher alkyl groups are not introduced in good yield by the sodium ethoxide procedure, even under conditions designed to minimize alcoholysis, as may be illustrated by the synthesis of ethyl butyl isopropenyl malonate.

A solution of sodium ethoxide was prepared in a 500-cc. three-necked flask by dissolving 5.75 g. (0.25 mole) of sodium in 200 cc. of absolute alcohol. The solution was cooled to −5° and 50 g. (0.25 mole) of ethyl isopropylidene malonate added with stirring at −5 to −10°. After stirring for thirty minutes at this temperature, 56 g. (0.30 mole) of *n*-butyl iodide was added in one portion and the solution was heated rapidly to the boiling point. After the vigorous reaction had subsided, the mixture was refluxed until neutral (one and one-half hours). The solution was cooled, diluted with water, and the ester extracted with benzene. Distillation gave 49 g. of crude ester, b. p. 110–128° (9 mm.), but after purification by shaking with concentrated ammonia for two days and redistilling, only 12 g. (19%) of ethyl isopropenyl *n*-butyl malonate was obtained.

Purity of the Alkylation Products.—The purity of the esters produced by the sodamide procedure (A) is indicated by the close correspondence of calculated and observed molecular refractions recorded in Table I. Several of the esters were hydrogenated quantitatively and the reduction products characterized as further proof of their purity and identity. The esters (0.01 to 0.03 mole) in 20 cc. of alcohol were hydrogenated at atmospheric pressure in the presence of 1 g. of palladinized charcoal,[5] containing 100 mg. of palladium. The reductions were carried out at room temperature in a 100-cc. mechanically shaken bottle attached to a large gas buret. Under these conditions the methyl, ethyl and allyl substituted isopropenyl malonic esters (described in Table I) absorbed 99.3, 99.6 and 97.8% of the theoretical quantity of hydrogen. The reductions required approximately one-half hour. The reduced esters were obtained in 85–90% yield by filtering the catalyst and distilling in vacuum. Ethyl methylisopropylmalonate, b. p. 100–102° (11 mm.), was identified by condensation with urea in the presence of alcoholic sodium ethoxide to give 5-methyl-5-isopropylbarbituric acid, m. p. 188–188.5°,[6] and by saponification with 10% barium hydroxide to methyl isopropylmalonic acid, m. p. 123.5–124.5°.[7] Ethyl ethylisopropylmalonate, b. p. 108–110° (11 mm.), was identified in a similar manner by conversion to 5-ethyl-5-isopropylbarbituric acid, m. p. 201.5–202.5°.[8]

The higher isopropenyl alkyl malonic esters are reduced very slowly with palladium at room temperature, but may be reduced rapidly and quantitatively at 150° over Raney nickel in the micro bomb described by Adkins.[9] Thus 0.02 mole of ethyl butyl isopropenyl malonate in 15 cc. of ethyl alcohol absorbed 99.7% of the theoretical quantity of hydrogen using 1 g. of catalyst. Ethyl butyl isopropyl malonate, b. p. 131–132° (11 mm.), was isolated as the reduction product in 90% yield by filtering and distilling in vacuum.

The esters obtained by the sodium alkylation procedure (B) contain a saturated impurity, which is presumably the corresponding isopropyl alkyl malonic ester, since it is not removed by long shaking with concentrated aqueous ammonia or by fractional distillation. Thus over palladium catalyst as previously described the methyl and ethyl substituted isopropenylmalonic esters prepared by sodium alkylation absorbed only 76 and 72% of the theoretical quantity of hydrogen, respectively.

Summary

Ethyl isopropylidene malonate, $(CH_3)_2C{=}C(COOEt)_2$, forms a sodium derivative (formula I) almost quantitatively by reaction with sodamide in liquid ammonia solution or in inert solvents. By alkylation of this sodium derivative in inert solvents, eight new isopropenyl alkyl malonic esters, $CH_2{=}C(CH_3)C(R)(COOEt)_2$, have been prepared. The sodium derivative has also been prepared by reaction of ethyl isopropylidene malonate with powdered sodium in inert solvents, but about 25% of the ester is reduced during the reaction.

If the sodium derivative is prepared and alkylated in alcoholic solution, the yields of alkylated esters are poor, due to extensive alcoholysis which occurs during the synthesis.

Interaction between Grignard Compounds and Maleic Acid Derivatives

BY CH. WEIZMANN AND F. BERGMANN

Recently, Tarbell[1] reported on reactions between maleic and dimethylmaleic anhydrides with phenylmagnesium bromide: maleic anhydride reacted with two and three mols of the Grignard compound, respectively, giving phenylbenzoylpropionic acid (I) and desylacetophenone (II, R = C_6H_5). As we have studied some time ago the action of various Grignard compounds on maleic anhydride and dimethyl maleate, in continuation of previous work on other dicarboxylic acid anhydrides, we may be allowed to describe briefly our results. In accordance with Tarbell's results, neither ethylmagnesium bromide nor butylmagnesium bromide or benzylmagnesium chloride gave the expected unsaturated keto acids, $RCOCH{=}CHCOOH$, even when the organometallic compound was added to the anhydride; the keto acids formed apparently react more quickly with the Grignard compounds than maleic anhydride (or dimethyl maleate). The experiments to be described have been carried out, using a large excess (8 mols) of the magnesium derivatives.

Dimethyl maleate reacted under these conditions with 3 mols of each Grignard compound. The reacting products are 1,4-diketones of the general formula (II): they are saturated, do not contain hydroxyl groups, as shown by their negative response to the Zerewitinoff test, and give the pyrrole reaction characteristic for 1,4-diketones. The keto groups, although resistant against the attack of semicarbazide in aqueous ethyl alcohol solution, react upon phenylmagnesium bromide: 6-butyl-5,8-diketododecane (II, R = C_4H_9) gave a crystalline diol (IV), while the corresponding

---

[1] Tarbell, THIS JOURNAL, **60**, 215 (1938).

3-benzyl-1,6-diphenyl-2,5-diketohexane (II, R = $CH_2C_6H_5$) took up only 1 mol of the Grignard compound, yielding (V); obviously, the second keto group is sterically hindered. The formation of the compounds (II) is completely analogous to the occurrence of desylacetophenone reported by Tarbell. The mechanism of the reaction leading to (II) is the following one: the methoxy groups are exchanged by the respective alkyl radicals, and subsequently 1 mol of the Grignard compound is added to the conjugated system, giving the enolate (III) of (II). The inverse order of the steps would not account for the formation of a diketone as primary addition to the conjugated system in dimethyl maleate would give the enolate (VI), which could undergo further alkylation only on one side of the maleate. Theoretically, the enolate (III) could react one-sided with the excess of the Grignard compound; but this reaction may be hindered for steric reasons.[2] In one case the unsaturated diketone, primarily formed according to the above mechanism, reacts with more Grignard compound in 1,2- and not in 1,4-position: from the interaction between dimethyl maleate and butylmagnesium bromide an isomeric tributyl product was secured in small amounts; it contained one hydroxyl group, was unsaturated and, therefore, has to be formulated as (VII). The same substance has been obtained from the analogous reaction with maleic anhydride.

The reaction of *maleic anhydride* upon the three Grignard compounds, in all cases, gave a mixture of acidic and neutral products. The acidic fractions proved homogeneous, they consisted of the respective γ,γ-dialkyl-γ-hydroxycrotonic acids (VIII), which have been characterized by their *p*-phenylphenacyl derivatives. The presence of the tertiary hydroxyl group was proved by the Zerewitinoff method; it causes the easy dehydration of these acids, which makes their purification somewhat tedious. It is rather surprising that phenylmagnesium bromide, according to Tarbell, introduced the two hydrocarbon radicals in a different manner (reaction at one carbonyl group and subsequently at the remaining conjugated system); our observations recall the behavior of phthalic and homophthalic anhydrides.[3] The neutral fractions, deriving from the interaction between maleic anhydride and the Grignard compounds, usually are complicated mixtures from which only the following individual reaction products have been secured: (a) in the case of benzylmagnesium chloride a hydrocarbon of the formula $C_{32}H_{28}$, therefore most probably (IX), the formation of which is analogous to that of tetraphenyldihydrofuran obtained by Purdie and Arup[4] in the case of phenylmagnesium bromide; (b) in the case of butylmagnesium bromide the same substance (VII) which had been isolated as by-product from the corresponding reaction with dimethyl maleate; (c) in the case of ethylmagnesium bromide, a compound $C_{12}H_{24}O_2$, which contains one hydroxyl group and therefore had to be formulated as (X). To the presence of a tertiary hydroxyl group points the inclination of the substance to spontaneous dehydration. The mechanism of the formation of (X) is self-explanatory.

In this connection, experiments on the interaction between butyrolactone (XI) and phenylmagnesium bromide may be mentioned briefly: 2 mols of the Grignard compound gave 1,1-diphenylbutane-1,4-diol (XII).[5]

in glacial acetic acid solution; the absence of hydroxyl and methoxyl groups was indicated by the micro-Zerewitinoff and the Zeisel methods, respectively.[6]

Reaction with Phenylmagnesium Bromide.—The foregoing substance (0.6 g.) was dissolved in benzene and added to the Grignard solution (prepared from 0.15 g. of magnesium and 1 g. of bromobenzene); the mass was boiled for six hours and then decomposed with ice and dilute sulfuric acid. The reaction product was a viscous oil which crystallized on trituration with acetone and light petroleum. From ligroin (b. p. 130°) 2-hydroxy-5-keto-1,2,6-triphenyl-4-benzylhexane (V) separated in the form of longish plates, m. p. 202°; concd. sulfuric acid gave a brown-red color reaction; yield 250 mg.

Anal. Calcd. for $C_{31}H_{30}O_2$: C, 85.7; H, 6.9. Found: C, 85.7; H, 6.9.

Dimethyl Maleate and Ethylmagnesium Bromide.—The reaction product, 5-ethyl-3,6-diketo-octane (II, R = C_2H_5), boiled at 143° (25 mm.) and 110° (1 mm.).

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.6; H, 10.6. Found: C, 70.5; H, 10.7.

The colorless liquid had n^{21}_D 1.4538, d_{21} 0.9661, hence $MR = 47.63$, while (II, R = C_2H_5) requires 47.27. Hydroxyl and methoxyl groups were absent, the pyrrole test was strongly positive.

Dimethyl Maleate and Butylmagnesium Bromide.—From the neutral reaction product, two homogeneous fractions were obtained by careful fractionation. At 115–120° under 0.1 mm. pressure boiled 5-butyl-5-hydroxy-8-keto-dodecene-(*6*) (VII), which according to its boiling point, refractive index (n^{18}_D 1.4536) and analysis was identical with the neutral product obtained analogously from maleic anhydride.

Anal. Calcd. for $C_{16}H_{30}O_2$: C, 75.6; H, 11.8, active H, 0.394. Found: C, 75.0, 75.3; H, 11.4, 11.7; active H (micro-Zerewitinoff), 0.483.

The main product, 6-butyl-5,8-diketododecane (II, R = C_4H_9) boiled at 136° under 0.05 mm. pressure; yield 9 g. from 14.4 g. (= 0.1 mole) of dimethyl maleate. *Anal.* Calcd. for $C_{16}H_{30}O_2$: C, 75.6; H, 11.8. Found: C, 75.2; H, 11.6. It contained no hydroxyl or methoxyl groups, its diketone character was proved by reaction with phenylmagnesium bromide (see below), the 1,4-position of the carbonyl groups by the positive pyrrole test. The molecular refractivity, too, is in accord with (II, R = C_4H_9): n^{21}_D 1.4643; d_{20} 0.9267; hence $MR = 75.60$, while (II, R = C_4H_9) required $MR = 76.11$. **Reaction with Phenylmagnesium Bromide:** The diketone (6 g.) was added to the Grignard solution (from 5 g. of magnesium and 30 g. of bromobenzene). After two hours of boiling, the reaction product was worked up as usual; it distilled at 175–180° under 2.5 mm. pressure; it crystallized partly spontaneously (0.300 g.), from propyl alcohol as leaflets, from light petroleum (80–100°) as stout needles, m. p. 122–123°; concd. sulfuric acid gave an intensely yellow solution. The analysis pointed to formula (IV).

Anal. Calcd. for $C_{28}H_{42}O_2$: C, 81.9; H, 10.2. Found: C, 81.7; H, 10.2. The oily fraction, which has not been obtained analytically pure, is most probably a dehydration product of (IV).

Maleic Anhydride and Benzylmagnesium Chloride.—The acid fraction, boiling under 0.7 mm. at 210–220°, was inhomogeneous, due to partial spontaneous dehydration, but on treatment with *p*-phenylphenacyl bromide the phenylphenacyl ester[7] of γ,γ-dibenzyl-γ-hydroxycrotonic acid (VIII, R = C_7H_7) could be obtained; from propanol it crystallized in stout needles, m. p. 142–143°.

Anal. Calcd. for $C_{32}H_{28}O_4$: C, 80.7; H, 5.9; active H, 0.219. Found: C, 80.6; H, 5.9; active H, 0.211.

The neutral reaction product boiled at 215–220° under 1.5 mm. pressure. It crystallized on trituration with light petroleum and after recrystallization from ligroin (b. p. 130°) formed prisms, m. p. 184°. Combustion analysis proved that 1,6-diphenyl-2,5-dibenzylhexatriene-(1,3,5) (IX) had been formed; maleic anhydride gave no addition product; most probably the ethylenic double bonds are too highly and not asymmetrically enough substituted.[8]

Anal. Calcd. for $C_{32}H_{28}$: C, 93.2; H, 6.8. Found: C, 93.3; H, 6.8.

Maleic Anhydride and Butylmagnesium Bromide.—The acid product after many fractionations had b. p. 114° (0.05 mm.) and consisted of γ,γ-dibutyl-γ-hydroxycrotonic acid (VIII, R = C_4H_9).

Anal. Calcd. for $C_{12}H_{22}O_3$: C, 67.3; H, 10.3; active H, 0.935. Found: C, 67.2; H, 9.8; active H, 0.915. It was characterized by its *p*-phenylphenacyl ester, which after crystallization from light petroleum had m. p. 79°. *Anal.* Calcd. for $C_{26}H_{32}O_4$: C, 76.5; H, 7.8; active H, 0.245. Found: C, 76.0; H, 8.0; active H, 0.265. The neutral product (VII) distilled at 114° under 0.1 mm. pressure; $n^{22.5}_D$ 1.4568; d_{21} 0.9069; yield, 4 g. (from 9 g. of maleic anhydride). *Anal.* Calcd. for $C_{16}H_{30}O_2$: C, 75.6; H, 11.8; active H, 0.394. Found: C, 76.2; H, 12.2; active H, 0.450.

Maleic Anhydride and Ethylmagnesium Bromide.—γ,γ-Diethyl-γ-hydroxycrotonic acid (VIII, R = C_2H_5), could not be obtained in analytically pure state, due to spontaneous dehydration; the main part of the product distilled at 115° under 0.6 mm. pressure, n^{21}_D 1.4510; d_{21} 1.0170. *Anal.* Calcd. for $C_8H_{14}O_3$: C, 60.8; H, 9.0. Found: C, 62.6; H, 9.5. But this preparation gave a well-defined *p*-phenylphenacyl ester, silky needles from alcohol, m. p. 77–78°. *Anal.* Calcd. for $C_{22}H_{24}O_4$: C, 75.0; H, 6.8. Found: C, 74.7; H, 6.8. From the filtrate of this ester, a second substance, from light petroleum (b. p. 80–100°) as quadratic plates, m. p. 138°, was isolated in minute quantities; it probably is the *p*-phenylphenacyl ester of the corresponding unsaturated γ-ethylsorbic acid.

The neutral fraction had b. p. 75° (112°) under 1.5 (37) mm. pressure; it gave a brown-red color reaction with concd. sulfuric acid. According to the analysis, it consisted of 3-keto-6-hydroxy-5,6-diethyloctane (X). *Anal.* Calcd. for $C_{12}H_{24}O_2$: C, 72.0; H, 12.0; active H, 0.500. Found: C, 73.0; H, 11.3; active H, 0.592. In the same direction points the molecular refractivity: n^{21}_D 1.4574;

d_{21} 0.9269; hence $MR = 58.82$, while (X) requires $MR = 59.15$. We were unable to obtain this substance absolutely free from an impurity of diketonic character, which gave a positive response to the pyrrole test.

Butyrolactone[9] (VIII, 7.5 g.), in ethereal solution was treated with phenylmagnesium bromide (prepared from 2.1 g. of magnesium and 13.7 g. of bromobenzene); violent reaction took place. The reaction product, isolated as usual, crystallized spontaneously. By recrystallization from benzene, the needles of 1,1-diphenylbutane-1,4-diol (XII), m. p. 108°, were obtained; yield 2 g. *Anal.* Calcd. for $C_{16}H_{18}O_2$: C, 79.3; H, 7.4; active H, 0.827. Found: C, 78.9; H, 7.5; active H, 0.728.

Summary

The reaction between dimethyl maleate and maleic anhydride and Grignard compounds (benzylmagnesium chloride, butylmagnesium bromide, ethylmagnesium bromide) has been studied. Dimethyl maleate gives, by interaction with 3 mols of the organometallic compound, 1,4-diketones of the general formula $RCOCH_2CH(R)COR$, while from maleic anhydride γ,γ-dialkyl-γ-hydroxycrotonic acids and a variety of neutral products are obtained.

The reaction mechanism is discussed.

The Influence of α-Halogen Substitution on the Enolization of Ketones

BY E. P. KOHLER[1] AND H. M. SONNICHSEN

Halogen substitution in the α-position is known to promote the enolization of ketones in acid media,[2] but the effect of α-halogen substitution on the enolization of ketones in basic solution has been investigated less extensively. Bartlett's measurements of the rate of bromination and chlorination of acetone in basic solution[3] have indicated that enolization is the rate-controlling step in the reaction of ketones with halogens in the presence of bases, and if this mechanism is correct there can be no doubt that α-halogen substitution promotes enolization in basic media, for in practically every case[4] the only product which can be isolated from the alkaline halogenation of a methyl ketone is a trihalo methyl ketone or its cleavage products. Furthermore, if mono- and dihalomethyl ketones are prepared, they are found to react with halogens in the presence of bases more rapidly than the corresponding unsubstituted ketones.[5]

Direct chemical evidence for the theory that α-halogen substitution promotes enolization of carbonyl compounds is not plentiful. Watson observed that brominated acetones and acetophenones are acidic, but later proved that this acidity was to be ascribed to hydrolysis rather than enolization.[6] Fisher[7] found that several substituted dibromo acetophenones were markedly acidic, but like Watson did not attribute this acidity to enolization.

Thus, all discussion of the influence of α-halogen substitution on the enolization of carbonyl compounds in basic solution has been based on assumptions concerning the mechanism of bromination of ketones. In the experiments with α-bromo-β,β-diphenyl propionyl mesitylene described below, we have found direct chemical evidence in support of the theory that α-halogen substitution promotes the enolization of ketones in basic media, independent of any assumptions concerning the mechanism of the reactions of carbonyl compounds.

Investigations in this Laboratory and elsewhere[8] have indicated that the mesityl radical has a marked influence on the stability of enols; therefore it might be expected that α-bromo-β,β-diphenyl propionyl mesitylene would be a rather easily enolized ketone. One would not expect the influence of the mesityl radical to be strong enough, however, to produce any marked peculiarities in the behavior of a monoketone, so it

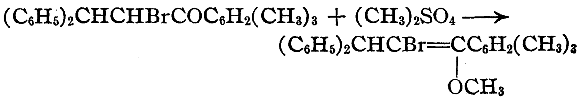
was with considerable astonishment that we first observed that the above-mentioned bromoketone was extremely soluble in cold methyl alcoholic potassium hydroxide, so soluble in fact that it is extracted easily from benzene by alcoholic alkali.

The solubility of the bromide in ethanol is 0.214 g. per 100 cc. at 25°. In saturated ethyl or methyl alcoholic potassium hydroxide the solubility is at least 50 g. per 100 cc. The bromide could be recovered quantitatively from these solutions by acidification or dilution with water, but if they were allowed to remain for any length of time at room temperature, enough unsaturated ketone, $(C_6H_5)_2C{=}CHCOC_6H_2(CH_3)_3$, was formed to color the product yellow. The corresponding saturated ketone, $(C_6H_5)_2CHCH_2COC_6H_2(CH_3)_3$, although it is quite soluble in alcohol, shows no evidence of solubility in methyl alcoholic potassium hydroxide. The corresponding α-bromoketone in the phenyl series, $(C_6H_5)_2CHCHBrCOC_6H_5$, was soluble in methyl alcoholic potassium hydroxide, but to a much smaller extent, and the original compound could not be recovered by acidification. Instead, a new substance melting at 230–240° was obtained, which was not investigated further.

The presence of the enolic modification of α-bromo-β,β-diphenyl propionyl mesitylene in solutions in alcoholic potassium hydroxide was demonstrated by the formation of the enol methyl ether in alkaline solution. Dimethyl sulfate gave a 30% yield of $(C_6H_5)_2CHCBr{=}\underset{OCH_3}{C}C_6H_2(CH_3)_3$, and 65% of the bromide was recovered unchanged, along with traces of β-phenyl benzalacetomesitylene. Traces of the same ether were produced by methyl iodide.

α-Bromo-β,β-diphenyl propionyl mesitylene prepared by bromination of the Grignard addition product of phenylmagnesium bromide and benzalacetomesitylene often contains more bromine than the theoretical percentage. A large batch of crude bromide was methylated with dimethyl sulfate, yielding 20% of the ether and about 75% of unchanged starting material. The recovered bromoketone was then recrystallized and analyzed. Methylation of the analyzed sample gave the methoxyl derivative in 30% yield, leaving little doubt that only the bromoketone in the crude bromide underwent reaction as follows



$$(C_6H_5)_2CHCHBrCOC_6H_2(CH_3)_3 + (CH_3)_2SO_4 \longrightarrow (C_6H_5)_2CHCBr{=}\underset{\displaystyle OCH_3}{C}C_6H_2(CH_3)_3$$

Proof of the position of the bromine atom in α-bromo-β,β-diphenyl propionyl mesitylene was hardly necessary, since the same substance has been prepared by direct bromination of the saturated ketone, and the reactions of the Grignard reagent formed by treating the bromoketone with $C_2H_5MgBr^{8b}$ leave little doubt as to its structure. Further evidence of the position of the bromine atom was furnished by the bromination of benzhydrylacetomesitylene in alkaline solution according to Fuson's method for brominating acetomesitylene.[9] The dibromide obtained, $(C_6H_5)_2CHCBr_2COC_6H_2(CH_3)_3$, was identical with that formed by the alkaline bromination of α-bromo-β,β-diphenyl propionyl mesitylene.

To prove that the methoxyl compound did not have an indene structure, it was heated for forty-eight hours on the steam-bath with methyl alcoholic potassium hydroxide. The insoluble crystals gradually changed to a clear colorless oil, and potassium bromide was deposited. On acidification of the solution, the oil became bright yellow, and from the ether extract crystals of pure β-phenyl benzalacetomesitylene were obtained. Their identity was proved by hydrogenation to the corresponding saturated ketone and by their failure to depress the melting point of an authentic sample.

Experimental

α-Bromo-β,β-diphenyl Propionyl Mesitylene.—Twenty-five grams of benzalacetomesitylene in ether was added to a solution of phenylmagnesium bromide prepared from 5 g. of magnesium and 34 g. of bromobenzene. The solution was boiled for one hour, then cooled to −10° and stirred vigorously while 11 cc. of dry bromine was added dropwise, keeping the temperature below −5°. The magnesium derivative was decomposed immediately with ice and sulfuric acid and the precipitated bromoketone filtered off. The ether solution was washed with water, dried over calcium chloride and evaporated to recover the remainder of the bromoketone. The crude solid was recrystallized from benzene: yield of purified material, 80 to 90%, m. p. 172–173°.

Preparation of $(C_6H_5)_2CHC(Br){=}C(OCH_3)C_6H_2(CH_3)_3$.—α-Bromo-β,β-diphenyl propionyl mesitylene was dissolved in saturated methyl alcoholic potassium hydroxide by adding to the dry solid a number of cubic centimeters of the basic solution equal to twice the number of grams of solid. To prevent formation of unsaturated ketone, the bromide was ground finely and dissolved as rapidly as possible. Addition of 1 cc. of ether per 10 cc. of alcoholic alkali facilitated solution of the bromide, but if more than this was added the yield of methoxyl compound was reduced. After the solution became clear it was cooled in an ice-bath

---

[9] Fuson and Walker, THIS JOURNAL, **52**, 3269 (1930).

and a number of cubic centimeters of dimethyl sulfate equal to the number of grams of bromide used was added with vigorous stirring and efficient cooling. The dimethyl sulfate was added as rapidly as possible without allowing the solution to boil. The maximum rate was three or four drops per second in runs on more than 25 g. of material and less in smaller runs. When about two-thirds of the dimethyl sulfate had been added, evolution of gas became noticeable, and the mixture became semi-solid. The gas evolved was the same as that produced when methyl alcoholic potassium hydroxide was treated with dimethyl sulfate; it was identified as dimethyl ether by its boiling point. The reaction mixture was allowed to stand at ice-bath temperatures for several hours, usually overnight, then thoroughly washed with water to remove sodium sulfate and filtered to remove the rather insoluble starting material. This recovered bromide was washed with ether to remove all traces of methoxyl compound. The ether filtrate contained the methoxyl compound, quite large amounts of bromide and barely enough unsaturated ketone to color the solution yellow. The ether solution, dried and evaporated to a small volume, deposited crystals of the bromide. The methoxyl compound separated from the filtrate, but, following this, a mixture of the reaction product and starting material was obtained, the bromide in fine needles and the methoxyl compound in large hexagonal plates. Separation of the mixture was effected by extracting the diluted ether solution with methyl alcoholic potassium hydroxide, thus removing the bromide completely. The crystals could also be separated mechanically.

The methoxyl compound, m. p. 115–116°, separates as hexagonal plates from ether, is slightly soluble in petroleum ether and quite soluble in acetone and benzene.

Anal. Calcd. for $C_{25}H_{25}OBr$: C, 71.3; H, 6.0; Br, 18.97; CH_3O, 7.36; mol. wt., 421. Found: C, 71.1; H, 6.2; Br, 19.1, 19.4; CH_3O, 7.0; molecular weight in boiling acetone, 410, 409, 403.[10]

The bromine determinations were carried out by the Carius method, but in order to decompose the sample completely it was necessary to heat the tubes for six hours at 250°, open them and boil out the spent acid, then add fresh fuming acid and heat above 300° for eighteen hours. Analyses by the Parr bomb method failed to decompose the sample.

α,α-Dibromo-β,β-diphenyl Propionyl Mesitylene.—β,β-Diphenyl propionyl mesitylene and α-bromo-β,β-diphenyl propionyl mesitylene both gave nearly quantitatively the same dibromide, $(C_6H_5)_2CHC(Br)_2COC_6H_2(CH_3)_3$, when shaken for one week with a solution of bromine in aqueous alkali.[9]

Anal. Calcd. for $C_{24}H_{22}OBr_2$: Br, 32.86. Found: Br, 33.0, 33.0.

The ether solutions of α,α-dibromo-β,β-diphenyl propionyl mesitylene rapidly became colored on standing and liberated bromine. The pure white solid dibromide, m. p. 135–136°, is stable at ordinary temperatures, but turns red on heating. When the dibromide was heated on the steam-bath for thirty hours with 20% aqueous potassium hydroxide, about 75% of the dibromide was recovered unchanged. The remainder was a yellow oil, which deposited crystals of β-phenyl benzalacetomesitylene. When 2 g. of the dibromide was boiled with 25 cc. of saturated methyl alcoholic potassium hydroxide for five hours, all of the bromine was removed, since the resulting oil, after it had been taken up in benzene and washed with water, no longer gave a Beilstein test. When the solvent was evaporated, crystals of β-phenyl benzalacetomesitylene were deposited.

Summary

α-Bromo-β,β-diphenyl propionyl mesitylene was shown to exist as the enolic modification in solutions in alcoholic potassium hydroxide by the preparation of the enol methyl ether in alcoholic alkali.

The ease with which α-bromo-β,β-diphenyl propionyl mesitylene is enolized by bases is attributed to the influence of the halogen atom in the α-position. This supports the theory that α-halogen substitution favors enolization in alkaline media.

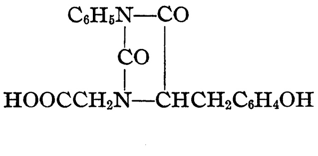
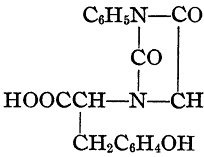
Hydantoins. LII.[1] The Synthesis of N-3-Phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic Acid from Tyrosine-N-acetic Acid[2]

BY ELINOR WARE[3]

The purpose of this investigation was to study the effect of substituent groups on the cyclization of a derivative of hydantoic acid which might theoretically undergo ring closure to give either of two isomeric hydantoins. A large number of α-amino acids and the symmetrical imino dibasic acid, iminodiacetic acid, have been converted into hydantoic acid and hydantoin derivatives through the action of aryl isocyanates and isothiocyanates,[4] but similar reactions of an unsymmetrical imino dibasic acid of the type of tyrosine-N-acetic acid have not been studied. Reactions of isocyanates with unsymmetrical imino dibasic acids are of especial interest since, for example, the substituted hydantoic acid prepared from tyrosine-N-acetic acid by treatment with phenyl isocyanate might be expected to undergo cyclization to give either of two isomeric hydantoins: N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid (I), or N-3-phenylhydantoin-N-1-*p*-hydroxybenzylacetic acid (II).



I

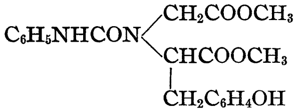


II

The fact that only one of these two isomeric hydantoins was isolated when this particular reaction was studied would appear to indicate that one of these hydantoins, because of the relative positions of its substituent groups, is formed much more readily from the corresponding acyclic hydantoic acid derivative than is its isomer.

When tyrosine-N-acetic acid was allowed to react with phenyl isocyanate in alkaline solution, the product obtained on neutralizing the cold alkaline reaction mixture was not the phenylureido derivative of tyrosine-N-acetic acid, but the closed hydantoin, N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid (I). This result is quite in accordance with the work of other investigators, who found that certain substituted hydantoic acids were so unstable that they underwent spontaneous ring closure in cold neutral solutions.[5] An attempt to prepare the acyclic phenylureido derivative of tyrosine-N-acetic acid by decomposing its copper salt with hydrogen sulfide gave similar results, the closed hydantoin (I) again being obtained when the filtrate from the copper sulfide was concentrated under reduced pressure at room temperature.

While the free acyclic dibasic phenylureidic acid was not isolated because of its strong tendency to undergo ring closure, it was obtained in the form of its dimethyl ester (III).



$$C_6H_5NHCON\begin{cases}CH_2COOCH_3\\ CHCOOCH_3\\ \quad|\\ CH_2C_6H_4OH\end{cases}\qquad \text{III}$$

This ester was obtained by treating the dimethyl ester of tyrosine-N-acetic acid with phenyl isocyanate in ether solution. Since this substance is only slightly soluble in ether, it was precipitated in crystalline form from the reaction mixture. This dimethyl ester of the phenylureido acid could be made to undergo cyclization to a hydantoin derivative by either of two methods. When boiled for half an hour with 25% hydrochloric acid, it was completely converted into N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid (I), the same compound which had been obtained when the alkaline reaction mixture of tyrosine-N-acetic acid and phenyl isocyanate was neutralized with mineral acid. Boiling of this ester in neutral aqueous solution for somewhat longer periods of time brought about the formation of the methyl ester of this same hydantoin-N-1-acetic acid.

The hydantoin prepared from tyrosine-N-acetic acid by the methods outlined above was proved

through synthesis to be N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid (I). N-3-Phenyl 5-anisalhydantoin was prepared according to the method of Wheeler and Hoffman,[6] and then converted into ethyl N-3-phenyl-5-anisalhydantoin-N-1-acetate by allowing ethyl chloroacetate to react with its sodium derivative in alcohol solution. By treatment with hydriodic acid in the presence of red phosphorus, this unsaturated ester was transformed into N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid (I), which proved to be identical with the substance obtained through the action of phenyl isocyanate on tyrosine-N-acetic acid. Therefore, in these particular experiments only one of the two theoretically possible isomeric hydantoins was obtained through the methods of ring closure employed.

This N-3-phenylhydantoin (I) will break down under alkaline hydrolysis to form tyrosine-N-acetic acid, carbon dioxide, and aniline. This decomposition follows the same course as that of the corresponding N-3-methyl derivative, which was found by Hahn and Renfrew to be converted by intensive alkaline hydrolysis into tyrosine-N-acetic acid, carbon dioxide, and methylamine.[7]

Experimental

N-3-Phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic Acid (I).—Four grams of tyrosine-N-acetic acid was dissolved in 25 cc. of water containing three equivalents (2.8 g.) of potassium hydroxide, 2.0 cc. of phenyl isocyanate (a small excess) slowly added to the cold solution during a period of fifteen minutes, and the mixture mechanically stirred for seven hours while cooled in an ice-bath. The resulting milky solution was allowed to stand overnight at room temperature, a little diphenylurea was removed, and the alkaline filtrate was again cooled and neutralized with an amount of hydrochloric acid equivalent to the potassium hydroxide used. After all of the hydrochloric acid had been added, a gum precipitated and then slowly crystallized. This precipitate weighed 4.8 g. and melted at 198–201° to a clear oil. After recrystallization from 200 cc. of water, the melting point was raised to 202–203°. Additional quantities of this substance were obtained by concentration of the mother liquor, so that the yield was practically theoretical. This substance was shown to be N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid through comparison with a sample of this substance prepared by another method, with which it proved to be identical.

Anal. Calcd. for $C_{18}H_{16}O_5N_2$: N, 8.24. Found: N, 8.25, 8.28.

This substance may be recrystallized most satisfactorily from boiling water, and can be made to separate in fairly large colorless crystals when its hot aqueous solution is cooled very slowly. It is quite soluble in alcohol and insoluble in ether.

This same hydantoin (I) was obtained by the decomposition of the copper salt of phenylureido-tyrosine-N-acetic acid with hydrogen sulfide. The copper salt was prepared by adding the theoretical amount of cupric chloride to an aqueous solution of the dipotassium salt of the phenylureido acid. Since it was almost insoluble in both alcohol and water, it was not recrystallized or analyzed. This blue copper salt was suspended in 95% alcohol, and gaseous hydrogen sulfide led into the mixture. After the removal of the precipitated copper sulfide, the filtrate was concentrated under reduced pressure at room temperature. When practically all the alcohol had been removed, the residue crystallized to give the same hydantoin (I) which previously had been obtained from solutions of the dipotassium salt of the phenylureido acid.

This hydantoin (I) was also prepared from the dimethyl ester of phenylureido-tyrosine-N-acetic acid (III) by boiling the latter with 25% hydrochloric acid. Two-tenths of a gram of the phenylureido ester was boiled for thirty minutes with 50 cc. of 25% hydrochloric acid. When the solution was cooled, a precipitate melting at 195–200° was obtained. After recrystallization from water it melted at 202–203°.

$CH_3OOCCH_2NHCH(CH_2C_6H_4OH)COOCH_3$, **Dimethyl Tyrosine-N-acetate.**—The hydrochloride of dimethyl tyrosine-N-acetate was prepared according to the method used by Hahn and Litzinger, through the treatment of tyrosine-N-acetic acid with a solution of dry hydrogen chloride in methyl alcohol.[8] In order to obtain the free ester, 2.0 g. of the ester hydrochloride was dissolved in 15 cc. of water and 0.55 g. of sodium bicarbonate, the amount necessary to free the ester from its hydrochloride, added to the aqueous solution. The free ester was then extracted with ether, the total volume used being about 100 cc. The ether extract was dried over anhydrous sodium sulfate, filtered, and concentrated to a small volume. When the ether was nearly evaporated and the free ester began to crystallize, water was added carefully in small portions to complete the crystallization of the ester. Dimethyl tyrosine-N-acetate is very soluble in both methyl alcohol and ether, but only slightly soluble in water. It was recrystallized by dissolving in a small amount of methyl alcohol and precipitating with water. It melts to a clear oil at 84–85°.

Anal. Calcd. for $C_{13}H_{17}O_5N$: N, 5.24. Found: N, 5.25, 5.02, 5.08.

Dimethyl Phenylureido-tyrosine-N-acetate (III).—The dimethyl ester of tyrosine-N-acetic acid was converted quantitatively into its phenylureido derivative by treatment with phenyl isocyanate in ether solution. One gram of dimethyl tyrosine-N-acetate was dissolved in 100 cc. of ether, and 0.8 cc. of phenyl isocyanate slowly added. The mixture was stirred in an ice-bath for three hours and then filtered from the precipitate which had begun to form at the end of twenty minutes. This precipitate consisted of the phenylureido derivative mixed with a small amount of diphenyl urea. It was purified by dissolving it in a small amount of methyl alcohol, filtering out the diphenyl urea, concentrating the alcoholic solution somewhat under

reduced pressure, and reprecipitating the phenylureido ester by the addition of ether. The melting point was 124–125° with evolution of a gas. This ester is very soluble in methyl alcohol, only slightly soluble in ether, and insoluble in water. The analyses of recently recrystallized samples indicate the presence of a molecule of methyl alcohol of crystallization.

Anal. Calcd. for $C_{20}H_{22}O_6N_2 \cdot CH_3OH$: N, 6.70. Found: N, 6.66, 6.79, 6.77.

Since heating will cause partial decomposition of this ester, it cannot be freed from solvents by this method. The methyl alcohol appears to be lost after long standing over dehydrating agents, as indicated by the analyses of a sample which had stood in a desiccator over calcium chloride for several months, although the melting point was unchanged.

Anal. Calcd. for $C_{20}H_{22}O_6N_2$: N, 7.26. Found: N, 7.33, 7.36.

$CH_3OOCCH_2NCON(C_6H_5)COCHCH_2C_6H_4OH$, **Methyl N-3-Phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetate.**—This ester could be prepared by either of two methods: (a) the esterification of the corresponding acid (I) with methyl alcoholic hydrogen chloride, or (b) the boiling of dimethyl phenylureido-tyrosine-N-acetate (III) in aqueous solution.

(a) Five-tenths of a gram of N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid (I) was dissolved in 25 cc. of methyl alcohol, and the solution saturated with dry hydrogen chloride. The reaction mixture was then heated for several hours and finally evaporated to an oil. Treatment of this oil with methyl alcohol–water mixtures brought about the crystallization of the ester, m. p. 140–141°. It was recrystallized by dissolving in a few cc. of methyl alcohol and reprecipitating through the addition of water.

Anal. Calcd. for $C_{19}H_{18}O_5N_2 \cdot CH_3OH$: N, 7.25. Found: N, 7.19, 7.32, 7.19.

(b) The preparation of this ester by boiling the dimethyl ester of phenylureido-tyrosine-N-acetic acid (III) in neutral aqueous solution was not so satisfactory, since only partial conversion occurred even after several hours of heating. One gram of the phenylureido ester was boiled with 200 cc. of water for one hour, during which time a large amount of gummy precipitate was formed. By repeated extraction of this gum with boiling water, several precipitates of the methyl ester of the hydantoin-N-1-acetic acid (I) were obtained. The rest of the gum was converted into the corresponding acid (I) by boiling it with 25% hydrochloric acid.

$C_2H_5OOCCH_2NCON(C_6H_5)COC{=}CHC_6H_4OCH_3$, **Ethyl N-3-Phenyl-5-anisalhydantoin-N-1-acetate.**—In order to prove that the substance obtained through the action of phenyl isocyanate on tyrosine-N-acetic acid was N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid (I), it was necessary to synthesize this compound by another method which could leave no doubt of the configuration of the compound. The first step in this synthesis was the preparation of N-3-phenyl-5-anisalhydantoin, $NHCON(C_6H_5)COC{=}CHC_6H_4OCH_3$, which was then converted into ethyl N-3-phenyl-5-anisalhydantoin-N-1-acetate. Five grams of N-3-phenyl-5-anisalhydantoin, prepared by the method of Wheeler and Hoffman[6] from N-3-phenylhydantoin,[9,10] was added to a solution of 0.43 g. of sodium in 50 cc. of absolute alcohol. The mixture was then heated for fifteen minutes, the phenylhydantoin dissolving as soon as the solution was hot, and 2.3 g. of ethyl chloroacetate (1.1 equivalents) added, together with 10 cc. more of absolute alcohol. The solution was now heated under reflux for three and a half hours. A heavy precipitate of sodium chloride began to separate at the end of one hour. At the termination of the heating period, the reaction mixture was poured into an equal volume of water, when a heavy precipitate was formed. This precipitate was extracted with chloroform in order to separate the reaction product from any unchanged N-3-phenyl-5-anisalhydantoin, and a residue of 2.5 g. of this hydantoin was obtained. The chloroform extract was evaporated almost to an oil and then treated with alcohol, when crystals of the reaction product, ethyl N-3-phenyl-5-anisalhydantoin-N-1-acetate, were obtained. After recrystallization from absolute alcohol, they melted at 89–91°.

Anal. Calcd. for $C_{21}H_{20}O_5N_2$: N, 7.38. Found: N, 7.22, 7.32.

This ester was converted by treatment with hydrogen iodide and red phosphorus into N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid (I), reduction of the double bond, demethylation, and hydrolysis of the ester group taking place under the action of this reagent. Five-tenths of a gram of the unsaturated hydantoin ester was refluxed for three hours with 10 cc. of concentrated hydriodic acid in the presence of a small amount of red phosphorus. The mixture was then subjected to distillation under reduced pressure at 110–120° in order to remove the methyl iodide formed during the reaction, as well as the excess of hydrogen iodide. Small amounts of water were added from time to time, and the distillation continued until the distillate gave no test for iodide ions. The residue was dissolved in hot water, filtered from red phosphorus, and the solution concentrated to five cc. Crystals of N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid (I), melting at 202–203° after recrystallization from hot water, were obtained from the cool solution. This hydantoin proved to be identical with the substance prepared from tyrosine-N-acetic acid and phenyl isocyanate, as shown by a mixed melting point determination, as well as by a comparison of their other properties.

Hydrolysis of N-3-Phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic Acid with Barium Hydroxide.—Hot aqueous solutions of 1 g. of N-3-phenyl-5-*p*-hydroxybenzylhydantoin-N-1-acetic acid (I) and 3 g. of barium hydroxide were mixed and heated on a steam-bath for five hours, the total volume being kept between 10 and 15 cc. During the hydrolysis the odor of aniline could be detected and a white precipitate was formed. The hot mixture was filtered and the filtrate concentrated to a small volume, when a second precipitate was obtained by the addition of alcohol. The two precipitates were suspended in hot water, and the barium exactly neutralized with sulfuric

(10) Mouneyrat, *ibid.*, **33**, 2399 (1900).

acid, the barium sulfate being subsequently filtered from the hot solution. After concentration of the filtrate, a precipitate of the imino dibasic acid, tyrosine-N-acetic acid, was obtained. This substance was identified by conversion into its characteristic hydrochloride, m. p. 212–213° with evolution of a gas, by treatment with 1:1 hydrochloric acid.[8]

Summary

Tyrosine-N-acetic acid, an unsymmetrical imino dibasic acid, will react with phenyl isocyanate to form a phenylureido dibasic acid which appears to be stable only in the form of its salts or esters. The free phenylureido acid undergoes spontaneous ring closure in cold aqueous solutions to give a trisubstituted hydantoin. Although the phenylureido derivative of tyrosine-N-acetic acid may theoretically undergo cyclization to give either of two isomeric hydantoins, only one of these isomers was obtained under the conditions studied.

The Synthesis of 1,4-Di-(3',4'-dimethoxyphenyl)-butanone-2 (Veratrylhomoveratryl Ketone)[1]

BY RICHARD CARROLL AND PAUL E. SPOERRI

The importance of a new general synthesis of the papaverine type of alkaloid was pointed out by Allen and Buck[2] in 1930. The published methods for the synthesis of papaverine itself involve the preparation of homoveratroylhomoveratrylamine[3–5] through the condensation of homoveratrylamine with homoveratric acid. No attempt has been made to prepare homoveratroylhomoveratrylamine from the oxime of 1,4-di-(3',4'-dimethoxyphenyl)-butanone-2 by means of a Beckmann rearrangement.[6]

It was felt that the synthesis of this tetramethoxy ketone would furnish a new approach to the preparation of a benzylisoquinoline alkaloid as illustrated by the following equations

$$(CH_3O)_2C_6H_3CH_2COCH_2CH_2C_6H_3(OCH_3)_2 \longrightarrow$$
$$(CH_3O)_2C_6H_3CH_2C({=}NOH)CH_2CH_2C_6H_3(OCH_3)_2 \longrightarrow$$
$$(CH_3O)_2C_6H_3CH_2CONHCH_2CH_2C_6H_3(OCH_3)_2$$

In a first attempt to prepare this ketone, 1,4-di-(3',4'-dimethoxyphenyl)-butanone-2, a Friedel–Crafts reaction between 1-chloro-4-(3',4'-dimethoxyphenyl)-butanone-2 and veratrole was studied. The chloro ketone was made from 3,4-dimethoxydihydrocinnamoyl chloride by means of the Nierenstein[7] reaction. The desired coupling, as shown by the following equation, did not take place and the method was abandoned.

$$(CH_3O)_2C_6H_3CH_2CH_2COCH_2Cl + C_6H_4(OCH_3)_2 \longrightarrow$$
$$(CH_3O)_2C_6H_3CH_2CH_2COCH_2C_6H_3(OCH_3)_2$$

The ketone was finally prepared by the following series of reactions

$$(CH_3O)_2C_6H_3CH_2CN + (CH_3O)_2C_6H_3CH_2CH_2COOC_2H_5 \longrightarrow$$
$$(CH_3O)_2C_6H_3CH(CN)COCH_2CH_2C_6H_3(OCH_3)_2 \longrightarrow$$
$$(CH_3O)_2C_6H_3CH(CONH_2)COCH_2CH_2C_6H_3(OCH_3)_2 \longrightarrow$$
$$(CH_3O)_2C_6H_3CH_2COCH_2CH_2C_6H_3(OCH_3)_2$$

Ethyl 3,4-dimethoxydihydrocinnamate was condensed with 3,4-dimethoxybenzylcyanide to give 1-cyano-1,4-di-(3',4'-dimethoxyphenyl)-butanone-2. This ketonitrile was hydrolyzed to 1-carbamyl-1,4-di-(3',4'-dimethoxyphenyl)-butanone-2. This was further hydrolyzed and decarboxylated to yield 1,4-di-(3',4'-dimethoxyphenyl)-butanone-2.

The hydrolysis of the ketonitrile, 1-cyano-1,4-di-(3',4'-dimethoxyphenyl)-butanone-2, presented some difficulty. It was finally accomplished by prolonged treatment of the material with an acetic–hydrochloric acid solution. The resulting amide, 1-carbamyl-1,4-di-(3',4'-dimethoxyphenyl)-butanone-2, was decarboxylated to 1,4-di-(3',4'-dimethoxyphenyl)-butanone-2 by means of dilute hydrochloric acid.

During the course of attempts to hydrolyze the above-mentioned ketonitrile, a product, melting at 209°, was obtained whose analysis corresponded to the calculated values for 1-(3',4'-dimethoxy-

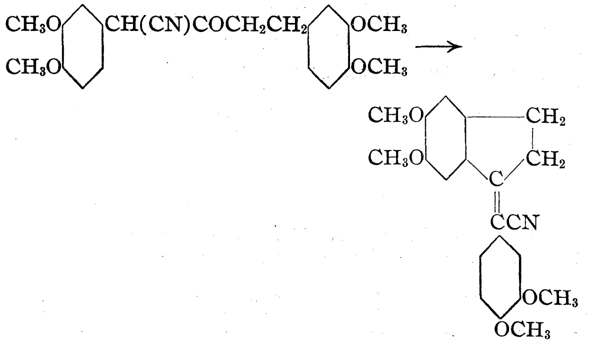
α-cyanobenzylidene)-5,6-dimethoxyindane. This material resulted from treatment of the ketonitrile with sulfuric acid. It could be formed in accordance with the following reaction



Experimental

3,4-Dimethoxydihydrocinnamoyl Chloride.—Thirteen grams of 3,4-dimethoxydihydrocinnamic acid[8] was treated with 6 g. of thionyl chloride. After standing for fifteen minutes the mixture was heated on a steam-bath for one hour and then distilled. The fraction boiling at 138–142° at 0.5 mm. was collected and redistilled. It solidified to a white solid melting at 40°[9,10] which was identified by conversion to the amide, melting at 121°.

1 - Chloro - 4 -(3',4' - dimethoxyphenyl) - butanone - 2.—Forty-eight cc. of nitrosomethylurethan was converted to diazomethane by the method of von Pechmann[11] and as used by Bradley and Robinson.[12]

To the ethereal solution (400 cc.) of diazomethane, cooled by ice, 27 g. of 3,4-dimethoxydihydrocinnamoyl chloride in 75 cc. of absolute ether was added slowly. There was a vigorous evolution of nitrogen during the addition. The solution was then placed in an ice chest overnight. After standing, dry hydrogen chloride was passed into the solution until the evolution of nitrogen ceased.

The solution was then evaporated to constant weight and allowed to stand. The chloro ketone crystallizes in rosets and has strong lachrymatory and vesicant properties. It can be recrystallized from alcohol and melts at 53°.

Anal. Calcd. for $C_{12}H_{15}ClO_3$: C, 59.38; H, 6.23; Cl, 14.60. Found: C, 59.04, 59.15; H, 6.14, 6.02; Cl, 14.71.

1 - Cyano - 1,4 - di - (3',4' - dimethoxyphenyl) - butanone-2.—Twenty-three grams of 3,4-dimethoxybenzyl cyanide, prepared by the method of Pfeiffer, Quehl and Tappermann,[13] was added to 32 g. of ethyl 3,4-dimethoxydihydrocinnamate and heated to 60°. This mixture was added to a warm solution of 3.1 g. of sodium in 50 cc. of absolute alcohol.[14]

The reaction mixture was refluxed[15] on a steam-bath for three hours and then allowed to stand for two days. During the heating, yellow colored crystals appeared. After standing, the solid material (sodio derivative of 1-cyano-1,4-di-(3',4'-dimethoxyphenyl)-butanone-2) was removed by filtration, washed with absolute alcohol and air dried. It was then dissolved in 400 cc. of water and the solution was extracted with ether. The aqueous layer was then placed under a vacuum to remove the dissolved ether. This was followed by the addition of 25 cc. of hydrochloric acid. The heavy gum which precipitated, crystallized in a few hours; yield 39 g. It was recrystallized from a dilute alcoholic solution and melted at 76°.[16]

Anal. Calcd. for $C_{21}H_{23}NO_5$: C, 68.28; H, 6.27; N, 3.79. Found: C, 67.72, 67.60; H, 6.05, 6.14; N, 3.80, 3.86.

1 - Carbamyl - 1,4 - di - (3',4' - dimethoxyphenyl) - butanone-2.—Fifteen grams of 1-cyano-1,4-di-(3',4'-dimethoxyphenyl)-butanone-2 was dissolved in a mixture of 112 cc. of glacial acetic acid and 112 cc. of concentrated hydrochloric acid contained in a glass-stoppered flask. After standing for four days between 15 and 20°, the solution was poured into 1800 cc. of water and allowed to stand for twenty-four hours. A gum separated which clung to the walls of the beaker (if a crystal is added at the time of dilution a solid is obtained). The water layer was removed and the residue was dissolved in hot alcohol and filtered. The filtrate was evaporated to 10 cc. The product crystallized very slowly in buff colored plates. It gives a violet coloration with ferric chloride and dissolves in aqueous sodium hydroxide. It can be recrystallized from alcohol and melts at 123°; yield 4 g.

Anal. Calcd. for $C_{21}H_{25}NO_6$: C, 65.10; H, 6.50; N, 3.61. Found: C, 65.08, 65.18; H, 6.41, 6.58; N, 3.80.

1,4 - Di - (3',4' - dimethoxyphenyl) - butanone - 2.—Two grams of 1 - carbamyl - 1,4 - di - (3',4' - dimethoxyphenyl)-butanone-2 was added to 120 cc. of a solution of 12 cc. of concentrated hydrochloric acid in 138 cc. of water. This mixture was boiled for two hours. After cooling, the water solution was decanted and the remaining gum was dissolved in hot alcohol. This solution was filtered and evaporated to 4 cc. Buff colored crystals were deposited on standing; yield 0.90 g. The material was recrystallized from alcohol and melted at 76°.

Anal. Calcd. for $C_{20}H_{24}O_5$: C, 69.75; H, 7.02. Found: C, 69.45, 69.85; H, 7.04, 7.13.

Dinitro Derivative.—Nitration in acetic acid yields a dinitro derivative which can be recrystallized from acetic acid, and melts at 195°.

Anal. Calcd. for $C_{20}H_{22}N_2O_9$: C, 55.30; H, 5.10; N, 6.45. Found: C, 54.92, 55.09; H, 4.89, 5.03; N, 6.34, 6.27.

Compound Melting at 209°.—One-fifth gram of 1-cyano - 1,4 - di - (3',4' - dimethoxyphenyl) - butanone-2 was added to 5 cc. of a sulfuric acid solution (3 volumes H_2SO_4:2 volumes H_2O) and warmed on a steam-bath for ten minutes.

(9) After standing several weeks the material changed to a dark gummy paste.

(10) Pictet and Finkelstein, *Ber.*, **42**, 1985 (1909), prepared this chloride by using phosphorus pentachloride.

(11) Von Pechmann, *Ber.*, **28**, 856 (1895).

(12) Bradley and Robinson, *J. Chem. Soc.*, 1545 (1928).

(13) Pfeiffer, Quehl and Tappermann, *Ber.*, **63**, 1301 (1930).

(14) Pfeiffer, Quehl and Tappermann[13] used an alcoholic solution of sodium ethoxide for this type of condensation, while Haworth and co-workers, *J. Chem. Soc.*, 1426 (1934), employed a suspension of potassium ethoxide in benzene.

(15) All of the glassware was previously dried and the solution protected from moisture by a calcium oxide tube.

(16) A portion of this material was recrystallized after standing several months. It then melted at 122° and gave the following analytical results: C, 68.49, 68.66; H, 6.11, 6.05; N, 3.92, 4.04.

The solid first dissolved, this was followed by the appearance of yellow colored needles. After cooling, the solution deposited a curdy yellow precipitate. The solid was recrystallized from ethyl acetate and melted at 209°; yield 0.12 g.

Anal. Calcd. for $C_{21}H_{21}NO_4$: C, 71.78; H, 6.02; N, 3.99. Found: C, 71.76, 72.15; H, 5.85, 6.14; N, 4.32, 4.24.

Summary

1. Methods have been described for the preparation of 1-cyano-1,4-di-(3′,4′-dimethoxyphenyl)-butanone-2, 1-carbamyl-1,4-di-(3′,4′-dimethoxyphenyl)-butanone-2 and 1,4-di-(3′,4′-dimethoxyphenyl)-butanone-2.

2. Attempts to prepare 1,4-di-(3′,4′-dimethoxyphenyl)-butanone-2 by means of a Friedel–Crafts reaction were unsuccessful.

BROOKLYN, N. Y. RECEIVED AUGUST 17, 1938

The Influence of Branched Chains on Optical Activity. The Configuration of Propyl-*t*-butylcarbinol, with a Note on the Relation between Rotatory Power and Chemical Character

BY PHILIP G. STEVENS, W. EDWARD HIGBEE[1] AND ROBERT T. ARMSTRONG[2]

In a previous paper on this subject[3] the configuration of dextro methyl-*t*-butylcarbinol, as determined by Freudenberg's displacement rule, was found to be the same as dextro methyl-*n*-butylcarbinol. It was therefore apparent from their molecular rotations, +7.8° and +12.0°, respectively, that the *t*-butyl group did not cause as great a shift in the rotation as the isopropyl (+4.7°), or the cyclohexyl (+7.4°) group. This result was unexpected as it was felt that, if branching of the chain were responsible for the observed shift, the completely branched *t*-butyl group would cause a greater shift. Therefore the suggestion was made that the real effect of the singly branched group was due to the presence of a tertiary hydrogen atom. According to the theories advanced by Kuhn and Freudenberg,[6] this hydrogen atom might well bring about a shift in the rotation, since it represents another center of chemical reactivity close to the asymmetric carbon atom.

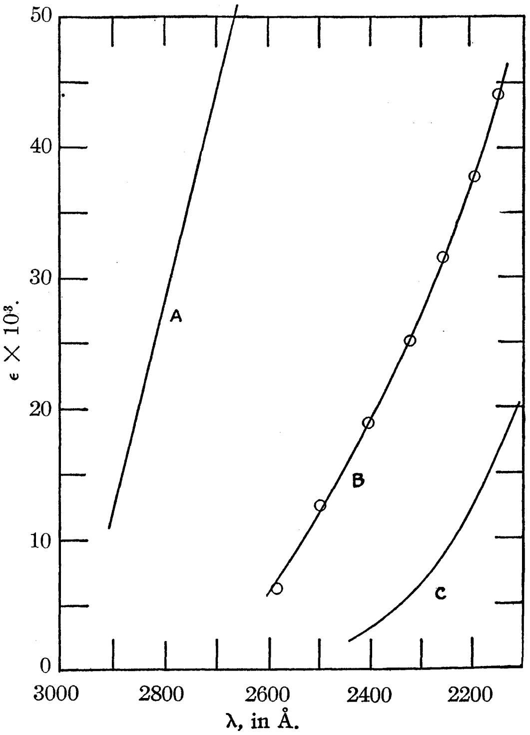

Fig. 1.—A, *n*-Butyl alcohol[4]; B, pinacolyl alcohol; C, ethyl alcohol.[5]

On the other hand, something may be abnormal about the *t*-butyl group. However, methyl-*t*-butylcarbinol shows no anomalous absorption bands in the near ultraviolet, and is similar to other carbinols as shown in Fig. 1. The high transmission of this carbinol as compared with other carbinols with a fewer number of carbon atoms may possibly be attributed to the high purity of the sample used.

Anomalous properties are often found in the lowest member of various series. This has been found to be true for the rotations of the isopropyl series.[7] A determination of the configuration of

the third member of the *t*-butyl series, propyl-*t*-butylcarbinol, has now demonstrated that this is also the case here. This determination shows that levo propyl-*t*-butylcarbinol has the same configuration as dextro methyl-*t*-butylcarbinol on the basis of Freudenberg's displacement rule, for a dextro shift occurs in the rotations on passing from the acetates to the benzoates, and to the phthalates.

$C_6H_{11}CHOH$–	+ 7.4	−11.5	−17.0
$(CH_3)_3CCHOH$–	+ 7.8	....	−55.2

The high levo rotation of propyl-*t*-butylcarbinol shows that in cases where anomalies are avoided, the fully branched *t*-butyl group causes a much greater shift in the rotation than either of the other branched groups.[10]

It is therefore obvious that the controlling factor is not the tertiary hydrogen atom of the isopropyl and cyclohexyl groups, but rather the chemical character of the group as a whole. The chemical effect of branched chain groups is well established, as evidenced by the great difference in reactivity between primary, secondary and tertiary alcohols and halides. There is also a chemical effect of these groups when once removed from the hydroxyl group. This is shown by the marked tendency of carbinols containing these groups to undergo rearrangement when dehydrated or converted to halides.[11]

It is significant that only those carbinols which rearrange readily show a large shift in the rotation from the first to the next two higher members of the series. The sign of rotation is actually reversed in the latter two. Cyclohexylcarbinols, which show this large shift, have likewise now been found to rearrange. There seems therefore to be a connection between the chemical effect and rotatory effect of branched groups.

Table III shows the results on the conversion of several active carbinols to halides under standard conditions. The rotations and per cent. of rearrangement may be compared. There appears to be a relationship between the amount of rearrangement caused by each branched chain group, and the degree of rotatory shift, the order being cyclohexyl < isopropyl < *t*-butyl.

We are indebted to Professor James F. Norris for the facilities of the Laboratories of the Massachusetts Institute of Technology where the major part of this work was done, and also to the Mallinckrodt Chemical Works for donating so generously the large amounts of strychnine necessary in this work.

Experimental Part

In this work, all rotations are for the homogeneous state unless otherwise stated.

Dextro Propyl-*t*-butylcarbinol.—The carbinol, prepared from *t*-butylmagnesium chloride and *n*-butylaldehyde, was converted into the acid phthalate, and resolved with strychnine in 95% alcohol. After twelve crystallizations, the salt was decomposed, the phthalate examined, $(M)^{24}_D$ ($CHCl_3$) −7.2° (max. −8.4°), and converted to the carbinol in the usual way, b. p. (36 mm.) 74.5–75.0°, n^{25}_D 1.4251, d^{25}_4 0.8215, $(M)^{25}_D$ +47.2°. The activity of the carbinol obtained from the corresponding unsaturated carbinol by reduction indicates that this value is not the maximum. By calculation the highest observed $(M)_D$ would be +55.2°. This is probably close to the maximum, and is tentatively therefore designated as the maximum.

Anal. Calcd. for $C_8H_{18}O$: C, 73.8; H, 13.9. Found: C, 73.9; H, 13.9.

Dextro Propyl-*t*-butylcarbinol Acetate and Benzoate.—These derivatives were prepared as described earlier for

Anal. Calcd. for $C_{15}H_{22}O_2$: C, 76.9; H, 9.4. Found: C, 77.1; H, 9.5.

Dextro Propenyl-*t*-butylcarbinol.—The highest rotation obtained with this carbinol, previously described,[16] was $(M)^{23}D$ +23.5°, with a phthalate of $(M)^{23}D(CHCl_3)$, −16.2°. Another sample, $\alpha^{22}D$ −0.60°, yielded the saturated carbinol, when reduced with Adams platinum catalyst in alcohol solution, with $\alpha^{22}D$ −1.41°.

Chloride Formation from Secondary Carbinols.—Seven to eleven cc. of each carbinol was sealed in a tube with 40–60 cc. of concentrated hydrochloric acid saturated with dry hydrogen chloride at −10°. The mixture was then allowed to warm up to 25°, shaking frequently. In all cases, except those of the octanols, the solution was homogeneous. In the latter, the carbinols did not dissolve in the hydrochloric acid, and the carbinol layer at first expanded, and then slowly contracted as the reaction proceeded. When the volume remained constant for a considerable length of time, the reaction was deemed complete. Generally, however, after one to two days, the chlorides had separated completely, and were then washed 2–5 times with concentrated hydrochloric acid, once each with ice water and iced sodium bicarbonate, and dried over anhydrous potassium carbonate. The chlorides were in every case free of olefins as shown by their failure to absorb bromine in either carbon tetrachloride or acetic acid. The chlorides were analyzed by Michael's method[11] for tertiary chlorides. This was carried out by shaking one gram of each with 250 cc. of water[17] until no more acid was evolved. This took about one-half to one hour, except in the cases of the more insoluble octyl chlorides which required three to four hours for hydrolysis to reach a standstill.[18]

Dextro Methyl-*t*-butylcarbinol.—The carbinol, b. p. 120° (760 mm.), $\alpha^{27}D$ + 3.78°, was redistilled in an all-glass apparatus before determining the absorption spectrum with a Hilger Spekker Photometer and E316 Quartz Spectrograph. The molal extinction coefficient, *e*, was calculated from the formula $e = \frac{1}{cd} \log \frac{I_0}{I}$ where *c* was 7.97, the concentration in moles per liter, and *d* was 2, the length of the cell in centimeters. The sample examined showed continuous absorption as indicated in Fig. 1. After standing for several weeks, the same sample showed an intense absorption band at 2800 Å., due no doubt to partial oxidation to pinacolone.

Summary

1. Dextro methyl-*t*-butylcarbinol is configurationally related, according to the displacement rule of Freudenberg, with levo propyl-*t*-butylcarbinol.

2. The *t*-butyl group, in the third member of that series, causes a greater shift in the rotation than either the isopropyl or cyclohexyl groups.

3. A relation between rotatory power and chemical character has been pointed out, and in a number of cases confirmed.

"Glorieta" Monazite

BY O. B. MUENCH

Several years ago, Dr. A. C. Lane secured a large and almost perfect crystal of monazite from P. Krieger, who had obtained it from someone near Glorieta, New Mexico, and was under the impression that originally it had come from a deposit in that neighborhood. A small fragment of this crystal was sent by Lane to Dr. F. Hecht in Vienna. The microanalysis made by F. Hecht and Edith Kroupa is reported on page 44 of "The Report of the Committee on the Measurement of Geologic Time," of the National Research Council, April, 1935.

The Committee on the Measurement of Geologic Time is interested in obtaining a quantity of "thorium-lead," free from "uranium-lead" and common lead, for an atomic weight determination and other experimental purposes. Mr. Rufus C. Little of Albuquerque, who was in possession of twenty to thirty pounds of the monazite, kindly agreed to furnish specimens of the mineral which he had personally collected from the old Cribbenville Mica Mine near Petaca, New Mexico. It is quite possible that the crystal which Krieger had obtained came from the same deposit.

Monazite is suitable material to use for an age determination by the lead–uranium method. This particular monazite sample consisted of large pieces (crystal fragments, etc.) and besides smaller lumps, some fines. The fines were separated and not used in this analysis. The largest piece weighed 252 g. and all the better pieces used in this determination weighed over 100 g. The material was fresh, tan to reddish brown in color, most of it clear of any other adhering mineral and showing hardly any alteration.

The larger pieces were broken in a clean iron mortar and then finely powdered in a clean agate mortar to pass through an 80-mesh sieve. Precautions were taken to avoid contamination, especially by lead, not only during the preparation of the sample, but throughout the entire analysis.

Analysis

Fenner[1] has worked out a detailed method for the analysis of monazite. His method with several modifications was used in the decomposition of the sample and the lead determination. The details of analysis will not be included in this paper. Hecht[2] makes the statement, "By solution of monazite in sulfuric acid, one would find too little lead." A. C. Lane adds to this the following, "Possibly such an error has crept into many analyses heretofore."

The solution of the monazite was accomplished according to the method of Fenner by heating the powdered sample in a platinum dish for about six hours with a mixture of sulfuric and hydrofluoric acids. This treatment usually disintegrates the sample, but occasionally it was found that all was not decomposed completely. This residue was given further treatment till all of it was decomposed.

In the lead determinations, care was taken to test all residues and filtrates for traces of lead and add these when necessary. This is important, for in the hydrofluoric acid method of decomposition, much of the lead may be found in the residue after hydrofluoric and sulfuric acid treatment and even after the extraction with ammonium acetate. There is very little possibility of any lead being lost in this determination. All reagents used in this analysis were tested and found lead free. The lead was determined as the sulfate.

The iodate method as described with references in previous papers[3] was followed for the thorium determinations.

The uranium was determined as the pyrophosphate,[3] also described in detail in previous papers.

RESULTS OF ANALYSES

Lead

Sample, g.	$PbSO_4$, g.	Lead, %
30.0000	0.1475	0.336
30.0000	.1502	.342
30.0000	.1498	.341
30.0000	.1490	.339
	Average	.339

Thorium

Sample, g.	ThO_2, g.	Thorium, %
2.0035	0.1707	7.49
2.0024	.1720	7.54
3.0044	.2615	7.55

---

(1) Fenner, *Am. J. Sci.*, **16**, 369 (1928).

(2) Report of the Committee on the Measurement of Geologic Time, Natl. Research Council, p. 45, April 27, 1935.

(3) Muench, THIS JOURNAL, **59**, 2269 (1937).

Thorium (*Concluded*)

Sample, g.	ThO_2, g.	Thorium, %
2.5011	.2131	7.49
2.0015	.1700	7.46
2.0550	.1762	7.52
	Average	7.50

Uranium

Sample, g.	$(UO_2)_2P_2O_7$, g.	Uranium, %
3.0044	0.0050	0.109
2.5011	.0038	.101
2.0015	.0033	.109
	Average	.106

Loss on ignition	0.838%
Loss at 110°, three hours	.14%

There were no indications of ordinary lead mineral associated with the sample. If we assume the absence of ordinary lead and make use of the conversion factor 0.36 for thorium, the lead-uranium ratio is

$$\frac{0.339}{0.106 + 0.36 \times 7.50} = 0.1208$$

The approximate age of the mineral is

$$\frac{0.121 \times 1.15 \text{ million years}}{1.57 \times 10^{-4}} = 886 \text{ million years}$$

With so old a mineral, the more exact or "logarithmic" formula for calculating age gives a materially different result from that found by the above "approximate" formula, and should be used in calculating the age of this material. Age, based on formula

$$\frac{\log(U + 0.36Th + 1.155Pb) - \log(U + 0.36Th)}{6.6 \times 10^{-5}} \text{ million years} = 858 \text{ million years}$$

As a pilot analysis for this work, Hecht made a complete microanalysis of a small piece from the crystal in Dr. Lane's possession. His results show, 9.36% thorium, 0.392% lead and give no figures for the uranium. Hecht obtains an age of 800 million years from his determination.

Acknowledgment.—The author is grateful to Mr. Rufus C. Little for the samples; to the Geological Society of America for financial assistance in part, for this research; to Dr. A. C. Lane for his constant interest in this work with helpful suggestions; and to the late Dr. Herman Schlundt and the University of Missouri for the use of the laboratories and other facilities.

Summary

This monazite is not a suitable source for pure "thorium-lead," as the analysis shows evidence of 0.106% uranium. The other analytical results are, 7.50% thorium and 0.339% lead. The age of the monazite is 858 million years, placing it in the Pre-Cambrian Age. Hecht, from his pilot analysis, obtains an age of 800 million years. It is probable but by no means certain that this material and the material Hecht used in his analysis came from the same deposit.

The Effect of the Triple Bond on the Rate of Reaction of ω-Chlorides with Potassium Iodide in Absolute Acetone

BY M. J. MURRAY

Conant and his students[1] have studied the rates of reaction of a variety of organic chlorides with potassium iodide in absolute acetone. The only triple bond compound they reported on, however, was $CNCH_2Cl$. Truchet[2] has shown qualitatively that chlorine attached directly to a triple bond carbon is very unreactive toward sodium iodide in acetone.

The present investigation was made because no study has been reported showing the effect of the acetylenic linkage on the reactivity of chlorine in the ω-position. The series selected was $C_6H_5C{\equiv}C(CH_2)_nCl$, all members of which were prepared from phenylacetylene. Cinnamyl chloride was available for comparison of the effect of the ethylenic linkage.

The method of measuring the velocity of the reaction and of calculating the constant for the reaction was essentially that given in detail by Conant and students.

The results are summarized in Table I. It is seen that in this series of acetylenic chlorides there is a definite alternation of reactivity, the order with respect to the triple bond being $\alpha > \gamma > \beta$. This order of reactivity is the same as that found

---

[1] (a) Conant and Kirner, THIS JOURNAL, **46**, 232 (1924); (b) Conant and Hussey, *ibid.*, **47**, 476 (1925); (c) Conant, Kirner and Hussey, *ibid.*, **47**, 488 (1925).

[2] Truchet, *Ann. chim.*, [10] **16**, 309 (1931).

by Conant and Kirner[1a] for the simple C_6H_5 series without the triple bond ($C_6H_5CH_2Cl$, $K_{50} = 8.07 > C_6H_5CH_2CH_2CH_2Cl$, $K_{50} = 0.0713 > C_6H_5CH_2CH_2Cl$, $K_{50} = 0.0466$).

The inactivity of the chlorine attached to the triple bond carbon verifies Truchet's qualitative experiment and is to be expected in the light of the similar behavior of chlorine attached to an ethylenic carbon. Although chlorine α to a triple bond has somewhat smaller reactivity than when α to a double bond in the example studied, the order of activity is the same. The effect of the phenyl group in the 1-position can be evaluated approximately by the comparison of the values of the constants for allyl chloride[1c] and for cinnamyl chloride. It is apparent that the phenyl group extends its influence quite markedly by raising the value of the constant from 0.288 to 5.0. The effect of geometrical isomerism has not been studied, as only the *trans* form, cinnamyl chloride, was available.

TABLE I

REACTION VELOCITIES OF ω-CHLORIDES WITH POTASSIUM IODIDE IN ABSOLUTE ACETONE

Compound	K_{25}	K_{60}	Relative reactivity at 60°
$CH_3CH_2CH_2CH_2Cl$[1]	...	0.101	1
$C_6H_5C{\equiv}CCl$	...	0	0
$C_6H_5C{\equiv}CCH_2Cl$[a]	2.9	(79)	(782)
$C_6H_5C{\equiv}CCH_2CH_2Cl$	...	.048	0.48
$C_6H_5C{\equiv}CCH_2CH_2CH_2Cl$	...	.19	1.9
$C_6H_5CH{=}CHCH_2Cl$[a]	5.0	(138)	(1370)
$CH_2{=}CHCH_2Cl$[1]	0.288	(7.9)	(78)

[a] The values for K_{60} were calculated from the equation

$$\log \frac{K_{60}}{K_{25}} = 4000\left(\frac{1}{298} - \frac{1}{333}\right)$$

Experimental

Phenylethynyl Chloride (2-Chloro-1-phenylethyne).—This substance was prepared from sodium phenylacetylide and *p*-toluenesulfonyl chloride by the method of Truchet.[2] As he noted, phenylethynyl chloride begins to turn yellow very soon following distillation. After a few months, a sample of 9 g. yielded on distillation only 2 g. of the compound. Colorless crystals were found in contact with the viscous, dark brown resin. This resinification sets in so quickly that the first experiment carried out to determine the reaction velocity of this compound was misleading. The experiment was not started until three days after distillation of the chloride. As soon as the potassium iodide–acetone solution came into contact with the slightly yellow chloride, there was a gradual darkening of the solution; and after a short time a precipitate of potassium chloride began to form. At the end of seventeen hours the reaction was stopped, and titration showed that about 15% of the potassium iodide had disappeared. When the experiment was repeated immediately after distillation of the compound, the solution remained practically colorless; and after forty hours at 60° the difference between the "blank" and the reaction mixture was too small to be significant.

Chloromethylphenylacetylene (3-Chloro-1-phenylpropyne-1).—The compound was prepared by the action of phosphorus trichloride on phenylpropargyl alcohol in the presence of pyridine and ether. Tchao[3] prepared the corresponding bromide in an analogous way, using phosphorus tribromide. Into a flask containing 13.8 g. of phenylpropargyl alcohol dissolved in 10 ml. of dry ether and 1 ml. of pyridine, was slowly dropped 6.6 g. of phosphorus trichloride. The mixture was refluxed for two hours. A large volume of water was poured in, the layers separated, and the water extracted with ether. The ether layers were combined and washed with sodium bicarbonate solution, then with water, and dried over calcium chloride. The ether was driven off and the liquid distilled *in vacuo*. There was obtained 8 g. (51% yield) of purified product, b. p. 99° (7 mm.); d^{20}_{20} 1.112, n^{20}_D 1.5834.

Anal. Calcd. for C_9H_7Cl: Cl, 23.6. Found: Cl, 23.8.

Because of its great activity the reaction velocity of this compound was determined at 25° rather than at 60°.

β-Chloroethylphenylacetylene (4-Chloro-1-phenylbutyne-1).—This compound was prepared from the directions given by Johnson, Schwartz, and Jacobs:[4] b. p. 99° (3 mm.); d^{20}_{20} 1.085.

Anal. Calcd. for $C_{10}H_9Cl$: Cl, 21.6. Found: Cl, 21.5.

When the reaction velocity is as low as in the case of this compound, a saving in time can be effected by weighing the chloride directly into the reaction tube, adding the acetone–potassium iodide solution, sealing the tube at once, and placing it in the bath as soon as possible. The accuracy of estimating the time of starting is considerably greater than that of titration. The latter, according to Conant and Kirner,[1a] is subject to a variation of ±4%.

γ-Chloropropylphenylacetylene (5-Chloro-1-phenylpentyne-1).—This compound also was prepared according to the method given by Johnson, Schwartz, and Jacobs:[4] b. p. 125° (6 mm.); d^{20}_{20} 1.064.

Anal. Calcd. for $C_{11}H_{11}Cl$: Cl, 19.9. Found: Cl, 19.7.

Cinnamyl Chloride (3-Chloro-1-phenylpropene-1).—Eastman product redistilled, b. p. 106° (10 mm.).

Because the cinnamyl iodide, formed by the action of potassium iodide on cinnamyl chloride, liberates iodine during the titration of potassium iodide with potassium iodate in strongly acid solution, it is necessary to extract the mixture to be titrated before adding the potassium iodate. The liberation of iodine by cinnamyl iodide is especially rapid in sunlight but takes place too rapidly even in weak artificial light to permit titration without extraction.

All the chlorides were purified by distillation through a heated column 30 cm. long, packed with a spiral of No. 20 wire. A reflux ratio of at least 10 was used.

Acknowledgments.—This work was supported in part by a grant-in-aid from the Virginia Academy of Science from funds allotted it by the American Association for the Advancement of

Science. The writer wishes to thank Dr. John R. Johnson not only for suggesting the investigation but also for helpful advice.

Summary

1. The reaction velocity of a series of acetylenic chlorides has been measured according to the method of Conant.

2. A definite alternation in reactivity has been observed.

3. The most active acetylenic chloride measured has a somewhat lower activity than the corresponding ethylenic compound.

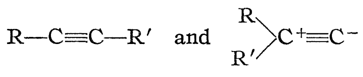
Raman Spectra of Acetylenes. I. Derivatives of Phenylacetylene, $C_6H_5C{\equiv}CR$

BY M. J. MURRAY AND FORREST F. CLEVELAND

The Raman spectra of disubstituted acetylenes have been investigated by various workers, who have found that the characteristic acetylenic frequency in the region 2200–2300 cm.$^{-1}$ is usually double or triple, although in a few cases it is reported as a single, broad line.[1] Several explanations of this splitting have been given: Glockler and Davis[2] attribute the two strong lines in dimethylacetylene to symmetrical and asymmetrical vibrations. Gredy[3] suggests, as a working hypothesis, that two isomeric forms



$$R{-}C{\equiv}C{-}R' \quad \text{and} \quad {}^{R}_{R'}\!\!>\!C^{+}{\equiv}C^{-}$$

may exist simultaneously. Kohlrausch, Pongratz and Seka[4] regard the existence of two or more frequencies, if only one molecular form is present, as difficult to understand. Badger[5] attributes the doubling to a Fermi resonance interaction between the fundamental acetylenic frequency in this region and an overtone of a lower frequency near 700 or 1100 cm.$^{-1}$.

Gredy[3] found two lines for $C_6H_5C{\equiv}CCH_2OH$, while Faucounau[6] reported a single broad line for $C_6H_5C{\equiv}CCH_2CH_2OH$, and Bourguel and Daure[7] only a single frequency for $C_6H_5C{\equiv}CCl$. In view of these results and of the difference in opinion as to the cause of the splitting, it appeared worth while to investigate carefully the Raman spectra of disubstituted acetylenes in order to determine how the nature of the splitting varies for closely related molecules and to determine, if possible, whether there is a certain kind of substitution that yields only a single frequency. The present paper gives the results obtained for a series of compounds of the type $C_6H_5C{\equiv}CR$.

Experimental Procedure

The apparatus and experimental technique were essentially the same as previously described.[8] All the compounds were purified carefully by distillation in a heated column, using a high reflux ratio. Since the acetylenic compounds suffered photochemical decomposition when exposed to the exciting light and since the decomposition products were fluorescent and added greatly to the continuous background, it was necessary to redistill, from a flask attached to the scattering tube, at one-hour intervals during the exposures. In spite of these precautions, the continuous background was strong, especially in the case of the bromide.

The general procedure was to obtain several plates with both long and short exposure times, using both Hg 4047 Å. and 4358 Å. for excitation. The more intense lines could be measured with greater accuracy on the short exposure plates. In order to secure better definition of the stronger lines, the camera lens was stopped down to 5 mm. and a final exposure made. The time of this exposure was ten hours. The lines on these plates were exceedingly sharp and the acetylenic frequency in the 2200 cm.$^{-1}$ region, which on the other plates appeared as a single broad line, was resolved.

The comparator was illuminated with light from a yellowish-brown incandescent lamp, a practice which resulted in increased distinctness for the weaker lines.

Results

The results are given in the sections below, in which *k*, *f*, and *e* represent excitation by Hg 4047, 4347, and 4358 Å., respectively. Broad lines are designated by *b* and estimated intensities are given by the numbers in parentheses.

$\Delta\nu$ = [180(2)*e*], [195(2)*e*], 250(1b)*ke*, 270(2)*ke*, 282(2)*ke*, 302(1)*ke*, 336(1)*ke*, 350(2)*ke*, 366(3)*ke*, 382(4)*e*, 426(1)*ke*, 438(1)*ke*, 458(2b)*k*, 476(2b)*ke*, 512(2b)*ke*, 530(2)*ke*, 553(2)*ke*, 573(2)*ke*, 590(2)*ke*, 605(1)*ke*, 625(2b)*ke*, 648(1)*ke*, 663(1)*ke*, 703(1)*ke*, 721(2)*ke*, 743(3)*ke*, 761(3)*ke*, 789(2)*ke*, 956(3)*ke*, 985(2)*ke*, 1000(7)*ke*, 1028(3)*ke*, 1151(2)*ke*, 1164(4)*ke*, 1179(4)*ke*, 1238(4)*ke*, 1258(6)*ke*, 1285(1)*k*, 1331(1)*k*, 1439(3)*ke*, 1456(3)*ke*, 1496(3)*ke*, 1603(9)*ke*, 2202(3)*ke*, 2231(5)*ke*, 2242(10)*ke*, [2290(2)*e*], 2818(1)*ke*, 2951(2)*e*, 2978(1)*ke*, 3061(4)*ke*.

6. **4-Phenyl-3-butynol-1** ($C_6H_5C{\equiv}CCH_2CH_2OH$).—Synthesized by way of ethylene oxide on phenylacetylenemagnesium bromide;[13] b. p. 130° (7 mm.); previous data, Faucounau.[6]

$\Delta\nu$ = 248(1)*ke*, [265(3)*k*], 386(2)*ke*, 405(1)*ke*, 510(2)*ke*, 528(3b)*ke*, 558(2b)*ke*, 609(2)*ke*, 624(3)*ke*, 700(3b)*ke*, 730(1)*ke*, 747(2)*ke*, 759(3)*ke*, 847(2)*ke*, 874(1)*ke*, 893(1)*ke*, 936(1)*ke*, 980(3)*ke*, 1000(7)*ke*, 1027(2)*ke*, 1162(3)*ke*, 1181(3)*ke*, 1241(5)*ke*, 1259(5)*ke*, 1288(1)*k*, 1308(1)*k*, 1329(1b)*ke*, 1374(1)*ke*, 1432(3)*ke*, 1440(3)*ke*, 1469(1)*k*, 1492(3b)*ke*, 1530(1)*ke*, 1602(9)*kfe*, 2214(4)*ke*, 2233(10)*ke*, 2895(2)*ke*, 2918(2)*ke*, [2935(2)*ke*], 3053(3)*ke*, 3070(3)*ke*.

7. **3-Chloro-1-phenylpropene-1 (Cinnamyl Chloride,** $C_6H_5CH{=}CHCH_2Cl$).—Eastman product, redistilled in column; b. p. 94° (5 mm.); previous data, none.

$\Delta\nu$ = 248(2)*e*, 264(2)*e*, 302(2)*e*, 413(1)*ke*, 447(1)*ke*, 457($^1/_2$)*ke*, 507(2)*ke*, 605(4)*ke*, 619(3)*ke*, 670(5)*ke*, 678(4)*ke*, 699(3)*ke*, 746(1)*ke*, 814(2)*ke*, 823(1)*ke*, 849(3)*ke*, 915(2)*ke*, 924(2)*ke*, 963(1)*ke*, 1000(6)*ke*, 1033(2)*ke*, 1065(1)*ke*, 1080(2)*ke*, 1157(5)*ke*, 1184(3)*ke*, 1212(4)*ke*, 1251(7)*ke*, 1282(3)*ke*, 1303(4)*ke*, 1442(3b)*ke*, 1497(3)*ke*, 1538(1)*ke*, 1600(9)*ke*, 1660(10)*ke*, 2876(2b)*e*, [2944(1)*e*], 2967(2)*e* 3054(3)*e*, 3072(2)*e*.

Discussion of Results

The frequencies obtained agree quite well with those reported by Gredy[3] for $C_6H_5C{\equiv}CCH_2OH$ and with those reported by Faucounau[6] for $C_6H_5C{\equiv}CCH_2CH_2OH$ and for $C_6H_5C{\equiv}CCH_2CH_2Cl$, but the present results show many lines not listed by these earlier investigators. The compounds were prepared by essentially the same methods and were carefully purified. As a check upon the possibility that impurities might be the source of the additional lines, $C_6H_5C{\equiv}CCH_2CH_2Cl$ was prepared by a different method.[10] The resultant spectrograms were comparatively free from continuous background and showed not only the forty more prominent lines listed above but also forty-nine weaker ones which were quite generally checked by both Hg4047 Å. and 4358 Å.

It is possible that a few of these may be due to traces of impurities which were not removed by the careful fractionation, but the source of others cannot be laid to this as they occur in regions

(13) Danehy, Vogt and Nieuwland, THIS JOURNAL, **57**, 2327 (1935), reported a yield of 21% for this synthesis. However, by use of benzene as a diluent,[12] p. 299, and by allowing the rearrangement of the intermediate product to take place at 70–80°, yields of the alcohol approaching 70% were obtained in the present investigation.

where prominent lines are rare in organic compounds. Furthermore, a considerable number of the frequencies correspond to the weaker Raman lines in the spectra of benzene,[14] monosubstituted benzenes,[15] and compounds containing one or more —CH_2— groups. Because of certain remaining inconsistencies and difficulties in the measurement of the weaker lines, only the more prominent frequencies of the various compounds are listed at present.

The use of a low pressure mercury arc, with a consequent diminution in the amount of continuous radiation in the exciting light, and the method of illuminating the comparator are, without doubt, two of the factors contributing to the observance of so many lines. The number obtained is greater for some of the compounds than for others. This is due to the fact that some compounds decompose more readily when illuminated, resulting in the presence of small amounts of fluorescent materials. The consequent increase in the strength of the continuous background makes the measurement of weak lines extremely difficult.

Acknowledgment.—This work was aided in part by a grant from the Virginia Academy of Science from funds allotted it by the American Association for the Advancement of Science.

Summary

1. The principal lines in the Raman spectra of 3-chloro-1-phenylpropyne-1, 4-chloro-1-phenylbutyne-1, 5-chloro-1-phenylpentyne-1, 3-bromo-1-phenylpropyne-1, 3-phenyl-2-propynol-1, 4-phenyl-3-butynol-1, and 3-chloro-1-phenylpropene-1 (cinnamyl chloride) are reported.

2. Many other lines of very low intensity have been observed. Many of these are characteristic of benzene, monosubstituted benzenes, and compounds containing the —CH_2— group.

Hydrogen Bonds Involving the C–H Link. IV. The Effect of Solvent Association on Solubility

BY M. J. COPLEY, G. F. ZELLHOEFER AND C. S. MARVEL

In a series of papers,[1–3] by the authors, solubility data have been reported on a number of gaseous halogenated hydrocarbons (of the types CH_3X, CH_2X_2, CHX_3, CX_4, and C_2X_6) in a variety of solvents containing donor atoms (oxygen, nitrogen, and sulfur). The successive replacement of three of the hydrogen atoms of methane by halogen atoms results in each case in an increase of solubility, and for the type CHX_3 solubilities much in excess of the theoretical have been observed in many solvents; however, replacement of the fourth hydrogen produces an enormous drop in solubility compared to that shown by the haloform type. These results readily are interpreted by assuming that complex formation takes place through the bonding of a hydrogen atom of the halogenated hydrocarbon to an exposed pair of electrons on the nitrogen or oxygen atoms in solvent molecules. The presence of the strongly electron-attracting halogen atoms on the carbon activates the hydrogen atom and makes it available for coördination to the donor atom.

Latimer and Rodebush[4] first suggested the theory that a proton in certain cases is capable of forming a bond between two atoms. Since then numerous investigations have confirmed this theory and shown its great utility. The possibility that the hydrogen atom of a haloform molecule might be capable of forming such a bond to an oxygen or nitrogen atom in a molecule was proposed by Glasstone[5] to account for the dielectric behavior of binary mixtures, containing a haloform and either an ether, an ester, or an amine. The ease with which the large amount of solubility data[2] accumulated by the authors may be

correlated on the basis of this idea affords strong support for it. Rodebush[6] has informed the authors that infrared absorption measurements on solutions in carbon tetrachloride of chloroform with an ether or amine show definite evidence of complex formation.

Although extremely high solubilities were observed for halogenated hydrocarbons of the haloform type in practically all solvents containing an effective donor atom (nitrogen or oxygen), an exception was found in the case of alcohols. These low solubilities in alcohols[2] are related to the intermolecular association through hydrogen bonding which takes place between alcohol molecules.[7,8] It was thought that a more extended study should be made of solvents where association between solvent molecules is known to occur. Such an investigation should furnish data to aid in stating more precisely the factors which are important in producing solubility and should also provide new information about the amount and type of association occurring in these liquids. For this purpose measurements were made of the solubility of monofluorodichloromethane ($CHCl_2F$) in a number of alcohols, ethers, acids, esters, amides, substituted amides, primary and tertiary amines, and oximes. The effect on solubility of each of the two factors (a) unsaturation and (b) chelation was studied also by measuring solubility of this haloform in compounds containing an aliphatic double bond and in compounds where chelation is known to exist.

Experimental

The method used in making the solubility measurements has been described previously in detail.[1] The solvents tested were all purified carefully and their boiling or melting points checked. The solubility measurements on the monofluorodichloromethane were made over a range of pressures at a temperature of 32.2°. While it is important that complete pressure–composition studies be made on the various mixtures, it is felt that at present it is more important to have partial data on a large number of combinations. The results of these measurements are shown in Figs. 1–3. To compare the solvents tested the mole fraction solubilities at a partial pressure of monofluorodichloromethane corresponding to its vapor pressure at 4.5° are used in the following discussion and given in Table I. The "ideal" or theoretical mole fraction stated at the top of Table I was calculated using Raoult's law, and it is the ratio of the vapor pressure (0.847 atm.) of monofluorodichloromethane at 4.5° to its value (2.221 atm.) at 32.2°. The statement in the table that the solubility is *very low* in the case of acetamide and diphenylamine, is based on the observation that when these solvents, which are solids at 32.2°, were melted, insufficient monofluorodichloromethane dissolved in the liquid in the pressure range used, to lower the melting point appreciably.

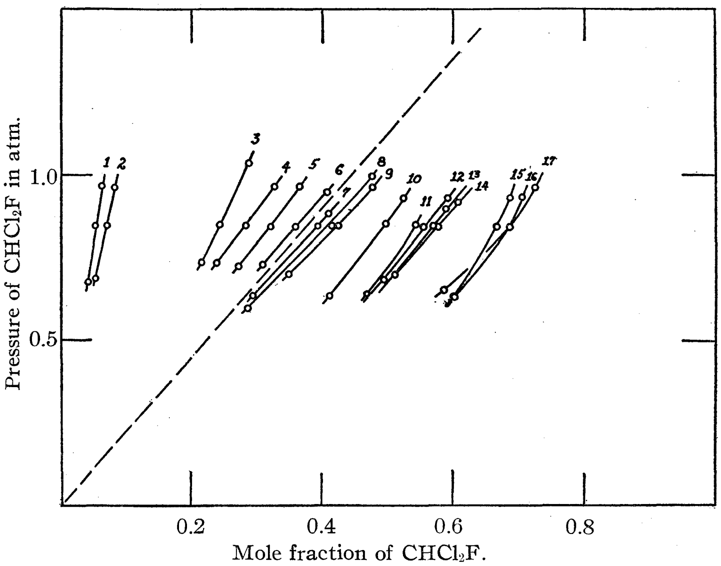

Fig. 1.—The solubility of monofluorodichloromethane as a function of pressure in alcohols, ethers, acids, and esters. The dotted line represents the "ideal" solubility: 1, ethylene glycol; 2, triethylene glycol; 3, phenol; 4, acetic acid; 5, propionic acid; 6, dimethyl sulfate; 7, phenyl vinyl ether; 8, anisole; 9, phenetole; 10, cyclohexylmethyl ether; 11, *n*-butyl butyrate; 12, diethyl oxalate; 13, 1,4-dimethoxycyclohexane; 14, dimethyl ether of ethylene glycol; 15, triethyl phosphate; 16, tributyl phosphate; 17, tri-(β-methoxyethyl) phosphate.

In a few cases a slow reaction was noted between the monofluorodichloromethane and the solvent used. This was particularly true with the amines and the values given for the solubility in these compounds are subject to a possible error of several per cent.

Discussion

Alcohols and Ethers.—In a preceding paper[2] the extremely low mole fraction solubilities of monofluorodichloromethane in ethylene glycol (0.055) and trimethylene glycol (0.073) were reported. In the present paper data are presented on the solubility of monofluorodichloromethane in phenol (0.197) and a similar low solubility compared to the theoretical (0.381) was observed.

When the hydrogen of the hydroxyl groups of alcohols is replaced by alkyl groups the resulting ethers show a high solvent power in excess of the theoretical as is illustrated by the examples in Table I and the results on a large number of ethers reported in a previous paper.[2] This difference in behavior of alcohols compared to ethers is to be traced to the association that exists in alcohols. Cryoscopic measurements[9] in non-polar solvents and analysis by Zachariasen[10] of X-ray data indicate that alcohols polymerize to form large linear or string polymers. This association takes place as first suggested by Latimer and Rodebush,[4] and later by Huggins,[11] through the bonding of a hydrogen of a hydroxyl group to the oxygen of a neighboring molecule. Recent infra-red absorption measurements[7,8] tend to confirm this picture of association. The low solubility of monofluorodichloromethane in alcohols is then due to the fact that a hydrogen bond formed by a hydrogen atom attached to a carbon atom with an oxygen atom, C–H ← O, is less stable than the O–H–O bonds already present in the alcohols. Hence the monofluorodichloromethane molecules are practically excluded from entering the large complexes present in the alcohol. Intermolecular association is blocked by the replacement of the hydrogen of the hydroxyl by an alkyl group, and then it is possible for C–H ← O bonds to form between the hydrogen of the monofluorodichloromethane and the oxygen atoms of an ether. The formation of this type of complex between the ether and the monofluorodichloromethane is responsible for the enormous solubilities observed for monofluorodichloromethane in ethers.

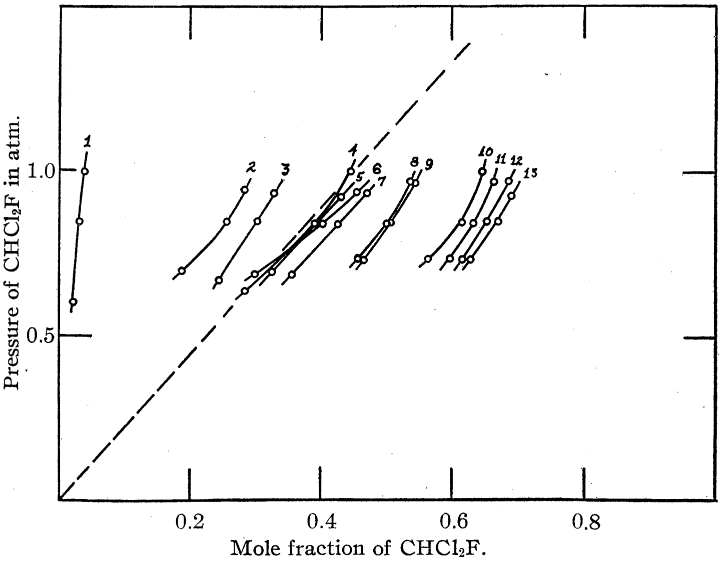

Fig. 2.—The solubility of monofluorodichloromethane as a function of pressure in amines and amides: 1, formamide; 2, aniline; 3, methylformamide; 4, methyldiphenylamine; 5, methylacetamide; 6, dimethylformamide; 7, dimethylaniline; 8, dimethylcyclohexylamine; 9, cyclohexylamine; 10, dimethylacetamide; 11, N-methyl-N-cyclohexylacetamide; 12, tetraethyloxamide; 13, tetramethylsuccinamide.

Acids and Esters.—The mole fraction solubility of monofluorodichloromethane is distinctly higher in the fatty acids (0.286 in acetic acid) than in the alcohols although an active hydrogen is present in the carboxyl group of these molecules. This result confirms the viewpoint that a different type of association takes place in the fatty acids than in the alcohols, which previously has been

shown by the fact that the polymerization in acetic acid stops at the dimer stage. The existence of the dimers of acids is shown by numerous cryoscopic and distribution measurements. Recent vapor density,[12,13] and electron diffraction measurements[14] show the presence of these dimers in the vapor whereas there is no appreciable association in the vapor phase of alcohols. The association presumably takes place through hydrogen bonding and results in an eight-membered ring. The stability of the ring as suggested by Pauling and Brockway[14] probably is due to a resonance between the two structures (I and II) of equal energy.

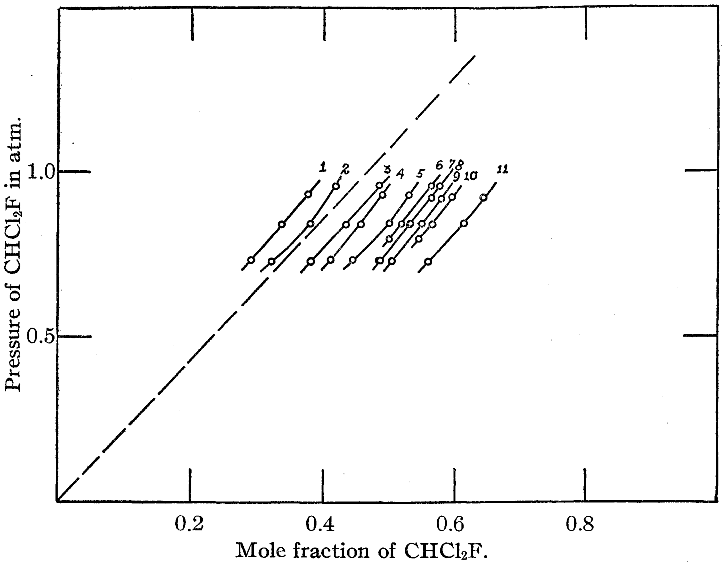

Fig. 3.—The solubility of monofluorodichloromethane as a function of pressure in aldehydes, ketones, and oximes: 1, ethylmethylketoxime; 2, salicylaldehyde; 3, benzaldehyde; 4, cyclohexenone; 5, acetylacetone; 6, heptaldehyde; 7, paraldehyde; 8, ethyl acetoacetate; 9, cyclohexanone; 10, acetonylacetone; 11, ethyl diethylacetoacetate.

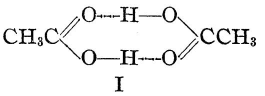
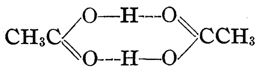


I



II

When the mole fraction solubility of acetic acid is calculated using the molecular weight of the dimer instead of that of the monomer, its value (0.445) does not exceed the theoretical (0.381) to any marked extent. This result indicates that when an oxygen atom has shared one of its two exposed electron pairs its basic or donor properties are strongly reduced. Further evidence of this decrease in donor property of an oxygen atom after sharing one of its electron pairs will be given in the section on chelated compounds.

As in the case of alcohols the replacement of the active hydrogen of an acid by an alkyl group blocks association and extremely high solubility is observed for monofluorodichloromethane in esters. In general the solubility in an ester is of about the same magnitude as in an ether of similar structure although the ether has only one oxygen. Apparently this is due, as was shown in a previous paper,[3] to steric hindrance. The close proximity of the two oxygens prevents the simultaneous attachment of two monofluorodichloromethane molecules to the two oxygen atoms of the ester group.

Some measurements of solubility were also made using esters of phosphoric and sulfuric acids. The esters of phosphoric acid are extremely effective as solvents for monofluorodichloromethane but the one ester of sulfuric acid tested showed rather poor solvent power.

Amines and Substituted Amines.—Very high solubilities in excess of the theoretical were observed in cyclohexylamine (0.506) and dimethylcyclohexylamine (0.499). The almost equal solubilities of monofluorodichloromethane in these two compounds suggests that aliphatic amines are unassociated and that an aliphatic amine hydrogen is not sufficiently active to form hydrogen bonds. The failure to form bonds certainly cannot be due to any lack of donor properties on the part of the nitrogen atom since the high solubility of monofluorodichloromethane indicates ready sharing of the electron pair of the nitrogen to form C–H ← N bonds. This conclusion of lack of association in liquid amines from our solubility measurements is in accord with their cryoscopic[15] behavior in non-polar solvents. Also the substitution of a methyl group for the hydroxyl hydrogen of an alcohol causes a lowering of the boiling point, whereas the replacement of one or both hydrogens on the nitrogen of a primary amine raises the boiling point.

The considerably lower solubility of monofluorodichloromethane in aniline (0.258) than in dimethylaniline (0.425) suggests that in aromatic

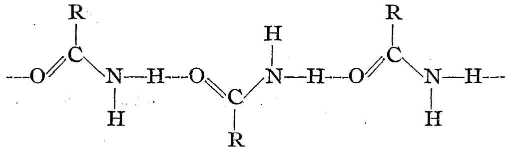
[15] E. N. Lassettre, *Chem. Rev.*, **20**, 259 (1937).

amines some association, probably of the linear polymer type, takes place.

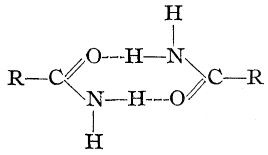
The almost equal solubilities observed in methylcyclohexyl ether (0.500), cyclohexylamine, and dimethylcyclohexylamine indicate that the donor properties of an aliphatic ether oxygen and an aliphatic amine nitrogen are almost equivalent.

Amides and Substituted Amides.—Extremely low solubilities were observed for monofluorodichloromethane in formamide (0.0318) and acetamide (*very low*). These much lower solubilities than those observed in the fatty acids suggest that dimers are not formed in amides but instead polymers of indefinite size. Cryoscopic measurements[15] on amides also indicate the formation of large polymers in non-polar solvents. A possible reason for the polymerization failing to stop at the dimer stage might be the formation of linear polymers as shown in structure III

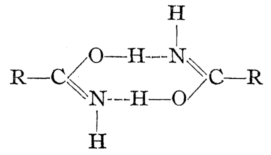


III

since the two resonating structures of the dimer illustrated in IV and V would be of unequal energy.

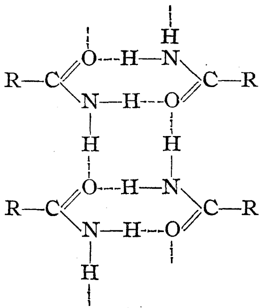


IV



V

On the other hand, the formation of linear polymers in alcohols does not lead to excessively high melting points, while amides melt much higher than alcohols containing the same number of carbon atoms. A different type of association is also indicated by the ease with which amides crystallize compared to alcohols which tend to form glasses. A type of association which might account for these differences in behavior of amides and alcohols is shown in structure VI where the association takes place through the fusing of dimers. It is true that the formation of such a polymer requires the sharing of the second pair of electrons on the oxygens; however, the behavior of acetic acid and chelated compounds indicates that this tendency while small is not negligible; also the numerous possible resonating structures in such a polymer would contribute to its stabilization. An association through the fusing of dimers would explain the intermediate solvent power for monofluorodichloromethane of a monosubstituted amide between that of the amide and the disubstituted amide (where no association exists) as is illustrated by the data in Table I. The substitution of an alkyl group for one of the hydrogens on the nitrogen would block the fusing of the dimers and should lead to a solubility comparable to that observed in the fatty acids. Chaplin and Hunter[16] have made some cryoscopic measurements on solutions of monomethyl and monoethyl acetamide in benzene which indicate that these compounds are associated, but the measurements are not complete enough to establish whether large polymers or only dimers are formed. Jenkins and Taylor[17] have investigated solutions of α-piperidone in benzene and find no evidence for polymerization proceeding past the dimer stage. It is recognized that the high dielectric constants of the amides and of the monosubstituted amides[18] appear to offer an objection to this latter picture of association, since the formation of such a symmetrical structure would apparently involve a neutralization of dipole moments of the amide molecules. However, it is possible that there are present in the liquid a sufficient number of the monomers to account for the observed dielectric constants.



VI

The solubility in N,N-dimethylacetamide (0.614) is extremely high and a similar high solubility has been observed in all completely substituted amides with the exception of N,N-dimethylformamide (0.398). This difference in behavior of dimethylformamide as a solvent may be caused by the existence of some polymerization involving the hydrogen on the carbon of the formic acid residue. The strong negative groups attached to

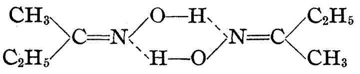
(18) Kumler, THIS JOURNAL, **57**, 600 (1935).

this carbon might be expected to cause its activation. If this is correct, a similar activity on the part of the hydrogen in formic acid would be expected, and indeed has already been suggested by Huggins[11] to account for the high dielectric constant of formic acid[18] compared to that of the other fatty acids.

A comparison of our solubility data in amines and amides shows that the tendency for hydrogen bonding is directly connected with the activity of the hydrogens on the nitrogen. However, the basicity of their solutions in water apparently is not related to the donor properties of the nitrogen in forming hydrogen bonds.

Ketones and Aldehydes.—The high solubilities observed for monofluorodichloromethane in aldehydes and ketones are in agreement with the well-known fact that these liquids are unassociated and suggest that the oxygen present in a carbonyl group is an excellent electron donor so that C–H ← O bonds readily form.

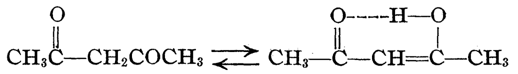
Oximes.—One oxime, methylethylketoxime, was tested. The almost normal solubility (0.338) of monofluorodichloromethane in this compound suggests that oximes form dimers similar in type to those formed by fatty acids and N-monosubstituted amides. A probable structure for this dimer is shown in formula VII.



VII

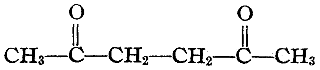
Cryoscopic measurements[15] on acetoxime and *d*-camphoroxime indicate that these compounds form either dimers or relatively small polymers in non-polar solvents.

Effect of Chelation.—The almost normal solubility observed in acetic acid dimers suggests, as was pointed out earlier, that when one pair of electrons on an oxygen is shared, its donor properties decrease. A study of the solubility of monofluorodichloromethane in compounds containing a chelate ring and a comparison of these solubilities with solubilities in compounds containing a similar structure but without chelation, gave further evidence on this point. Two pairs of compounds were tested. One of each pair is known to be chelated and in the other there is no opportunity for chelation. These compounds are shown in the four formulas below with the mole fraction solubility of monofluorodichloromethane in each.



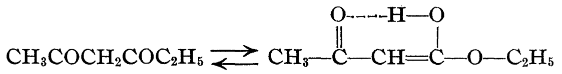
$$CH_3\overset{\overset{O}{\|}}{C}-CH_2COCH_3 \rightleftharpoons CH_3-\overset{\overset{O---H-O}{\|\qquad\quad|}}{C-CH=C}-CH_3$$

Acetylacetone
(0.499)



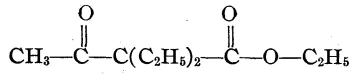
$$CH_3-\overset{\overset{O}{\|}}{C}-CH_2-CH_2-\overset{\overset{O}{\|}}{C}-CH_3$$

Acetonylacetone
(0.563)



$$CH_3COCH_2COC_2H_5 \rightleftharpoons CH_3-\overset{\overset{O---H-O}{\|\qquad\quad|}}{C-CH=C}-O-C_2H_5$$

Ethyl acetoacetate
(0.536)



$$CH_3-\overset{\overset{O}{\|}}{C}-C(C_2H_5)_2-\overset{\overset{O}{\|}}{C}-O-C_2H_5$$

Ethyl diethylacetoacetate
(0.617)

The results indicate an appreciable decrease in the formation of C–H ← O bonds by the compounds in which chelation occurs. A similar conclusion is obtained by comparing the solubility of monofluorodichloromethane in benzaldehyde (0.436) with that in strongly chelated salicylaldehyde (0.372).

Effect of Unsaturation.—A few compounds were examined to test the effect on solubility of an aliphatic double bond in the donor molecule. The solubility in phenyl vinyl ether (0.394) is so near that in anisole (0.415) and phenetole (0.425), as to indicate only a small effect. However, the effect is much more pronounced for Δ^2-cyclohexenone (0.457) when compared to cyclohexanone (0.548).

A phenyl group attached to an oxygen or a nitrogen atom markedly decreases its donor properties. This is clearly shown by the lower solubilities given in Table I for aromatic ethers and amines compared to aliphatic ethers and amines. On the other hand, the hydrogens of an aromatic amine are more active (leads to association) and hence the higher solubility of monofluorodichloromethane in dimethylaniline (0.425) compared to aniline (0.258).

Conclusion

The simple assumption of complexes formed through the medium of C–H ← O bonds in a remarkable manner correlates the large amount of solubility data that has been obtained. Furthermore, as stated earlier in this paper, recent infrared absorption measurements[6] on mixtures of chloroform with ethers, esters, ketones, and amines lead to the same conclusion. The strength of the C–H ← O or C–H ← N bond in the case of halogenated hydrocarbons of the CHX_3 type is less than that of N–H–O and O–H–O bonds, hence the addition of chloroform and monofluorodichloromethane does not cause dissociation in compounds associated by means of hydrogen bonding between two oxygen atoms, or a nitrogen atom and an oxygen atom. In this connection it should be recalled that it has been known for a long time that the haloforms behave essentially as non-polar solvents similar to benzene and hexane in cryoscopic measurements on alcohols, acids, and amides.

The considerations outlined above also should be applicable to the solution of solid organic compounds in monofluorodichloromethane, or other halogenated hydrocarbons of the type CHX_3, C_2HX_5, etc. (and to a lesser extent to the type CH_2X_2), and should allow the qualitative prediction of solubility in such cases.

Summary

The concept of $C–H \leftarrow O$ bonds between a hydrogen of a halogenated hydrocarbon and donor atoms in solvents has been shown readily to correlate solubility data on solutions of halogenated hydrocarbons in a large number of solvents of different types.

The most important factors governing the solubility of the types of compounds investigated are: (1) the donor properties of atoms in the solvent for forming $C–H \leftarrow O$ or $C–H \leftarrow N$ bonds; (2) the presence or absence of intermolecular association through hydrogen bonding in the solvent.

It has been shown that it is possible to predict the type of association occurring in a liquid by means of a solubility measurement. The presence of large linear polymers in the solvent inhibits the solution of monofluorodichloromethane but if the polymerization stops at the dimer stage nearly normal solubility is observed.

The Reaction of Esters with Aluminum Isopropoxide

BY ROBERT H. BAKER

Aluminum alkoxides react with alcohols[1,2] and catalyze the alcoholysis of esters,[3] but their reaction with esters alone has been studied very little.[1,4]

For the simple esters the reaction is one of exchange of groups and possibly may be of use in the preparation of alkoxides whose alcohols themselves are either unstable or which fail to react with amalgamated aluminum. The reaction also may be used in the preparation of esters.

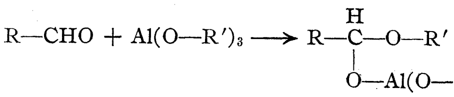
In this work the equilibrium

$$3R—COOR' + Al(O—i\text{-}Pr)_3 \longleftrightarrow 3R—COO—i\text{-}Pr + Al(O—R')_3$$

has been shifted as far to the right as possible by carrying out the reaction under a fractionating column which permits the removal of only the isopropyl ester. *t*-Butyl acetate failed to react completely, the reaction stopping when two of the isopropyl (or isopropoxide) groups had been replaced. This is in accord with the observations of Tischtschenko,[1] who found that the tertiary alkoxides reacted best with the alcohols.

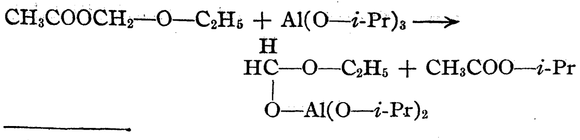
The isopropoxide, which is easily made and purified and which gives rise to low boiling esters, has been used exclusively in this work.

Only one ester, ethoxymethyl acetate, gave rise to reduction products similar to those which the simple esters give with sodium alkoxides.[5] This ester was used in an attempt to prepare an alkoxide of the type which Verley[6] postulated as an intermediate in both the Tischtschenko reaction[4] and in the reduction of aldehydes. This aluminate of a hemiacetal, which Verley claims is formed thus



$$R—CHO + Al(O—R')_3 \longrightarrow R—\overset{\displaystyle H}{\underset{\displaystyle O—Al(O—R')_2}{C}}—O—R'$$

was expected to be formed as follows



$$CH_3COOCH_2—O—C_2H_5 + Al(O—i\text{-}Pr)_3 \longrightarrow \overset{\displaystyle H}{\underset{\displaystyle O—Al(O—i\text{-}Pr)_2}{HC}}—O—C_2H_5 + CH_3COO—i\text{-}Pr$$

n-Hexadecyl acetate	1.4438	100	98[e]	44			3.60	3.70
Ethyleneglycol diacetate	1.4184	80	120[d]	dec.			24.05	21.20

[a] Calcd. from fractions of isopropyl acetate n^{20}D 1.3770–1.3786 and of isopropyl formate n^{20}D 1.3720–1.3735. A dry refractionated synthetic sample of the latter had distillation range (Widmer) 66.9–67.0°; n^{20}D 1.3716; d^{20}_4 0.8726; *M*D calcd., 22.33, found 22.92. [b] Assumed to be aluminum di-*t*-butoxide monoisopropoxide, pure *t*-butyl acetate could be distilled from this even after heating together at 150° for two hours. [c] Attempts to purify this for analysis were unsuccessful. It begins to distill at 220° (5 mm.) and then decomposes violently. The crude product melts over a narrower range than that reported.[1] [d] A very light powder retaining ester even at 150° (2 mm.) for two hours. Completely insoluble in xylene, but retains xylene which is removed only at 150° (2 mm.). [e] These alkoxides gave a negative iodoform test after hydrolysis.

Such a compound was not isolated and no evidence for or against its formation[7] can be gained from the experiment, but it is of interest that the products of the reaction were those which one would expect from Tischtschenko reactions, reductions, and group exchanges between alkoxides and esters.

Experimental

Reagents.—Aluminum isopropoxide, b. p. 134° (5 mm.), m. p. 118°, was prepared in 91% yield by the method of Adkins.[8] Before each experiment the powdered material was tested for complete solubility, without opalescence, in dry benzene. The esters were prepared by the standard methods and distilled through a Widmer column, refractive index and boiling range rather than the boiling point being used as a criterion of purity. The esters were tested for moisture immediately before use by adding a few drops of a benzene solution of aluminum isopropoxide to a few cc. of the ester. If opalescence did not appear within a few minutes, the esters were considered to be dry. Ethoxymethyl acetate n^{20}D 1.3950, distillation range 129.5–130.0°, was prepared by the method of Farren[9] except that the final distillation was through the Widmer column.

The general procedure was to mix 0.4 mole of the ester with 0.1 mole of aluminum isopropoxide in a flask protected from moisture and fitted to a Widmer column equipped with a partial condensation head. Slow distillation was carried out collecting 1- or 2-g. fractions and following the fractionation by means of the refractive index. When all the isopropyl ester had distilled and the index corresponded to that of the starting ester, the remainder was distilled by diminished pressure to leave the alkoxide in weighable form. The results from several esters are found in Table I.

***n*-Butyl benzoate,** n^{20}D 1.5001, 53.4 g. (0.3 mole) and aluminum isopropoxide 20.4 g. (0.1 mole) were heated at 130° for two hours, cooled, poured into cold water containing 25 cc. of 6 *N* sulfuric acid, and extracted with ether. The ether solution was washed successively with water, saturated solution of calcium chloride, saturated solution of potassium carbonate, and then was dried over anhydrous magnesium sulfate. The ether solution gave upon fractionation through the Widmer column isopropyl benzoate n^{20}D 1.4975–1.4978, 27.0 g. (0.165 mole), and *n*-butyl benzoate n^{20}D 1.4998–1.5001, 18.9 g. (0.105 mole). This is a 90% recovery of the esters and, since the acidic hydrolysate gave negative tests for aldehydes and ketones, no reverse Tischtschenko reactions[5] take place.

Ethoxymethyl acetate, 35.4 g. (0.3 mole) and aluminum isopropoxide 20.4 g. (0.1 mole) were heated in an oil-bath from 50 to 150° over a period of eight hours. The reaction started quickly, as the odor of formaldehyde or acetaldehyde could be noticed. The exhaust gases were passed first through a drying tube and then through water. The water gave a positive Schiff test for aldehydes, but a negligible quantity of their 2,4-dinitrophenylhydrazones. Seven fractions, 36.2 g., distilling between 50 and 85° were collected and refractionated into fifteen fractions, b. p. 40–87°; n^{20}D 1.3570–1.3770. Four "flats" appeared in the refractive index–weight distilled diagram at n^{20}D 1.3640, 1.3680, 1.3730, and 1.3770. These constants, their respective distillation ranges, 56–58, 62–67, 71–75, and 80–87° and the fact that they were all saponifiable, were interpreted as indicating the presence of methyl acetate, isopropyl formate (possibly), ethyl acetate, and isopropyl acetate. The weights of the fractions in these "flats" were 4.4, 4.6, 6.6, and 7.7 g., respectively. Although acetone was found throughout the first six fractions, it was concentrated mainly, along with formate esters, in the first two, 3.7 g., from which it was identified (dibenzylideneacetone, m. p. 111–111.5°). The residue in the distilling flask, 16.5 g., was a mixture of alkoxides; when hydrolyzed it gave negative tests for aldehydes, esters, and acids.

Acknowledgment.—The author is indebted to Professor Charles Barkenbus for his coöperation and helpful suggestions.

Summary

The alkoxyl groups of esters and aluminum alkoxides are easily interchangeable and the resulting equilibrium has been shifted so as to prepare new alkoxides in good yield.

---

(7) For more definite information concerning the probability of definite compound formation between aldehyde and catalyst see Child and Adkins, THIS JOURNAL, **47**, 798 (1925).

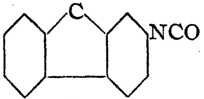
Fluorene Compounds. Nitrogen Derivatives

BY FRANCIS EARL RAY AND GEORGE RIEVESCHL, JR.

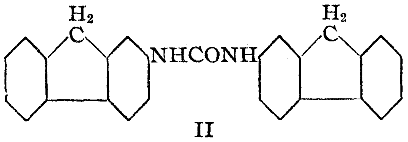
In the present work we undertook the preparation of new derivatives of 2-aminofluorene and of 9-N substituted 2-benzoylfluorene.

The preparation of 2-aminofluorene was first accomplished by Strasburger[1] from 4-aminodiphenic acid. A more convenient synthesis by the reduction of the normal mono-nitration product of fluorene is described in "Organic Syntheses."[2]

When we attempted to prepare 2-fluoryl-isocyanate, I, from the amine and phosgene, the *sym*-di-urea resulted, II.



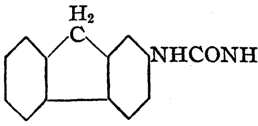
I



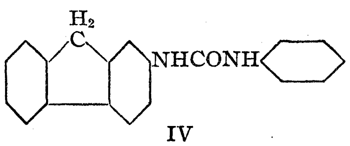
II

The isocyanate, I, was obtained by the modification of Hardy.[3] When dry it was quite stable but moisture caused its conversion into the di-urea, II. This di-urea was formed quantitatively when equimolar solutions of 2-aminofluorene and 2-fluoryl isocyanate were mixed.

When treated with ammonia, the mono-urea, III, was obtained. *sym*-Phenyl-2-fluorylurea, IV, was prepared in two ways: by treating 2-fluoryl isocyanate with aniline and by treating 2-aminofluorene with phenyl isocyanate.



III



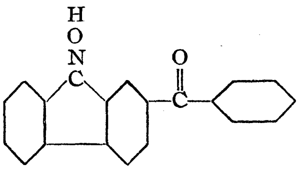
IV

Due to the sensitivity of 2-fluoryl isocyanate to water and the insolubility of the resulting di-urea in ether, acetone, etc., it may be a useful reagent to detect small amounts of water. The factor is 0.0464.

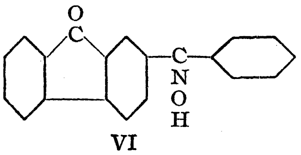
The methyl, ethyl and *n*-propyl urethans were prepared from 2-fluoryl isocyanate and the corresponding absolute alcohol.

Derivatives of 2-Benzoylfluorene

In 1902 Fortner[4] prepared a monoxime from 2-benzoylfluorenone which he described as bright yellow leaves from alcohol which sintered at 185° and melted at 199°. Fortner did not determine which of the configurations, V or VI, this compound possessed.



V



VI

As it seemed probable that the 9-position of the fluorene would be the more active, we set out to prepare V by methods that would leave no doubt as to its constitution.

Using Nenitzescu and Isăcescu's[5] method we condensed benzyl chloride with potassium 2-benzoyl-9-*aci*-nitrofluorene[6] and obtained an oxime melting at 207–208°.

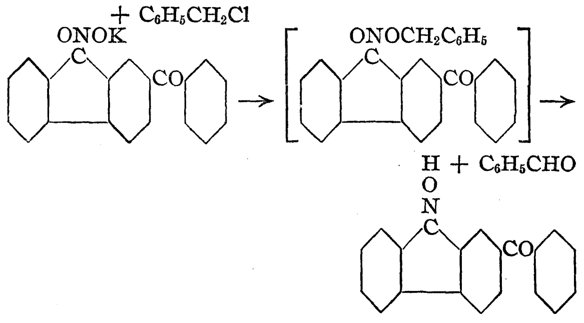
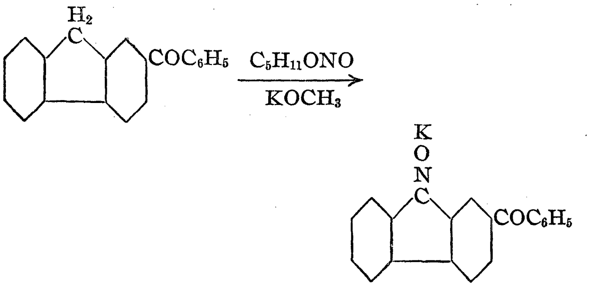
[6] Ray and Palinchak, in press.



As this was somewhat troublesome to purify we also carried out the preparation by the method of Wislicenus and Waldmüller.[7]



In carrying out this reaction in an ether–benzene mixture some material seemed to precipitate out after standing several hours. On evaporating the filtrate to small volume and adding ether, a second batch of crystals was obtained.

Each was separately acidified and recrystallized. The first (insoluble), α, melted at 213–214° and was a pale yellow powder. The second, β, was obtained in long, golden needles melting at 207–208°.

As neither of these corresponded to the description of Fortner's compound we prepared some material by his directions. It is true that this material first melted at 198–199° but on repeated crystallization, first from benzene and then from alcohol, we obtained the compound in long needles melting at 207–208°, identical with our lower melting, β, oxime. We then mixed equal portions of our two oximes and on recrystallization the mixture melted at about 199°.

To characterize further these oximes the acetyl derivatives were prepared. That from the α-oxime (213–214°) melted at 144–145° while the acetyl derivative of the β-oxime (207–208°) melted at 150–151°. A mixed melting point mixture sintered at 116–126°. Which of these is *cis* and which *trans* remains to be determined.

Moore and Huntress[8] reported the melting point of *syn*-2-nitrofluorenone oxime, prepared in an alkaline solution, as 262.5–263°. Langecker,[9] preparing the oxime in a neutral solution, reported the melting point to be 249°. With this possible exception no other fluorenone oxime has been isolated in *cis* and *trans* forms.

Experimental

2-Aminofluorene was prepared by the method described in "Organic Syntheses."[2] It melted at 127°.

2-Fluoryl Isocyanate.—Eleven grams of 2-aminofluorene was dissolved in 250 cc. of warm toluene and dry hydrogen chloride was passed in until saturation was reached. The 2-aminofluorene hydrochloride separated as a cream-colored mass. The flask was heated to gentle reflux and a steady stream of carbonyl chloride was passed into the mixture. The precipitate gradually dissolved until at the end of one and one-half hours a clear liquid was obtained.

The solution was filtered and the toluene removed under diminished pressure. The tan colored product was recrystallized from ligroin. A pure white product was obtained melting at 69–70° which was readily soluble in most organic solvents. The yield was 11.2 g. or 89%.

Anal. Calcd. for $C_{14}H_9ON$: N, 6.76. Found: N, 6.85.

Methyl 2-fluorylcarbamate was prepared in the usual manner. It crystallized in shining laminae and melted at 118°.

Anal. Calcd. for $C_{15}H_{13}O_2N$: N, 5.85. Found: N, 5.92.

Ethyl 2-fluorylcarbamate was obtained as white plates from ligroin; m. p. 121–122°.

Anal. Calcd. for $C_{16}H_{15}O_2N$: N, 5.53. Found: N, 5.75.

***n*-Propyl 2-fluorylcarbamate** also crystallized in plates; m. p. 113°.

Anal. Calcd. for $C_{17}H_{17}O_2N$: N, 5.24. Found: N, 5.58.

2-Fluorylurea was prepared by passing dry ammonia gas into an ether solution of 2-fluoryl isocyanate. It was obtained as plates from alcohol. It did not melt at 360°.

Anal. Calcd. for $C_{14}H_{12}ON_2$: N, 12.49. Found: N, 12.67.

sym-Phenyl-2-fluorylurea was prepared from aniline and 2-fluoryl isocyanate and also by the reaction between 2-aminofluorene and phenyl isocyanate. White cottony fibers were obtained from dioxane, melting at 305° (block).

Anal. Calcd. for $C_{20}H_{16}ON_2$: N, 9.33. Found: N, 9.37.

sym-Di-2-fluorylurea was prepared from the isocyanate and 2-aminofluorene and also by treating the isocyanate with water. White cottony clusters were obtained from pyridine which did not melt at 360°. It is insoluble in most organic solvents.

Anal. Calcd. for $C_{27}H_{20}ON_2$: N, 7.21. Found: N, 7.37.

2-Benzoylfluorene was prepared by Perrier's[10] modification of the Friedel–Crafts reaction. It melted at 122°.

Potassium 2-benzoyl-9-aci-nitrofluorene was obtained by the method of Ray and Palinchak.[6]

2-Benzoyl-9-fluorenoneoxime.—Three and one-half grams of potassium 2-benzoyl-9-*aci*-nitrofluorene, 3.5 g. of benzyl chloride and 40 cc. of 95% alcohol were refluxed for eight hours. Potassium chloride slowly separated and the orange color faded to yellow. The solution was filtered and treated with water. An oil separated which solidified on stirring. After three recrystallizations from alcohol the melting point was 207–208° (β-form).

As this material was somewhat difficult to purify we condensed 27 g. of 2-benzoylfluorene with 13.7 cc. of isoamyl nitrite in the presence of 5.5 g. of potassium in 30 cc. of absolute methyl alcohol, 100 cc. of anhydrous ether and 200 cc. of pure benzene.

The product that precipitated weighed 16.1 g. It was separated, acidified and recrystallized from alcohol. This α-form of the oxime was obtained as a pale yellow powder melting at 213–214°.

Anal. Calcd. for $C_{20}H_{13}O_2N$: N, 4.67. Found: N, 4.66.

The acetyl derivative was prepared with acetyl chloride in pyridine–ether solution. Greenish-yellow fibers were obtained that melted at 144–145°.

Anal. Calcd. for $C_{22}H_{15}O_3N$: N, 4.11. Found: N, 4.31.

β-Oxime.—The filtrate from the α-potassium salt was evaporated to 50 cc. and 500 cc. of ether was added. The precipitate weighing 12.4 g. was separated, acidified and recrystallized three times from alcohol. Long, bright yellow crystals were obtained melting at 207–208°. These were identical with those prepared by Fortner's[4] method.

Anal. Calcd. for $C_{20}H_{13}O_2N$: N, 4.67. Found: N, 4.63.

This acetyl derivative crystallized in brilliant yellow plates that melted at 150–151°.

Anal. Calcd. for $C_{22}H_{15}O_3N$: N, 4.11. Found: N, 4.33.

Summary

The following new compounds of fluorene have been prepared: 2-fluoryl isocyanate; methyl, ethyl and *n*-propyl 2-fluorylcarbamate; 2-fluorylurea; *sym*-phenyl-2-fluorylurea; *sym*-di-2-fluorylurea; and the potassium salts and the acetyl derivatives of the α- and β-9-oximes of 2-benzoylfluorenone, as well as the free α- and β-oximes.

The compound obtained by the reaction between 2-benzoylfluorenone and hydroxyl amine reported by Fortner[4] is shown to have been a mixture of the α- and β-forms of the 9-oxime.

The Analytical Separation of Various Classes of Sugars

BY CHARLES D. HURD AND SIDNEY M. CANTOR[1]

The purpose of this investigation was to develop a method for the separation of various classes of sugars, such as monosaccharoses from di- or trisaccharoses, or pentoses from hexoses. It was hoped that the method would achieve not only separation but also analysis of the mixture as well. The importance of a direct method of analysis is obvious, in view of the fact that most of the analytical methods which have been suggested for sugars are empirical and depend largely on a preëxisting knowledge of the identity of the sugar. Methods based on the reducing action of copper salts or on the preferential fermentation by specific microörganisms are obviously limited in scope.

Methylation and fractional distillation of sugar mixtures appeared to be the most promising plan of attack for several reasons: (1) the methyl ethers are known to distil *in vacuo* without decomposition, (2) sizable boiling point differences exist between the methyl ethers of the sugar classes, (3) the methylation procedure would be satisfactory on a wide variety of sugars since it brings about no serious structural changes, (4) the fact that physical constants of a large number of methylated sugars are known would be of help in subsequent identifications.

Preliminary experiments indicated the feasibility of the plan but they also demonstrated the inapplicability of the customary procedure of direct methylation of the sugar by Haworth's method. For example, glucose, lactose and sucrose were methylated by means of methyl sulfate and alkali and the methylated derivatives distilled. The yields, respectively, were 50, 45 and 46%. These results seemed acceptable but it was found that no such uniformity in yields was at-

---

[1] Corn Products Refining Company Fellow, 1933–1936.

tainable when mixtures were taken at the outset. A 50:50 mixture of glucose and lactose gave an apparent per cent. value of 63:37. Such a preferential methylation of the monosaccharose demonstrated the inapplicability of Haworth's method of direct methylation as an analytical procedure. Although the yields in methylation reactions are far from quantitative, equivalence in the yields is the only requirement for a satisfactory analytical separation.

Two other disturbing features were revealed in these preliminary experiments. One was the fact that the glucose derivative, even upon repeated methylation, did not show the correct specific rotation for β-methyl tetramethylglucoside. A mixture containing about one-fifth of the α-isomer seemed to be indicated. A similar observation is known to occur with xylose[2] but glucose seems not to have been tested before. The specific rotation of the methylated glucose fractions, therefore, would have been useless for purposes of identification.

The other item concerned the methylation of sucrose. During this process there was found to be an appreciable hydrolysis, for which a correction factor would need to be applied to interpret the results on an unknown mixture containing sucrose. The yields, respectively, of methylated mono- and disaccharoses were 6 and 46%.

Attention was next directed to experiments on direct acetalization with a view to subsequent direct methylation of the methyl glycosides thus produced. The hemi-acetal hydroxyl of the reducing sugars seemed to promote the non-uniformity observed when Haworth's method was applied directly.

Glucose and methanol, when treated with 1–3% hydrogen chloride by Fischer's method, gave rise to 45% of crystalline α-methyl glucoside (A) and a sirup (B). Methylation by Haworth's method of A and B yielded, respectively, 60 and 67% of α-methyl tetramethylglucoside. It was evident, therefore, that separation of A from B was not necessary for the subsequent methylation.

Trouble was encountered with maltose, however, because some hydrolysis was noticed. α-Methylglucoside was isolated from the reaction mixture. This was substantiated later when a mixture (57:43) of glucose and maltose was methylated first by Fischer's method, then by Haworth's method. The products isolated on distillation indicated an apparent composition of 67:33. Therefore, this procedure also was poor from an analytical viewpoint.

Methylation in liquid ammonia[3] was tried and abandoned because the method required methyl glycosides or other derivatives wherein the hemiacetal hydroxyl was protected. The free sugars could not be used.

Feist[4] observed that methyl dibromoformal, $Br_2C(OCH_3)_2$, was a methylating agent toward sodium phenoxide or sodium acetate, yielding anisole and methyl acetate, respectively. It was thought that it might convert the monosodium derivative of glucose (prepared by glucose and sodium methoxide in methanol) into methyl glucoside but such a reaction was not observed.

Likewise, there was non-reaction when glucose, suspended in ether, was treated with diazomethane, although Schmid[5] has reported the methylation of starch in this way. Water or aluminum ethoxide[6] were not effective in catalyzing the reaction between diazomethane and glucose.

The plan of direct methylation, therefore, was changed to that of indirect methylation. Acetylation of the sugar by acetic anhydride and pyridine at 0° was the first step in a successful procedure. In the acetylation of glucose, Hudson and Dale[7] obtained an 88% yield of pure glucose pentaacetate. Maltose has not been acetylated in this manner, but in the present work it was found that a 90% yield of β-maltose octaacetate was isolable. One may infer that the acetylation reaction gives rise to practically quantitative yields of the acetyl sugars.

The problem, therefore, was to substitute uniformly the acetyl groups by methyl groups. To do this, the following steps were visualized and found to be satisfactory: replacement of the acylal[8] group by chlorine, substitution of this chlorine by methoxyl, hydrolysis of the ester groups without disturbing the acetal function, methylation of the alcoholic hydroxyl groups and separation by fractional vacuum distillation.

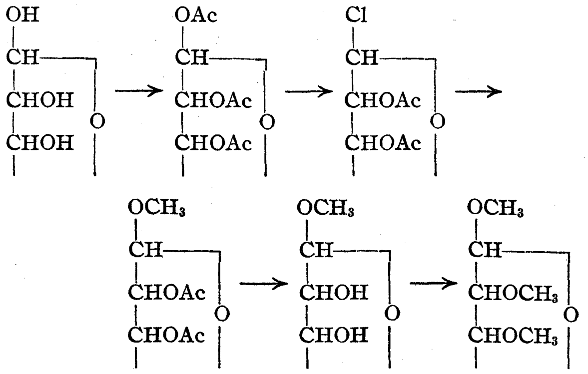
[8] If C, C′ and C″ represent, respectively, the states of oxidation of alcohol, aldehyde and acid, then C–O–C, C–O–C′, C–O–C″, C″–O–C″ represent the familiar functional groups of ether, acetal, ester and acid anhydride. No term exists for C′–O–C″ or C′–O–C′. The name "acylal" is proposed for the former and "aldal" for the latter.



Each of these steps will be discussed in turn.

Glucose pentaacetate may be converted into acetobromoglucose by the use of liquid hydrogen bromide[9] or by a mixture of hydrogen bromide in acetic acid.[10] It may be changed into acetochloroglucose by liquid hydrogen chloride, or phosphorus pentachloride[9] or by a mixture of phosphorus pentachloride and aluminum chloride[11] (but this method may bring about structural changes), or by titanium tetrachloride[12] in chloroform. The last method was far better than the others because of high yields and because of its freedom from causing structural changes. Pacsu's directions were followed for the preparation of tetraacetylglucosyl chloride with a resulting yield of 90%. In an analogous experiment with β-maltose octaacetate, not studied by Pacsu, heptaacetyl-α-maltosyl chloride was obtained in 86% yield. Also it was established that under comparable conditions there was no action between titanium tetrachloride and sucrose octaacetate or levoglucosan triacetate, neither of which contained acylal groups.

Maltose.—Five grams of β-maltose octaacetate, m. p. 157–158°, was dissolved in 35 g. of dry chloroform in a flask equipped with a reflux condenser and a dropping funnel. To the solution was added gradually 3 g. of titanium tetrachloride dissolved in 25 g. of chloroform. The reaction was carried out on a water-bath at 50° for two hours, then at 70° for one hour, at which time the original yellow, mushy precipitate had changed to a clear yellow solution. Crystallization of the product from ether and petroleum ether netted 2.2 g. of crystalline solid, and 2 g. of a sirup which was desiccated to a white powder. The crystals melted at 77–80°, and the specific rotation in chloroform, $[\alpha]^{20}_D$, was 151.8°. The rotation of the powder was 142.1°. From the viewpoint of an analytical procedure, the important item is the high yield of isolated product (86.5%) which suggests that the reaction itself was practically quantitative.

The melting point of heptaacetylmaltosyl chloride prepared by other methods is variously listed in the literature[13] as 88, 119, 125°. Both Foerg and Brauns reported 159.5° as the value of the specific rotation.

Sucrose.—Ten grams of sucrose octaacetate, m. p. 68°, dissolved in 150 cc. of dry chloroform was added to a solution of 5.6 g. of titanium tetrachloride in 50 cc. of chloroform. After three hours of refluxing and twelve more hours of standing it was possible to recover 9.6 g. of recrystallized sucrose octaacetate (m. p. and mixed m. p., 68°).

Levoglucosan.—Two grams of levoglucosan was prepared by pyrolysis of starch.[14] It was placed with 10 cc. of pyridine and 15 cc. of acetic anhydride and left at 0° for twenty-four hours. The solution was then poured into chloroform, washed thoroughly, first with acid then with sodium carbonate solution, then water, after which it was dried and the chloroform removed by distillation. The residual sirup was taken up in alcohol and water added until the acetylated material precipitated as a gum. Extraction of the gum with ether and decolorization of the solution finally yielded 0.2 g. of white crystals melting sharply at 108° and showing $[\alpha]^{20}_D$ $-58.6°$ in absolute ethyl alcohol. Pictet gives as the melting point 110°, while the rotation as determined by Vongerichten and Müller[15] is $-45.5°$ in alcohol, a value which may be questioned in view of the present work.

Rotation: sample, 0.0449 g.; ang. rotn., $-0.20°$; tube length, 1.89 dm.; volume solution, 25.0 cc.; $[\alpha]^{20}_D$ $-58.6°$.

A portion of this crystalline material, 0.138 g., was dissolved in chloroform and made up to exactly 25.0 cc. The rotation was then determined in a 2.00-dm. tube: ang. rotn., $-0.70°$; $[\alpha]^{20}_D$ $-63.6°$. To the chloroform solution was added approximately 0.5 g. of titanium tetrachloride in 5 cc. of chloroform. The resulting yellow solution was kept at 60–70° for ninety minutes. It was then poured into water, and the chloroform layer washed in the usual manner. After drying, it was made up again to 25.0 cc. and the rotation redetermined in the 2.00-dm. tube: ang. rotn., $-0.68°$; $[\alpha]^{20}_D$ $-61.8°$. The chloroform was then removed and the residue taken up in ether. On cooling, 0.1 g. of crystals, m. p. 107–108°, separated. A mixed melting point with the original material was also 107–108°.

Of the various methods for the replacement of the chlorine of the hemi-acetal chloride by methoxyl, the best was that which used methanol and silver carbonate. Koenigs and Knorr[16] discovered that hot methanol converted tetraacetylglucosyl bromide into β-methyl tetraacetylglucoside, but the beneficial effect of silver carbonate was discovered by Fischer and Armstrong.[9] It

was found that very satisfactory results were obtained in the present work if the reaction mixture was shaken for twelve to fifteen hours.

Alternative procedures for the chloride to acetal conversion were tried and found ineffective. For example, when tetraacetylglucosyl chloride was left for four hours with methanol and pyridine at 0°, the only result was crystallization of the acetochloroglucose. This is in contrast to the known conversion of heptaacetyl-α-maltosyl chloride[17] into β-methyl heptaacetylmaltoside under similar treatment. When the reaction with tetraacetylglucosyl chloride was performed at reflux temperatures, some β-methyl tetraacetylglucoside (21% yield) was formed but secondary reactions also were indicated. For a time, it was thought that sodium methoxide might be effective in introducing the acetal methoxyl and removing the acetyl groups concurrently. However, the method was discarded when it was found that no β-methyl glucoside was obtainable from tetraacetylglucosyl chloride and sodium methoxide. Thus, the silver carbonate method, although time-consuming, seemed to be the only one wherein yield and purity of product were satisfactory.

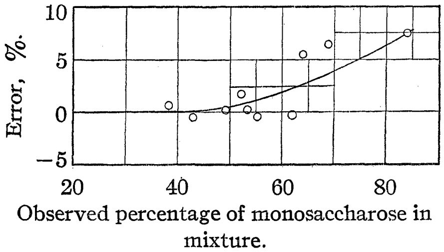

Fig. 1.—Correction curve.

Zemplén's method, namely, the use of sodium methoxide,[18] appeared to be the best means of removing the acetyl groups because of its simplicity and because of the high yields (nearly quantitative) obtained. The necessity of removing the acetyls prior to the final methylation was demonstrated in an attempted methylation of α-methyl tetraacetylglucoside. Only 2.7 g. of a sirup soluble in chloroform was obtained when 20 g. of it was treated with methyl sulfate and 20% aqueous sodium hydroxide solution for four hours at 70° followed by one-half hour at 100°.

For the final step of methylation of the methyl glycosides, Haworth's method was selected, although Muskat's liquid ammonia method might have served equally well. Simpler technique favored Haworth's method. It was recognized that this method would not give complete methylation in one operation, but this did not interfere with the analytical separation.

When glucose and maltose were carried separately through this procedure, the yield of methylated sirup from glucose was 38.3% and that from maltose 37.1%. Thus, no serious preferential action on the two classes of sugars was observed. Neither of the sugars was completely methylated but the sirup from glucose approached tetramethylglucose whereas that from maltose approached heptamethylmaltose.

The procedure was now standardized rigorously, and several duplicate runs were made on mixtures of glucose and maltose over a wide range of composition. The results, collected in Table I, showed that an error in favor of the monosaccharose existed which appeared to increase as the percentage of monosaccharose in the mixture was increased. To compensate for this error, a curve was constructed on the basis of known mixtures, and all unknown mixtures analyzed were corrected from this curve. Later results gave a better observation of the error involved so that the curve shown in Fig. 1 is based upon the average error of fourteen runs.

TABLE I

STANDARDIZATION RUNS ON THE PROCEDURE

Run	Sugars	Composition taken	% by weight, obsd.	Error, %
7A	Monosac.	30.0	29.9	−0.1
	Disacc.	70.0	70.1	.1
8A	Monosac.	30.0	32.2	2.2
	Disacc.	70.0	67.8	−2.2
7B	Monosac.	50.0	49.2	−0.8
	Disacc.	50.0	50.8	.8
8B	Monosac.	50.0	49.6	− .4
	Disacc.	50.0	50.4	.4
7C	Monosac.	70.0	64.4	−5.6
	Disacc.	30.0	35.5	5.6
8C	Monosac.	70.0	64.5	−5.5
	Disacc.	30.0	35.5	5.5

The efficacy of the curve is best demonstrated by the results on two mixtures whose composition was unknown to the observer. A mixture made up to contain 62% glucose and 38% maltose analyzed for a "corrected composition" of 64.3% glucose and 35.7% maltose. A second mixture containing 53.4% glucose and 46.6% lactose gave a "corrected composition" of 55.2% glucose and 44.8% lactose. The absolute error of the method

---

[17] Freudenberg, *Ber.*, **55**, 929 (1922); Pacsu, THIS JOURNAL, **57**, 587 (1935).

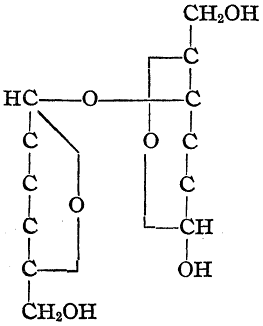
[18] Zemplén, *Ber.*, **56**, 1705 (1923).

varies considerably, but in only one observed case was greater than 3%.

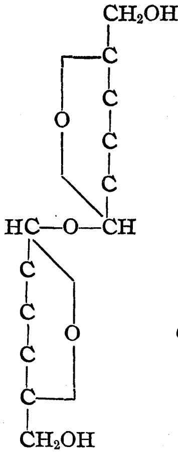
Types of Sugars Studied

Monosaccharoses.—Glucose was chosen as the representative aldohexose. Work with xylose showed that aldopentoses would respond equally well. That methylpentoses were also amenable was shown by results on a mixture of rhamnose (desoxy-*l*-mannose) and maltose. The standardization runs indicated that all such aldohexoses would undergo the procedure successfully. Attempts to apply the technique to mixtures containing fructose, a representative ketohexose, however, were unsuccessful.

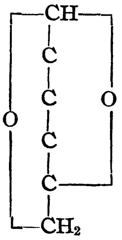
Disaccharoses.—Types of disaccharoses studied were necessarily more varied. The application to the maltose or reducing type of disaccharose was shown by the standardization runs. Further results with mixtures containing lactose and gentiobiose showed that such factors as the point of glucosidic attachment, alpha or beta modification of the parent sugar, or the nature of the hexose constituents of the disaccharoses were unimportant in the reactions listed. The chief factor concerned itself with the nature of the hydroxyl group, whether it was alcohol or acetal.



Maltose type
maltose (α at 4)
lactose (β at 4)
gentiobiose (β at 6)



Trehalose type
trehalose (αα at 1)
sucrose (α at 1)



Anhydrose type
levoglucosan

In the trehalose type all eight hydroxyl groups are alcoholic. The trehalose type would, therefore, be expected to undergo acetylation, hydrolysis of acetyl groups and methylation, but no other reactions. Results with sucrose, a trehalose type, indicated that sucrose octaacetate was stable to the action of titanium tetrachloride, but that hydrolysis occurred in the final methylation step, to the extent of 11% by weight. When this correction was applied the analytical data were satisfactory. Trehalose itself, being of a more stable configuration, acted normally and exhibited no hydrolysis.

Applicability to the third or anhydrose type of disaccharose depended upon the ability of the oxygen bridge to withstand the action of titanium tetrachloride. When the triacetate of levoglucosan (1,6-anhydro-*d*-glucose) was treated with the reagent under the conditions of the procedure, no hydrolysis occurred. Other investigators[19] have reported that hydrolysis will result from use of an excess of titanium tetrachloride.

Constants of the Sugars Studied

Monosaccharoses.—Evidence that monosaccharoses were unaltered through the procedure was obtained easily. For example, the methylated glucose fractions showed specific rotations near −20°. The specific rotation of pure β-methyl tetramethylgucoside is −22.4°. Further evidence was obtained by hydrolyzing a portion of the glucoside to tetramethylglucose and preparing the known aniline condensation product. In general, the evidence obtained from specific rotation, although not indicating absolute purity, was sufficient to demonstrate the nature of the fraction.

Disaccharoses.—Identification in the case of the disaccharoses was less clean cut. Derivatives of the methylated disaccharoses cannot be prepared since hydrolysis of the glucosidic methoxyl group always brings about concurrent hydrolysis of the disaccharose linkage. Thus the disaccharose fractions usually had to be remethylated and distilled in order to obtain a value for the specific rotation which approached the accepted value. The Purdie and Irvine method, involving silver oxide and methyl iodide,[20] was used. With only one remethylation of the maltose fraction a specific rotation of 68° was obtained. That for pure β-methyl heptamethylmaltoside is 79°. Several applications of this technique, accompanied by frequent distillation, would be necessary to obtain samples of optical purity.

Other Applications of the Procedure

Separation of a Pentose from a Hexose.—This separation was of interest to study since the two

---

[19] Zemplén and Czurös, *Ber.*, **62**, 993 (1929).

[20] Purdie and Irvine, *J. Chem. Soc.*, **83**, 1021 (1903).

sugar types, which differ by only one carbon atom, give methylated derivatives boiling relatively close together. A sample run on a 1:1 mixture of *d*-glucose and *d*-xylose in which volume of distillate was plotted against temperature of distillation (Fig. 2) showed that separation was feasible. An almost quantitative separation of glucose and xylose bore this out. β-Methyl trimethylxyloside, the pentose fraction, was obtained crystalline, indicative of high purity.

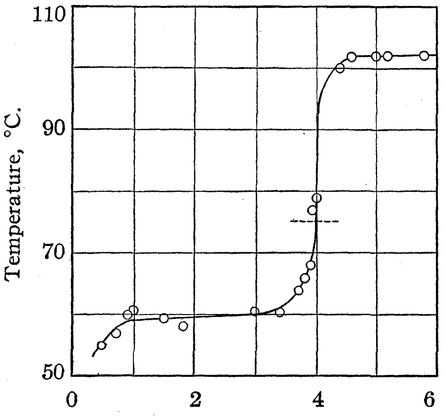


Fig. 2.—Separation of xylose–glucose mixture.

Analysis of Hydrols.—The application of the procedure to "hydrol," the mother liquor obtained after crystallization of glucose from the acid hydrolysate of corn starch, appeared to be an interesting extension of the problem since previous[21] investigators have shown that hydrol contains a mixture of disaccharoses as well as glucose. However, none of these investigators had ever analyzed a complete sample of hydrol, but had attacked the mixture after first fermenting away all fermentable sugars.

Three samples of hydrol were obtained from the Corn Products Refining Company which had various hydrolytic histories, but were alike in that they had all gone through a single crystallization of glucose after the final hydrolytic treatment. Subjection of these samples to the procedure gave the usual mono- and disaccharose fractions, but distillation of the disaccharose fraction after remethylation left a high boiling portion in each case. This material from molecular weight determinations was identified as partially methylated trisaccharoses. The results are shown in Table II.

TABLE II

	Original hydrol	Reconverted hydrol	Kansas City hydrol
Monosaccharoses, %	55.2	55.2	54.8
Disaccharoses	38.4	39.3	37.9
Trisaccharoses	6.4	5.5	7.3

The monosaccharose fraction was identified as glucose. Work is under way at the present time in this Laboratory on the separation and identification of the components of the disaccharose and trisaccharose fractions.

Apparatus for Analytical Vacuum Distillation.—In the standardized procedure (below), one of the steps is that of separation of methylated sugars by vacuum distillation. The details of this apparatus are shown in Fig. 3.

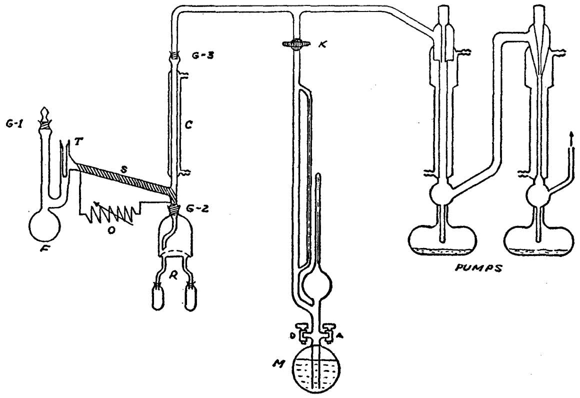

Fig. 3.—Distillation apparatus.

Low pressure was supplied by a set of two mercury vapor pumps connected in series and working against a back pressure of 10–20 mm., supplied by an ordinary water jet.[22] The first mercury pump was a high speed jet and the second was a diffusion pump. These pumps gave a minimum pressure of 1×10^{-5} mm., which was more than sufficient for the purpose.

The distillation flask, F (Fig. 3), was of the conventional Claisen type equipped with a thermometer well, T, and a ground glass stopper, G-1. Three of these flasks of capacities 125, 50 and 20 cc., were used interchangeably depending upon the amount of material to be distilled. The side-arm, S, connecting flask to receiver, was wrapped with nichrome wire surrounded by asbestos rope and was kept electrically heated by the introduction of a current controlled by the variable resistance, O. The temperature in the side-arm was usually kept at 80–90° during a distillation in order to avoid congealing the sirup and to bring to a minimum the holdover in the tubing. The receiver, R, was connected to the bent side-arm by a ground glass

[22] The use of mercury pumps backed by a water pump instead of an oil pump was a decided advantage in this work since it eliminated the necessity for a low temperature trap in the apparatus. Methylated sirups in chloroform solution could be transferred to the distillation flask and the solvent removed through the pumps without danger of corrosion or raising the pressure as is the case with oil pumps.

joint, G-2, and was of the multiple rotary type enabling five fractions to be taken. Two of the small receivers were later connected to the large receiver by ground glass joints which eliminated the necessity of breaking off and sealing on after each distillation. The condenser, C, prevented the entrance of any low boiling sugars into the connection tubing, and the ground glass joint, G-3, allowed removal of the distillation unit for cleaning. Pressures were read by means of the McLeod gage, M, connected to the system by a stopcock, K. The McLeod gage was of a modified variety. The mercury storage bulb was kept evacuated by a water pump at side-arm A. Opening side-arm D to the atmosphere resulted in the mercury rising into the gage from which the pressure was read off. The mercury could then be again lowered by evacuation of the storage chamber.

The Standardized Procedure

The anhydrous sample taken was always 25.0 g., for this quantity was found to give sufficient methylated material for the fractionation. Amounts of reagents were based upon the assumption that all of the material in the mixture was monosaccharose.

Step 1.—The mixture was treated with 120 g. of acetic anhydride and 156 g. of pyridine (dried over lime). This was 100% in excess of that required for complete acetylation if all of the material were monosaccharose. The reaction was allowed to proceed at 0° for forty-eight hours, then for four hours at 70°, which treatment usually completed the acetylation. Two hundred fifty cc. of chloroform was now added and the resulting solution washed twice with 300-cc. portions of 4 *M* hydrochloric acid, twice with 200-cc. portions of a dilute sodium carbonate solution and finally twice with 200-cc. portions of water. The chloroform solution was dried over anhydrous sodium carbonate.

Step 2.—The dried solution from (1) was treated with 28 g. of anhydrous titanium tetrachloride dissolved in 150 cc. of absolute chloroform. The mixture was heated at 70° for two hours on a water-bath, after which it was allowed to stand for five hours. A slight amount of pyridine or an excess of titanium tetrachloride often caused a darkening of this solution, but this effect apparently was not harmful. The resulting homogeneous solution was poured onto cracked ice, and the separated chloroform solution was washed until the washings showed no acid test. The solution was then dried over anhydrous sodium carbonate, and the chloroform removed on the steam-bath.

Step 3.—The sirup from (2) was taken up in 700 cc. of absolute methanol. Then, 25 g. of silver carbonate was added and the mixture shaken for twelve to sixteen hours. Upon completion the silver residues were filtered off.

The type of shaker for this step is sketched in Fig. 4. The box was rotated on its horizontal shaft at approximately 70 r. p. m. With the bottles set at an angle to the direction of rotation, and usually only two-thirds full, the mixing was very effective. The authors are indebted to Mr. Otto Stanger of the Miner Laboratories, Chicago, for suggesting this type of shaker.

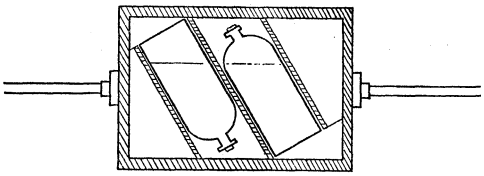

Fig. 4.—Shaking apparatus.

Step 4.—To the clear solution from (3) was added 200 cc. of dry chloroform and a solution made by dissolving 1 g. of sodium in 50 cc. of methanol. The mixture was allowed to stand at 0° for six hours and then diluted with an equal volume of water. The water layer was separated, made neutral to litmus with acetic acid, and reduced in volume to 30 cc. by distillation *in vacuo*. The glycoside sirup obtained at this stage was usually dark brown in color.

Step 5.—The sirup from (4) was transferred to the methylation apparatus, heated to 70° by means of a water-bath, and treated with 150 cc. (200 g.) of methyl sulfate and 140 g. of sodium hydroxide which was dissolved in 200 cc. of water. The reagents were added dropwise over a period of about three hours in an approximate ratio of two drops of methyl sulfate to three drops of sodium hydroxide solution. This kept the base slightly in excess and minimized the danger of hydrolysis. Upon completion of the addition, the mixture was heated with stirring for one-half hour at 100°. The cooled mixture was filtered, and the solid which separated was triturated four times with 25-cc. portions of chloroform. The filtrate was extracted four times with 100-cc. portions of chloroform. The extracts were combined with the washings and dried, without washing, over anhydrous sodium carbonate. Then, the chloroform was removed by distillation on the water-bath and the residual sirup transferred to the distillation apparatus. The chloroform was removed. Bumping under the high vacuum was

TABLE III

ANALYSIS OF MIXTURES OF GLUCOSE AND MALTOSE

relieved by means of small boiling chips. At pressures below 0.02 mm., the limit for removal of the monosaccharose fraction was 110°. If the sample contained only mono- and disaccharoses, the disaccharose fraction was not distilled but the residue was taken as disaccharose. When trisaccharoses were involved, the disaccharose fraction was distilled off and the residue was regarded as the trisaccharose. The fractions were then weighed directly, the weights calculated back to weight of free sugar using the correction curve (Fig. 1).

When glucose and maltose were carried through this procedure separately, the yield of methylated sirup from glucose was 38.3% and that from maltose 37.1%. Thus no serious preferential action on the two classes of sugars was observed. Neither of the sugars was completely methylated. The monosaccharose approached the tetramethyl stage and the disaccharose the heptamethyl. Macdonald[23] has shown that with a chloroform extraction of products obtained in the methyl sulfate methylation of glucose, less than 2% of the methyl dimethylglucoside passes into the chloroform. Hence the extracted material consists almost wholly of the methyl tri- and tetramethylglucosides (A and B). Carrying the analogy to the disaccharoses, one might expect that the chloroform extract would consist mainly of the methyl hexa- and heptamethylglycosides (C and D). From these considerations, it was decided to regard the separated fractions as equimolar mixtures of A and B, or C and D, and to correct the molecular weight accordingly. The molecular weights used for computation of the free sugar weights were thus 243 for the monosaccharose instead of 250, and 447 for the disaccharose instead of 454.

The procedure was now rigorously standardized. Some results on typical analyses of glucose–maltose mixtures are shown in Table III.

The glucose fractions from the first six runs were combined and identified as follows. The specific rotation in chloroform, $[\alpha]^{20}\text{D}$, was −20.5°, whereas that for pure β-methyl tetramethylglucoside is −22.4°. Ten grams of the liquid was hydrolyzed by heating for two hours at 100° with 7% hydrochloric acid, then neutralizing with calcium carbonate, evaporating to dryness and extracting with ether. In this way, 5.5 g. of tetramethylglucose was obtained. From this, by heating with aniline,[24] a good yield of tetramethylglucose-aniline, m. p. 135°, was obtained.

The maltose fractions were identified by refluxing 10 g. of the maltose residues (Table III) for six hours with 35 g. of silver oxide and 60 g. of methyl iodide. The silver residues were filtered off and the methyl iodide removed by distillation. The residual sirup was vacuum distilled. A fraction of 3.62 g., b. p. 158° (0.008 mm.), possessed a specific rotation in chloroform, $[\alpha]^{20}\text{D}$ of 67.7°. The specific rotation of β-methyl heptamethylmaltoside is accepted as 78.9°.

The method has been tested recently by Mr. P. J. Baker, Jr., of this Laboratory, who reported these data on a glucose–maltose mixture:

Components, g.		Methylated deriv., g.	Equiv. wt. of free sugar, g.	% Components		
				Obsd.	Corr.	Calcd.
G	17.5	11.75	8.70	67.7	70.7	70.0
M	7.5	5.42	4.15	32.3	29.3	30.0

Analysis of Other Mixtures

Details for glucose and sucrose are listed in Table IV. If the correction for the 11% hydrolysis of sucrose, noted above, is applied, then the weights of components would be changed from 12.5 g. apiece to 13.9 g. of glucose and 11.1 g. of sucrose. The methylated sucrose was characterized by refluxing it for eight hours with silver oxide and methyl iodide. After the usual procedure, 2.5 g. of liquid was secured: b. p. 130–140° (0.001 mm.), $[\alpha]^{20}\text{D}$ in chloroform +63.6°. The rotation of octamethylsucrose[25] is only reported with methanol as solvent, $[\alpha]^{20}\text{D}$ + 69.3°.

TABLE IV

ANALYSIS OF MIXTURES OF SUGARS

Components Name	G.	Methylated derivs., g.	Free sugar, g.	% Components Obsd.	Corr.	Calcd.
Glucose	12.5	6.8	5.04	52.4	53.4	56.0
Sucrose	12.5	6.0	4.59	47.6	46.6	44.0
β-Glucose Pentaacetate	35.7	12.6	9.34	63.2	..	62.6
β-Gentiobiose Octaacetate	19.5	6.8	5.20	36.6	..	37.4
Glucose	10.0	4.0	2.96	38.6	39.3	40.0
Trehalose	15.0	6.15	4.70	61.4	60.7	60.0
Glucose	13.3	7.34	5.43	52.5	53.5	53.3
Trehalose	2.77	6.40	4.90	47.5	46.5	46.7
Gentiobiose Octaacetate	17.6					
Rhamnose	11.1	5.54	4.03	43.5	43.9	42.5
Maltose	15.0	7.05	5.22	56.5	56.1	57.5
Glucose[a]	15.35	6.3	4.67	62.8	64.3	62.0
Maltose	9.41	3.6	2.76	37.2	35.7	38.0
Glucose[a]	13.9	6.0	4.45	54.2	55.2	53.4
Lactose	12.1	4.9	3.75	45.8	44.8	46.6

[a] These mixtures were supplied to the analyst as unknowns.

To include gentiobiose in the mixtures it was necessary to start at Step 2, since only gentiobiose octaacetate (Pfanstiehl's), $[\alpha]^{20}\text{D}$ in chloroform −5.3°, was available. Therefore, the correction curve was not applied to the data for this run in Table IV. The methylated gentiobiose fraction solidified on standing: $[\alpha]^{20}\text{D}$ −7.0° in chloroform. For β-methyl heptamethylgentiobioside, Haworth and Wylam[26] list −29.9° for the specific rotation in alcohol.

Anhydrous trehalose was obtained by heating Pfanstiehl trehalose monohydrate at 105° for three hours. After the analysis (Table IV), 10 g. of the methylated disaccharose fraction was refluxed for eight hours with 37 g. of silver oxide and 70 g. of methyl iodide. When the mixture was worked up, a 5-g. fraction was obtained: b. p. 165–168° (0.01 mm.), $[\alpha]^{20}\text{D}$ in chloroform +166.2°. The rotation given for octamethyltrehalose[27] in benzene is +199.8°.

In the mixture of glucose, trehalose and gentiobiose octaacetate, the weight of 17.6 g. of the acetate is equivalent to 8.9 g. of gentiobiose. This represents a total of 11.67 g. of gentiobiose plus trehalose.

In the mixture of rhamnose and maltose, the rhamnose fraction was collected to 110°; $[\alpha]^{20}\text{D}$ +12.0° in chloroform. The specific rotation of β-methyl trimethylrhamnoside[28] in water is given as −15°.

The methylated lactose fraction (Table IV) was remethylated with 20 g. of silver oxide and 50 g. of methyl iodide for eight hours. Three grams was obtained: b. p. 170–175° (0.02 mm.), $[\alpha]^{27}\text{D}$ +6.19° in chloroform, $[\alpha]^{27}\text{D}$ +3.00 in methanol. The specific rotation of β-methyl heptamethyllactoside[29] in methanol is listed at −13.04°.

Separation of a Pentose–Hexose Mixture

Ten grams each of xylose and glucose were mixed and treated by the analysis procedure. The mixture of methylated derivatives obtained in the last step was distilled at a rate of 3–5 drops per minute in the vacuum apparatus. The height of the side-arm on the distillation flask was approximately 10 cm. One of the receivers was previously calibrated in cc., so that temperature of distillation could be plotted against volume of distillate. The curve shown in Fig. 2 was obtained. The pressure was 0.03–0.04 mm.

In a second run 12.5 g. of xylose $[\alpha]^{20}\text{D}$ +17.7° and 12.5 g. of glucose were mixed and treated by the standardized procedure. The methylated sirup obtained in the final step was distilled, the cut being made at 75° as indicated by the curve. The pressure was 0.005 mm.

Components	Methylated deriv., g.	Free sugar, g.	% Components Obsd.	Corr.	Calcd.
Pentose	5.63	4.10	49.3	50.1	50.0
Hexose	5.85	4.21	50.7	49.9	50.0

Pentose.—A portion, 3.5 g., of the methylated pentose, crystallized during the distillation. The rotation was determined in chloroform. Sample: 0.1205 g.; ang. rotn., −0.64°; $[\alpha]^{20}\text{D}$ −69.9°; volume solution, 25.0 cc.; tube length, 1.89 dm. The melting point of the crystals was 45°. The recorded constants of β-methyl trimethylxyloside are: melting point 51°; $[\alpha]^{20}\text{D}$ −69.5° in chloroform.[2]

Hexose.—The specific rotation of the sirupy hexose portion was determined in chloroform. Sample, 0.9276 g.; ang. rotn., −1.75°; $[\alpha]^{20}\text{D}$ −33.7°; tube length, 1.89 dm.; volume solution, 25.0 cc. The specific rotation of β-methyl tetramethylglucoside is −22.4° in chloroform.

Analysis of Hydrol

The Drying of Hydrol.—The hydrols used in this work were obtained through the courtesy of Mr. W. B. Newkirk of the Corn Products Refining Company. Hydrol is the term used to represent the mother liquor after glucose has been crystallized from the acid hydrolysis of starch. Ordinarily, starch is hydrolyzed by 0.25 to 0.5% hydrochloric acid under pressure of about 40 pounds (3 atm.) of steam. It is then neutralized, filtered, clarified, concentrated and crystallized. Ordinary hydrol is the residue obtained from one such hydrolytic conversion and crystallization. If the hydrol is again subjected to a second hydrolytic conversion and crystallization, the mother liquors are the so-called Reconverted Hydrol. The material which had undergone two crystallizations for glucose after but one hydrolytic conversion is called Kansas City Hydrol.

(28) Purdie and Young, *J. Chem. Soc.*, **89**, 1194 (1906).

(29) Haworth and Leitch, *ibid.*, **113**, 195 (1918).

All of the hydrols used for analysis by the procedure were dried in the following manner. One part of the hydrol was taken up with an equal volume of toluene and distilled at 11–15 mm. from an ordinary Claisen flask surrounded by a water-bath at 95°.

Five such operations usually served to remove almost all of the water, leaving the hydrol as a hard glassy mass. By continued warming on the water-bath the sirup could be softened and poured from the flask. Samples were weighed in this manner. That most of the water was eliminated by this procedure was indicated by a water analysis on dried hydrol. A sample weighing 6.151 g. lost 0.020 g. after four hours of heating at 110–120° in an air-bath; final weight 6.131 g.; % water, 0.32.

Application of the Procedure to Hydrol

The size of the original samples was in all cases 25.0 g. Acetylation with pyridine and acetic anhydride proceeded normally as in other sugar samples. It was found, however, that if the pyridine–hydrol mixture was warmed slightly before adding the acetic anhydride an appreciable amount of the sirup dissolved and hastened the reaction. In this way complete acetylation was usually accomplished in forty-eight hours at 0°.

In the final distillation, after removal of the low boiling fraction, as much as possible of the residual material was distilled by taking the bath temperature to 250°. Conditions for the distillation were substantially the same in all of the runs. The pressure varied from 0.001 to 0.008 mm. All material up to 110° was regarded as monosaccharose; the disaccharose distilled was collected between 160–190° at these pressures.

The weights of the fractions collected in the final distillations of the runs with the hydrols are listed in Table V.

TABLE V

METHYLATED PRODUCTS FROM HYDROLS

Run	Hydrol, g.				Reconverted hydrol, g.		Kansas City hydrol, g.	
	1	2	3	4	1	2	1	2
Fraction 1	5.40	6.44	5.94	4.88	4.94	5.90	5.12	4.86
Fraction 2	3.19	3.50	2.34	3.22	3.29	3.09	2.67	2.58
Residue	1.34	1.66	2.31	0.96	0.83	1.67	1.52	1.45
Calculated to basis of free sugars, g.								
Monosacch.	4.00	4.76	4.40	3.62	3.68	4.37	3.79	3.55
Disacch.	3.02	3.39	2.78	2.88	2.88	3.08	2.70	2.60
Trisacch.	0.45	0.56	0.78	0.32	0.27	0.56	0.51	0.49
Observed percentages of components								
Monosacch.	53.6	54.7	55.3	53.1	53.9	54.6	54.2	53.5
Disacch.	40.4	38.9	36.2	42.2	42.2	38.5	38.6	39.2
Trisacch.	6.0	6.4	8.5	4.7	4.9	6.9	7.2	7.3

Treatment of the Residue: Presence of Trisaccharoses.—To determine the nature of the residue, comparable experiments were performed on the methylated residues from maltose and from hydrol. About 10 g. of undistilled methylated maltose was dissolved in a minimum of chloroform, placed in a 500-cc. bottle, and 250 g. of methyl iodide and 25 g. of silver oxide added. The mixture was heated to boiling, the bottle stoppered and insulated with an asbestos wrapper. The bottle was now shaken mechanically for three days, the shaking being interrupted and heat applied as described about every six hours during the day.

The residues from the four runs of hydrol were treated in exactly the same manner. Upon completion of the shaking, the solutions were filtered, dried and the solvent removed. The sirups obtained were distilled *in vacuo* up to a bath temperature of 250°. Under this condition only would the disaccharose distil; any higher boiling fraction would remain. Upon completion, the distilled portion and the residues were weighed. The results with maltose and hydrol are summarized.

	Maltose	Hydrol
Distilled portion or disaccharose, g.	7.12	3.40
Residue, g.	0.92	2.64
Total, g.	8.04	6.04

The molecular weights of the residues were now determined in camphor:

	Maltose	Hydrol
Wt. camphor	0.0946	0.0907
Wt. sample	.0274	.0397
M. p. camphor, °C.	179.4	179.4
M. p. mixture, °C.	153.0	151.0
Difference, °C.	26.4	30.4
Constant for camphor	407.6	407.6
Molecular weight	429	587

Calculated for fully methylated disaccharose, 454
Calculated for fully methylated trisaccharose, 658

Although the molecular weights did not agree exactly with calculated values, they were different enough to signify that a portion of the original hydrol residues was trisaccharose.

Calculated from the weights obtained by fractionation of the residues, this appeared to be:

Disaccharoses	56.3%
Trisaccharoses	43.7%

The weights of residues obtained in the original fractionation were now corrected using these figures. The weights of methylated sugars were calculated back to the weights of free sugars as was done with the known mixtures, and the percentages of components thus obtained (Table V). The correction from the correction curve was applied only to the mono- and disaccharose fractions.

Molecular Weights Used

Monosaccharose	180	Methylated monosaccharose	243
Disaccharose	342	Methylated disaccharose	447
Trisaccharose	506	Methylated trisaccharose	658

The corrected percentages of components are summarized in Table VI. The whole analysis, including water and ash which were determined in the usual way, for each hydrol is also included.

Only glucose seemed to be present in the monosaccharose portion from hydrol. In two of the runs, the specific rotations taken in chloroform at 20° were −19.5 and −18.1°. This is reasonably near the rotation (−22.4°) for pure β-methyl tetramethylglucoside. Furthermore, glucose crystals separated from hydrol on standing.

Work is being continued on the identification of the sugars in the disaccharose portion. These specific rotations were obtained in chloroform on the methylated disaccharose fractions: hydrol, $[\alpha]^{20}\mathrm{D}$ +38.7°; reconverted hydrol, $[\alpha]^{20}\mathrm{D}$ +30.8°; Kansas City hydrol, $[\alpha]^{27}\mathrm{D}$ +66.7°.

TABLE VI

Summary

A procedure has been developed for the direct analysis of sugar mixtures of these types: mono- and disaccharoses; mono-, di- and trisaccharoses; pentoses and hexoses. The procedure involves indirect methylation, vacuum distillation of the methylated derivatives, and weighing of the fractions thus obtained. An accuracy of 3% was attained. Since the various fractions are separated from each other, they may be used for purposes of identification.

The indirect methylation is necessary to obtain uniformity in yields. Direct methylation of a mixture of mono- and disaccharoses gives results in the fractional distillation which are not indicative of the original percentage composition. The following steps are involved in the standardized procedure: acetylation at 0° by acetic anhydride and pyridine, replacement of the acylal function by chlorine by means of titanium tetrachloride, substitution of the chlorine by methoxyl by prolonged shaking with methanol and silver carbonate, hydrolysis of the remaining acetyl groups by sodium methoxide in methanol, methylation by one treatment with methyl sulfate and sodium hydroxide, and finally fractional distillation *in vacuo* of the methylated sirups.

Monosaccharoses such as xylose, rhamnose, glucose and levoglucosan undergo the procedure successfully. In its present form it does not apply to fructose. The disaccharoses studied included the maltose type (maltose, lactose, gentiobiose) and the trehalose type (trehalose, sucrose).

The procedure has been applied to three types of hydrol and the presence of trisaccharoses in these hydrols has been established.

The Mechanism of the Aqueous Hydrolysis of β-Butyrolactone

BY A. R. OLSON AND R. J. MILLER

In 1896 Walden[1] showed that *d*-malic acid was obtained when silver oxide was suspended in an aqueous solution of *d*-chlorosuccinic acid. Treatment of the chloro acid with potassium hydroxide yielded an *l*-malic acid. Holmberg[2] explained these results by assuming the primary formation of a lactone from the chloro acid, the lactone then hydrolyzing in several different ways, depending upon the hydrogen ion concentration. He[3] later succeeded in isolating the lactone. The generality of lactone formation from β-halogenated acids has been proved by Johansson's[4] work.

Holmberg[5] and Rørdam[6] studied the hydrolysis of the (+) malolactonic acid which was obtained from the (−) halogenosuccinic acids. They found that in dilute aqueous acids the hydrolysis was first order, and that the product contained a preponderance of (−) malic acid. In stronger acids, up to 2 *N* nitric acid and in basic solutions, the product was largely (+) malic acid. These results were confirmed and extended by Long and Olson,[7] who determined both rates and optical relations using buffered solutions. Their results are summarized in Figs. 1 and 2. The interpretation of these results is complicated by the difficulty of determining the total concentration of lactone and also by the possible existence of an α-lactone as well as a β-lactone. We have therefore turned to β-bromobutyric acid which readily yields a pure β-lactone. We have been able to show that this lactone hydrolyzes in neutral

aqueous solution to yield one optical form of hydroxybutyric acid exclusively and reacts with hydrogen ion and hydroxide ion by two other mechanisms to form the other optical isomer.

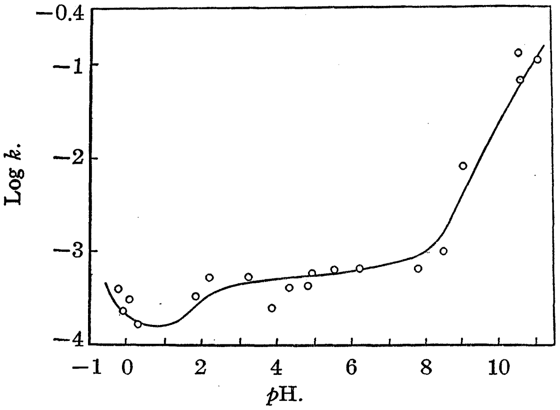

Fig. 1.—Velocity of hydrolysis of malolactonic acid.

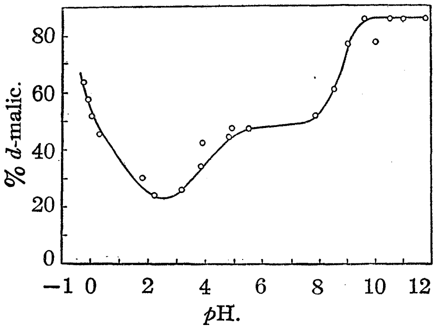

Fig. 2.—Optical form of malic acid produced by hydrolysis of (+) malolactonic acid.

The β-bromobutyric acid was prepared by Johansson's[8] method. The acid was resolved with morphine in methyl alcohol. Repeated recrystallization of the acid yielded a product which had a molar rotation of +116.5° in 2 *N* perchloric acid. This solution was 0.1632 *M* with respect to the β-bromobutyric acid. In water alone less than 1% decrease was observed. A 0.2361 *M* solution of the sodium salt had a molar rotation of 106.6°. The melting point of the purest acid was 44°. The β-butyrolactone was prepared from this acid by Johansson's procedure.

Hydrolysis of the β-Butyrolactone.—The lactone was weighed in volumetric flasks which then were filled to the mark with the solvent used for hydrolysis. The change of optical rotation with time and the final value reached were then observed using the polarimeter[9] described previously. This was a Bellingham and Stanley instrument designed so that 30-cm. polarimeter tubes in a thermostat with glass windows could be placed in the optical path. The thermostat was held at 25.0 ± 0.05° by means of a mercury regular and heaters. Light from a mercury lamp filtered through copper sulfate glass and a Wratten No. 77 filter was used for the readings with the Hg 5461 line. Unfiltered light from a sodium lamp was used for the sodium D lines. All readings were made to the nearest hundredth of a degree, and, except for the faster kinetic runs, the mean of six to ten readings was taken as an observation.

Results and Discussion.—It was known from the work of Johansson[4] that the hydrolysis of the lactone involves not only a first order reaction with water but also a second order reaction with hydroxide ion. In those solvents, therefore, where a change in the hydrogen ion concentration was apt to prove troublesome, we used buffers. In Table I we have collected the rate constants in various solvents. Those marked with an asterisk are copied from Johansson, who used a titration method for following the rate. In Fig. 3 we have plotted the rates which have been determined in this Laboratory, against the *p*H. For the 7.87 *N* sulfuric acid the activity of the hydrogen ion was taken arbitrarily as 7.87. The solid line in Figure 3 is the plot of the total rate at various hydrogen ion concentrations as calculated from the well-known equation for the catalytic catenary

$$-\mathrm{d}\log_e(\text{lactone})/\mathrm{d}t = k = k_{\mathrm{H_2O}} + k_{\mathrm{H}}(\mathrm{H}^+) + k_{\mathrm{OH}}(\mathrm{OH}^-)$$

where $k_{\mathrm{H_2O}}$ and k_{OH} were determined by Johansson and k_{H} was determined in 2 *N* perchloric acid.

A change in the hydrogen ion concentration of the solvent in which the β-butyrolactone is hydrolyzed produces not only a change in the rate of hydrolysis as discussed above, but produces also a change in the ratio of the amount of (+) hydroxybutyric acid to the amount of (−) hydroxybutyric acid in the product. In order to determine this ratio the observed final rotation for each run must be corrected for the optical purity of the initial lactone. The corrected final rotation must then be compared with the molar rotation of pure hydroxybutyric acid in the same solvent. The correction was obtained by comparing the molar rotation of the bromobutyric acid from which the lactone was made with the rotation of the highly resolved bromobutyric acid. In Table III we enumerate the correction factors for the four preparations of bromobutyric acid which were used in this work. In Table IV we list the molar rotations of an optically impure sample of hydroxybutyric acid in the various solvents. Since the molar rotation of this sample of hydroxybutyric acid in water was only 18.5° we have multiplied all the experimentally determined molar rotations by a factor to obtain the rotation of pure hydroxybutyric acid. In Table V we have collected the data from the runs concerned with the optical form of the product. The first column indicates the preparation of bromobutyric acid from which the lactone was made, the second

the solvent in which the lactone was hydrolyzed, the third the initial molar concentration of lactone, and the fourth was observed final rotation. The percentages of (+) hydroxybutyric acid in the product as calculated from the corrected rotations are shown in the last column of Table V and plotted against the pH in Fig. 4. Where an unbuffered solution was used an arrow shows the change in pH during hydrolysis.

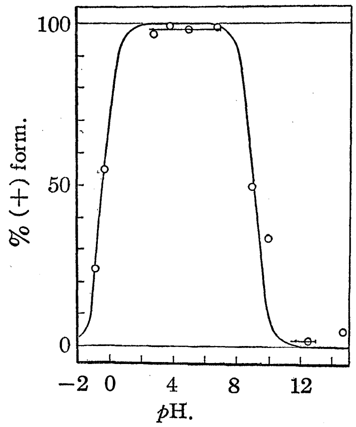

Fig. 4.—Optical form of hydroxybutyric acid produced by the hydrolysis of (+) β-butyrolactone.

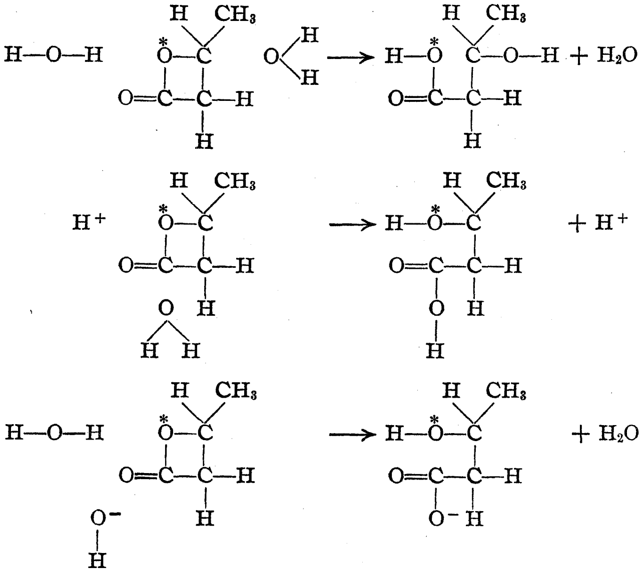
If we assume that (+) β-butyrolactone reacts with water molecules to form only (+) hydroxybutyric acid and with hydrogen ions or hydroxyl ions to form only (−) hydroxybutyric acid, and if we combine these assumptions with the rates as determined in the preceding sections, we can calculate the percentage of (+) hydroxybutyric acid formed in the various solvents. This we have done with the aid of the last column in Table II and have plotted the results as the solid line in Fig. 4. The agreement between the experimental and calculated percentages is quite satisfactory except for the point at pH of 10 and the point in 6 N sodium hydroxide. The agreement for the point corresponding to 7.87 N sulfuric acid is of course due to our arbitrary selection of an activity for the hydrogen ion. If we had calculated the activity from the mean activity rule of Lewis and Randall,[11] the point would have come to the right of that for 2 N perchloric acid. This procedure of course neglects a specific contribution to the rate by the acid sulfate ion. That this ion contributes to the rate is made very plausible by the work to be discussed later in connection with carbonate ion.

The low rotation in the 6 N sodium hydroxide may be due to reactions producing unsaturated compounds such as is observed with bromobutyric acid in alkaline solutions.

(11) Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., Inc., New York, N. Y., 1923, pp. 328 and 357.

Postponing for the present the discussion of the point at *p*H 10, we can conclude that the composite reaction is the resultant of the three reactions.



These reactions are written in conformity with the principle that inversion occurs for every substitution. The formation of the lactone from the bromobutyric acid must have involved an inversion even though there is no change in rotation, for the action of phosphorus pentachloride on (−) hydroxybutyric acid or its ester produces a (+) chlorobutyric acid[12] or its ester, respectively. It is of interest to recall in this connection that (+) bromosuccinic acid produces a lactone with negative rotation. The lactone is in reality an inner ester. The breaking of the carboxyl oxygen bond under acid or alkaline conditions is in agreement with the hydrolysis of esters under similar conditions.[13] The hydrolysis of the lactone by molecular water is fast enough to be observed. In this case it is the alcohol oxygen bond which is broken. Due to the fact that we used optically active materials, we see that the big speeding up of the reaction by hydrogen ions and hydroxyl ions therefore does not necessarily involve a catalysis of the water reaction, but rather the acceleration of independent, competing reactions. In view of these results we must disagree with Waters,[14] who states "Without exception hydrolyses are ionic reactions..."

In Fig. 3 the point corresponding to the hydrolysis of a 0.789 *M* solution of the lactone in pure water shows a slower rate than that calculated for a 0.15 *M* solution. This is in agreement with Johansson's work in which it was found that the first order rate constants decreased as the concentration of the lactone increased. We already have mentioned the difficulty of assigning an activity to the hydrogen ion in the 7.87 *N* sulfuric acid. In addition to this the rate also should deviate from that calculated for a dilute solution due to the changes of the activity of water and of lactone as we go to such a concentrated solution. These effects are likewise very prominent in the runs with phosphate and carbonate buffers where the salt concentrations are several moles per liter. Thus the velocity of the run in the phosphate solution is about three times the calculated rate. A distribution experiment using dibutyl ether as the second solvent showed that the activity of the lactone in the phosphate solution was about twice as great as it was in water solution, accounting for the major portion of the rate change. The run in the carbonate buffer cannot be explained in this way, for here we get not only a thirteen-fold increase in the composite rate but also a change in the optical ratio of the product. This ratio would not be changed by a change in the activity of the lactone. Therefore, even after allowing for a two-fold change in the activity of the lactone by the salt, we find a five-fold increase in the rate of the reaction with hydroxide ion and fifteen-fold increase in the water reaction rate. If we think of the carbonate ion in solution as hydrated and write a structure for it $:\underset{\cdot\cdot}{\ddot{O}}:\overset{:\ddot{O}:}{\underset{\cdot\cdot}{C}}:\underset{\cdot\cdot}{\ddot{O}}:H:\underset{\cdot\cdot}{\ddot{O}}:H$, we see that the water in this complex is intermediate between molecular water and hydroxide ion since the hydrogen which forms the bond is no longer completely the property of the water. Assuming that the behavior of such a particle is intermediate between that of hydroxide ion and molecular water, we would expect the observed changes in the rates and products.

Reactions of β-Bromobutyric Acid.—The disappearance of β-bromobutyrate ion in aqueous solution at 25° gave a first order rate constant of 1.09×10^{-3} min.$^{-1}$. Runs which were followed by Volhard titration or by change of optical rotation gave identical results. The rate of this re-

[14] Waters, "Physical Aspects of Organic Chemistry," Routledge and Sons, Ltd., London, p. 262.

action at 38° was found by Johansson[8] to be 0.0093. Combining these results we get $k = 1.3 \times 10^{17}e^{-29,800/RT}\text{sec.}^{-1}$. Later Johansson[15] found that at 32° about 15% of the β-bromobutyrate decomposed into propylene, carbon dioxide, and bromide ion. At 25° we found a 17% discrepancy between the production of bromide ion and of acid after the hydrolysis of sodium β-bromobutyrate was complete, indicating about the same amount of decomposition. If all of the hydrolysis of the sodium bromobutyrate proceeds through the lactone intermediate, the optical activity of the product should be the same as that which is obtained from the hydrolysis of the lactone. Correcting for the 15% decomposition reaction this was found to be the case.

An aqueous solution of sodium bromobutyrate and thiosulfate ion shows an induction period when the rate is followed by titration of the thiosulfate ion. The induction period becomes shorter the greater the initial concentration of thiosulfate ion. The limiting value for the rate appears to be the same as the rate of production of bromide ion when thiosulfate ion is absent. The reaction therefore probably involves the preliminary production of lactone and bromide ion. In corroboration of this, the rate of the bimolecular reaction between lactone and thiosulfate ion was determined by following the change in concentration of thiosulfate ion and found to be 0.05 liter per mole-minute. The results therefore are completely analogous to those obtained by Long and Olson[16] with sodium bromosuccinate.

In solution by itself or with 2 N perchloric acid the β-bromobutyric acid loses its optical activity only very slowly, the rotation in 2 N perchloric acid being 55% of the beginning rotation after two months at 25°. In basic solution, however, a fast bimolecular reaction with hydroxide ion occurs, producing an optically inactive substance, probably crotonate ion, such as Fischer and Scheibler[12] found with sodium β-chlorobutyrate. The rate constant as determined by the decrease in optical activity with time was about 0.08 liter per mole-minute at 25°.

The racemization by bromide ion was followed in approximately 0.2 N β-bromobutyric acid and 2 N hydrobromic acid by the decrease in optical activity. The rate constants, uncorrected for decrease in optical activity due to other causes, since this correction was small and known only in the case of the lower temperature, were 1.27×10^{-5} minute^{-1} at 25° and 9.2×10^{-5} minute^{-1} at 39.3° as the results of a single run at each temperature. The rate constant can then be expressed as $k = 4.2 \times 10^{11}e^{-24,900/RT}\text{sec.}^{-1}$ as a preliminary result.

Summary

Pure optically active β-bromobutyric acid has been prepared. Its molar rotation, $[M]^{25}_{5461}$, in acid solution is 116.5°. In aqueous solution the salt gave $[M]^{25}_{5461}$ equal to 106.6°.

The rates of hydrolysis of optically active β-butyrolactone prepared from optically active β-bromobutyric acid have been measured over a range of hydrogen ion concentrations.

From the rates and the optical activity of the final hydrolysis products it has been shown that the mechanisms of hydrolysis by water, by hydrogen ion, and by hydroxide ion are distinct.

It has been shown that the addition of an ion, such as carbonate ion, has a big influence on both the water rate and the hydroxide ion rate. An explanation is advanced for this behavior.

Tentative values of the heats of activation for the reaction by which β-bromobutyrate ion produces lactone and for the reaction by which bromide ion racemizes β-bromobutyric acid have been determined.

The rate of the bimolecular reaction between β-bromobutyrate ion and hydroxide ion was determined to be about 0.08 liter per mole-minute.

The reaction between β-bromobutyrate ion and thiosulfate ion has been shown to involve the unimolecular formation of lactone as a primary step.

The Heats of Solution of Gaseous Di- and Trimethylamines

BY ANDREW PATTERSON, JR., WITH W. A. FELSING

Object of the Investigation.—In a previous paper[1] there were reported calorimetrically determined values for the heats of solution of gaseous monomethylamine in water at different concentrations of methylamine produced. Since the di- and trimethylamines have been investigated[2] partially in this Laboratory with the view of determining their value in refrigerating systems of the absorption type and since it would be desirable to complete the heats of solution for this series of amines, this investigation was undertaken.

Existing Data.—Very few data on the heat of solution of these amines are recorded in chemical literature.

Bichowsky and Rossini[3] estimated the heat of solution of dimethylamine gas to be 12,700 cal. Other values, estimated in various ways, are due to Bonnefoi[4] (14,635 cal.), to Moore and Winmill[5] (12,290 cal.), and the "International Critical Tables"[6] (14,581 cal.), based upon data by Bonnefoi.[7] In no instance was there specified the concentration of the dimethylamine solution produced.

The values for the heats of solution for gaseous trimethylamine are also discordant. Berthelot[8] gives the value of 12,900 cal. when one mole of the amine is dissolved in 270 moles of water (*i. e.*, at $N = 270$). Other values are those of Moore and Winmill[5] (12,820 cal.), of the "International Critical Tables"[6] (12,908), and of Colson,[9] who gave a value of 8750 cal. for the heat of solution of *liquid* trimethylamine. This value may be combined with the molal heat of vaporization of 5540 cal./mole at 30°, based upon the data of Felsing and Phillips,[2] yielding a value of 14,290 cal./mole for the heat of solution.

Berthelot[8] cites some values for the heats of dilution of a saturated trimethylamine solution (410 g./1000 g. of water at 19°) and of some solutions ranging in concentration from near saturation to about one-half molar, the solutions in each case being diluted to approximately one-fourth molar.

Experimental Procedure.—The total heat of solution of these gaseous amines was determined by passing the dry gas into distilled water, observing the temperature effect, and determining the concentration of the amine solution produced. The method of procedure is that of Felsing and Wohlford;[1] only minor modifications were introduced.

The energy equivalent of the calorimeter system was determined by the usual electrical energy input method. Approximately 200 g. of distilled water measured to 0.001 g. was used for each of the seven determinations. The maximum deviation (a single determination) from the *mean* was 0.32 cal. (0.14%), whereas the average deviation was only 0.147 cal. (0.067%). The international calorie was used, 1 calorie being 4.1833 international joules.

No radiation corrections were applied to the heat of solution determinations since: (1) the time of a calibration run (the energy equivalent determinations) was made, by actual trial, the same as the time of a heat of solution determination; (2) the temperature rise of the calibration runs was made the same as the *average* rise of a heat of solution determination; (3) the stirring rate was held constant throughout; (4) the calorimeter vessel (a special Dewar flask) was highly evacuated and silvered; and (5) the surroundings were kept constant at 30 ± 0.05°. The initial temperature of each run was exactly 30°.

The gaseous amines were generated from the Eastman C. P. hydrochlorides by treatment with 50% potassium hydroxide in the apparatus of Felsing and Wohlford. The gases were dried by passing through tubes filled with pellet potassium hydroxide and were completely dried by storage over sodium wire. These dried gases (mixed with a very small amount of hydrogen resulting from the sodium wire drying process) were allowed to pass into the water of the calorimeter, the temperature rise was noted on a calibrated 2° Beckmann thermometer, and two samples (approx. 50 cc.) of the resulting solution were removed by

means of a sampling pipet. From this pipet the sample was added to a weighed quantity of standard sulfuric acid, containing one drop of methyl red indicator, until faint alkalinity was indicated. To this essentially neutral solution was added the standard sulfuric acid to produce a slightly acid solution. This excess was then titrated with standard sodium hydroxide, the whole procedure being that of Moore and Winmill.[5] The use of methyl red as indicator has been recommended by Treadwell and Hall[10] and by Thompson.[11] All titrations and standardizations were made by weight; duplicate determinations always were made and the usual precautions for highest accuracy were observed.

1.745	1.8104	199.712	361	12,533	12,458

Maximum deviation, 0.93%; average deviation, 0.43%.

The Data.—The data are listed in the table, in the order of increasing amine concentration; this is not necessarily the order of determination. A plot of the heat of solution against *N* (the ratio of moles of H_2O to moles of amine) was made for each amine. A straight line represents best the variation of the total heat of solution with change in the concentration of the solution produced for each of the amines. These functional relations are given by

$$\text{Dimethylamine:}\quad -\Delta H_1\ (\text{cal./mole}) = 12{,}470 + 0.35149N \qquad (1)$$

$$\text{Trimethylamine:}\quad -\Delta H_2\ (\text{cal./mole}) = 12{,}344 + 0.31645N \qquad (2)$$

These relations apply only to the range of concentrations investigated.

The rate of change of the total heats of solution per mole with change in concentration of amine solution produced, for any concentration over the limited range investigated, is given by

$$d(-\Delta H_1)/dN = 0.35149, \text{ for dimethylamine}$$
$$d(-\Delta H_2)/dN = 0.31645, \text{ for trimethylamine}$$

The data of Berthelot[8] on trimethylamine apply only to the dilution of concentrated solutions up to a concentration which is even greater than the most concentrated of this investigation. Hence his data cannot be compared with the results of the heat of dilution relations of this investigation.

Summary

1. The total heats of solution for gaseous di- and trimethylamines have been determined at 30° for various concentrations of amine solution produced.

2. The relation between $-\Delta H$ (heat of solution in cal./mole of amine) and *N* (moles water/mole amine) is given by two linear equations:

---

(10) Treadwell and Hall, "Analytical Chemistry," Vol. II, 7th Ed., 1928, p. 470.

(11) R. T. Thompson, *Analyst*, **53**, 315 (1928).

$-\Delta H_1$ (dimethylamine) $= 12{,}470 + 0.35149N$ and $-\Delta H_2$ (trimethylamine) $= 12{,}344 + 0.31645N$. The experimental values agree with the values calculated by these relations on the average to 0.43%; the maximum deviation is 0.93%.

The Densities of Fine Powders. II

BY J. L. CULBERTSON AND MARTIN K. WEBER

In a recent study of the apparent densities of fine powders made in this Laboratory[1] the differences in values obtained when different liquids were used as the buoying fluids were noted and conclusions were reached which were somewhat at variance, in their detail, from those reached by previous investigators. In a second study[2] there was evident a rough correlation between apparent density values and the heats of wetting of the powders when wetted by the same liquids. Further studies seemed desirable in order to test the conclusions reached in that work, and it was proposed that these should be developed along two lines, namely, (a) density determinations should be made of the fine powders used in the previous work (silica gel and active, practically ash-free, charcoal) using a number of liquids not yet investigated and (b) a study should be made of apparent densities of a non-porous powder in liquids of different types.

In the previous work[1] the conclusion was reached that variations in the apparent density of a porous powder might be due either to differences in the degree of penetration of the porous solid by the liquids or to differences in the degree of compression of the liquids at the solid–liquid interface. In either case the density differences noted must have been due primarily to the differences in surface energy decrease on wetting the solid, though in the second case differences in the compressibilities of the liquids would have been a conditioning factor. The measurements on a non-porous powder were proposed with the hope that by such means the first of these possible explanations might be confirmed or disproved.

Experimental.—In the previous work[1] a modification of the method of Harkins and Ewing[3] was used. Since this method requires considerable time, the method used by Tschapek[4] was investigated. This in brief consists of weighing a sample of the solid into a suitable specific gravity bottle and adding to the sample liquid sufficient to submerge it. The bottle is then placed in a vessel provided with suitable means of air-tight closure and a connection to a vacuum pump. This vessel is then evacuated to a pressure slightly below the vapor pressure of the liquid used on the sample. With such a pressure the adsorbed air is removed rapidly from the surface of the solid particles and after a sufficient time period (determined by increasing to time intervals yielding constant value determinations) the vacuum is broken, the specific gravity bottle filled, brought to the standard temperature and weighed. After making the necessary buoyancy corrections, the density is calculated directly. Tests of this method in comparison with that used in the previous work[1] demonstrated a satisfactory agreement, and, since it is considerably faster than the one formerly used, it was adopted for the present investigations.

Results and Discussion.—In the first study, samples of the same solid materials as were used previously[1] were employed. These were powdered silica gel and active ash-free charcoal. The methods for their preparation have been described.[1] Water, benzene, nitrobenzene, carbon disulfide, acetone, ethyl alcohol, and *n*-butyl alcohol were purified carefully by standard methods and used in the density determinations. The density values for each of the solids in each liquid are given in Table I(a). It is of interest also to add to these values those of Table I(b) taken from the previous work.

TABLE I(a)

used in the determination and in consideration of the fact that the charcoals were of different origins the data above are in satisfactory agreement with their values. As noted in the previous paper,[1] however, the observed values of the density of silica do not agree with such a concept. It appears significant that those liquids possessing the greatest compressibility yield the greatest values for the density of charcoal, while those with polar groupings, as indicated by high electric moment, show the greatest values for the density of silica; considering specific cases, the dipole moment of acetone is high and its compressibility is comparatively high. The density values of both charcoal and silica are high when determined by means of acetone. Water with high dipole moment and low compressibility yields a high density for silica and low density for charcoal, while petroleum ether with high compressibility and zero dipole moment yields a low density for silica and a high density for charcoal. The reader will of course observe that the extreme cases have been mentioned in illustrating the point made, and further that in some cases, particularly that of the density of charcoal in carbon tetrachloride and perhaps that of silica in carbon disulfide, the suggested relationship is not apparent. The data, however, offer considerable support for the generalization made. To the writers this would seem to indicate that on the silica surface polar groups are oriented to the interface and the large force of attraction causes compression of the liquid. Non-polar liquid molecules under the influence of less attractive force and feeble orienting influence even though of high compressibility fail to show such high densities for this solid. Generally speaking, opposite orientations and large forces of attraction between solid and non-polar groups and molecules seem to be indicated for the charcoal.

The data may, however, be explained on the basis of penetrability of the porous solids by the various liquids and the second series of determinations appear to be significant in this connection. For this study selected crystals of clear quartz were crushed and then ground in a pebble mill. The charge was removed from the mill at frequent intervals and screened. All material passing a 200-mesh sieve was retained and the rest returned to the mill. When approximately two pounds (1 kg.) of the 200-mesh material had been accumulated, the coarse fraction was discarded and the fine powder mixed and sampled. The fine material was then returned to the mill and the grinding continued for a period of five hundred hours, samples being taken at intervals. After approximately one hundred and twenty-five hours grinding, caking of the charge became so troublesome that the grinding was continued with the charge in the form of a slurry. The samples taken from the slurry were dried for twenty-four hours at 110°. Using the same method as was used in obtaining the data of Table I, the densities of these samples were determined using pure water and benzene. The results are given in Table II.

TABLE II

DENSITY OF GROUND QUARTZ

G./cc. at 25°

Grinding time, hours	Determination made in Water	Benzene
0	2.643	
4	2.642	
12	2.644	
24	2.641	
48	2.642	2.643
96	2.636	2.636
136	2.632	2.636
204	2.615	2.614
300	2.602	2.592
375	2.585	2.561
500	2.553	2.535

In the interpretation of these data cognizance must first be had of the falling trend of values as grinding is continued. This effect has been observed with ground quartz by Martin, *et al.*,[5] and the explanation has been offered that a part of the surface layer of the particles has been converted into amorphous material of lower density than the quartz crystal.[6] If this be the correct interpretation, then the relation between the two series of values becomes significant. Until well past two hundred hours of grinding, the density measurements in the two liquids show no appreciable differences, but from three hundred hours onward, the measurements in benzene fall definitely below those made in water. If it may be assumed that this material is non-porous, then only one of the suggested explanations will be applicable; *i. e.*, the water must be more strongly compressed at the interface than the benzene, the effect becoming evident only when a high

---

(5) Alexander, "Colloid Chemistry," Vol. III, The Chemical Catalog Co., New York, N. Y., p. 305.

(6) That the effect cannot be due to attrition of the pebbles in the mill seems assured from the fact that the mean density of the pebbles was 2.577 g./cc. which, though much less than that of the original quartz, is appreciably greater than the final values obtained.

degree of subdivision is attained. Positive assurance can be had, however, only when the surface structure of the quartz particles is definitely known.

Summary

Density measurements of silica and charcoal, using a series of liquids as the buoying fluid, indicate that polar liquids yield high density values for silica, non-polar yield low values. The more compressible liquids yield the higher density values for charcoal. Polar liquids having large compression coefficients yield high density values for both solids.

Density measurements of ground quartz of varying degrees of fineness were made by means of benzene and water as the buoying fluids. These measurements confirm the foregoing statements and indicate that a different degree of penetration of different liquids into the surface of the solid is probably not a factor of significance in the variations of apparent density.

An Attempted Exchange of Phosphorus between Phosphorous and Phosphoric Acids

BY J. NORTON WILSON

The hydration of hypophosphoric acid, which takes place according to the equation

$$H_4P_2O_6 + H_2O \longrightarrow H_3PO_3 + H_3PO_4 \qquad (1)$$

has been shown[1,2] to proceed at a rate which is first order with respect to hypophosphoric acid and increases with increasing hydrogen ion concentration. It has been suggested[1] that this reaction is irreversible, but it seems probable that an equilibrium may be reached in which the concentration of hypophosphoric acid remaining is too small to be detected readily by chemical methods. If the structure of hypophosphoric acid is such that the phosphorus atoms are equivalent, as in the structure  $(HO)_2\underset{\underset{O}{\|}}{P}-\underset{\underset{O}{\|}}{P}(OH)_2$ which has been suggested on the basis of X-ray absorption spectra and chemical properties by Nylen and Stelling[3] and by Hantzsch,[4] the reverse of reaction (1) should lead to an exchange of radioactive phosphorus between phosphorous and phosphoric acids according to the following mechanism (the radioactive phosphorus atom is denoted by an asterisk)

$$H_3P^*O_4 + H_3PO_3 \rightleftarrows H_2O_3P^* - PO_3H_2 + H_2O \rightleftarrows H_3P^*O_3 + H_3PO_4 \qquad (2)$$

An attempt has been made to detect this exchange using radioactive phosphorus[5] obtained as a by-product of the formation of radio-sulfur by bombardment of sulfur with fast deuterons. The material was separated from most of the accompanying sulfur and oxidized to phosphoric acid; a small amount of ordinary phosphoric acid was added as a carrier. The phosphate was precipitated as magnesium ammonium phosphate and converted to lead phosphate which was treated with hydrogen sulfide to liberate radioactive phosphoric acid. The reaction mixtures were made up from this material and "C. P." phosphorous and phosphoric acids. The phosphorous acid used was found to contain a small amount of phosphoric; this was determined and corrected for.

In order to determine whether exchange had occurred the mixture was diluted and the phosphate precipitated as magnesium ammonium phosphate; this was dissolved in acid and reprecipitated to remove co-precipitated phosphite. The phosphate precipitate was dried and its electroscopic activity measured. The phosphite contained in the filtrates was oxidized with bromine and similarly precipitated; the electroscopic activity of this precipitate was determined as before. Occurrence of activity in the latter precipitate would be evidence either of exchange or faulty separation.

The reaction mixtures were made up in duplicate; one of the pair, used as a blank, was subjected immediately after mixing to the separation process and radioactivity measurements described above; the other was sealed in a glass

VI	.36	.35	HCl, 5.63	37,900	25	$+.006 \pm .004$	24.8	$(2 \pm 2) \times 10^{-4}$	$(1 + 1) \times 10^{-4}$

ampoule and allowed to stand for a convenient time before separation.

The probability of error due to faulty separation was greatly decreased in experiments V and VI in which after the precipitation and separation of the radioactive phosphate some inactive phosphoric acid equal in amount to that originally present in the solution was mixed with the phosphite in the filtrates and precipitated in the same way. This treatment should remove practically all of any radioactive phosphoric acid left in solution after the first precipitation. Measurement of the activity of the resulting precipitate indicated that about 0.1% of the radiophosphoric acid originally present was left in solution after the first precipitation. After the extra precipitation the phosphite in the filtrate was oxidized and precipitated as in the earlier experiments.

From the observed extent of an exchange occurring during the time t in accordance with the mechanism suggested in (2), one can calculate the rate at which reaction (1) and its reverse proceed at equilibrium. If the first order rate constant k_1 for the hydration of hypophosphoric acid is known, one can calculate from this result the equilibrium constant K, defined as $K = (H_4P_2O_6)/(H_3PO_4)(H_3PO_3)$. It may be shown that for the case where exchange occurs to a very small extent over a long time a good approximation is

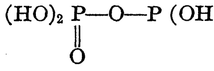
$$K = \frac{2}{(H_3PO_4)k_1t}\frac{\beta}{\alpha_0} \qquad (3)$$

where α_0 is the fraction of phosphoric acid initially radioactive corrected for radioactive decay to the time t and β is the fraction of phosphorous acid radioactive at time t.

In the following table are listed the concentrations, in formula weights per liter, of the reagents used in the experiments; the time t between the original mixing of the solutions and the separation of the phosphate; the temperature; the electroscopic activities of equal weights of the precipitates from the phosphite and phosphate fractions, corrected for radioactive decay and for the normal leak of the electroscope; and the values of β/α_0, which has been taken as the ratio of these activities. The values of β/α_0 for the "blank" experiments are also included. The normal leak of the electroscope was about 0.07 division per minute; fluctuations about this value were large enough to make a comparatively large uncertainty in the value of the activity of the phosphite precipitate. This uncertainty was estimated from the root mean square deviation from the mean of a number of alternate measurements of the normal leak and the phosphite activity. The results of experiments V and VI are the most reliable because of the care used to eliminate the error due to faulty separation.

It is apparent that in no case was definite evidence of exchange obtained. It can be stated, however, that the extent of exchange was less than a certain value determined by the estimated uncertainty; on the basis of the assumptions made a limit can then be placed on the value of the equilibrium constant K. Thus in experiment VI, β/α_0 was very probably less than 5×10^{-4}; k_1 for the given conditions may be estimated from the data of Van Name and Huff[1] to be 1.0×10^{-3} min.$^{-1}$. Then $K < 8 \times 10^{-5}$ mole^{-1} liters at 25° in 5.6 formal hydrochloric acid.

Unfortunately, an alternative conclusion is possible: that the phosphorus atoms in hypophosphoric acid are not equivalent, as for instance in the structure



$(HO)_2\underset{\overset{\|}{O}}{P}—O—P(OH)_2$

proposed on the basis of some slight chemical evidence by Blaser and Halpern.[6] If this is the case it is unlikely that the reverse of reaction (1) would lead to exchange. According to the evidence at present available,[1,2] however, it seems quite probable that the molecule contains two equivalent phosphorus atoms bonded to one another.

The author is grateful to Professor R. G. Dickinson for his advice, criticism and encouragement in connection with this investigation.

Summary

No exchange of radioactive phosphorus between

---

[6] Blaser and Halpern, *Z. anorg allgem. Chem.*, **215**, 33 (1933).

phosphorous and phosphoric acids in acid or alkaline solution was found to occur beyond the limits of experimental error. The results indicate that if the phosphorus atoms in hypophosphoric acid are equivalent, the equilibrium constant for the formation of hypophosphoric acid from phosphorous and phosphoric acids is less than 8×10^{-5} mole^{-1} liters at 25° in 5.6 formal hydrochloric acid.

The Instability of Liquid Isobutene

BY EDWIN E. ROPER

In the course of measurements of the vapor pressure of a number of unsaturated hydrocarbons, the results of which are to be presented in a later paper, it was found that the vapor pressure of originally pure isobutene (2-methylpropene) decreases over a period of time and from this aged material a relatively high-boiling liquid was isolated. The most probable explanation of this instability of isobutene is that a polymer is formed. Since there appears to be no mention in the literature of any such uncatalyzed polymerization of isobutene, although it is well known that in the presence of certain catalysts isobutene is converted into polymers,[1] and since we do not plan to continue the study of this behavior further, it appears worth while to present our findings at this time.

Experimental

Apparatus.—A simple static system was used, consisting of a small (*ca.* 5 cc.) vapor pressure tube immersed in an ice-bath, which was maintained at 0.000 ± 0.001° for the observations. The washing procedure required to establish this temperature reproducibility in the ice-bath has been described.[2] The pressure was measured on an absolute manometer, of 15-mm. inside diameter Pyrex tubing, by a high grade cathetometer; meniscus corrections were determined for each observation and the pressure converted to international millimeters[3] (int. mm.) of mercury. Accessory apparatus included vacuum line, fore and condensation pumps, McLeod gage and a system of stopcocks; the manometer had a reservoir sealed on at the bottom, allowing the U to be used as a mercury cut-off, which was the only access to the vapor pressure system, so that no stopcocks were exposed to the vapor for long periods of time.

Material.—Four samples of isobutene were available. Sample D was from Dr. Harold S. Davis; it had been prepared by the dehydration of *t*-butyl alcohol by means of oxalic acid and purified in a Davis[4] low-temperature fractionating column. The boiling point range of this sample was given as ±0.05°. Sample R was one we had prepared by the method described by Davis,[4] with a boiling range of *ca.* 0.5°. Sample K, obtained from Professor Kistiakowsky of these Laboratories, had been highly purified for a determination of the heat of hydrogenation;[5] the consistent value of this heat of reaction for different fractions from the distillation,[5] the method of distillation,[5] the value of the freezing point,[5,6] and our vapor pressure measurements in conjunction with isothermal vaporization, gave indication of exceptional purity of the sample, of the order of 99.9%. Sample F was presented to us by Professor Forbes of these Laboratories; it had been prepared by the same investigators as had sample K and was the remnant of the material used in the photochemical investigation of Forbes and Nelson.[7] The boiling range was the same as that for sample K, namely, 0.02°. Samples K, F and R were dried by a physical method, which consisted of a filtration of the liquid through glass wool held at low temperatures;[8] this effectively dried the hydrocarbon and possibly removed some of the polymer. The samples were stored in the liquid phase in all-Pyrex glass containers, fitted with a glass internal break-off seal, externally operated by an electromagnet. High vacuum technique was used in all operations of filtering and transferring.

Procedure.—Immediately previous to the vapor pressure determinations, a distillation from the storage container at −80°, to a bulb on the vapor pressure line, via the manometer-cutoff, at −188° was carried out; this operation required some time, because of the low vapor pressure of the hydrocarbon at −80° (12 mm.). The first few tenths of a cc. that distilled was discarded, as was the last portion. In the subsequent examination of the latter, the container having been removed from the vacuum line, it was noticed that a small amount of residue, with a distinctive odor, was left after the admixed isobutene had been allowed to vaporize into the atmosphere; this residue was liquid at −80° and crystalline at −188°. It was obvious that the residue had formed during the several months of storage in the glass container, for during the

initial treatment previous to storing, the same type of distillation had been performed.

The vapor pressure measurement was then carried out with this freshly distilled material and a small but definite decrease with time was observed. Part A of Fig. 1 shows the data for the first trial, using sample K. Some of the observations appear to be erratic; the only explanation that can be advanced is that possibly the pressure readings were taken too soon (*ca.* fifteen to thirty minutes) after the washing operation on the ice-bath. The ice-bath was replenished at suitable intervals so that 0.000 ± 0.004° was always maintained throughout the duration of the trial; previous to making an individual pressure determination, the ice-bath was brought to within ±0.001° of 0.000° by the washing procedure.[2] ±0.001° is equivalent to ±0.03 mm. in the vapor pressure as determined from the slope of the vapor pressure curve at 0°. At the end of the trial, an attempt was made to free thoroughly the system from polymer, by pumping for a long period.

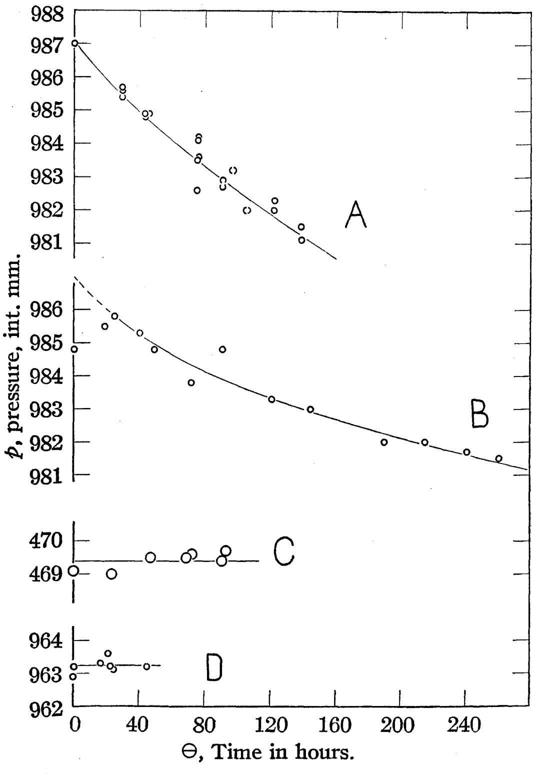

Fig. 1.—Comparison of results. Part A represents the vapor pressure change for isobutene, first trial, part B for the second trial; part C shows the data for the non-saturated vapor of isobutene. Part D gives data obtained for the vapor pressure of 1-butene. The diameters of the circles are 0.2 mm. in parts A, B and D, and 0.3 mm. in part C.

The identical apparatus had been in use for several months previous to this trial and no leaks were apparent. Nevertheless, it appeared necessary to investigate this point and accordingly the pressure was decreased to 470 mm. and readings made on the pressure over a period of time. The varying room temperature gave rise to different pressures of the non-saturated vapor but by means of the average change in p with T, the pressures were corrected to a common temperature. Part C, Fig. 1, presents the results; the data indicate that no leak existed and also that the hydrocarbon is stable in the vapor phase at this temperature.

The vapor pressure trial was then repeated, using a fresh sample of isobutene distilled into the vapor pressure bulb by the −80 to −188° procedure. Part B, Fig. 1, shows the results, which do not exactly parallel those of the first trial but the general behavior is the same. The low values at the commencement are not explainable.

Over a year after the conclusion of the above trials, sample K, which had been stored in glass, was distilled into a new vapor pressure system in the manner outlined. Again a small amount of the high-boiling liquid remained in the container. No attempt was made to study the change in the vapor pressure with time, although it was observed, but four determinations were obtained for the freshly distilled material, averaging 988.6 ± 0.3 int. mm. at 0.000 ± 0.001°.

In distillations after the manner described, of samples D, F and R, a residue of the high-boiling liquid from each has been noted, providing the hydrocarbon sample had been stored for some time in the liquid phase. A second distillation, immediately following the first, reveals no trace of the high-boiling liquid, nor does a distillation on material which has been stored in the gas phase. From sample F 0.25 g. (1.5 weight per cent.) and from sample R 0.40 g. (0.8 weight per cent.) of polymer was secured by collecting the residue remaining in the tube after a −80 to −188° distillation.

Investigation of the High-Boiling Liquid.—A rough freezing point was obtained by means of liquid air and a small pentane thermometer. The ranges −105 to −115° and −100 to −120° were found for the material from samples F and R, respectively. The refractive indices were kindly determined by Dr. J. B. Conn of these Laboratories, and $n^{20}\text{D}$ found to be 1.435 and 1.397 for the material from samples F and R, respectively. The product took up bromine (in carbon tetrachloride solution) first by addition and then shortly thereafter by substitution.

Discussion

With such small amounts of the high-boiling liquid available, purification and accurate boiling and freezing points were not feasible, especially if a mixture is present, for separation by distillation probably would prove to be impossible due to the similarity of the boiling points of the components; the freezing point would be inconclusive if separation were not effected. The physical properties of the two components of di-isobutylene as determined by Tongberg, *et al.*,[1c] are as follows: for 2,4,4-trimethylpentene-1 the freezing point is −93.6°, $n^{20}\text{D}$ 1.408, for 2,4,4-trimethylpentene-2 the freezing point is −106.5° (another form at −108.3°), $n^{20}\text{D}$ 1.416. For triisobutylene, $n^{20}\text{D}$ 1.431;[1c] since there are at least three hydrocarbons present,[9] a freezing point is meaningless, except for the equilibrium mixture. However, a hydrocarbon of the formula $C_{12}H_{24}$ should freeze in the vicinity of $-20°$ ($\pm 20°$). A comparison of the freezing points and refractive indices of the high-boiling liquid with those given above for three possible polymerization products shows that no very definite conclusion can be drawn as to the exact nature of the high-boiling liquid. According to the mechanisms given by McCubbin and Adkins[10] for the addition of isobutene to isobutene, four dimeric products are possible, namely, 2,4,4-trimethylpentene-1, 2,4,4-trimethylpentene-2, 2,5-dimethylhexene-1 and 2,5-dimethylhexene-2.

There does not seem to be any possibility that accidental contamination with some catalytic material can be the cause of this polymerization, since it has been observed with samples from three sources, prepared by two different methods, and under varying conditions. In view of this instability, the properties and reactions of isobutene, to a minor degree, will depend upon its past history.

For the other three butenes, no residue has ever been found in the -80 to $-188°$ distillation and the data obtained on the vapor pressures do not show evidence of change with time. These vapor pressure results were not collected for this particular illustration and it would have been desirable to extend the time of observation; unfortunately, this was not possible. Part D, Fig. 1, shows the results obtained with 1-butene, and gives some idea of the reproducibility of the measuring system. For 1-butene, *trans*-2-butene and *cis*-2-butene vapor pressures at $0.000 \pm 0.001°$, an analysis of the results indicates that the extreme variation is 0.4 mm. or less, the means ± 0.1 mm., measured over forty-five, twenty-nine and twenty hours duration, respectively; these three hydrocarbons were prepared by the collaborators of Professor Kistiakowsky.[5]

Thermodynamic data are available for the polymerization of liquid isobutene to the liquid dimer, trimethylpentene. By utilizing the data of Parks and co-workers,[6,11] the free energy of formation of the liquids may be approximated closely. The value of the equilibrium constant calculated from the free energy for the dimerization reaction is about 10^7 times greater than the value calculated from the weight concentration of high-boiling liquid found, making the assumption that it is trimethylpentene. Two factors could cause such a discrepancy: non-attainment of equilibrium, and a different mechanism than simple dimerization to trimethylpentene. It appears very likely that both factors are operative, although from the observed freezing points and the qualitative observations on the volatility of the high-boiling liquid, not a great quantity of trimer can be present. It is worth noting that the free energy changes for the three possible isomerization reactions of isobutene are all positive values, although rather small, so that isomerization to 1-butene or 2-butene should not occur spontaneously to complicate further the course of this polymerization reaction.

I wish to thank Professor Arthur B. Lamb, under whose direction this work was carried out, for facilities placed at my disposal and for advice in preparing this manuscript. I am grateful to him and to Dr. H. S. Davis, Professor G. S. Forbes, Professor G. B. Kistiakowsky and Dr. J. R. Ruhoff for making available the hydrocarbon samples.

Summary

It has been shown that isobutene in the liquid phase forms a high-boiling liquid, upon standing, which probably is a polymer, with certain evidence pointing to dimerization as the first step. At 0° this reaction causes a lowering of the pressure of the saturated vapor of pure isobutene to the extent of about 0.6%. The other three butenes do not exhibit such behavior.

The Structure of Ammonium Heptafluozirconate and Potassium Heptafluozirconate and the Configuration of the Heptafluozirconate Group

BY G. C. HAMPSON AND LINUS PAULING

The only work which has been reported so far on the structure of the so-called intercalation compounds of composition M_xAB_7 is that of Hassel and Mark,[1] who carried out an X-ray investigation of the crystals of ammonium heptafluozirconate, $(NH_4)_3ZrF_7$, and ammonium heptafluohafniate, $(NH_4)_3HfF_7$. Both crystals are cubic, the cube edge being 9.35 and 9.40 Å., respectively, and both contain four molecules in the unit cell. From their data Hassel and Mark were unable to deduce the space group absolutely, but they considered that O_h^4 was the most probable and suggested a structure based on this. This structure was built up of NH_4^+ ions, $[ZrF_6]^=$ ions, and F^- ions. It is of considerable interest to know whether odd coördination complexes involving seven atoms surrounding a central atom can or cannot exist, and the work of Hassel and Mark has been quoted[2] as proving the latter contention. It must be remembered, however, that Hassel and Mark's structure was put forward only as a possibility, and it is now clear from our knowledge of atomic and ionic radii that this particular structure is highly improbable.

In the first place, large numbers of ions of the same charge (*e. g.*, six NH_4^+ ions) are grouped together, which is a very unlikely arrangement. Moreover, taking even the most favorable limits of their parameter values it is found that their structure places an ammonium ion only 1.54 Å. from a fluoride ion, whereas the nearest possible distance even assuming hydrogen bond formation is about 2.6 Å. (2.63 Å. is observed in NH_4F[3] and 2.76 Å. in NH_4HF_2[4]).

In view of these facts a reinvestigation of the problem seemed to be justified. We have carried out a study of the structure of ammonium heptafluozirconate and potassium heptafluozirconate, using data obtained from Laue, oscillation, and powder photographs, and have found that the substances do not contain $[ZrF_6]^=$ and F^- ions, but instead contain the complex ion $[ZrF_7]^{\equiv}$, in which zirconium has the coördination number seven. The structure of the crystals is similar to that of $(NH_4)_3AlF_6$, with the $[AlF_6]^{\equiv}$ complexes replaced by $[ZrF_7]^{\equiv}$; the orientation of these complexes is not uniquely determined, however, but shows some randomness, permitting the crystals to assume higher point-group and space-group symmetry than would be possible otherwise.

Crystals of $(NH_4)_3ZrF_7$ and K_3ZrF_7 were grown by dissolving zirconium fluoride in a hot solution containing a large excess of ammonium fluoride or potassium fluoride and allowing the solutions to crystallize slowly.[5] Small transparent optically isotropic octahedra were obtained, with faces which do not show very good reflections; the crystals deteriorate fairly rapidly on exposure to the atmosphere, and were usually protected during the preparation of the X-ray photographs with a thin film of oil or vaseline.

The Structure of $(NH_4)_3ZrF_7$.—Oscillation photographs about [110] (copper Kα radiation), Laue photographs with the X-ray beam parallel to [111], and powder photographs (copper Kα radiation) were prepared of $(NH_4)_3ZrF_7$. No reflections were found to occur from planes with mixed indices (*hkl* part odd and part even). This observation is in disagreement with the results of Hassel and Mark, who reported the presence of reflections of this type. The only such reflections recorded in their tables are (110) and (310). We prepared 5° oscillation photographs permitting reflection from these planes, using long exposure times, and were unable to detect the reflections on our films; there is also no sign of these reflections on our powder photographs, which show more lines than those reported by Hassel and Mark. It seems likely that these investigators were misled by the X-ray continuum, by β lines, or by some other feature of their photographs, and that their report of reflections from planes of mixed indices was due to misinterpretation of their data. Their choice of space group (O_h^4) and their suggested structure were based on

this presumably erroneous observation, and need not be discussed further.

The absence of any reflections from planes of mixed indices on our oscillation, Laue, and powder photographs makes it highly probable that the crystal lattice is face-centered.

Laue photographs taken with the X-ray beam parallel to [111] of thin crystal sections obtained by grinding octahedra on parallel octahedral faces were found to show a three-fold axis and three planes of symmetry, corresponding to the point groups T_d, O, and O_h. Since the Laue symmetry is of great importance in this investigation, the photographs were very carefully inspected, and were also studied by use of the α-ray integrating microphotometer.[6] Carbon prints were made of the photographs and the intensities of Laue spots due to planes of various holohedral forms were measured with the microphotometer, the intensity measurements being reproducible to within about 5%. No deviation from holohedry was found.

The powder photographic data for $(NH_4)_3ZrF_7$ (Table I) correspond to the value $a_0 = 9.365 \pm 0.010$ Å. for the edge of the unit cube, in good agreement with the value 9.353 Å. given by Hassel and Mark. With $4(NH_4)_3ZrF_7$ in the unit the density is calculated to be 2.32 g./cc.; the directly measured experimental value, 2.20 g./cc. (Hassel and Mark), is slightly smaller.

We have now to locate 4Zr, $12NH_4$, and 28F in the unit. The space groups compatible with the observed holohedral Laue symmetry and based on the face-centered cubic lattice are T_d^2, T_d^5, O^3, O^4, O_h^5, O_h^6, O_h^7, and O_h^8. Of these T_d^5, O^4, O_h^6, O_h^7, and O_h^8 provide no positions for the four zirconium atoms, and are accordingly ruled out of consideration.[7] T_d^2 provides four sets of no-parameter positions (4a, 4b, 4c, 4d) for four equivalent atoms, and sets of positions for 16, 24, 48, and 96 equivalent atoms; with 4Zr, $4(NH_4)_{I}$, $4(NH_4)_{II}$, and $4(NH_4)_{III}$ occupying 4a, 4b, 4c, and 4d, there is no way of placing all of the 28 fluorine atoms, so that this space group is also ruled out. O^3 and O_h^5 are ruled out in the same way; *there is no set of atomic positions for $4(NH_4)_3ZrF_7$ in the unit compatible with the observed holohedral Laue symmetry and face-centered lattice of the crystal.*

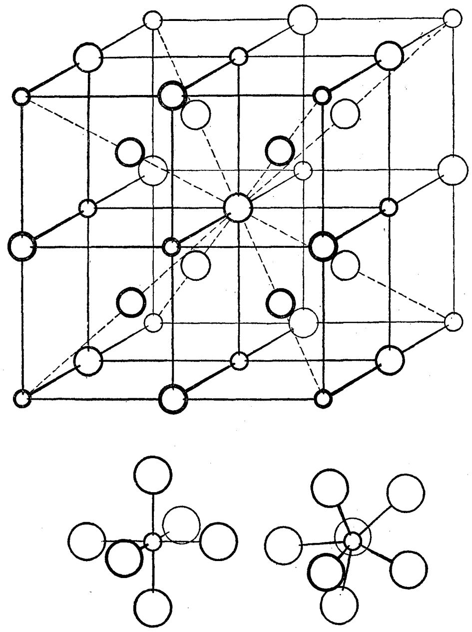

Fig. 1.—In the structure of $(NH_4)_3AlF_6$ each of the aluminum atoms (smallest circles) is surrounded by six fluorine atoms to form the octahedron shown below at the left side. In $(NH_4)_3ZrF_7$ and K_3ZrF_7 the $[AlF_6]^{\equiv}$ complexes are replaced by $[ZrF_7]^{\equiv}$ complexes such as that shown below at the right side.

The resolution of this difficulty might be achieved by assuming that the Laue symmetry is actually hemihedral or that the structure is actually based on a lattice with fewer lattice points than the face-centered lattice of the four-molecule unit, and that the intensities and intensity differences of X-ray reflections differentiating the actual Laue symmetry and lattice from those simulated are so small as to have been overlooked in our careful examination of the photographs. This is rendered improbable, however, by the fact that the crystal does not contain unlike atoms which resemble one another closely enough in stereochemical properties and X-ray reflecting power[8] to permit the simulation of a pseudo-unit in the usual way.

It is probable instead that ammonium heptafluozirconate is to be added to the list of crystals with structures involving some randomness of atomic arrangement, the treatment of which requires variation from the usual methods of application of the theory of space groups. We have found that a reasonable structure involving some randomness in orientation of $[ZrF_7]^{\equiv}$ complexes

[8] As, for example, tetrahedrally coördinated aluminum and silicon atoms in sodalite, $Na_4Al_3Si_3O_{12}Cl$; L. Pauling, *Z. Krist.*, **74**, 213 (1930).

can be formulated which accounts satisfactorily for the X-ray data for $(NH_4)_3ZrF_7$, and that a similar structure can also be assigned to K_3ZrF_7.

The number of possible structures involving randomness of atomic arrangement of one type or another is so great that a straightforward structure determination cannot be carried out; it is necessary instead to apply the method of suggesting reasonable structures and testing them by comparison with the X-ray data. Now the X-ray photographs of $(NH_4)_3ZrF_7$ are closely similar to those of $(NH_4)_3AlF_6$, and it accordingly seems likely that the structure of $(NH_4)_3ZrF_7$ is to be obtained by the introduction of an additional fluorine ion in the $(NH_4)_3AlF_6$ arrangement.[9] This arrangement (Fig. 1) places 12 NH_4 at $^1/_2{}^1/_2{}^1/_2$, $^1/_4\ ^1/_4\ ^1/_4$, $^3/_4\ ^3/_4\ ^3/_4$, etc. (plus the positions obtained by application of the translational operations of the face-centered lattice), and 4 octahedral MF_6 groups at 000, etc. Additional fluorine ions might then be inserted at positions such as *uuu* with $u \cong {}^1/_8$. A fluorine ion here is about 1.9 Å. from three fluorine ions and an ammonium ion. This distance is too small, the minimum distance of approach expected for two fluorine ions (ionic radius 1.36 Å.) being about 2.4 Å. and for a fluorine ion and an ammonium ion about 2.6 Å. It is possible, however, to distort the arrangement of the adjacent ions in such a way, described below, as to give acceptable values to the interionic distances.

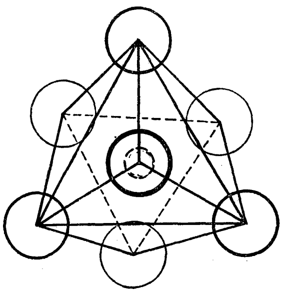

Fig. 2.—The $[ZrF_7]^=$ complex viewed along its three-fold axis.

The distance of the seventh fluorine ion at $^1/_8\ ^1/_8\ ^1/_8$ from the zirconium atom at 000 (1.9 Å.) is about the same as the zirconium–fluorine distance for the other six fluorine atoms—this way of inserting the seventh fluorine ion thus leads to the formation of a $[ZrF_7]^=$ complex. The existence of such a complex is to be expected. The ratio of univalent radii of zirconium and fluorine[10] is 0.80, which corresponds to stability of the coördination polyhedra[11] with coördination numbers 7, 8, or 9.

The distortion of the $[ZrF_6]^=$ octahedron accompanying insertion of the seventh fluoride ion will be such as to make the twelve small F–F distances equal, with the seven Zr–F distances also equal. The resulting polyhedron, shown in Fig. 2, has the angles F_3–Zr–F_7, F_3–Zr–F_6, F_4–Zr–F_6, etc., equal to 77°50′.

The sum of the crystal ionic radii for Zr^{4+} and F^- is 2.16 Å., and the sum of the octahedral covalent radius of zirconium and the covalent radius of fluorine is 2.15 Å. Oxygen and fluorine have nearly equal crystal radii, and the Zr–O distance in ZrP_2O_7 (octahedral coördination) is 2.02 Å.[12] These values suggest about 2.1 Å. for the Zr–F distance in the $[ZrF_7]^=$ complex. With Zr–F = 2.10 Å. the minimum F–F distance in the complex is 2.64 Å., which is only slightly less than twice the ionic radius of fluorine, 2.72 Å.

A reasonable way of orienting the various $[ZrF_7]^=$ groups in a cubic unit can be suggested, based not on the space group O_h^5, as for $(NH_4)_3AlF_6$, but on T^4. With this structure there are sequences of groups $[ZrF_7]^=$, $(NH_4)^+$, $(NH_4)^+$, $(NH_4)^+$, $[ZrF_7]^=$, . . ., along the non-intersecting three-fold axes of T^4. With Zr, $(NH_4)_I$, $(NH_4)_{II}$, and $(NH_4)_{III}$ in the positions 4a ($x,x,x;\ {}^1/_2 + x, {}^1/_2 - x, \bar{x};\ {}^1/_2 - x, \bar{x}, {}^1/_2 + x;\ \bar{x}, {}^1/_2 + x, {}^1/_2 - x$) of this space group and parameter values $x_{Zr} = 0.99$, $x_I = 0.28$, $x_{II} = 0.50$, $x_{III} = 0.72$, and with the $[ZrF_7]^=$ group oriented with F_7 at about $x = 0.12$, the interatomic distances are satisfactory, the minimum NH_4–F distance being 2.6 Å. This structure based on T^4 cannot be accepted, however; it leads to calculated intensity values (deviation from Laue holohedry and from the face-centered lattice) which are incompatible with observation.

If it is assumed that the $[ZrF_7]^=$ complexes have some randomness of orientation, complete agreement with experiment is obtained. Each $[ZrF_7]^=$ group is considered to have its choice of orientation with its three-fold axis parallel to any one of the eight [111] directions, the zirconium

[9] L. Pauling, This Journal, **46**, 2738 (1924); *Z. Krist.*, **74**, 104 (1930); G. Menzer, *ibid.*, **73**, 113 (1930).

[10] L. Pauling, This Journal, **49**, 765 (1927); **51**, 1010 (1929).

[11] The minimum radius ratio for stability of the seven-cornered polyhedron obtained by inserting a seventh atom at the center of a face of an octahedron (as in $[ZrF_7]^=$) is 0.592; those for stability of the square Archimedean antiprism and of the cube are 0.645 and 0.732, respectively; and that for stability of the nine-cornered polyhedron obtained by introducing three atoms at the centers of the vertical faces of a right triangular prism is 0.732.

Although Penney and Anderson[2] say that Li_4ZrF_8 and Na_3TaF_8 "are undoubtedly not examples of coördination number eight," it is probable that these substances do contain the complexes $[ZrF_8]^{4-}$ and $[TaF_8]^≡$. The radius ratio for tantalum and fluorine, 0.85, is still larger than that for zirconium and fluorine. On the other hand, the radius ratio for silicon and fluorine is only 0.48, and it is accordingly highly probable that the tetragonal crystal $(NH_4)_3SiF_7$ contains $(NH_4)^+$ ions, F^- ions, and octahedral $[SiF_6]^=$ complex ions.

[12] G. R. Levi and G. Peyronel, *Z. Krist.*, **92**, 190 (1935).

atom near 000 assuming one of the corresponding positions uuu, $u\bar{u}\bar{u}$, $\bar{u}u\bar{u}$, $\bar{u}\bar{u}u$, $\bar{u}\bar{u}\bar{u}$, $\bar{u}uu$, $u\bar{u}u$, $uu\bar{u}$, with $u \cong 0.010$. The planes of symmetry of the complex are not preserved in the T^4 structure, the complex being rotated about its three-fold axis by about 10° from the symmetrical orientation relative to the crystal axes. In the random structure this rotation occurs in either the positive or the negative direction. It is thus assumed that there are sixteen orientations accessible to each $[ZrF_7]^{=}$ group. The ammonium ions I and III are similarly considered to be distributed at random among sets of four positions near $^1/_4\ ^1/_4\ ^1/_4$, $^3/_4\ ^3/_4\ ^3/_4$, etc.

It is probable that the randomness is not complete—the immediate environment of each $[ZrF_7]^{=}$ complex is expected to be like that for the T^4 structure. The random structure might be described as involving unit cubes of the T^4 type with different orientations in different small regions of the crystal. In order to account for the non-occurrence of reflections from planes with mixed indices these regions must be smaller than the regions giving coherent X-ray scattering; that is, they are of the maximum order of magnitude of 100 Å. in linear dimensions.

The intensity calculations were made with the usual formula

$$I_{hkl} = C\frac{1 + \cos^2 2\theta}{\sin^2 \theta \cos \theta}\, p\, F^2_{hkl} \qquad (1)$$

in which C is a constant, p is the frequency factor of the form, and F_{hkl} is the structure factor

$$F_{hkl} = \Sigma_j f_j\, e^{2\pi i(hx_j + ky_j + lz_j)} \qquad (2)$$

the summation being over all of the atoms in the unit cell. Screening-constant f-factors[13] were used. The atomic distribution corresponding to the random structure is the following, based on the space group O_h^5:

4 Zr in 32 f: xxx, etc., with $x = 0.99$;
8 N_I, N_{III} in 32 f, with $x_{I,III} = 0.28$;
4 N_{II} in 4b: $^1/_2{}^1/_2{}^1/_2$, etc.;
4 F (F_7) in 32 f, with $x_F = 0.12$;
12 F (F_1, F_2, F_3) in 192 l: xyz, etc., with $x' = 0.20$, $y' = 0.96$, $z' = 0.91$;
12 F (F_4, F_5, F_6) in 192 l, with $x'' = 0.77$, $y'' = 0.94$, $z'' = 0.99$.

In Table I there are given the results of the powder photographic measurements. The indices which are bracketed together are those for planes whose reflections are superimposed on the powder photograph.

Mean		9.365 Å.		

The agreement between the visually estimated intensity values and the calculated values is satisfactory. It is felt that the parameter values are reliable to within about 0.01 or 0.02; satisfactory agreement was not obtained with the zirconium parameter x equal to 0.00 instead of 0.99, nor with the N_I, N_{III} parameter $x_{I,III}$ equal to 0.25,

---

[13] L. Pauling and J. Sherman, *Z. Krist.*, **81**, 1 (1932).

nor with the $[ZrF_7]^{\equiv}$ complex rotated about its three-fold axis through an angle much greater than or less than 10°.[14]

The Structure of K_3ZrF_7.—The powder photographic data for K_3ZrF_7 (Table II) are closely similar to those for $(NH_4)_3ZrF_7$, and indicate a similar structure. The value of a_0, 8.951 ± 0.010 Å., is nearly 5% less than for the ammonium salt. No reflections incompatible with a face-centered lattice were observed. The intensity values calculated for a random structure based on O_h^5 with the same parameter values as for $(NH_4)_3ZrF_7$ agree well with the estimated values. A small improvement is obtained by placing 4 K_{II} in 32 f with $x_{II} = 0.52$ instead of in 4b (corresponding to $x_{II} = 0.500$), and increasing $x_{I,III}$ from 0.28 to 0.29. Values of $I_{calcd.}$ for this arrangement are given in Table II.

1020 862	61°3′	8.962	Medium-strong	20.1
	Mean	8.951 Å.		

Discussion.—The interatomic distances in the crystals, Zr–F = 2.1 Å., F–F ⩾ 2.6 Å., NH_4–F ⩾ 2.6 Å., and K–F ⩾ 2.6 Å., have the magnitudes expected from comparison with other crystals. The parameter values cannot be determined with great accuracy, and the atomic positions are uncertain to about ±0.10 Å.

The existence of discrete MX_7 complexes has not been verified hitherto by structural investigation. It is probable that the configuration found for the $[ZrF_7]^{\equiv}$ ion is possessed also by IF_7 and by other complexes in which seven atoms are coordinated about a central atom. A similar coordination polyhedron is found[15] in the A-modification of La_2O_3 and other rare-earth sesquioxides, in which each rare-earth ion is surrounded by seven oxygen ions; in these crystals the neighboring MO_7 groups share oxygen ions.

It is of interest to note that whereas usually replacement of potassium ion by ammonium ion causes an increase in the dimensions of the crystal unit, a decrease is observed[16] from KHF_2 to NH_4HF_2, presumably as a result of the formation of strong N–H–F hydrogen bonds in the latter crystal. The observation that a_0 is larger for $(NH_4)_3ZrF_7$ than for K_3ZrF_7 indicates that there are not many strong N–H–F hydrogen bonds in the fluozirconate.[17]

Summary

X-Ray photographs of ammonium heptafluozirconate indicate a Laue holohedral face-centered cubic unit of structure with $a_0 = 9.365$ Å., containing 4 $(NH_4)_3ZrF_7$. The theory of space-groups provides no way of placing all of the atoms in definite positions in the unit. A structure involving some randomness of distribution among positions provided by the space group O_h^5

---

[14] Satisfactory calculated intensity values were also not obtained with use of the structure factor $\left(\sin \frac{2\pi r_0}{d}\right) \Big/ \frac{2\pi r_0}{d}$ for the fluorine atoms, corresponding to random distribution over the surface of a sphere.

[16] L. Pauling, *ibid.*, **85**, 380 (1933).

[17] Weak hydrogen bonds, as in NH_4N_3 [L. K. Frevel, *ibid.*, **94**, 197 (1936)], do not lead to decrease in dimensions of crystals of ammonium compounds relative to the corresponding potassium compounds.

is found to account satisfactorily for the X-ray data. This structure is closely related to that of $(NH_4)_3AlF_6$; the $[AlF_6]^{\equiv}$ complex ions are replaced by $[ZrF_7]^{\equiv}$ complex ions in which zirconium has coördination number seven. Potassium heptafluozirconate is found to have a similar structure, with $a_0 = 8.95$ Å.

The Binary System Cadmium Nitrate–Water: Vapor Pressure–Temperature Relations

BY WARREN W. EWING AND WALTER R. F. GUYER

This article presents the vapor pressure data for the binary system cadmium nitrate–water, and is a continuation of the series of studies being made on the alkaline earth nitrates in this Laboratory. Results for calcium nitrate, magnesium nitrate, and zinc nitrate already have been published. The alkaline earth nitrates are a particularly fruitful group for these investigations for several reasons: the water–nitrate system is quite stable; various hydrates exist, making crystalline mixture studies possible. The salts are very soluble in water, yielding solutions which can be supercooled. Vapor pressures have been obtained for a concentration as high as 86% cadmium nitrate (26 molal).

In addition to the anhydride, three hydrates of cadmium nitrate are mentioned in the literature: the dihydrate, which melts incongruently at 56.8°; the tetrahydrate, which melts congruently at 59.5°; and the enneahydrate which melts incongruently at 3.5°. Although the tetrahydrate was observed as early as 1855, by v. Hauer,[1] the existence of the dihydrate was not satisfactorily demonstrated until the work of G. Malquori[2] was published.

Sieverts and Petzold,[3] in their work on the nitrates of the second group in the periodic system, recently determined the solubility curve of the cadmium nitrate–water system. In the "I. C. T." very fragmentary data of vapor pressure for cadmium nitrate are found.

Preparation of Materials.—C. P. cadmium nitrate tetrahydrate was recrystallized three times as the tetrahydrate. The tetrahydrate was dried by putting it over 55% sulfuric acid in a vacuum desiccator. The single phase solutions were analyzed after the vapor pressure had been determined by ignition in porcelain crucibles to the oxide at 600° for two hours. These solutions had been concentrated almost to dryness in a rapid drier before ignition.

Experimental.—The vapor pressure measurements were made in the modified Smith–Menzies apparatus.[4–6] The dibutyl phthalate trap, having two capillaries, introduced by Ewing and Fisher in their work on zinc nitrate,[7] was used for all of the vapor pressure measurements.

Vapor pressure measurements were made for the following systems: (1) the metastable anhydride–tetrahydrate mixture of crystals from the eutectic melting point, 33°, to 15° (Table III); (2) the dihydrate–tetrahydrate from the eutectic melting point, 49°, to 20° (Table III); (3) the dihydrate–anhydride from the transition temperature, 56.8°, to 40° (Table III); (4) saturated solutions of the tetrahydrate, the dihydrate and the anhydride in the stable and the metastable regions (Table I); (5) fourteen solutions ranging in concentration from 10 to 86% in various temperature ranges (Table II). Table II also presents the relative humidity, P/P_0 (Babo's constant), for the fourteen solutions.

The data for the saturated solutions (Table I) are the experimental data. The data for the fourteen solutions (Table III) are tabulated for whole degrees, having been extrapolated over a short range, usually less than 0.05°, but occasionally as much as 0.10°, by obtaining the best equation of the form $\ln p = A/T + B$ for the solutions (and this was done for the crystalline

mixtures also), and then calculating the change in ln/p for the temperature increment. The data are estimated to be accurate to ±0.03 mm.

Figure 1 is a plot of the complete vapor pressure data for this system over the range covered in this work. Curve AKBC is the saturated tetrahydrate curve; BC is the metastable saturated tetrahydrate curve and is supersaturated with respect to dihydrate. Curve GBH is the saturated dihydrate curve, and GB is supersaturated with respect to tetrahydrate. Curve JHCE is the anhydride saturated curve; curve HC is supersaturated with respect to dihydrate and CE is supersaturated with respect to both tetrahydrate and dihydrate.

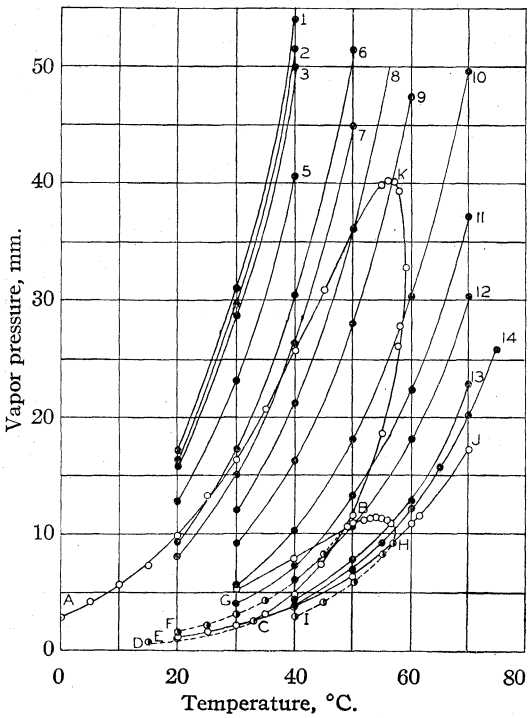

Fig. 1.—●, solution; ◑, crystalline mixture - - -; ○, saturated solution.

The tetrahydrate–dihydrate curve is FB; the anhydride–tetrahydrate, DC; and the dihydrate–anhydride, IH. (In order to avoid confusion in the curves, some of the individual points for these mixtures of crystals are not indicated, but they fall nicely on the curves.)

Solutions are numbered 1 to 14 in accordance with Table II (curve 4 is not plotted because it nearly coincides with curve 3) and are represented in the metastable regions also. The intersections of these solution curves with the saturated solution curves give the freezing points of the solutions of the respective concentrations. The freezing points obtained in this manner are plotted in Fig. 3, along with data of Sieverts and Petzold,[3] for concentrations above 50% $Cd(NO_3)_2$. The vapor pressure method confirms their data obtained by the freezing point method and extends the diagram into the metastable region.

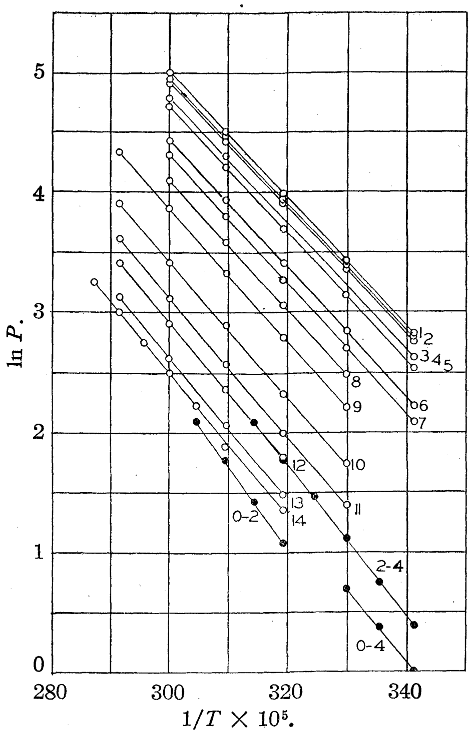

Fig. 2.

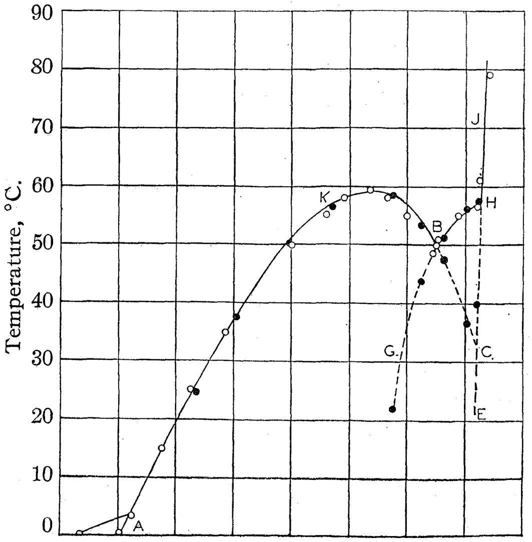

Fig. 3.—○, Sieverts, Petzold; ●, Ewing, Guyer (vapor pressure).

The equation ln $p = A/T + B$ applies to the single phase solutions and to the mixtures of crystals, as is shown in Fig. 2, which is a plot of ln p versus $1/T \times 10^5$ for the fourteen solutions and three crystalline mixtures. Straight lines result in each case.

This equation is applicable to water also in the temperature range 0 to 60° within the error in plotting on ordinary semi-log paper, but above 60° a third term has to be added to the equation. This condition also applies to our dilute solutions. For the more concentrated solutions the two term equation fits the data even more closely than it does the water data, or the dilute solution data.

Discussion

The vapor pressure measurements are considered of sufficient accuracy to study the variation of Babo's constant, P/P_0 (relative humidity), with temperature. In general, the data available up to this paper indicate that this value is constant within the experimental accuracy. Leopold and Johnston[8] stated that there would be a slight increase in relative humidity with increase of temperature for accurate measurements. Table II confirms this statement; there is a definite rise in Babo's constant with rise in temperature. This trend was found for all of the experimental data except the 20° readings for the two most dilute solutions. Duplicate determinations of these two values, however, fell in the general trend. This trend obtained regardless of the order in which the vapor pressure readings were taken for the various temperatures. This same trend has been obtained in general in all of the measurements on the nitrates in this series of studies.

Quite serious errors would arise in measuring the vapor pressure for a solution at one temperature, and then calculating the vapor pressure at another temperature, far removed, by assuming that P/P_0 is constant. For solution 6 [61.70% $Cd(NO_3)_2$], which may be considered typical, determining P/P_0 at 30° (0.5385) and then calculating the vapor pressure at 60° ($P/P_0 = 0.5661$ actually) would cause an error of 4.61%. This is an error of 3.90 mm. for the vapor pressure at this temperature.

Summary

Complete vapor pressure data for the system cadmium nitrate–water are given from 0 to 86% concentration and for the temperature range 20–60°. These vapor pressures are for the unsaturated, saturated, and supersaturated solutions, and for the mixtures of crystals.

Babo's constant (P/P_0) is shown to increase appreciably with temperature for the binary system cadmium nitrate–water.

The Standardization of Hydrogen Ion Determinations. II. A Standardization of the *p*H Scale at 38°

BY DAVID I. HITCHCOCK AND ALICE C. TAYLOR[1]

In a recent paper[2] a revision of the *p*H scale was proposed, as a result of hydrogen electrode measurements made with buffer solutions at 25°, in cells including a stationary liquid junction with saturated potassium chloride solution. This revision involved the use of the thermodynamic dissociation constants of the buffer acids together with an extrapolation based, in part, on the Debye–Hückel theory. A consistent scale was obtained for solutions of about *p*H 4 to 9. Since this range includes that part of the *p*H scale which is of primary importance in physiology and biochemistry, it seemed worth while to extend the work by making similar measurements at 38°, a temperature which is close to that of physiological fluids.

Experimental

The materials, apparatus and technique were practically the same as in the earlier work.[2] The concentrations of the solutions were expressed, as before, in moles per liter of solution at room temperature, 21–23°. The series of buffer solutions was extended by preparing mixtures of hydrochloric acid with sodium or potassium acetate or disodium hydrogen phosphate, in such proportions as to yield 1:1 buffers.

[1] This work was aided by a grant from the Fluid Research Funds of the Yale University School of Medicine.

[2] Hitchcock and Taylor, THIS JOURNAL, **59**, 1812 (1937).

E_0	−0.0657	−0.0668	−0.0665

In addition to the control of temperature given by the water-jacketed electrode vessels, which remained at 38 ± 0.05°, the whole apparatus was placed in an electrically controlled air-bath at 38 ± 0.5°. This served to prevent the deposition of solid potassium chloride in the bridge tubes and the condensation of moisture in the hydrogen train. The purity of the commercial hydrogen was tested in a few experiments by passing it over hot reduced copper; since this purification produced no change in the electromotive force obtained with hydrochloric acid (*p*H 1 or 2) or borax solutions (*p*H 9), it was generally omitted, and the hydrogen was passed only through distilled water at 38°. As before, the experiments consisted in the measurement of the electromotive force of cells of the type

H_2, acid or buffer solution, KCl (satd.), HgCl, Hg (+) (A)

Several different calomel half cells were used at different times, and their constancy and reproducibility were tested by daily measurements against hydrogen electrodes in 0.1 N hydrochloric acid or an acetate buffer. Since the different calomel cells varied, in some cases, by as much as a millivolt, the results were expressed in terms of the following cell, of which the right half served as a constant reference electrode

H_2, acid or buffer solution, KCl (satd.), HCl (0.1 N), H_2 (+) (B)

The values of the electromotive force of this cell are given in Tables I and II.

Method of Calculation and Extrapolation

Tables I and II include also values of E_0, the extrapolated value of the electromotive force which cell B would have if the activity of hydrogen ions in the solution in the left half cell were unity. The values of E_0 were obtained by extrapolation to zero ionic strength of a function E'', obtained from the experimental results by the following equations

Acetate buffers: $$E'' = E - 0.06173\left(4.766 - \log \frac{C_{HA}}{C_A} - 0.520\sqrt{\mu}\right)$$

Phosphate buffers (1:1): $$E'' = E - 0.06173\,(7.190 - 1.560\sqrt{\mu})$$

Borax buffers: $$E'' = E - 0.06173\left(9.143 - \log \frac{C_{HA}}{C_A} - 0.520\sqrt{\mu}\right)$$

Hydrochloric acid solutions: $$E'' = E + 0.06173\,(\log C_H - 0.520\sqrt{\mu})$$

The basis of similar equations was given in the previous paper.[2] Here E is the electromotive force of cell B in volts, 0.06173 is 2.3026 RT/F, 0.520 is the constant of the Debye–Hückel limiting law, μ is the ionic strength of the solution and the numbers 4.766, 7.190 and 9.143 are the negative logarithms of the thermodynamic dissociation constants of the buffer acids, interpolated for 38° from the data of Harned and Ehlers,[3] Nims[4] and Owen,[5] respectively. The ionic strength was calculated on the basis of concentration, in moles per liter at 21–23°, and the same basis was used for C_H of the hydrochloric acid solutions. Strictly this is not consistent with the pK values used, which were obtained on the molal basis. Density determinations showed a maximum discrepancy of 1.2% between the values of C and m for certain solutions at 0.1 ionic strength, but this difference becomes less than 0.25% for very dilute solutions. It was calculated that these differences could not affect the values of E'' and E_0 by more than 0.1 mv., and that the extrapolation therefore yielded

Results

The E_0 values for the buffer mixtures at 38°, as given in Tables I and II, are less concordant than those obtained for 25°. There is evidence of a specific effect of different ions, in the order to be expected if the E_0 values include a part of the liquid junction potentials. Solutions containing cations of higher mobility (hydrogen or potassium in place of sodium ions) yielded higher values of E'' and E_0, while those containing anions of higher mobility (chloride in place of acetate or phosphate ions) yielded lower values. If the high figure obtained for the hydrochloric acid solutions without salt is disregarded, as in the previous work[2] at 25°, the mean value of E_0 is −0.0668, with an average deviation of ±0.0002 v. This value, which is identical with that obtained for solutions of hydrochloric acid with sodium chloride (*p*H 2 to 3), acetic acid with sodium acetate (*p*H 4.7), and borax (*p*H 9), was adopted as a basis for a *p*H scale applicable at 38°. The *p*H values were calculated, without correction for liquid junction potentials, by the usual simple equation, which is

$$pH = (E + 0.0668)/0.06173$$

for cell B at 38°.

In Table III are given the *p*H values obtained in this way for a number of standard solutions which may be used for checking electrodes. Values obtained for the same solutions at 25° are included for comparison. Except for 0.1 *N* hydrochloric acid, whose *p*H value is determined by that of E_0 for cell B, the results are reported only to the nearest 0.005 *p*H, which corresponds to 0.3 mv. Since more measurements were made with 0.1 *N* hydrochloric acid and with the 0.1 *N* acetic acid–sodium acetate buffer than with other

TABLE III

STANDARD SOLUTIONS FOR CHECKING ELECTRODES AT 38 AND 25°

Composition in moles per liter at 21–23°	*p*H (38°)	*p*H (25°)
0.1 HCl	1.082	1.085
.1 $KH_3(C_2O_4)_2 \cdot 2H_2O$	1.495	1.480[a]
.01 HCl + 0.09 KCl	2.075	2.075
.05 $KHC_8H_4O_4$	4.025	4.010
.1 CH_3COOH + 0.1 CH_3COONa	4.655	4.645
.025 KH_2PO_4 + 0.025 $Na_2HPO_4 \cdot 2H_2O$	6.835	6.855
.05 $Na_2B_4O_7 \cdot 10H_2O$	9.070	9.180

[a] The *p*H value 1.490, which was published previously[2] for 25°, referred to a tetroxalate solution of lower concentration, 0.0965 *M*.

solutions, their values are particularly recommended as a basis for a *p*H scale applicable at 38°.

Discussion

Table III includes *p*H values for 0.1 *N* hydrochloric acid, although the E_0 values obtained from experiments with this acid alone were not used. This procedure did not invalidate the use of this solution in the reference half cell, since the *p*H scale was determined by the behavior of the various solutions in the left half of cell B. In spite of the discordant E_0 value obtained from data with more dilute hydrochloric acid, it seemed desirable to assign to 0.1 *N* hydrochloric acid, which is a reproducible standard solution, *p*H values consistent with those of the acid–salt mixtures and the buffer solutions.

There is practically no difference between the *p*H values obtained for hydrochloric acid of ionic strength 0.1, either with or without salt, at 25 and 38°. It may be calculated from the data of Harned and Ehlers[6] that the negative logarithm of the mean activity of the ions in 0.1 molal hydrochloric acid is 1.099 at 25° and 1.102 at 38°. Evidently the effect of temperature on these thermodynamic activities is of the same small magnitude as its effect on the non-thermodynamic *p*H values for hydrochloric acid solutions.

The *p*H values given in Table III for the buffer solutions show a somewhat larger variation with temperature, although the effect exceeds 0.02 *p*H in only one case. For the acetate, phosphate and borate solutions the differences, *p*H (25°) − *p*H (38°), are −0.01, +0.02 and +0.11, respectively. The corresponding differences in the *pK* values of the buffer acids at the two temperatures are −0.010, +0.016 and +0.094. Although it is recognized that *p*H values cannot have a strictly thermodynamic significance, it seems worth while to point out that an agreement between these two sets of differences might be deduced from the thermodynamic law of mass action if *p*H were a measure of either the concentration or the activity of hydrogen ions and if the variation with temperature of the activity coefficients of the buffer acids were negligibly small.

The only previous work in which a scale of *p*H values has been based on thermodynamic dissociation constants is that of MacInnes.[7] His experimental data, which have appeared in a paper by MacInnes, Belcher and Shedlovsky,[8] were obtained principally with very dilute acetate buffers, 0.001 to 0.01 in ionic strength, and were extrapolated by a method which gives marked curvature when applied to results for higher concentrations. If their data for 25° are reduced to our reference electrode and plotted by our method, they agree fairly well with ours at 0.01 ionic strength. Below that point, where we have no data, their results approach an E_0 value about 0.5 mv. higher than ours. Hence their *p*H scale should be lower than ours by about 0.008 *p*H. A comparison of their Table VII with Table III of the present paper shows that this is approximately true, except for their 0.1 *N* acetate buffer at 38°. Here they give a *p*H value slightly lower than their value for 25°, while our *p*H value, like that of *pK*, is about 0.01 unit higher for 38 than for 25°. For many purposes a discrepancy of 0.01 *p*H is not significant. It may be concluded that either our scale or theirs gives *p*H values which are reasonably consistent with thermodynamic dissociation constants.

Our work on the standardization of hydrogen ion determinations is being continued by an experimental study of a measure of acidity obtained from cells without liquid junction, according to ideas expressed by Guggenheim[9] and by one of us.[10]

Summary

Measurements of electromotive force at 38° are reported for cells of the type

H_2, buffer or acid solution, KCl (satd.), HCl (0.1 *N*), H_2 (+)

Acetate, phosphate and borax buffers were used, as well as solutions of hydrochloric acid with and without an added chloride. On the basis of the thermodynamic dissociation constants of the buffer acids and a nearly linear extrapolation, a value of E_0 was obtained for the reference electrode: KCl (satd.), HCl (0.1 *N*), H_2. On this basis *p*H values for 38° were assigned to several standard solutions, including 0.1 *N* hydrochloric acid (*p*H 1.082) and 0.1 *N* acetic acid in 0.1 *N*

Hydrogen Bonds Involving the C–H Link. V. The Solubility of Methylene Chloride in Donor Solvents

By M. J. Copley, G. F. Zellhoefer and C. S. Marvel

Recent publications[1–3] by the authors have shown that hydrogen bonding, involving the C–H link, occurs in solutions of the haloforms in solvents containing the donor atoms, oxygen or nitrogen. In one article[1] data were included on the solubilities of the two dihalogenated methanes, methylene chloride and monofluoromonochloromethane, in three donor solvents (diethylene glycol dimethyl ether, ethyl ether of diethylene glycol acetate and tetraethylene glycol dimethyl ether). Their solubilities were in considerable excess of the values predicted by Raoult's law and almost comparable with the solubilities observed for the haloforms in the same solvents. These results led the authors to suggest that a hydrogen atom of a dihalogenated methane is also capable of forming a hydrogen bond with an oxygen or nitrogen atom having an exposed pair of electrons. Such an activity for hydrogen bonding on the part of the hydrogen atoms, in these very stable compounds, was somewhat unexpected and it seemed important to extend the investigation to include a larger number of types of solvents.

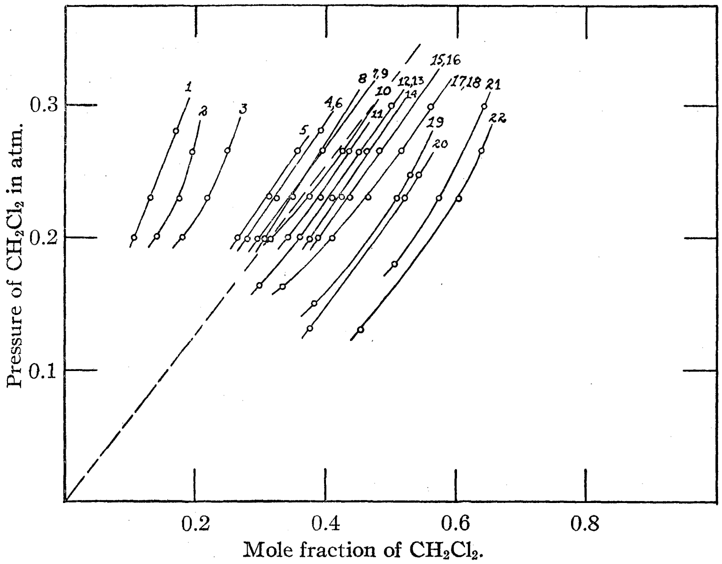

Fig. 1.—The solubility of methylene chloride as a function of pressure in alcohols, ethers, acids, esters, aldehydes, and ketones: 1, phenol; 2, acetic acid; 3, propionic acid; 4, anisole; 5, salicylaldehyde; 6, phenyl vinyl ether; 7, benzaldehyde; 8, Δ^2-cyclohexenone; 9, acetylacetone; 10, paraldehyde; 11, heptaldehyde; 12, ethyl acetoacetate; 13, triphenyl phosphite; 14, cyclohexanone; 15, acetonylacetone; 16, 1,4-dimethoxycyclohexane; 17, ethyl diethylacetoacetate; 18, tri-*o*-cresol phosphate; 19, ethyl ether of diethylene glycol acetate; 20, diethyl ether of diethylene glycol; 21, tri-*n*-butyl phosphate; 22, dimethyl ether of tetraethylene glycol.

The present paper reports the solubilities of methylene chloride in the same group of solvents[3] as was used by the authors in their study of the effect of solvent association on the solubility of haloforms. The remarkable similarity we have observed in the behaviors of dihalogenated methanes and haloforms clearly demonstrates that a hydrogen atom in either type of compound interacts with an unshared pair of electrons on an oxygen or nitrogen atom of a solvent and thus gives rise to the phenomenon called hydrogen bonding.

Experimental

The method[4] used in making the solubility determinations has been described previously in detail. The solvents tested were purified carefully and their boiling or melting points checked. The solubilities were determined over a range of pressure at a temperature of 32.2°. The results of the solubility measurements are plotted in Figs. 1 and 2. To compare the solvents conveniently, the gram per gram and mole fraction solubilities at a partial pressure of methylene chloride corresponding to its vapor pressure at 4.5° are given, re-

spectively, in columns 3 and 4 of Table I. The "ideal" or theoretical mole fraction stated at the top of Table I is calculated using Raoult's law, and it is the ratio of the vapor pressure (0.230 atm.) of methylene chloride at 4.5° to its value (0.739 atm.) at 32.2°. The statement in Table I that the solubility of methylene chloride in each of the two compounds, acetamide and diphenylamine, is *very low* is based on the observation that when these compounds were melted (they are solids at 32.2°) and brought in contact with the vapor of the solute only a minute amount of it dissolved.

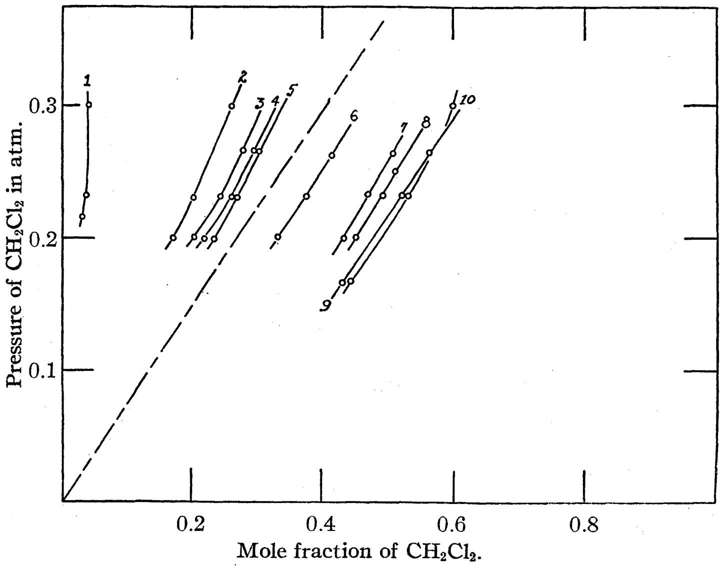

Fig. 2.—The solubility of methylene chloride as a function of pressure in amines, amides, and oximes: 1, formamide; 2, methylformamide; 3, ethyl methyl ketoxime; 4, dimethylformamide; 5, N-methylacetamide; 6, cyclohexylamine; 7, dimethylacetamide; 8, N-methyl-N-cyclohexyl-*n*-butanesulfonamide; 9, N-methyl-N-cyclohexylacetamide; 10, N-ethyl-N-cyclohexylacetamide.

Discussion

A comparison of the solubilities which we have observed for methylene chloride with those reported in a previous communication[3] for monofluorodichloromethane, in the same group of solvents, shows that these two compounds correspond almost exactly in the manner in which their solubilities vary in different types of solvents. In unassociated solvents (ethers, esters, amines and N-disubstituted amides) they both show uniformly high solubilities compared to the values predicted for them by Raoult's law. In solvents which are associated into large polymers (alcohols and amides), by means of the more stable O–H–O and N–H–O bonds, they both show extremely low solubilities compared to the solubilities calculated for them by Raoult's law. In fatty acids, N-monosubstituted amides, and oximes, where the association of the solvent stops at the dimer stage, they have intermediate or almost normal solubilities. It also should be noted that the influence of each of the factors, unsaturation and chelation, is to produce a lowering of solubility in the case of each compound in solvents where these factors are present.

The similar solubilities of methylene chloride and monofluorodichloromethane in widely differ-

ent types of solvents show that the same influence, *viz.*, complex formation by means of hydrogen bonding, is operative in the solutions of each compound.

Summary

The solubilities of methylene chloride have been determined over a range of pressure in several types of organic solvents.

The solubilities are high in esters, ethers, amines and N-disubstituted amides; roughly normal in acids, N-monosubstituted amides and oximes; extremely low in alcohols, and amides.

The remarkable similarity between methylene chloride and monofluorodichloromethane with respect to the way in which their solubilities vary in different types of solvents shows that hydrogen bonding is also present in solutions of methylene chloride in donor solvents.

A Study of Organic Parachors. I. The Parachors of a Series of Isomeric Esters[1]

BY OSBORNE R. QUAYLE, KATHERINE OWEN AND REIDUS R. ESTES[2]

Of the many attempts to relate physical properties and structure the parachor[3] has been one of the most successful. It has been of value in the determination of semi-polar bonds,[4] chelation,[5] singlet linkages[6] and degree of aromaticity and unsaturation.[7] From his first observations Sugden[3] concluded that the assigned constants held for all series, that the parachor was not influenced by temperature and that the parachors of isomers were identical. The differences between calculated and observed parachors and the differences between isomers were ascribed to experimental error. However, the parachors of branched heptanes[8] and octanes[9] were found to be

Surface tension = γ = 27 dynes/cm. at T'°; D' = density at T'°.

consistently lower than those of the normal isomers. The parachors of the lower members of the fatty acids series were found to be consistently higher than the calculated while the reverse was true of the higher members of the series.[10] Since many of these variations are greater than experimental error, it has been recognized that the parachor is constitutive as well as additive.[11]

The deviations from calculated parachors have thrown doubt upon the value of this physical constant. Certain regularities in these deviations from the hitherto accepted theoretical values have appeared. Further investigations of these deviations should be made. If the deviations are, in fact, generally or even frequently regular in nature, as a result of constitutive differences, the parachor will become of more rather than of less value once these regularities are determined.

This paper concerns the results of parachor measurements at four temperatures (25, 35, 50, 65°) of fifteen normal isomeric esters of the formula $C_{16}H_{32}O_2$.[12] Desreux[13] questioned the validity of comparing parachors calculated from unequal surface tensions because of the variation of C in Macleod's[14] relation, $\gamma = C(D-d)^4$. Since the comparison of parachors is tantamount to the comparison of molecular volumes at constant surface tension, it should be possible to overcome this objection by calculating molecular volumes from densities taken at temperatures where the surface tensions equal some convenient arbitrarily chosen

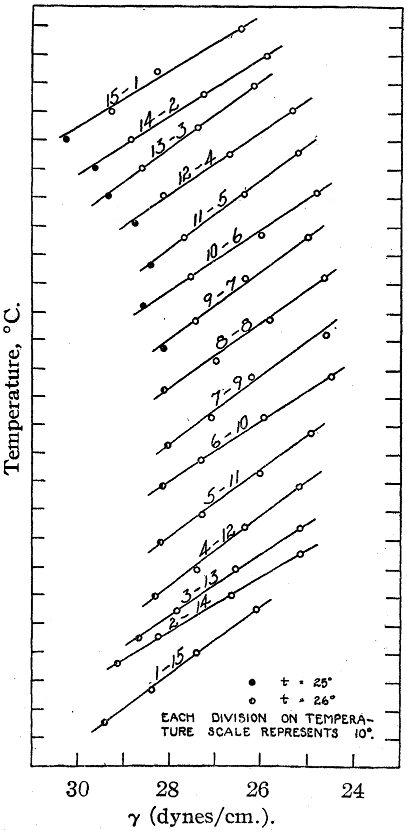

Fig. 1.—Variation of surface tension with temperature.

The parachor at all four temperatures measured and molecular volume when $\gamma = 27$ dynes/cm. showed a gradual decrease from either end of the series to a minimum for the central members (Figs. 3 and 4). The parachor values at 25° fall more nearly on a smooth curve than at higher temperatures. The general shape of the curve, however, at all the temperatures measured is unmistakably the same. The parachor variation in the series was found to be 9.67 or 1.38% at 25°, and 13.10 or 1.86% at 65° (Table II) while that for molecular volumes was found to be 4.51 or 1.46% (Table I) (estimated experimental error in parachor, ±0.20%).

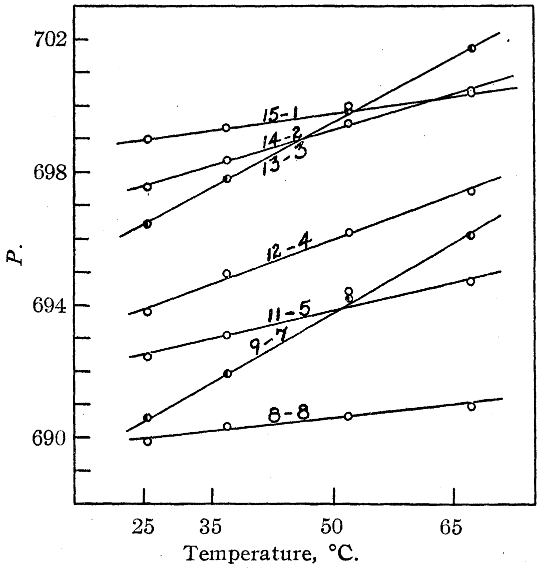

Fig. 2.—Variation of parachor with temperature.

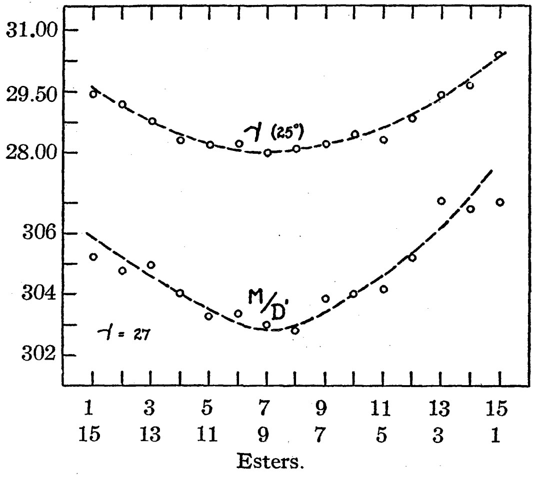

Fig. 3.—Variation of surface tension and molecular volume.

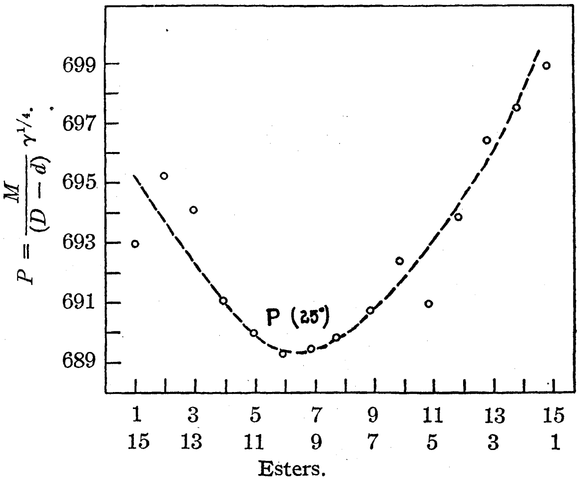

Fig. 4.—Variation of the parachor in the series.

Since unsaturation increases the parachor, it is indicated that the unsaturation of the ester group suffers least reduction by the combination of small and large groups present near the ends. Thus the parachor of methyl pentadecylate is 6.12 units less than that of pentadecyl formate

---

[15] The calculated value of the parachor for each of these esters, using the atomic constants of Mumford and Phillips,[11] is 699.0.

because of greater reduction of unsaturation by the methyl group in the former than by the hydrogen in the latter.

Similarly, large values for formates and small values for branched isomers have been observed in eight pairs of esters by Wender[16] in a study of parachors previously determined or calculated from previously recorded surface tensions.

Experimental.—Surface tensions were measured by Sugden's[3] modification of the method of maximum bubble pressure, using *m*-xylene[13] in the manometer and carefully purified benzene as a standard[17] for calibration of the apparatus. To ensure equal hydrostatic pressures, a maximum stable bubble was left on the large capillary while bubble pressures were being measured from the small capillary.[13] The manometer readings were taken with a cathetometer with an accuracy of 0.01 cm. Temperatures were controlled to ±0.08°. After calibration of the bubbler using accepted values of benzene (28.88 dynes/cm. at 20°),[18] readings were taken to check the calibration of CCl_4 and C_6H_5Cl. The observed values of 26.77 and 33.25 (20°) agree with accepted values (26.81 and 33.2).

Summary

1. The surface tensions of 15 normal isomeric esters ($C_{16}H_{32}O_2$) have been measured at 25, 35, 50, and 65° by the method of maximum bubble pressure.

2. The calculated parachors were found to decrease gradually from maxima of 695.3 and 699.1 at the ends of the series to a minimum of 689.3 near the center of the series.

3. Molecular volumes calculated from densities taken at constant surface tension (27 dynes/cm.) varied similarly to parachor.

4. The parachors were found to increase, in general, with the temperature.

Pantothenic Acid. II. Its Concentration and Purification from Liver

BY ROGER J. WILLIAMS, JOHN H. TRUESDAIL, HARRY H. WEINSTOCK, JR., EWALD ROHRMANN, CARL M. LYMAN AND CHAS. H. MCBURNEY

In the first article of this series[1] was announced the discovery of a growth determinant of universal biological occurrence, which was named "pantothenic acid." At the time of this initial report no progress had been made toward the concentration or isolation of the substance and the evidence for the existence of a single effective substance in the various sources was based upon electrolytic, diffusion, hydrogenation, esterification and other experiments in which the behavior of the physiologically active principle was the crucial question.

The concentration of a substance offering the particular difficulties encountered in connection with pantothenic acid had never been accomplished previously and much exploration was required before effective methods could be devised. The difficulties mentioned are based upon the following facts. (1) It is predominantly an acid rather than a basic substance and hence the techniques and precipitants extensively useful with nitrogenous bases cannot be applied except indirectly. (2) The richest convenient source (liver) contains on the order of 40 parts per million, and hence 250 kg. of liver after an extended process yielded only about 3 g. of crude (approximately 40%) material from which the remaining impurities were removed with great difficulty. (3) The substance is highly hydrophilic and we have yet to find any salt or simple derivative which is not highly soluble in water. (4) Due, presumably, to the presence of several types of functional groups, even after purification the substance has failed to crystallize.[2] In this respect it appears to behave somewhat like β-hydroxyglutamic acid, which, according to Dakin,[3] makes up 10% of casein; yet is not available on the market at any price. (5) Pantothenic acid is itself

[2] We are indebted to Professor Linus Pauling for X-ray examination of a sample which was suspected of possessing crystalline character. No diffraction pattern was observed and further study confirmed the non-crystalline character of the material.

[3] H. Dakin, *Biochem. J.*, **12**, 290-317 (1918).

unstable and can be handled safely only as a neutral salt. It is readily broken down by acids or bases and is particularly susceptible to destruction by acidic alcohol. (6) Unlike riboflavin and ascorbic acid, pantothenic acid could be tested for by biological tests only, since it has no color, reducing properties or other known outstanding property which can be used as a guide during its isolation. (7) Unlike the amino acids and biotin,[4] pantothenic acid has not been purified successfully by distillation of its ester. Whereas in later studies we have found it possible to esterify it and hydrolyze the ester without great loss, the process is attended by complete destruction unless carefully controlled, and the use of the ester (which seems scarcely more volatile than the acid itself) did not offer promise as a means of purification.

The crucial problem was first to devise some method whereby the acid could be separated from a variety of sugars and other neutral or basic water-soluble material. A solution to this problem was found in converting the acid into its brucine salt (as explained below) and extracting with chloroform, which fails to dissolve the sugars and similar compounds. It was found better to adsorb the acid on charcoal and elute first and later apply the brucine salt conversion. The essential steps in the process as applied to a 9-kg. batch of liver are given below. Sheep liver was used because of its uniformity and convenience. Beef or hog liver can be used. It was necessary, of course, that biological tests be made continuously during the process of concentration. For this purpose "G. M." yeast, the medium previously described[5] and the techniques previously developed[5,6] were used. As a standard material we used first a stable preparation made by the extraction of rice bran with 60% methanol, and assigned to this dry material a "potency" of 1. Other preparations were compared to this *at low dosage levels*. Later in our work a highly concentrated material dissolved in a concentrated sucrose solution was used as a secondary standard, but the ultimate standard remained the rice bran extract tested at a low dosage level. A "unit" of pantothenic acid is that amount which when tested as indicated is equivalent to 1 g. of the dry rice bran extract. The high potency of the material as compared to the low toxicity of brucine for the yeast, allowed us to test brucine salts directly for their effect on yeast growth.

Preparation of Autolysis Extract.—Nine kilograms (20 lb.) of ground sheep liver was mixed thoroughly with 20 liters of water (40°) in a ten-gallon milk can. One liter of benzene was then added and stirred thoroughly into the mixture, which was allowed to autolyze for twenty-four hours at 37°. The vessel was closed to avoid evaporation of benzene.

After twenty-four hours the vessel was placed in a larger barrel or other suitable vessel containing water and the water in the outer jacket was heated as rapidly as possible by means of live steam until its temperature reached 95–100°. In the meantime the liver mixture was stirred frequently in order to heat evenly and prevent local coagulation on the walls of the container. When the liver mixture reached a temperature of 75–80° a coagulum formed. Between 80–86° some frothing took place due to evaporation of benzene. (Inhaling the vapor was avoided.) Finally all the benzene was removed in ten to fifteen minutes at 97° by passing live steam directly into the extract. (For some unknown reason the extract is not consistently obtained in a suitable condition if the amount of benzene originally used is materially decreased.)

While still hot the coagulum was filtered off through muslin with greatest ease, using large funnels. The filtrate was perfectly clear, orange colored and possessed a greenish fluorescence. The "potency" of the extract (19 liters) on a moist basis under most conditions was 0.3 and therefore it contained 5700 "units" of pantothenic acid. Under less favorable conditions (presumably due to the liver) the units obtained might be as low as one-half the above value.

Fuller's Earth Adsorption.—In order to remove organic bases which would interfere with later purification, the solution was treated while still warm with 360 g. of technical fuller's earth (B-K-H). The solution was stirred thoroughly with the earth for fifteen minutes and then filtered. The solution loses substantially no pantothenic acid by this treatment and its appearance remains about the same except for the loss of fluorescence.

Adsorption and Elution from Norite.—Previous to adsorption with Norite the *p*H of the solution was brought approximately to 3.6 after thorough mixing, by the addition of 10–30 ml. of 1–1 sulfuric acid. A flocculent precipitate formed and was filtered off using kieselguhr as a filtering medium.

At this stage the filtrate was cooled (some dilution with ice is permissible) to about 15°, after which about 450 g. (2 g. per 100 cc.) of Norite was added and the mixture kept agitated for two hours. The Norite was then filtered off and the colorless filtrate containing very little pantothenic acid was discarded.

The activated Norite should be eluted immediately after adsorption. It is not necessary, nor desirable, to dry the charcoal before elution. If the charcoal is heated, satisfactory elution becomes impossible. In each of the three elutions, 1500 ml. of 1.6 *N* ammonium hydroxide solution was used. For elution, the mixture was suspended (using a rolling machine) for two hours. The filtration was carried out at the pump on hardened filter paper (S & S 602 h). The combined elutions and rinse

[6] Williams, McAlister and Roehm, *J. Biol. Chem.*, **83**, 315 1929).

were brought to neutrality (*p*H *ca.* 6.5) by adding a saturated water solution of oxalic acid.

The amount of activity recovered at this stage varied considerably with different batches. In typical cases 85–95% of the active substance was adsorbed by the charcoal and about 60% of that adsorbed was recovered in the eluate. This initial loss of about 50% of the activity was compensated for by the fact that the introduction of the charcoal adsorption step made the material easier to purify later. An average batch of eluate from 9 kilos of liver contained, therefore, about 3000 units.

Brucine Treatment.—To the eluate was added 30 g. of oxalic acid in water solution, then 180 g. of brucine alkaloid in methanol solution, and the *p*H of the resulting solution adjusted to 7. This solution was then evaporated to dryness after adding 225 g. of kieselguhr during the latter part of the evaporation. The evaporation was accomplished by using specially constructed water-jacketed evaporating pans. By use of electric fans the temperature was kept from 50–70°.

During the evaporation, acid production from the liver constituents evidently takes place[7] and it is necessary to add brucine from time to time to keep the solution neutral. Approximately 10 g. of brucine may be required for this purpose. In the end there was obtained from an average batch about 700 g. of dried pulverized material with a "potency" of 3.5 which was dried in a desiccator and ground in a ball mill.

Chloroform Extraction.—The dry kieselguhr residue above was extracted successively three times with 700-ml. portions of chloroform for an hour each. The chloroform solutions were extracted successively with 70, 70 and 35 ml. portions of water and the water solutions combined. Upon partial evaporation (or previously during extracting) some brucine oxalate crystallizes out and can be discarded. The final mixture of dry brucine salts obtained from a sample batch weighed about 20 g. and had a potency of 80. Over-all yields up to this point were in some cases much higher than this, but relatively large losses during the preceding three stages seemed inescapable.

Fractionation of the Brucine Salts.—This step in the process cannot be carried out economically with small batches and hence is described in terms of the material from 250 kg. of liver. The fractionation involved starting with approximately 600 g. of brucine salt mixture and from it obtaining about 9 g. of brucine salts containing over 50% of the activity and therefore about thirty times as concentrated as the original material. Most of the remaining active material was saved in the form of partially concentrated material. The process extended through many months and involved the carrying out of thousands of culture tests. Altogether about 700 fractions were separated besides numerous discards which were not numbered. To give a complete picture of how the fractionation was carried out would be impossible, but we feel that it will be useful to outline briefly the method of attack.

From the standpoint of novelty of operation, probably the most outstanding feature is the fact that we made extractions using quantities of solvents which superficially might seem absurd. For example, if the extraction demanded it we did not hesitate to extract 2 liters of (water-saturated) chloroform with 0.5 ml. of water. Even in such an extreme case the manipulation is not difficult.

When relatively pure brucine pantothenate is shaken with equal volumes of chloroform and water, only about one part in a thousand will remain in the chloroform, *i. e.*, its distribution coefficient is roughly 1000. However, the presence of other salts in crude material alters the characteristics of the solvents so that the distribution coefficient of brucine pantothenate under these conditions may be as low as 70.

The crude mixture of brucine salts obtained from sheep's liver contains about 5% of material with a higher distribution coefficient than brucine pantothenate and about 95% of material with a lower coefficient. The former are termed type *w* salts due to their greater tendency to go into the water layer. The latter are termed type *c* material since they have a greater tendency to go into chloroform solution.

The success of this process depends on taking several fractions in such a manner that the type *w* and type *c* materials can be sorted separately according to potencies, fractionated and discarded independently, at the same time losing but a small amount of activity.

All the crude brucine salt was put through the following first step in batches of about 50 g. The crude material was dissolved in chloroform and shaken with successive small portions of water. The volumes of water taken were small enough so that approximately 20–25% of the original activity would be found in the water layer. (To judge these amounts required extensive experience and many physiological tests.) Under these conditions type *w* material was obtained largely in the first fractions and type *c* material in the later.

The next steps in the process involved combination of type *c* salts (which are large in amount) of similar potency and their refractionation in a manner similar to that described above.

Continued fractionation by dissolving type *c* material in chloroform and extracting with water, would lead to an accumulation of type *w* material and a piling up of the active principle in these fractions. In order to avoid this the extraction procedure was reversed as the process demanded—that is, the material was dissolved in water and extracted with chloroform containing 1% of brucine alkaloid.

Throughout the whole fractionation process very small losses were sustained, but to work up all the material into "high potency" fractions involved an inordinate length of time and hence we were content with a yield of approximately 18,000 units in this form out of about 34,000 units of starting material. Though we were constantly on the lookout for such phenomena, we observed at no time during this fractionation any results which suggested that two or more substances were being concentrated simultaneously.

Conversion to Calcium Salts and their Fractionation.—Brucine salts at any stage of purification were converted readily into calcium salts by treating in solution with an excess of lime water and freeing from brucine by filtration and repeated extraction with chloroform. The purified brucine salts from the fractionation procedure were, therefore, treated in this way and the alkaline solution immediately freed from excess calcium (final *p*H about 7.5) by the

---

[7] Kapeller-Adler and Luisada, *Biochem. Z.*, 269–397 (1934).

use of oxalic acid. Solutions containing the calcium salts were then completely decolorized with high-grade blood charcoal and the almost colorless calcium salts were obtained by evaporation, in the form of a varnish. From 9 g. of brucine salts, potency 1600–2300, there was obtained a little over 3 g. of calcium salts, potency about 5000.

We shall not attempt to mention all the devices attempted before we developed the process outlined for the further concentration of pantothenic acid. The procedure adopted for the purification of calcium pantothenate consisted in (a) the precipitation of the active principle from concentrated aqueous solution with absolute alcohol, (b) treatment with mercuric chloride in aqueous and alcoholic solution to remove the presumably basic impurities still present in the concentrate, (c) a thrice repeated fractional precipitation of the calcium salt from an aqueous alcohol solution with isopropyl ether, and finally (d) a fractional precipitation from pyridine with acetone.

Precipitation from Aqueous Solution with Alcohol.—Calcium pantothenate, 431 mg. of "potency" 5700, was dissolved in 3 ml. of water in a 15-ml. centrifuge tube. There was added 10 ml. of absolute ethanol dropwise and with vigorous stirring. A precipitate which was formed was centrifuged from the solution and washed twice with 10 ml. of 95% ethanol. On addition of the washing liquor and 10 ml. additional absolute ethanol to the solution, a further slight precipitate was formed. These low activity fractions weighed 104 mg. and had a potency of 270.

Mercuric Chloride Treatment.—The solution was evaporated almost to dryness in a 15-ml. centrifuge tube, and 3 ml. of ethanol added. An excess (800 mg.) of mercuric chloride was added, the suspension allowed to stand overnight, and the precipitate centrifuged. The precipitate was washed three times with 5-ml. portions of ethanol. The washings were added to the solution, which was then evaporated almost to dryness. On addition of 10 ml. of water, a further precipitate formed, which was centrifuged. The mercuric chloride precipitate retained approximately 3% of the total activity. The solution was saturated with hydrogen sulfide, the mercuric sulfide washed twice with 1-ml. portions of water. The solution and washings were evaporated to half volume to remove the hydrogen sulfide. There was added 500 mg. of silver oxide. This was allowed to stand for two hours, the precipitate being broken up frequently with a stirring rod. On removal of the precipitate of silver chloride and excess silver oxide, the *p*H of the solution was found to be 5.2. It was adjusted to 7.2 with calcium hydroxide solution, and evaporated to dryness.

The above two steps were carried out, in six separate runs, on 3.16 g. of average potency 5000, containing 15,800 units. Ninety-three per cent. of the activity was accounted for, 85% being in the high activity fractions, weight 1.76 g. The potency of these fractions varied from 6500–8900. The remainder of the recoverable activity was found in the low activity fractions and the mercuric chloride precipitate.

Ethanol–Isopropyl Ether Fractionation.—The isopropyl ether used in this fractionation was treated with slightly acid ferrous sulfate solution, sodium carbonate solution, and dried over anhydrous sodium carbonate. Isopropyl ether was used in preference to ethyl ether because of its lower volatility and hygroscopicity. Calcium pantothenate, 216 mg., potency 7600, was dissolved completely in 0.30 ml. of water in a centrifuge tube. There was added 4.0 ml. of absolute ethanol in 0.2-ml. portions. A slight precipitate formed, which was not removed. There was added slowly dropwise, with vigorous stirring, 1.0 ml. of isopropyl ether, to yield fraction A. This was removed by centrifugation. Further addition of 1.2 cc. of isopropyl ether precipitated fraction B. Evaporation of the solution gave fraction C.

Fraction	Weight, mg.	Potency
A	83.5	6250
B	36.9	8250
C	88.9	9100

More of the calcium salt, 485 mg., was treated similarly in three runs, with essentially the same results.

The combined fractions C were again fractionated in the same manner with ethanol and isopropyl ether.

Fraction	Weight, mg.	Potency
D	37.8	9330
E	63.0	10300
F	56.5	10400
G	64.3	8160

A third ethanol–isopropyl ether precipitation of fractions E and F caused no further purification.

Acetone–Pyridine Fractionation.—The pyridine used in these fractionations was dried by allowing to stand over fused potassium hydroxide and distilling from barium oxide. The acetone was distilled from calcium carbonate. Acetone was added slowly dropwise to 95.2 mg. of fractions E and F above, in a solution of 0.15 ml. of water and 2.0 ml. of pyridine. Precipitates were removed at intervals.

Fraction	Weight, mg.	Potency
H	5.6	10,300
I	21.3	10,800
J	55.3	10,250
K	12.6	11,000

These highly active fractions of calcium pantothenate were prepared in the form of a clear, colorless varnish, very difficult to obtain in an entirely anhydrous condition. Pulverization gave a white powder, which was found to be quite hygroscopic. It took up 4–6% moisture under ordinary laboratory conditions.

Fraction J after being pulverized and dried at 56° *in vacuo* was found to have a potency of 11,100. As indicated in succeeding papers this fraction represents nearly pure material. We are able to get a quantitative measure of the amount in a culture solution when only 0.0005 γ per ml., or 5 parts per 10 billion, is introduced.

We desire to acknowledge our indebtedness to Anne King Stout and Ruth Carleton Scott for capable and painstaking help in connection with the concentration and the accompanying physiological tests.

We wish also to express our sincere thanks to those who have supported this work financially. This includes: the local institution; the National

Research Council; Standard Brands Inc. of New York, who have supported the investigation generously for many years; and the Rockefeller Foundation, who have made possible the large scale work by a substantial grant.

Summary

The concentration and purification of pantothenic acid from liver is described. Because of the character of the material this has proved an unusually difficult task. The final preparation (amorphous) has a potency of 11,100 as compared with a standard rice bran extract which was chosen as unity. Further fractionation of this material resulted in no increased purity. For this and other reasons it is thought to be substantially pure. Its presence can be determined quantitatively when only 5 parts is present in 10 billion parts of culture medium (0.0005 γ per ml.).

A Study of Reduction with Hydriodic Acid: Use in Micro Determinations of Hydroxyl Groups

BY HERSCHEL K. MITCHELL AND ROGER J. WILLIAMS

The work described in this paper was undertaken primarily for the purpose of establishment of a new method for the micro determination of hydroxyl groups in amorphous, hydrophilic compounds such as pantothenic acid.[1] It was also desirable to develop a method for the quantitative estimation of a given type of hydroxyl as well as the total number per molecule.

A semi-micro method depending on acetylation with acetic anhydride in pyridine, has been described by Freed and Wynne.[2] Recently the description of a similar micro method has been published by Stodola.[3] A more or less standard procedure for the micro determination of hydroxyl groups in conjunction with other groups containing active hydrogens is that given by H. Roth.[4] This is based upon the Zerewitinoff (Grignard) reaction. A gravimetric method for accomplishing the same purpose, based upon the replacement of hydrogen with deuterium, has been proposed by Williams.[5]

None of the above methods proved suitable for the determination of hydroxyls in highly hygroscopic amorphous materials. In any case the adhering water interferes seriously and in the case of the Zerewitinoff method no solvent (lacking active hydrogen) could be found to dissolve the hygroscopic material.

It was believed probable that the following normal reactions of hydriodic acid with alcohols would be analytically useful

$$\text{(1)}\quad \text{ROH} + \text{HI} \longrightarrow \text{RI} + H_2O$$
$$\text{(2)}\quad \text{RI} + \text{HI} \longrightarrow \text{RH} + I_2$$

Hydroxyl groups, if completely reduced, must pass through both of the steps above. Complete reduction is difficult, however, and the second step may take place only partially. It was assumed that conditions might be found in which at least the first reaction would take place quantitatively.

If the first reaction only, takes place

$$\text{Milliequiv. of OH groups} = \text{Milliequiv. of HI used up}$$

If an additional amount of hydriodic acid is used to complete the second reaction, this amount (which is equivalent to the millimoles of iodine liberated) is subtracted from the total and

$$\text{Milliequiv. of OH} = \text{Milliequiv. HI used up} - \text{Millimoles of } I_2 \text{ liberated}$$

The milliequivalents of OH groups reduced are equal to the millimoles of I_2 liberated and the milliequivalents of OH groups merely replaced are equal to the total hydroxyl groups minus those reduced.

It seemed probable that the stage of completion of reaction (2) above would give information concerning the type of grouping being reacted upon. This was based on the statement[6] given that the reactivity of alkyl halides toward hydrogen iodide is in the decreasing order; tertiary, secondary and primary.

Other Reactive Groups.—There are several types of functional groups that are readily at-

tacked by concentrated hydriodic acid. It is well known that HI adds quantitatively to olefin double bonds and various studies of the conditions required have been made.[7] Reduction of halogen compounds also would take place. A quantitative study of a reaction of this type has been made by Shoesmith.[8] Nitroso groups,[9] phenylhydrazine,[10] thiophene or furan derivatives[11] and ethers are reacted upon readily by hydriodic acid. In many of these cases the reaction may be quantitative and hence need not prevent the simultaneous determination of hydroxyl groups.

Experimental Procedure

Samples for analysis (0.5–10 mg. depending on hydroxyl content) are weighed into Pyrex capillary tubes on the micro balance. Forty λ (0.04 cc.) of hydriodic acid (sp. gr. 1.96) is introduced into the sample tubes with a capillary pipet. Extreme care should be taken to prevent droplets of the reagent being deposited near the top of the tubes. Following the introduction of the reagent into a capillary, the pipet is rinsed into a 50-ml. Erlenmeyer flask that has been labeled to correspond to the sample. Each tube is sealed within a few minutes by use of a fine pointed oxygen flame. The sealed tubes are then placed in a bath of constant boiling liquid for five hours (or in some cases for a different period). After the reaction has thus been carried out, each tube is placed in its correspondingly labeled flask and crushed with the end of a glass rod. The solutions are titrated to the usual starch–iodine end-point with sodium thiosulfate (0.015 *N*), followed by titrations of the same solutions to the phenolphthalein end-point with standard sodium hydroxide (0.05–0.15 *N*). Blank tubes containing 40 λ of hydriodic acid alone must accompany each set of determinations. This determines the H^+ and I_2 in the reagent itself.

In carrying out the reactions on esters, the H^+ from the acid produced on hydrolysis introduces a correction in the calculation. A peptide requires no correction since both acidic and basic groups are formed simultaneously on hydrolysis.

The technique in use and the description of the micro pipets used in the procedure given have been published by Kirk.[12] The Pyrex capillary chambers are thin walled, about 4 mm. in diameter and 4 cm. long.

Materials.—The chemicals used were, for the most part, Eastman highest purity products, and were used without further purification. The hydroxybutyric acids used were obtained through the kindness of Professor J. W. E. Glattfeld, of the University of Chicago. Kahlbaum hydriodic acid (sp. gr. 1.96) was used throughout as the reducing agent.

Experimental Data

Table I illustrates the reproducibility of analytical results on a single compound. These were not consecutive analyses but were made over a period of several months. The effect of sample size on the amount of reduction also is shown.

TABLE I

DETERMINATION OF HYDROXYL GROUPS IN MANNITOL AT 100° IN FIVE HOURS

	Mannitol, mmol.	Total OH groups found/mol.	Reduced OH groups found/mol.

Table II is a condensation of analytical results obtained on several hydroxy compounds at three temperatures.

Discussion of Results

A careful study of the data leads to the following conclusions of analytical significance.

1. Satisfactory analytical results can be obtained on primary alcohols, poly alcohols, hydroxy acids and negative substituted compounds, but simple secondary and tertiary alcohols, phenols, inositol and threonine fail to give useful results. A variation of from 0 to 4% low is noted on the more reactive types of compounds. These results compare favorably with existing methods for hydroxyl determination.
2. The reactions should be carried out in the range 100–134°.
3. From data not included here it was found that the reaction time of from five to twenty hours was satisfactory. Over the longer periods the thermal decomposition of hydrogen iodide produced a high blank and low results on compounds giving high reduction values. It was observed also that the presence of non-reducing organic compounds decreases thermal decomposition of the reagent.

It becomes evident on a careful consideration of the data that the ease of reduction is not dependent on the type of hydroxyl group as originally assumed, but does depend on the adjacent groupings about the hydroxyl. It may be stated that hydroxyls with what the organic chemists have called "negative groups" on adjacent carbon atoms, are reduced easily by hydriodic acid. The presence of adjacent methyl groups decreases the ease of the reaction. These generalizations

β-Alanine		2	1	0	0	0	0	0	0	0

[a] High results are due to reactions with groups other than hydroxyls.

are supported by an observation of the number of reduced hydroxyl groups as listed in Table II. The following comparisons illustrate these facts:

1. Primary alcohols such as hexyl, isoamyl or pentaerythritol substitute completely and do not reduce, while secondary butyl, tertiary butyl and tertiary amyl alcohols show only partial substitution.

2. Poly alcohols such as mannitol or erythritol show high reduction.

3. Benzyl alcohol shows a high reduction value, while an additional negative group, as in mandelic acid, promotes complete reduction.

4. Erythronic lactone and α,β-dihydroxybutyric acid have a tendency to be both substituted and reduced, while in the case of β-hydroxy-γ-butyrolactone and α-hydroxy-γ-butyric lactone less reduction follows the substitution. In the first two compounds the functional groups are all on adjacent carbon atoms, while such is not the case with the latter two substances.

5. α-Hydroxy-γ-butyrolactone reacts with hydriodic acid readily at 134° but not at 100°. Compounds with the hydroxyls adjacent react readily at 100°.

The last three compounds listed in Table II indicate application of the method described to other groups than hydroxyls. These, and others previously mentioned, must be taken into account if present in a compound along with hydroxyl groups. The reaction of butyl ether with hydriodic acid is shown to be of a more complex nature than expected from the textbook reaction

$$ROR + HI \longrightarrow ROH + RI$$

A similar observation has been made by Earl and Kenner.[9]

Summary

1. A new method for the quantitative determination of hydroxyl groups is described and shown to be useful down to quantities of about 1 mg. Satisfactory results were obtained on primary mono alcohols, poly alcohols, hydroxy acids and various negatively substituted hydroxy compounds. The hydroxyl groups in phenols, simple

secondary and tertiary alcohols, inositol, threonine and tartaric acid could not be quantitatively determined by this method.

2. On the basis of experimental data, a generalization is offered for the variation in reactivity of aliphatic hydroxy compounds toward hydriodic acid. The presence of adjacent negative groups increases the reactivity of a hydroxyl while an adjacent methyl group decreases its reactivity.

3. The analytical data give some indication of structural relationships of the functional groups in a compound.

4. It is suggested that the analytical method described might be useful in the determination of any group readily reacted upon by hydriodic acid.

The Kinetics of the Periodate Oxidation of 1,2-Glycols

BY CHARLES C. PRICE AND HARRY KROLL

The cleavage by periodic acid oxidation of the carbon to carbon bond in compounds in which the two carbon atoms each bear an oxygen atom either as a hydroxyl or carbonyl group was first observed by Malaprade.[1]

$$\text{RCHOHCHOHR} + \text{HIO}_4 \longrightarrow 2\text{RCHO} + \text{H}_2\text{O} + \text{HIO}_3$$

$$\text{RCHOHCOR} + \text{HIO}_4 \longrightarrow \text{RCHO} + \text{RCOOH} + \text{H}_2\text{O} + \text{HIO}_3$$

The original investigator, as well as Fleury and Lange,[2] were concerned chiefly with the analytical applications of the reaction. Fleury, Hérissey and Joly[3] made use of the reaction in studying the problem of the ring structure of the sugars, an application which was extensively and successfully investigated by Karrer and Pfaehler and by Jackson and Hudson.[4]

Although Malaprade made the observation that the reaction was much more rapid in acid than in neutral or basic solution, no measurements of the kinetics of the reaction have been made. The purpose of the present investigation was to study the kinetics under various conditions with the object of elucidating the mechanism of this oxidative cleavage in the particular case of 1,2-glycols.

Ethylene glycol and 2,3-butylene glycol consumed the theoretical amount of periodate almost instantaneously in acid solution. Pinacol, however, was found to oxidize at a conveniently measurable rate and was therefore the material used for the kinetic investigation.

Experimental

Standard aqueous solutions of periodic acid or sodium periodate and pinacol were mixed at 25.0° after adjusting the *p*H with 0.5 *N* solutions of sulfuric acid or sodium hydroxide. The course of the reaction was followed by withdrawing samples which were added to acidified potassium iodide solution, the liberated iodine then being titrated with sodium thiosulfate to the disappearance of the iodine color.

The hydrogen ion concentration of the reaction mixture was determined with a Beckmann *p*H meter. It did not vary appreciably during the course of the oxidation.

The Kinetics of the Reaction at Constant *p*H.—The dependence of the rate of the oxidation on the concentrations of the periodate and pinacol was first determined by measurements at a particular hydrogen ion concentration. The reaction was found to follow simple second order kinetics, the rate being directly proportional to the glycol and periodate concentrations as is illustrated by the results of these experiments summarized in Table I. The average deviation for the constants in any of the experiments was less than 5%.

TABLE I

THE RATE CONSTANTS FOR EXPERIMENTS WITH VARIOUS PINACOL AND PERIODATE CONCENTRATIONS AT A CONSTANT *p*H

latter factor remained constant during any one particular experiment, however, the rate constants for each experiment readily were determined. The variation of these constants with the *p*H of the reaction mixture is illustrated in Fig. 1.

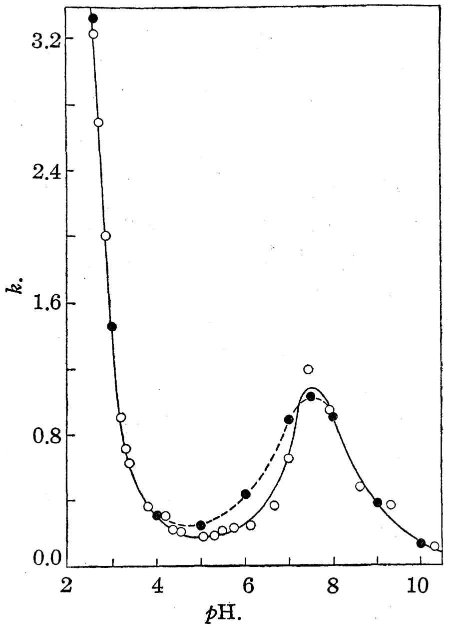

Fig. 1.—The second order rate constants plotted against the *p*H: ○, experimental values; ●, calculated values.

Comparison of Pinacol and Ethylene Glycol.—It has been reported[5] that pinacol and other highly substituted glycols react more readily with lead tetraacetate than those substituted to a lesser degree such as ethylene or 2,3-butylene glycols. This order of reactivity, however, holds for periodate oxidation only in alkaline solution. In acid the relative rates are reversed, since ethylene glycol and 2,3-butylene glycol react much more rapidly than pinacol. The results of experiments demonstrating this fact are summarized in Table II.

TABLE II

COMPARISON OF THE RATE OF OXIDATION OF ETHYLENE GLYCOL AND PINACOL IN ACID AND BASE

	*p*H 4		*p*H 9	
Time, min.	% ethylene glycol oxidized	% pinacol oxidized	% ethylene glycol oxidized	% pinacol oxidized
2	95	20	..	...
5	99	32	26	33
10	100	58	..	...
30	...	86	34	65
240	...	100	51	100

Discussion of Results

It was found that the variation of the simple second order rate constant, *k*, with the *p*H could be accounted for by assuming an uncatalyzed, an acid catalyzed and a base catalyzed reaction between the pinacol and a monovalent periodate ion. The acid reaction was directly proportional to the hydrogen ion concentration while the base reaction was proportional to the square root of the hydroxyl ion concentration.

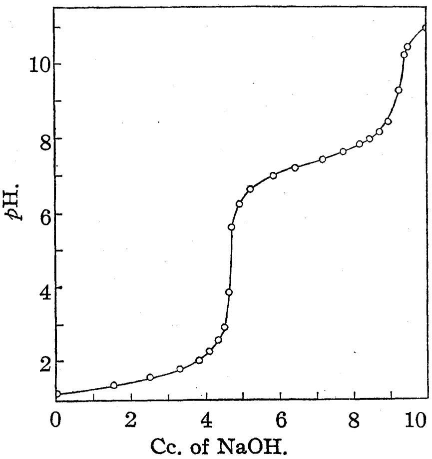

Fig. 2.—The titration of periodic acid (0.1 *N*) with sodium hydroxide (1.0 *N*).

The simple second order rate constant *k*, as calculated from the equation

$$dx/dt = k(A - x)(B - x)$$

where *A* is the total initial periodate concentration, *B* the initial pinacol concentration and *x* the amount of pinacol oxidized (equivalent to the decrease in the periodate titer), is thus a function of the *p*H of the solution which may be expressed as

$$k = k_0 + k_1[H^+] + k_2[OH^-]^{1/2}$$

By substituting the experimentally determined values for *k* at the various values for the *p*H and solving the resultant simultaneous equations, these constants were found to be $k_0 = 0.14$, $k_1 = 1.3 \times 10^3$ and $k_2 = 3.0 \times 10^3$.

The simple rate equation above also must be corrected for the fact that the rate is dependent on the monovalent periodate ion rather than the total periodate concentration. The ratio of these two concentrations as a function of the hydrogen ion concentration may be calculated from the dissociation constants of periodic acid as a mono- and dibasic acid.[6]

$$H_5IO_6 \overset{K_1}{\rightleftharpoons} H^+ + H_4IO_6^- \overset{K_2}{\rightleftharpoons} H^+ + H_3IO_6^=$$

From these equilibria two independent equations

---

(5) Criegee, Kraft and Rank, *Ann.*, **507**, 159 (1933).

(6) From the titration curve of periodic acid with sodium hydroxide (Fig. 2) the values for these two constants were determined as $K_1 = 0.11$ and $K_2 = 2.5 \times 10^{-8}$.

for the concentration of the monovalent ion may be derived.

$$[H_4IO_6^-] = K_1[H_5IO_6]/[H^+] \qquad (1)$$
$$[H_4IO_6^-] = [H^+][H_3IO_6^=]/K_2 \qquad (2)$$

Expressing the total periodate concentration as A, that of the monovalent ion as x, and that of the divalent ion as y these equations become

$$x = K_1(A - x - y)/[H^+] \qquad (1')$$
$$x = \frac{[H^+]y}{K_2} \text{ or } y = \frac{K_2x}{[H^+]} \qquad (2')$$

Substitution of (2′) in (1′) leads finally to equation (3) for the ratio of monovalent ion to total periodate as a function of hydrogen ion concentration.

$$x = \frac{K_1\left(A - x - \frac{K_2x}{[H^+]}\right)}{[H^+]}$$
$$[H^+]^2\frac{x}{A} = K_1[H^+] - K_1[H^+]\frac{x}{A} - K_1K_2\frac{x}{A}$$
$$\frac{x}{A} = \frac{K_1[H^+]}{[H^+]^2 + K_1[H^+] + K_1K_2} \qquad (3)$$

Multiplication of the original rate equation by this factor leads to an equation for k as follows

$$k = \frac{(k_0 + k_1[H^+] + k_2[OH^-]^{1/2})K_1[H^+]}{[H^+]^2 + K_1[H^+] + K_1K_2} \qquad (4)$$

Values for k calculated from this expression, using the constants as noted, have been included in Fig. 1 for comparison with those determined experimentally.

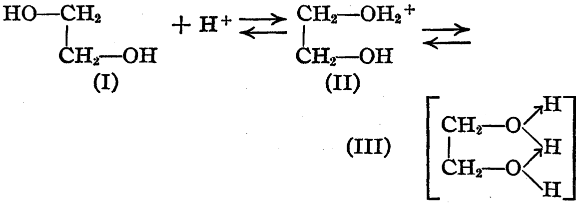
No simple and completely plausible explanation for the dependence of the rate on the square root of the hydroxyl ion concentration seems apparent although it may be accounted for on the basis of some such equilibrium as

$$\underset{\text{metaperiodate ion}}{2IO_4^- + OH^-} \rightleftarrows \underset{\text{dimesoperiodate ion}}{HI_2O_9^=}$$

If now the rate of the reaction were dependent on the square root of such a dimesoperiodate ion value, the kinetics of the reaction would indeed agree with those observed.

The direct dependence of the rate on the hydrogen ion concentration is capable of two simple interpretations: (1) that the rate is dependent not on the periodate ion but on the undissociated periodic acid concentration, the effect of the hydrogen ion being to repress the ionization of the latter; or (2) that the reaction is a hydrogen ion catalyzed reaction between the glycol and periodate ion. The second concept is in better agreement with other observations on the reaction but the first cannot be rigorously excluded.

The reversal of the relative rates of oxidation of ethylene glycol and pinacol on shifting from an acidic to a basic reaction medium, as well as the fact that the order of glycol reactivity toward oxidation in acidic periodate is the reverse of the order with lead tetraacetate, may be due to the effect of hydrogen ion on the relative position of the two hydroxyl groups. In non-aqueous solvents (as for the lead tetraacetate oxidation) or in basic aqueous solution, the glycol probably exists largely as the free molecular species in which the negative character of the two hydroxyl groups may favor a configuration with these two groups on opposite sides of the molecule. On the addition of acid, however, the oxygen of an hydroxyl group may associate with a proton, resulting in a change in the configuration.



It is reasonable to suppose that there is at least considerably more glycol present as (II) or (III) in acid than in base and that (I) should, as an average, tend more toward a *trans* configuration for the hydroxyl groups while in (II) they would tend to be *cis*. Furthermore, the separate or combined effect of dipole moment, electrical charge and hydrogen bonding on promoting or inhibiting the *cis* configuration should be more pronounced the smaller the molecule, *i. e.*, ethylene glycol should tend to be more *trans* in base and *cis* in acid than pinacol in corresponding solutions. On the basis of these premises the experimental facts lead to the conclusion that the *cis* configuration is that more readily oxidized by periodate, a fact which has been experimentally established for lead tetraacetate.[5] Experiments to test the validity of this conclusion by comparison of glycols of known *cis* and *trans* configuration are under way. An alternative interpretation of the experimental facts, however, may be made simply on the basis of the relative base strength of the various glycols. If the acid-catalyzed reaction depends solely on the formation of the complex ion (II), regardless of configuration, then the oxidation of the glycol with the greater base strength (which must be ethylene glycol) would be more effectively catalyzed by acid.

The further experimental work may lead to a decision between these alternatives, although actual measurements of base strength may be required.

Summary

The oxidation of pinacol with aqueous solutions of sodium periodate has been found to obey simple bimolecular reaction kinetics. The variation of the rate with the *p*H of the reaction mixture may be interpreted accurately on the basis of reaction between pinacol and the monovalent periodate ion catalyzed by both acid and base.

The reversal of the relative rates of oxidation of pinacol and ethylene glycol on shifting from an acidic to a basic reaction medium may be interpreted either on the basis of the configuration of the hydroxyl groups or on the relative base strengths of the two glycols.

URBANA, ILLINOIS RECEIVED AUGUST 13, 1938

[CONTRIBUTION FROM THE GRADUATE SCHOOL OF DUQUESNE UNIVERSITY]

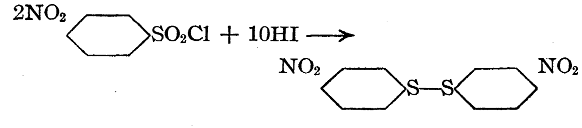
Some Unsymmetrical Aryl Sulfides[1]

BY NOEL E. FOSS,[2] JOHN J. STEHLE, HOWARD M. SHUSETT AND DAVID HADBURG

Zincke and Lenhart[3] and Foss, Dunning and Jenkins[4] have prepared a number of unsymmetrical aryl sulfides of the general type  where R may be various phenolic groups, and NO_2 may be in either the ortho or para position. The present investigation is concerned with the preparation of *m*-nitrophenyl sulfur phenols,  where R may be *p*-hydroxyphenyl, resorcyl, or *β*-hydroxynaphthyl.

The new nitro derivatives were chemically characterized by the preparation of their acetates and bromine substitution products. Two of the series were further identified by the synthesis of their benzyl and benzoyl derivatives, as well as by the reduction of the nitro compounds to the amino compounds.

The general scheme consists in preparing *m,m'*-dinitrodiphenyl disulfide by the following reaction



m-Nitrophenylsulfur chloride was prepared by allowing chlorine to react on the *m,m'*-dinitrodiphenyl disulfide by the method of Zincke and Lenhart[3] and subsequently condensed with the respective phenols. The reactions with phenol are represented by the scheme

$$NO_2C_6H_4SSC_6H_4NO_2 \xrightarrow{Cl_2} 2NO_2C_6H_4SCl$$

$$NO_2C_6H_4SCl + C_6H_5OH \longrightarrow NO_2C_6H_4SC_6H_4OH \xrightarrow{H_2} NH_2C_6H_4SC_6H_4OH$$

Experimental

m,m'-Dinitrodiphenyl disulfide was prepared by a modification of the method of Ekbom.[5] Two moles of the *m*-nitrobenzenesulfonyl chloride were reduced directly by the addition of the calculated amount of 45% hydriodic acid (ten moles). The reaction proceeded smoothly as evidenced by the precipitation of iodine crystals. After refluxing for several hours on the water-bath, the mixture was cooled and sodium bisulfite added until the iodine had been entirely reduced. The crude crystalline material was washed with water and recrystallized from hot acetone. Yellow crystals melting at 81–82° were obtained. The yield of pure product was about 80%.

Condensation of *m*-Nitrophenylsulfur Chloride with Phenols.—*m*-Nitrophenylsulfur chloride was prepared from *m,m'*-dinitrodiphenyl disulfide and condensed with the respective phenol according to the method described by Foss, Dunning and Jenkins.[4] In the case of the resorcinol derivative, 1,3-dihydroxy-2,6-*bis*-(3-nitrophenylthio)-benzene is formed principally unless the resorcinol is kept in excess during the reaction. The crude condensation products were recrystallized from sodium hydroxide and hydrochloric acid. The mononitro derivative also could be recrystallized from hot alcohol. These yellow compounds were insoluble in water, fairly soluble in hot alcohol, and very soluble in acetone and ether.

Acetylation.—The hydroxynitrosulfides and hydroxyaminosulfide were acetylated in the regular manner by refluxing with acetic anhydride and anhydrous sodium acetate. The pale yellow acetyl derivatives were very insoluble in cold water and slightly soluble in hot water,

	Diacetyl	$NO_2C_6H_4SC_6H_3(O_2CCH_3)_2$	77–78	9.23	9.23
	Dibromo	$NO_2C_6H_4SC_6H(Br)_2(OH)_2$	128–130	7.90	7.89
β-Naphthol		$NO_2C_6H_4SC_{10}H_6OH$	106	10.76	10.78
	Monoacetyl	$NO_2C_6H_4SC_{10}H_6(O_2CCH_3)$	85.0–85.5	9.25	9.45
	Monobenzyl	$NO_2C_6H_4SC_{10}H_6(OCH_2C_6H_5)$	136–137	8.09	8.28
	Monobenzoyl	$NO_2C_6H_4SC_{10}H_6(O_2CC_6H_5)$	110.0–110.5	7.85	7.99
	Amino	$NH_2C_6H_4SC_{10}H_6OH$	193	11.81	11.99
	Acetylaminoacetyloxy	$(NHCOCH_3)C_6H_4SC_{10}H_6(O_2CCH_3)$	163–164	9.06	9.12
Resorcinol (2 moles:1 mole)		$(NC_2C_6H_4S)_2C_6H_2(OH)_2$	179–180	15.32	15.41
	Diacetyl	$(NO_2C_6H_4S)_2C_6H_2(O_2CCH_3)_2$	109.5–110.5	12.54	12.52
	Monobromo	$(NO_2C_6H_4S)_2C_6H(Br)(OH)_2$	189–190	13.14	12.95

The acetylated hydroxy compounds were easily soluble in the usual organic solvents. The acetylated hydroxyamino compounds were sparingly soluble in alcohol and benzene, and very soluble in chloroform.

Bromination.—The hydroxynitrosulfides were brominated by adding the calculated amount of bromine to a glacial acetic acid solution of the compound. Recrystallization from dilute alcohol yielded canary yellow crystals. The bromo derivatives were insoluble in water, slightly soluble in benzene, and fairly soluble in alcohol.

It was found impossible to prepare the bromo substitution product of the β-hydroxynaphthyl derivative by this method. Subsequent analysis and determination of melting point indicated that the compound formed corresponded to the original *m,m'*-dinitrodiphenyl disulfide. No explanation for the phenomenon is attempted.

Benzylation and Benzoylation.—The benzyl and benzoyl derivatives were prepared in the usual manner by the well known Schotten–Baumann reaction. Recrystallization from alcohol yielded canary yellow crystals which were found to be insoluble in water, slightly soluble in alcohol and chloroform, and very soluble in benzene.

Reduction to the Amines.—One part of nitrosulfide dissolved in ten parts of 95% ethyl alcohol was reduced by hydrogen with 0.01 part of Adams[6] platinum black as catalyst. The amino derivatives were insoluble in water, fairly soluble in benzene and alcohol, and very soluble in chloroform.

The accompanying table lists the compounds together with their melting points and analyses.

Summary

Eighteen compounds have been prepared. They are of the general type SR', where R may be NO_2 or NH_2, and R' may be the *p*-hydroxyphenyl, resorcyl, or β-hydroxynaphthyl radical. Some bromo derivatives, acetates, benzoates, and benzyl derivatives have been made.

[CONTRIBUTION FROM THE RESEARCH LABORATORIES OF THE UNIVERSAL OIL PRODUCTS COMPANY]

Reaction of Aliphatic Olefins with Thiophenol[1]

BY V. N. IPATIEFF, HERMAN PINES AND B. S. FRIEDMAN

The alkylation of aromatic hydrocarbons[2] and the C- and O-alkylation of phenols[3] with olefins in the presence of catalysts such as sulfuric or phosphoric acid lead to the formation of compounds having structures which are in accordance with Markownikoff's rule. The mechanism for these reactions has been described[2,3c,4] as involving intermediate ester formation between the acid catalyst and the olefin. Posner,[5] however, reported that the reaction of thiophenol and olefins in the presence of a mixture of sulfuric acid and acetic acid proceeds abnormally, *i. e.*, contrary to Markownikoff's rule.

If Posner's proof of structure, which is open to criticism, is accepted, then one must conclude that either sulfuric acid played no part in the reaction or, what would be less probable, that it formed an intermediate ester of abnormal structure.

Repetition of some of Posner's experiments revealed several errors. The reaction of thiophenol with trimethylethylene in the presence of sulfuric acid yields *t*-amyl- and not *s*-isoamyl phenyl sulfide as reported by him. The compound Posner reported as *t*-amyl phenyl sulfone (m. p. 70°, no analysis) obtained by the metathesis of sodium benzene sulfinate and *t*-amyl bromide was probably benzene sulfinic acid (m. p. after first recrystallization 71°). All attempts to synthesize *t*-alkyl phenyl sulfones by this method led to the isolation only of benzene sulfinic acid and diphenyl disulfide. The disulfide no doubt results from the decomposition of the sulfinic acid by heat in the presence of solvents.[6,7]

Because of the discrepancies in Posner's work further investigation of the reaction of thiophenol with aliphatic olefins was deemed necessary. It was found that in the absence of catalysts thiophenol adds to aliphatic olefins[8] contrary to the mode of addition implied by Markownikoff's rule. Sulfuric acid (diluted with water or acetic acid), however, catalyzes the reaction to yield the normal alkylation product, and not the abnormal product as erroneously reported by Posner. The presence of phosphoric acid scarcely affects the course since the olefins react more readily with thiophenol than with the acid.

The yield of the alkyl phenyl sulfide formed in the absence of any added catalyst depends upon the temperature, contact time and reactivity of the olefin used.

The alkyl phenyl sulfides obtained in these reactions were identified by comparison of their physical properties with those synthesized by the reaction

$$C_6H_5SNa + RBr \longrightarrow C_6H_5—S—R + NaBr \quad (A)$$

and by preparation of solid derivatives (Table II). *t*-Butyl- and *t*-amyl phenyl sulfides could not be prepared by (A) but were obtained for the first time by treating thiophenol with the corresponding *t*-alkyl sulfides according to the method of Lee.[9] All the alkyl phenyl sulfides are water-white liquids possessing a pleasant odor.

It is interesting to note that in the presence of both 75% sulfuric acid, and the sulfuric acid–acetic acid catalyst used by Posner, isopropylethylene underwent isomerization at 0–20° during the alkylation of the thiol group—just as it has been found[10] to do in the presence of 96% sulfuric acid at 0° during the alkylation of benzene—to give a high yield of product containing only the *t*-amyl group.

This study is being extended to investigate the mode of addition to olefins of other compounds containing the thiol group, such as hydrogen sulfide, aliphatic mercaptans and thio acids. The application of these reactions to the problem of identification of olefins is also under investigation.

[b] Based on mercaptan charged. Method A gave yields ranging from 60 to 85% of the theoretical. [c] Mann and Purdie, *J. Chem. Soc.*, 1549 (1935) report 137–139 (12 mm.) for *n*-butyl phenyl sulfide and 126–127 (12 mm.) for isobutyl phenyl sulfide. [d] Taylor, THIS JOURNAL, **58**, 2649 (1936), reported 104–105 (25 mm.). [e] Trimethylethylene. [f] *t*-Amyl alcohol. [g] Isopropylethylene.

Experimental Part

Preparation of the Alkyl Phenyl Sulfides

Method A.—Two-tenths of a mole each of thiophenol and potassium hydroxide was dissolved in 50 cc. of hot 95% ethanol. To this mixture kept at 60–70°, 0.2 mole of the alkyl bromide was added dropwise (ten minutes); potassium bromide began to separate at once. The reaction mixture was refluxed for fifteen to twenty minutes longer, cooled, diluted with water, and extracted with ether. The ether layer was washed with alkali, then with water, and dried over anhydrous sodium carbonate. After removal of the solvent the product was distilled. The yields ranged from 60 to 85% of the theoretical.

The attempts to prepare *t*-alkyl phenyl sulfides by this method failed. If the reactants were kept at room temperature, potassium bromide was formed, but the thiophenol was recovered unreacted.

Method B.—The method consisted of placing approximately 0.2 mole of thiophenol, 0.15 to 0.2 mole of olefin, and 0.2 mole of 90% phosphoric acid in a glass liner, provided with a capillary closing, and placed in an Ipatieff type rotating bomb. The latter was charged with 30 atm. (at 25°) of nitrogen to keep the reactants inside the liner during the reaction. After being heated at 120° for five to ten hours, the bomb was opened. The product consisted of two layers: the lower of catalyst, and the upper of alkyl phenyl sulfide. The upper layer was washed with water, alkali, and water, then dried over anhydrous sodium carbonate, and distilled.

Method C.—Propene or the butenes and thiophenol were placed in the glass liner of an Ipatieff bomb and left at room temperature or heated overnight in an atmosphere of nitrogen, the initial pressure of which was 20–30 atm. The pentenes in slight excess and thiophenol were placed in sealed glass tubes which were left at room temperature or heated for a number of hours. The products were washed with alkali, water, dried and distilled.

Method D.—An excess of propene was heated with 90% phosphoric acid in the glass liner of an Ipatieff bomb for six hours at 100°. To 40 g. of the isopropyl phosphate so formed was added 23 g. of thiophenol and the mixture heated at 120° for six hours in the bomb charged with nitrogen (initial pressure being 20 atm.). The acid layer of the product weighed 28.5 g. From the upper layer 6 g. of unreacted thiophenol was separated by washing with alkali, leaving 26 g. of alkali insoluble product which was distilled. Much of it appeared to be products of nuclear alkylation of the isopropyl phenyl sulfide, but a few grams of material boiling in the propyl phenyl sulfide range was isolated and shown to consist of the isopropyl thioether.

Method E.—Lee's[9] method for preparing *t*-alkyl sulfides was used with slight modifications for the preparation of (1) *t*-butyl- and (2) *t*-amyl-phenyl sulfides.

One hundred grams of 75% sulfuric acid was placed in a 3-necked, 500-cc. flask which was equipped with a mercury-sealed stirrer, a dropping funnel and an inlet tube at the bottom of the flask. The flask was surrounded by an ice-water bath. To prepare (1), isobutene was bubbled through the rapidly stirred acid until 0.2 mole was absorbed. To prepare (2), isopropylethylene or *t*-amyl alcohol (0.2 mole) was added dropwise from the dropping funnel with stirring. Then 0.1 mole of thiophenol was added dropwise with stirring. When the addition was complete, the ice-water bath was removed to allow the flask to come to room temperature. Stirring was continued for another fifteen minutes. Crushed ice was added to the reaction mixture, after which it was extracted with ether. The ether extract was washed with water, alkali, and water, then dried over anhydrous potassium carbonate, and distilled.

Method F.—Posner's directions were followed in mixing the reactants. However, it is not at all necessary to wait two weeks for the reaction to become complete: the yield at the end of one hour was 80%; at the end of two weeks it was 88%.

Preparation of the Derivatives

Derivative Pd: Palladous Chloride Complexes of Alkyl Phenyl Sulfides.—To an aqueous solution containing a slight excess of palladous chloride was added 0.1 cc. of the alkyl phenyl sulfide, and the mixture shaken for a few minutes. The brown precipitate was separated by filtration and recrystallized by use of *cold* solvents. Usually it was dissolved in acetone; the acetone solution was then filtered and diluted with water until a turbidity just appeared. The yellow or orange needles or prisms which appeared on standing were usually sufficiently pure for a melting point determination. Instead of water, heptane or ligroin may be used with the acetone; alcohol may replace the acetone.

On recrystallization of the *t*-butyl- and *t*-amyl-phenyl sulfides, insoluble brick red powders not melting below 250° were obtained. In the presence of an excess of *t*-butyl- or *t*-amyl-phenyl sulfides, palladous chloride gave soluble yellowish precipitates which after a thorough pressing on a porous plate had fairly satisfactory melting points.

Derivative S: Alkyl Phenyl Sulfones.—Two cc. each of 30% hydrogen peroxide and glacial acetic acid was added to 1 cc. of alkyl phenyl sulfide, and the mixture was heated in a 50-cc. beaker on a water-bath in a hood until the acetic acid and water were evaporated. The beaker was then cooled in dry ice–acetone mixture and scratched with a stirring rod to induce crystallization of the sulfone, which was then recrystallized from hexane or dilute alcohol. Or the crude sulfone was taken directly for nitration to form *m*-nitrophenyl alkyl sulfones.

Derivative NS: *m*-Nitrophenyl Alkyl Sulfones.—To the sulfone (from 1 cc. of sulfide) was added 2 cc. of nitrating mixture (3 parts concentrated sulfuric acid; 1 part

[a] See Footnote (*a*), Table I. [b] Pd = palladous chloride coördination compound; S = sulfone; NS = *m*-nitrophenyl alkyl sulfone; AS = *m*-aminophenyl alkyl sulfone. [c] Colorless unless otherwise stated. [d] See experimental part for directions for recrystallizing palladous chloride complexes; dilute alcohol for all others unless otherwise specified. [e] Baldwin and Robinson, *J. Chem. Soc.*, 1445 (1932), reported 80° for *n*-propyl and 113° for isopropyl. [f] Mann and Purdie, *ibid.*, 1549 (1935) reported 96° for *i*-butyl and 118° for *n*-butyl. Repeated recrystallizations of the latter from various solvents always gave yellow needles melting not higher than 106–106.5°. [g] The low-melting derivatives of the probable formula $(C_6H_5—S—R)_2 \cdot PdCl_2$ were not analyzed. On recrystallization these were always converted to brick red powders which did not melt below 250°. [h] Weighed as metal.

concentrated nitric) and the mixture heated on a water-bath for five minutes, after which it was poured on crushed ice and extracted with ether. The ether solution was washed with water, dried over anhydrous sodium sulfate, and evaporated on a water-bath. The crude nitro compound was recrystallized from dilute alcohol, or used without purification for preparation of the corresponding amine.

Derivative AS: *m*-Aminophenyl *s*-Isoamyl Sulfone.—The reduction of nitrophenyl *s*-isoamyl sulfone was made according to a modified method of Waldron and Reid.[11] The crude nitrophenyl sulfone obtained from 1 cc. of the sulfide was mixed with ten times its weight of iron powder (reduced by hydrogen), 10 cc. of water, and one drop of dilute sulfuric acid. With frequent stirring and adding of water to replace that lost by evaporation and the addition of a drop or two more of the acid, the mixture was heated on a water-bath for one-half to one hour. Sodium bicarbonate was added to the reaction mixture, and the aminosulfone was taken up in ether. The ether extract was treated with dilute hydrochloric acid. The free amine was then isolated by rendering the acid solution basic and extracting with ether. The ether solution was dried over anhydrous potassium carbonate and evaporated on a water-bath. The residue was recrystallized from a mixture of ether and heptane.

Summary

The addition of thiophenol to aliphatic olefins proceeds contrary to Markownikoff's rule. Propene, butene-1, isobutene, pentene-1, isopropylethylene, and trimethylethylene react with thiophenol in the absence of acid catalysts to yield *n*-propyl-, *n*-butyl-, *i*-butyl-, *n*-amyl-, *i*-amyl and *s*-isoamyl phenyl sulfides, respectively. The presence of 90% phosphoric acid scarcely affects the course of the reaction since the olefins react more readily with thiophenol than with the acid.

In the presence of sulfuric acid (diluted with water or acetic acid) the reaction proceeds in accordance with Markownikoff's rule: isobutene and trimethylethylene yield *t*-butyl- and *t*-amyl phenyl sulfides, respectively.

Isomerization occurs during the reaction of isopropylethylene with thiophenol in the presence of sulfuric acid. The product is *t*-amyl phenyl sulfide and not the expected *s*-isoamyl phenyl sulfide.

The physical properties of a number of alkyl phenyl sulfides are described. Several of these were characterized by preparation of solid derivatives.

t-Amyl phenyl sulfone cannot be prepared by the metathesis of *t*-amyl halide and sodium benzene sulfinate, as reported by Posner.

Studies on the Chemistry of the Fatty Acids. IV. The Purification of Linolenic Acid by Fractional Crystallization of the Fatty Acids of Linseed and Perilla Oils, with Observations on the Properties of this Acid Prepared by Crystallization and by Debromination*

By G. Y. Shinowara and J. B. Brown

Linolenic acid is the principal unsaturated fatty acid of the vegetable drying oils; it occurs in small amounts in some of the semi-drying oils. Although it is rarely, if ever, found in animal lipids, unless the animal has eaten vegetable oils containing it, linolenic acid has been shown to replace linoleic as an essential fatty acid.[1] No new methods for the isolation of linolenic acid have been offered for over twenty-five years. The zinc salt purification proposed by Erdmann and Bedford[2] apparently has not been successful in other hands. The hexabromide reduction method[3] has been the one universally employed. This method has the advantage of starting with a pure solid derivative of the acid and gives a water-white product with an iodine number and molecular weight which are close to the theoretical. As in the case of linoleic acid, the method involves bromination–debromination procedures, which greatly reduce the yield, and the product may or may not be the same as the linolenic acid present in the original oil.

In the present work we have attempted to apply the crystallization procedures described by Brown and Stoner, and Brown and Frankel,

which were effective in purifying linoleic acid,[4] to the fatty acids of linseed and perilla oils. Fractional crystallization of the acids of these oils from acetone at −23, −45, −60 and −75° gave a final filtrate which contained 75% linolenic acid. Further crystallization from acetone was effective in raising the purity only slightly but when the 75% acid was crystallized from petroleum ether the precipitate contained 83–88% of the acid, assuming the impurity to be only linoleic acid. Four of the crystallization preparations have been compared with the pure so-called α-acid prepared by debromination.

Specimens of the acid prepared by crystallization gave hexabromide numbers ranging from 72–83. Calculating these to the basis of 100% acid, these values would range from 84.5 to 99. The average value for the four crystallization specimens was 92 as compared to 70–75 for the α-acid. The theoretical is 272. Rollett[3] found the yield of hexabromide to be 23%. From these results and from a comparison of other data it seems likely that the acids prepared by crystallization and by debromination are not identical; they may be different mixtures of isomers, either of the *cis–trans* or double bond position type.

In a previous paper[4b] a method for calculating the amount of linoleic acid in a fatty acid mixture was proposed, the method being based on a comparison of the tetrabromide number of the mixture with the tetrabromide number of pure α-linoleic acid. However, the fact that α-linolenic acid prepared by debromination gives a considerably lower hexabromide number than the acid prepared by crystallization makes us hesitate to apply the same principle to linolenic acid. It is suggested, however, that a similar formula, based on the hexabromide number of a fatty acid mixture in ether, will give much more accurate results than any of the procedures now available for calculating the linolenic acid content. Such a formula is proposed and discussed.

Experimental Part

Raw Materials.—The linseed and perilla oils employed in this work were authentic specimens furnished us through the courtesy of E. E. Ware of the Sherwin–Williams Company. The oils were saponified and the acids liberated from the resultant soaps with hydrochloric acid. The acids were distilled *in vacuo*. The constants of the oils and fatty acids appear in Table I. Iodine numbers were determined by the Wijs method with one hour reaction time. Hexabromide numbers were determined as described by Brown and Frankel for linoleic acid, except that dry ether was used as a solvent. Further, it is important, in view of the results below, to note that not more than 2–2.5-g. samples were used in 35–40 cc. ether. The resultant hexabromides were washed four times with ether cooled to 0° in 50-cc. tared centrifuge tubes.

TABLE I

CONSTANTS OF LINSEED AND PERILLA OILS AND OF THE CONSTITUENT FATTY ACIDS

	Linseed	Perilla
	Original Oils	
Iodine no.	189.2	208.4
Sap. no.	196.2	201.1
	Fatty Acids	
Iodine no.	191.7	214.6
Mean mol. wt.	278.0	277.9
Hexabromide no.	49.7	58.7
Linolenic acid, %[a]	54.0	63.8

[a] Calculated from the hexabromide number, as explained later.

Fractional Crystallization of the Fatty Acids from Acetone. Acetone was added to 500 g. of the acids to a total volume of 6 l. The solution was allowed to stand overnight in a cold room at −20° and was then filtered with suction on a Büchner funnel. The crystals were washed with cold acetone (−20°) and are designated as fraction I. The filtrate was cooled to −45° in a dry-ice–alcohol bath and a second crop of crystals removed (II). The filtrate was further cooled to −60 and −75°, the crystal crops representing fractions III and IV. The acids in the final filtrate constitute fraction V. The solid acids in (I) were recovered by simply drying in air to constant weight. Those in (II) to (V) were recovered by removing the acetone under reduced pressure and distilling the residue at 2 mm. pressure. The analytical data on the fractions are given in Table II.

The iodine numbers of the several fractions progressively increase, indicating a concentration of linolenic acid in the successive filtrates as the temperature was lowered. This bears out our prediction that linolenic acid would be the most soluble acid present. Fraction I with both oils contains most of the saturated acids. The separation into saturated and unsaturated acids is especially efficient in the case of linseed oil. Oleic and linoleic acids in part come out and are removed in the intermediate fractions. The final filtrate acids, fraction V, gave iodine numbers of 252.9 and 249.1, respectively. Assuming these acids to be binary mixtures of linoleic and linolenic acids, and calculating from the iodine numbers, the linolenic acid contents were 77 and 74%, respectively, for linseed and perilla oil acids. Fractions IV of these oils contained 66 and 67%, respectively, of the acid. Values for linolenic acid, thus calculated from the iodine number, are low because small but unknown amounts of oleic acid and traces of saturated acids unavoidably are present in each instance.

In another experiment a similar crystallization was carried out, except that the later fractions were taken off

IV	−65°	120	225.0	45[a]	52.5
V	Filtrate	140	249.0	73[a]	63.0

[a] Calculated from iodine number.

It is obvious that this procedure has resulted in a much higher yield (28%) of a product of slightly lower purity (73%). Numerous other experiments were conducted in the hope of increasing the yield and the purity. Apparently the degree of success so far as the purity is concerned is limited to the relative solubilities of oleic, linoleic and linolenic acids in acetone.

An attempt to improve the procedure by using petroleum ether as a solvent was unsuccessful, the final filtrate giving an iodine number of only 216. This would indicate that linoleic and linolenic acids are more equally soluble in petroleum ether than in acetone and perhaps explains the success in further purification by recrystallizing the 75% product from petroleum ether described below.

The Further Purification of Linolenic Acid by Crystallization from Petroleum Ether.—Ninety grams of crude linolenic acid (iod. no. 250.4), prepared by crystallization from acetone, was added to 1200 cc. of petroleum ether and cooled to −50°. The acids which crystallized were recovered: yield 66 g.; iodine number 258.1; that of the filtrate was 244.7. This procedure therefore resulted in a considerable improvement in purity (83.5%). The preparation is further described as (1) in Table IV.

Several fractions of iodine number 218–220 were combined and 544 g. of this mixture was made up to 6 liters with acetone. After crystallizing at −60°, the acids in the filtrate (234 g.) were recovered and made up to 3 liters with petroleum ether. Crystal crops were obtained at −55 and −65°; these were combined and distilled. The first 30 g. of distillate (iodine no. 247) was rejected. The next 114 g. was found to have an iodine number of 260 (85%) (see Table IV).

Repeated crystallization from petroleum ether was investigated, starting with 250 g. of acid of iodine number 245 (69%) made up to 4 liters. Six successive crystallizations were made at this volume at −60°, the crystal crop each time being employed. The final yield was 60 g.; iodine number 262; purity 88% (see (3) Table IV).

Still another preparation was made from perilla oil. One kg. of the fatty acids of this oil was made up to 12 liters with acetone and cooled directly to −65°. The precipitate was again dissolved in acetone (8 l.) and cooled to this temperature. The acids of the combined filtrates amounted to 500 g., iodine number 245, purity 69%. This was crystallized five times from petroleum ether at −60°, the crystals each time being used. The product after distilling at low pressure amounted to 130 g., iodine number 259, purity 83% (see (4) Table IV).

Preparation of α-Linolenic Acid by Debromination.—Bromine was added slowly to 2 kg. of the mixed acids of perilla oil in 20% solution in ether, the temperature being kept below 10° with an ice-bath. The resultant bromides were washed very thoroughly seven times with 8 liters of ether, the supernatant wash ether being removed each time by suction. The yield of dried hexabromostearic acid was 640 g., m. p. 179.5–180°.

The hexabromide number as obtained here is only 32, which is much lower than reported above (see Table I). However, when the bromination experiment was repeated starting with 420 g. of the same batch of original acids and making up to only 5% with ether, a much higher yield of insoluble bromides resulted, 256 g. The hexabromide number was 60.9, which is in close agreement with the value obtained under analytical conditions, −58.7. It is apparent from these and other results that the concentration of acids during bromination is an important factor in the yield of bromides obtained.

Six hundred and thirty grams of hexabromostearic acid was suspended in 1500 cc. of hot 95% ethyl alcohol and 630 g. of zinc dust added very slowly in small portions since the reaction is quite vigorous. A few drops of concentrated hydrochloric acid were added occasionally. When all of the zinc had been added, the mixture was refluxed for one hour, the alcohol solution was separated and acidified with hydrochloric acid. About half of the alcohol was removed under reduced pressure. The partly esterified linolenic acid was recovered and distilled and, to remove ethyl ester, it was saponified, the acid recovered and again distilled: yield, 138 g., water-white acid (see (5) Table IV).

Discussion of Results

The analytical data on four crystallization preparations are compared in Table IV with the data on α-linolenic acid. By α-linolenic acid we refer to the debrominated product which may

TABLE IV

ANALYTICAL CONSTANTS OF LINOLENIC ACID PREPARED BY CRYSTALLIZATION AND BY BROMINATION

Specimen and method of prepn.	Purity, %	Mol. wt.	M. p., °C.	n^{20}	Iod. no.	Thiocyanogen no.	Hexabromide no.	Br., %	M. p. bromide, °C.

(4) Crystal.	84.0	278.6	−11.6–.5	1.4795	259.0	151.3	83.2	63.38	180.4– .5
(5) α-Acid	100.0	278.8	−14.5–.4	1.4795	269.5	161.0	70.1[a]	63.13	178.5–9.5
Calcd.	100	278.2			273.7	182.5	272.3	63.32	

[a] This value was slightly higher, *i. e.*, 75, when a large amount of the acid was brominated in 5% solution. Hexabromide numbers reported above were averages of at least two determinations. It is worthy of note that redeterminations of these values eight months later, the specimens having been kept under inert gas at −20°, did not differ appreciably from the above values.

or may not be a mixture of isomeric linolenic acids.

Specimens (1), (2) and (3), described in Table IV, were derived from linseed oil while (4) and (5) originated from perilla oil. With regard to (5), the α-acid, it is assumed that this would be the same acid or mixture of isomeric acids no matter which oil was used in its preparation, since it is derived from ether-insoluble hexabromides. On the other hand, it seems possible that the crystallization acids may be mixtures of isomeric linolenic acids, either of the *cis–trans* or of the double bond position type. Mixtures, resulting from fractional crystallization, may not be identical either as a result of differences in the component linolenic acids of the original oil or as a result of differences in physical properties (solubilities) of these isomers so that certain of the isomers are concentrated by the fractionation. Some of the data support this idea. Specimen (3), 88.0% pure, melted at −11.2°, whereas specimen (4), 84.0% pure, melted at −11.6°. On the other hand, the nearly pure α-acid melted at −14.5°, lower than either. Further, the n^{20} of the 84% acid from perilla oil was actually higher than of the 88% acid from linseed oil and as high as the α-acid. The hexabromide numbers of the 88 and 84% acids were about equal and much higher than that of the α-acid. For these reasons we are inclined to the belief that the crystallization acids prepared from the two oils do not represent identical mixtures of isomeric linolenic acids and, further, with greater emphasis, the crystallization acids as a group are even more different from α-linolenic acid. No evidence for similar differences has been noted in our previous work with linoleic acid. We do not wish at this time to enter into the unanswered question of the occurrence of one or several linolenic acids in the original oils. Nevertheless, we believe that the above evidence seems to favor the multiple nature of "linolenic acid" despite the fact that the melting points of (3), (4) and (5) were quite sharp. The melting point of linolenic acid has not been reported previously.

Three methods have been available previously for the estimation of linolenic acid in fatty acid mixtures: (1) calculation from the iodine number; (2) the thiocyanogen method of Kaufmann[5] which is based on calculation from simultaneous equations using iodine and thiocyanogen numbers; and (3) the hexabromide number. The first of these methods is rarely practical since linolenic acid always occurs with unknown amounts of oleic and linoleic acids which cannot be separated quantitatively by any known procedure. The second method is the best of the three, but fails in being specific since it does not differentiate possible isomeric linolenic acids and also because thiocyanogen does not react quantitatively with two of the double bonds. The thiocyanogen number of the pure α-acid above fails by 21.5 units to approach the theory as expected from reaction with two double bonds. This point has been verified likewise by Kimura.[6] The third method is the oldest of the three and is based on calculation of the amount of linolenic acid present in a mixture from the amount of ether-insoluble hexabromides assuming the formation of such bromides to be quantitative. With one exception, however,[2] no one ever has claimed to have isolated a linolenic acid which would give the theoretical hexabromide number. Both Erdmann's and Rollett's linolenic acids, prepared by debromination, gave yields of hexabromides which were only 23–25% of the theoretical, which agrees well

with our results for the α-acid. The hexabromide numbers of the five preparations in Table V calculated to the basis of 100% purity are as follows:

Preparation	Purity, %	Hexabrom. no.	Hexabrom. no. calcd. to 100%
(1)	83.5	75.5	91.6
(2)	85.2	72.0	84.5
(3)	88.0	83.0	94.3
(4)	84.0	83.2	99.0
(5)	100.0	70–75	70–75*

In previous work on arachidonic acid[7] an equation was suggested for the determination of the amount of this acid present in fatty acid mixtures based on the polybromide numbers of pure arachidonic acid and of the fatty acid mixture. A similar equation was proposed for linoleic acid, based on tetrabromide numbers.[4b] We hesitate to apply this principle to linolenic acid other than as an approximation, because obviously, from the above data, the hexabromide number is dependent on the concentration of acids being brominated and especially because it varies in different preparations of linolenic acid. The average hexabromide number for the four crystallization specimens, calculated to 100% purity, is 92.3 or in round numbers 92. From this an approximate value for the content of linolenic acid in a mixture could be found from the equation

$$\% \text{ linolenic acid} = \frac{\text{H. N.} \times 100}{92}$$

where H. N. is the hexabromide number of the fatty acid mixture and 92 is the average hexabromide number for crystallization linolenic acid. In calculating the average, the H. N. for the α-acid is omitted for the reason of its obvious difference from the crystallization acids. It also should be pointed out that the hexabromide numbers calculated to 100% are slightly high because the percentage purities were calculated from the iodine numbers as a mixture of linoleic and linolenic acids. In spite of these objections to the method, we believe it to constitute a decided advance over any other now available both in accuracy and in specificity.

Summary

1. Low temperature crystallization procedures for the isolation of linolenic acid have been applied to the fatty acids of linseed and perilla oils.

2. By fractional crystallization of the fatty acids of these oils in acetone, 75% linolenic acid remained in the filtrate at −75°.

3. Crystallization of the 75% acid from petroleum ether resulted in preparations of 83.5 to 88% purity.

4. The constants of the crystallization acids are compared with those of α-linolenic acid, prepared by debromination.

5. The possibility of the multiple nature of linolenic acid is discussed; also the application of the hexabromide number as a method of estimating the amount of linolenic acid present in fatty acid mixtures.

The Colloid Chemistry of Leaf and Flower Pigments. I. The Precursors of the Anthocyanins[1]

BY WILDER D. BANCROFT AND JOHN E. RUTZLER, JR.

Introduction

Most of the research work on leaf and flower pigments has been done by organic chemists who were interested primarily in preparing and analyzing pure compounds, or by biologists who were interested primarily in genetics. It has seemed worth while to us to present to some extent the viewpoint of those colloid chemists who are interested especially in the changes of color with changing conditions.

Some points are much simpler when considered as colloid chemistry. Chlorophyll is soluble in benzene; but benzene will take scarcely any chlorophyll out of the green leaf.[2] Tswett[3] has shown that this is due to marked selective adsorption of the pigment of the leaf tissue. The phenomena of co-pigments or intensifying agents, studied by the Robinsons,[4] become more simple when considered as due to adsorption.

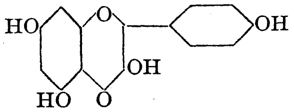
Since chlorophyll is the most important plant pigment and the one best known to the public, it might seem wise to begin with that. We shall get into a more controversial and to us a more interesting field if we start with the red autumn leaves and most of the red and blue flowers. These pigments are known as anthocyanin pigments and there is a wide difference of opinion as to the way they originated. The German chemist, Willstätter, believes that they are formed in the plant by reduction of flavones, while the English chemist, Robinson, believes that they are produced in the plant by hydrolysis and oxidation of what are known as leuco-anthocyanins. In this paper we plan to show how to differentiate between these two diametrically opposed views. Each is right in certain cases and each is wrong in others.

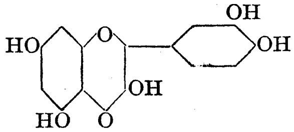
Anthocyanins and Anthocyanidins

In general the anthocyanins vary in color from red or purple through blue and green to yellow as the *p*H of the sap increases. The green is not a pigment color but is due to the combined effect of the yellow and blue. When one starts with a red flower and exposes it to ammonia vapor, the blue is apt not to be permanent in the absence of a stabilizer. If it changes fairly rapidly to yellow one gets no blue but only a green. If it changes very rapidly to yellow one gets neither blue nor green. The red leaves of the poinsettia are a case of this. It seems probable therefore that all blue flowers contain a color-stabilizer, but there apparently has been no systematic study of this point. Sodium chloride, sodium nitrate and alum solutions[5] are said to stabilize the blue in particular cases; but we do not know how general this is or what salts are found in blue flowers. The blue of *Salvia patens* extends over a *p*H range of 4–8.[6] Hirsutin, methyl malvin, is turned blue by a number of co-pigments:[7] tannin, 2-hydroxyxanthone glucoside, rutin, quercetin, vanillin and quinaldine.

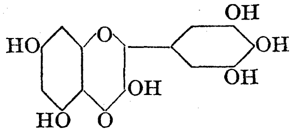
Pedagogically, most anthocyanins and anthocyanidins may be considered as reduction products of one of three flavonols or derivatives of them.[8] The three flavonols are kaempferol, quercetin and myricetin.



Kaempferol

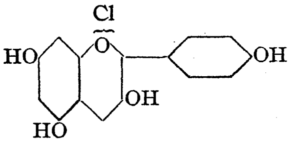


Quercetin

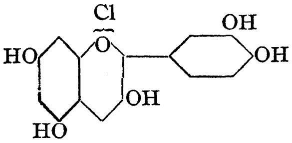


Myricetin

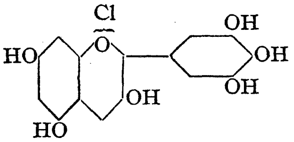
The corresponding anthocyanidin chlorides are pelargonidin chloride, cyanidin chloride and delphinidin chloride



Pelargonidin chloride



Cyanidin chloride



Delphinidin chloride

An anthocyanin differs from an anthocyanidin in having one or more glucose, galactose or rhamnose molecules attached to it. One or more of the hydroxyl groups may be methylated, giving a substituted anthocyanin if there are sugar molecules attached and a substituted anthocyanidin if the molecule is an aglucone.

Willstätter and Mallison[9] showed that cyanidin can be obtained by reduction of quercetin with a metal and an acid. Shibata, Nagai and Kishida[10] got quicker results with magnesium and mercury in acid solution. They consider the mercury as essential to a good result.

At Cornell we have obtained excellent data by

electrolysis in an acid solution, using a mercury cathode to give high over-voltage. Dr. T. S. Chapman[11] extracted shredded leaves cold with dilute formic acid (2–5%). A pink solution shows the presence of anthocyanins or anthocyanidins. If the pink color appears only after heating, leuco-anthocyanins are present. If a pink, yellowish or colorless solution is shaken with ether and if aqueous ammonia is added to the ether layer, the appearance of a distinctly deeper yellow going practically completely into the water layer indicates the presence of anthoxanthins. Not much deepening of the yellow, with much of the color staying in the ether, indicates the presence of "Tswett's water-soluble yellows."

To carry out the reduction, some of the formic acid extract was poured off the leaves and mixed with an equal volume of approximately molar sulfuric acid solution. Half of the mixture was poured into the reduction cell and half retained for comparison. On electrolysis with a platinum anode and a mercury cathode a change of color was usually noticeable within a few minutes and almost always within fifteen minutes; but it was customary to electrolyze for an hour to ensure a satisfactory reduction. It is wise to keep the solution cold to prevent hydrolysis, which would give a red color if leuco-anthocyanins were present.

Some sixty-five different kinds of leaves containing anthoxanthins were examined by Dr. Chapman and all but five gave satisfactory anthocyanin-like pigments as shown by the red color. The locust, the California privet, the hawthorn and the wayfaring tree yielded reduction products which were rather yellow or orange in comparison with the others. The reduction of the extract from the privet in particular gave a very yellow color to the solution.

There are marked differences in the ease of reduction. The flavones from the forsythia and the jonquil reduce much more readily than those from the sugar maple.

From these and other experiments it is clear that anthocyanins or anthocyanidins can be obtained from flavone or flavonol solutions by chemical or electrolytic reduction; but there is no proof that this happens in the living plant. Willstätter believes that anthocyanins are formed by reduction, but all that has been proved is that they might be so formed.

Many of the English chemists do not agree with Willstätter that anthocyanins and anthocyanidins are produced in the plant by direct reduction of flavones or flavonols. Keeble, Armstrong and Jones[12] came to the conclusion that the decolorization of anthocyanins by alcohol was due to the action of a reducing agent. Unfortunately, this paper was published before the one in which Willstätter showed that decolorization of anthocyanin by alcohol was not due to reduction. That eliminated Keeble's argument.

Robinson is the present leader of the movement in favor of the anthocyanin pigments being produced by oxidation. One reason for believing that flavones are not the immediate precursors of anthocyanins is that in many cases the anthocyanins do not correspond structurally with the flavones existing in the flower. This is not absolutely conclusive, because there might have been two sets of flavones originally and only one was reduced in the plant. Sands, Milner and Sherman[13] say: "We cannot assume that, because a certain flavonol is not found coexisting with its homologous anthocyanidin, the latter was formed independently rather than by way of the flavonol. As mentioned, the particular flavonol in question may have been converted fully into anthocyanidin." This may be true, but it has not yet been proved and we do know that anthocyanins can be made differently in the plant.

Leuco-anthocyanins and Leuco-anthocyanidins

Robinson and Robinson[14] believe that many and perhaps all anthocyanins are derived from leuco-anthocyanins[15] and leuco-anthocyanidins, substances which were not known as such to Willstätter.[16] Laborde found that unripe green or red grapes contain colorless chromogens which are converted into pigment on heating with dilute hydrochloric acid. Malvézin showed that the same chromogen developed color on heating with water at 85°, but only in the presence of air which may have caused oxidation to acid. Dezain, Tswett, Rosenheim, Jonesco and Kozlowski also have showed the formation of pigments of anthocyanin-like nature from colorless or pale yellow chromogens without the use of a reducing agent.

"Rosenheim[17] prepared a white amorphous pow-

der of glycosidic nature from the unripe berries of purple grapes or from ripe white grapes and stated that anthocyanidin could be obtained from it by the action of hydrochloric acid in the absence of oxygen. He proposed the expression leuco-anthocyanin for the new group of natural products."

Robinson and Robinson report that leuco-anthocyanins are of widespread occurrence in the vegetable kingdom and that a majority of them yield cyanidin on treatment with hot hydrochloric acid. A 10% sulfuric acid solution is even better because there is no difficulty about volatility. In 1933 Robinson and Robinson[18] said that it is probable that the leuco-anthocyanins and the anthocyanidins formed from them are in the same state of oxidation. In 1937 Mrs. Robinson[19] reported that the gum of *Butea fondosa* contains a substance which cannot be converted into cyanidin chloride by the action of hydrochloric acid alone; preliminary oxidation is necessary.

Robinson and Robinson[20] now consider that the state of oxidation of a leuco-anthocyanidin is that of a dihydroflavylium salt. If this is always true, hydrolysis and oxidation are necessary to produce an anthocyanin pigment from a leuco-anthocyanin. There seems to be nothing to show that an oxidation is always necessary. If Rosenheim is right there must be some cases not involving oxidation. Over-reduction of an anthocyanin or anthocyanidin gives a colorless system which turns red on oxidation,[21] but we do not yet know whether this ever happens in the plant.

Regardless of the question of oxidation it is clear that an anthocyanin pigment can be obtained in the laboratory from a leuco-anthocyanin; but we do not yet know definitely whether this occurs in the plant or, if so, in which plants. One reason for this general uncertainty is that much of the work has been done on flowers where there is usually no change in pigments and one cannot well analyze the flowers for flavones and leuco-anthocyanins before and after the change, though Hugo Fischer[22] says that the first appearance of color in the flower buds is generally two weeks before the time of blooming in the case of red and blue flowers. This is not necessarily true, because cases are known of flowers starting white under suitable conditions and then developing a color.

Variable White Flowers

The flowers of *Hibiscus* L. *mutabilis*[23] and of *Diervilla grandiflora*[24] open white and turn pink or red in the course of the first day. Quite a number of flowers are pale or white when grown in the dark.[25] Among them is the mountain laurel. A low temperature also makes some flowers come white.[25b] With some the reverse is true.[26]

We have not found in the literature any systematic study of the chemistry of these pigments of these variable white flowers. Shibata seems to have shown that the change of color of the white *Diervilla grandiflora* to red is due to a reduction of a flavone-like substance, but in 1916 he of course did not test for the presence of leuco-anthocyanin and consequently there is a possibility of error.

Red Autumn Leaves

If we shift from flowers to green leaves which turn red, it is a simple matter to analyze them before the red color appears. If we take a green leaf, moisten it with dilute sulfuric acid to ensure acidity and electrolyze it with a platinum anode and a mercury cathode, we shall get a red at the cathode if a flavone or flavonol is present because of the reduction and no red, or at most a red at the anode, if a leuco-anthocyanin is present because it does not go red on reduction. Of course precautions must be taken against an error due to hydrolysis. It may not always be easy to see small amounts of red pigment on the mercury; but rinsing it with normal butyl alcohol will concentrate the red color in the alcohol and make it visible. The presence of leuco-anthocyanin can be shown by shredding the green leaf and heating it with approximately 10% sulfuric acid solution until the solution becomes red or pink. Extracting the solution with normal butyl alcohol will make the red color more visible.

We have made tests on the green leaves of the sugar maple and the sumach in August, and on the

green leaves of the flowering dogwood, the Virginia Creeper (*Parthenocissus quinquefolia*) and the Japanese Creeper (*Ampelopsis*) in September; also on the green skin of a Seckel pear.

The leaves of the sumach, the barberry and the flowering dogwood, contain flavones and no, or practically no, leuco-anthocyanins though there may be a mere trace of leuco-anthocyanin in the leaf of the dogwood. The leaves of the sugar maple and the Virginia Creeper and the skin of the Seckel pear contain leuco-anthocyanin and no, or practically no, flavone, while the leaves of the Japanese Creeper contain both flavone and leuco-anthocyanin. We can, therefore, say definitely that the red autumn leaves of the sumach, the dogwood and the barberry, are due to reduction of flavones, in accord with the view of Willstätter. The red autumn leaves of the sugar maple and of the Virginia Creeper and the red color of the ripened Seckel pear owe their color to the decomposition of leuco-anthocyanin in accord with the view of Robinson, while the red color of the leaves of the Japanese Creeper may be due either to flavones or to leuco-anthocyanins or to both simultaneously. We shall have to devise a new technique for this case or perhaps resort to quantitative analysis. It is now merely a question in most cases of collecting data on other leaves which turn red or which change from red to green.

DeVries[27] says that the leaves of *Drosera rotundifolia* are red when grown in strong light, but otherwise green. There should, therefore, be no difficulty in determining the precursors of the anthocyanins in this plant. Schanz[28] showed that when light less than 400 mμ was cut off by euphos glass, the leaves of red cabbages, young beets and begonias were green and not red. The colors returned in the sunlight. He concluded that the red was developed as a protection against the long ultraviolet. With oak seedlings grown in the open air, the young leaves were a beautiful yellowish-red; under ordinary glass the color was paler; under euphos glass and under red glass the yellow-red did not appear and the leaves were uniformly green.

After the red disappears from the young leaves of the copper beech in summer, leuco-anthocyanins are found to be present. On this statement of facts it seems probable that the red is developed from the leuco-anthocyanins. Abbott[29] has found that leaves of the copper beech are green in the spring when grown in the dark and turn red when exposed to light. He did not analyze these leaves for flavones or leuco-anthocyanins, and consequently one step in the proof is missing.

We do not yet know what factors determine the formation of flavones and leuco-anthocyanins, and consequently we do not know how the relative amounts of these two kinds of substances will vary with changing soil and climatic conditions. In Ithaca the leaves of a certain sugar maple contain flavones and no, or practically no, leuco-anthocyanins in May, and leuco-anthocyanins with practically no flavones in September. It is because of this that we do not yet dare to say definitely that the red of the copper beech is derived from leuco-anthocyanins.

To answer the question whether the conversion of leuco-anthocyanins into anthocyanidins necessarily involves an oxidation we have tried heating equal amounts of the leaves of the sugar maple with sulfuric acid in the presence and in the absence of hydroquinone. There was no marked difference in the amount of red color, and consequently there is no reason to assume that the leuco-anthocyanins must be considered as derivatives of dihydroflavylium salts. Since oxygen is apparently of very little importance in this case, we confirm the observations of Rosenheim. This does not in any way contradict the results obtained by Mrs. Robinson with the gum of *Butea fondosa*. There is no reason as yet why all leuco-anthocyanins should be derivatives of dihydroflavylium salts because some may be.

Enzyme Reactions

Whether in the formation of anthocyanin we are dealing with the reduction of flavone-like substances or with the hydrolysis of leuco-anthocyanins with or without accompanying oxidation, the reaction must apparently be an enzyme reaction because we know of no straight reducing agent that the plant could use which would carry a flavone to an anthocyanin, and because it seems improbable that there would ever be sufficient acidity to produce the hydrolysis of a leuco-anthocyanin without the presence of an enzyme. Miss Wheldale[30] says that "there is little doubt but that the formation of anthocyanin does in-

volve a series of progressive reactions, each of which is controlled by a certain enzyme."

Enzymes can cause the reduction of sulfates,[31] a reaction which cannot be carried out chemically or electrochemically in the test-tube in the presence of water at ordinary temperatures.

If people can learn how to concentrate the enzymes and to inoculate leaves with them, it should be possible to make the leaves of the Norway maple red. That ought not be a very difficult task, because the stems of the leaves are apt to be red and once in a while one sees an occasional red leaf. When we know more about the enzyme reactions, we shall be able to explain why European forests do not show the brilliant coloring that we get in this country.

In front of the chemistry building at Cornell there is a sugar maple and a copper beech. Both sets of leaves contain leuco-anthocyanin but those in the copper beech do not turn red in the autumn, while those in the sugar maple do. There is no reason to attribute this behavior to differences in climatic or soil conditions and consequently there must be at least one other factor, apparently a genetic one. The green leaves of the Norway maple in Ithaca contain flavones and no leuco-anthocyanins. Since the stems of the leaves are usually red and the leaves only rarely so, there must be some reason why the proper enzyme is found only occasionally in the leaves. Flavones are present in the ginkgo; but we have never seen any red in Ithaca either on stems or leaves. The formic acid extracts of the leaves of the Norway maple and of the ginkgo turn red when electrolyzed with a mercury cathode. The yellowed leaf of the American elm will sometimes develop a little red when bitten by an insect. There is no experimental evidence that the insect causes a preliminary formation of leuco-anthocyanin and we must therefore attribute the red to flavones for the present.

Summary

1. Anthocyanin pigments may be obtained in the laboratory or in the plant by reduction of flavones or by decomposition of leuco-anthocyanins.

2. The red autumn pigments of the sumach, the dogwood and the barberry come from a flavone and those of the sugar maple, the Virginia Creeper and the Seckel pear from a leuco-anthocyanin. The Japanese Creeper contains both flavone and leuco-anthocyanin. We do not yet know which gives rise to the anthocyanin or whether both do.

3. On present data the red of the copper beech comes probably from a leuco-anthocyanin; but this is not yet proved.

4. There is no necessary contradiction between the experiments of Rosenheim and those of Mrs. Robinson. There are apparently some leuco-anthocyanins which require oxygen to develop the full red color and some which do not. On present data the sugar maple belongs in the second class or partly so.

5. The development of anthocyanins is always due to enzymes. If one could inactivate the enzymes without killing the leaves one would prevent the development of red. If one could supply the proper enzyme to the Norway maple, its leaves would turn red in the fall. The stems of the leaves usually turn red in the summer.

6. Since the leaves of the copper beech and of the sugar maple both contain leuco-anthocyanins but behave differently in the autumn, there is apparently a genetic factor to be considered in addition to the effects of soil and climate.

7. A method has been developed which will enable us to distinguish between the views of Willstätter and of Robinson in particular cases.

8. All blue flowers contain a stabilizing agent. A systematic study of this matter will lead to the production of blue roses.

9. There seem to be no satisfactory data on the reds which develop early and temporarily in the tropics.

10. The behavior of the sugar maple suggests the possibility of a flavone being the precursor of a leuco-anthocyanin; but there is no proof of this as yet.

11. There seem to be no data to show whether glucose as a nutrient or a suitable exposure to ultra-violet light will produce anthocyanins more rapidly from leaves containing flavones or from leaves containing leuco-anthocyanins.

The Conductance and Ionization Constants of Propionic and Normal Butyric Acids in Water at 25°

BY DONALD BELCHER

The modern theories of interionic attraction, which are now accepted in the form of limiting laws, are particularly useful in the interpretation of weak electrolytes. It has been shown by several investigators[1–3] that accurate conductance measurements of a weak binary electrolyte should suffice in theory to yield values of the limiting conductance and thermodynamic ionization constant. In media of high dielectric constant, such as water, there is strong evidence for the complete dissociation of the salts of weak acids (or bases) and therefore the limiting conductance of the weak electrolyte may be obtained by use of the additive law of Kohlrausch. But in nonaqueous solvents of low dielectric constant there are no strong electrolytes and hence to determine the limiting conductance it is necessary to apply methods of extrapolation to conductance data on the weak electrolyte alone.

For the additive method it is sufficient to determine the limiting conductance of the sodium salt of the weak acid, since the other necessary data are obtainable from the work of Shedlovsky.[4]

The extrapolation methods are based on a solution of the three simultaneous equations

$$K = \frac{C\theta^2 f_\pm^2}{1-\theta} = K^1 f_\pm^2 \tag{1}$$

where K and K^1 are the thermodynamic and stoichiometric ionization constants, respectively, θ is the degree of dissociation, C is the total concentration of the acid in equivalents per liter, and $f_\pm$ is the mean activity coefficient of the ions. The activity coefficient of the undissociated acid is assumed to be unity.

$$-\log f_\pm = a\sqrt{C\theta} \tag{2}$$

where a is the Debye–Hückel coefficient.

$$\theta = \frac{\lambda}{\lambda_0}\left[\frac{1}{1-\frac{A}{\lambda_0}\sqrt{C\theta}}\right] \tag{3}$$

where λ is the equivalent conductance of the acid at the total concentration C, λ_0 is the limiting conductance of the acid, and A is the Onsager coefficient for uni-univalent ions in water at 25°.

If the right-hand side of (3) is expanded, and terms of order higher than $\sqrt{C}$ discarded, the simple quadratic expression used by Shedlovsky[5]

$$\theta = \frac{\lambda}{\lambda_0}\left[1+\frac{A}{\lambda_0}\sqrt{C\theta}\right] \tag{4}$$

is obtained. A combination of (1), (2), and (4) leads to a simultaneous solution which is much easier to use and, moreover, equation (4) has been shown to fit conductivity data over a much longer range of concentration than the original Onsager expression.

When λ_0 is not known, a trial value is assumed and adjusted until the equations are self-consistent.

With these considerations in mind I have determined accurately the conductance of propionic and normal butyric acids in water at 25°. An examination of this data by the extrapolation method made it clear that data on the salts of these acids were necessary. The determinations of conductances of sodium propionate and sodium butyrate, given later in this paper, were made in collaboration with Dr. Theodore Shedlovsky.

Experimental Assembly and Technique.—The apparatus and technique used follow so closely the practice of Jones and his associates[6,7] and of Shedlovsky[8] that only the briefest description is necessary.

The bridge, of the Jones and Josephs type (with shielding, following the practice of Shedlovsky[8]), was constructed by the Cambridge Instrument Company to order.

A two-stage audio amplifier and telephones of 2000 ohms resistance formed the detector circuit.

A vacuum tube oscillator of the "push-pull" type, constructed as described by Shedlovsky,[8] supplied current to the bridge. The frequency could be varied in steps over a range of 850 to 4000 cycles by a bank of condensers in parallel. The frequency for various condenser settings was determined roughly by audio comparison with a General Radio oscillator which in turn was calibrated by a tuning fork. Several times in each series of measurements the frequency was varied, but since the conductances were found to be independent of frequency an accurate knowledge of the latter was unnecessary.

A shielded decade resistance box, supplied by the Cambridge Instrument Company, permitted direct reading to 11,111 ohms, to the nearest 0.01 ohm. It was calibrated by the National Physical·Laboratory with direct current. None of the coils was thermostated, but the box was enclosed in a lagged wooden case and the temperature was known to the nearest degree.

The thermostat was filled with Mineral Colza Oil and controlled to ± 0.001° by a Thyratron relay.

Two pipet cells of Jena glass were used for the more concentrated solutions. They were calibrated with 0.1 demal potassium chloride, using the recent values of Jones and Bradshaw.[9] The temperature of the thermostat was set to 25 ± 0.005° by using a thermometer recently calibrated by the National Physical Laboratory.

Two flask cells, one of Pyrex and one of clear quartz, were used for the more dilute solutions. The electrodes were lightly platinized. After each run the cells were cleaned with redistilled alcohol and ether, and occasionally with hot chromic acid.

Conductivity water was obtained from a still which followed the general design of Ellis and Kiehl.[10] The boiler was of Pyrex and the condenser of fused silica. Purified nitrogen was passed up the column and out through a water trap. A ball and socket joint connected the Pyrex and silica portions of the still and gave great flexibility and freedom from breakage. The boiler was charged with a good grade of distilled water made 0.025 molar in phosphoric acid. The still yielded one liter per hour of fair conductivity water ($k = 5 \times 10^{-7}$ mhos), and about 400 cc. per hour of the best water ($k = 0.8$ to 2×10^{-7} mhos). For the more dilute solutions the water was distilled directly into the flask cells.

Densities were determined with an ordinary Sprengel pycnometer in a water thermostat.

All solutions were made up by weight. The more accurate weighings were performed on an analytical balance which could be read to 0.1 mg. Water and stock solutions were weighed on a large balance to the nearest 10 mg. Weights were calibrated against a set standardized by the National Physical Laboratory.

Materials.—The propionic and normal butyric acids were Kahlbaum "purest." They were further purified by fractional crystallization and distillation. The freezing point of the recovered portion of propionic acid was −22.4°, which may be compared with −20.8° (Timmermans and Hennaut-Roland[11]) and −22.3° (Broughton[12]). The final portion of butyric acid melted at −5.37°, very close to the value given by Timmermans and Hennaut-Roland.[11] As a check on the purity of the acids they were analyzed by weight titrations against carbon dioxide free sodium hydroxide. By using phenolphthalein and a technique which excluded carbon dioxide it was possible to titrate with a precision of 0.04%. Several titrations gave the purity of the propionic acid as 100.02%, and that of the butyric acid as 99.96%. Accordingly the acids were assumed to be pure within the experimental error. The sodium hydroxide was standardized against a standard brand of benzoic acid.

The molecular weights of the acids were taken from the "International Critical Tables."

Several determinations of the densities of solutions of both acids checked so well with the data of Drucker[13] that the latter's measurements were used to compute concentrations.

Results.—Tables I and II give the data for the two acids. The columns are, respectively, the concentration in equivalents per liter, the equivalent conductance, the degree of dissociation, the mean activity coefficient of the ions; the stoichiometric ionization constant, and the thermodynamic ionization constant. These ta-

bles are based on λ_0 values obtained from salt conductances by the additive method. Furthermore, the values of $\theta, f_{\pm}$, etc., have been computed by the new and more convenient method due to Shedlovsky.[5] It should be noted that for the present data the various extrapolation methods give identical results in the range of concentration where K is reasonably constant. No water correction has been made in computing the equivalent conductances since the specific conductivity of the water used never exceeded 0.2×10^{-6} mho, and is due largely to the presence of carbon dioxide.

Discussion of Results.—Table I shows that the measured conductances of the four most dilute points are in error. This is undoubtedly due to the use of a Pyrex flask cell. The effect of glass on the conductivity of very dilute solutions of weak acids was noted many years ago by Kraus and Parker.[14] The data of Table II do not show this effect since the butyric acid measurements were made in quartz.

A plot of the logarithm of the stoichiometric ionization constant against the square root of the ionic strength for these two acids gives straight lines for total acid concentrations not exceeding 0.01 normal. These lines have very nearly the Debye–Hückel slope (1.013), and the intercepts give the logarithm of the thermodynamic ionization constant. At higher concentrations log K^1 falls off rapidly with increasing ionic strength, an effect noted by MacInnes and Shedlovsky[15] for acetic acid. Davies[16] showed that this so-called "medium effect" is largely due to viscosity in the case of acetic acid, and I propose to discuss the effect of viscosity in a forthcoming paper.

The extrapolation method yields a thermodynamic ionization constant of 1.343×10^{-5} for propionic acid, in fair agreement with the value 1.332×10^{-5}, obtained by Harned and Ehlers[17] from electromotive force measurements. The latter figure has been reduced from a molar to a concentration basis.

For normal butyric acid extrapolation gives 1.508×10^{-5}, in excellent agreement with the value 1.510×10^{-5}, obtained by Harned and Sutherland[18] from electromotive force measurements.

The Conductance of the Sodium Salts of Propionic and Normal Butyric Acids in Water at 25°

Materials.—Kahlbaum acids were used, but no further purification was attempted since the salt concentrations of stock solutions were known accurately from titrations.

Preparation of Solutions.—A carbonate-free solution of sodium hydroxide was prepared and standardized by weight titrations against Bureau of Standards acid potassium phthalate. The latter was dried before using. Phenolphthalein was used as indicator and nitrogen was passed through the titration vessel for some time before the alkali was added and during the titration. It so happens that the phenolphthalein end-point corresponds very closely to the *p*H of neutralized acid phthalate so that it is possible to titrate to an accuracy of 1 or 2 parts in 10,000. As a check, however, the *p*H of the final solution was determined with the glass electrode and if necessary a small correction applied. The acids were titrated in a similar manner, but since in this case the *p*H of the neutralized solutions does not correspond to the phenolphthalein end-point, the correction was important. By applying the correction it was possible to titrate the acids to a precision of 3 parts in 10,000. This method has the advantage of being much more rapid and convenient than the method of differential electrometric titration of MacInnes and Dole.[19]

When a sufficient number of titrations had established the strength of the acids, stock solutions were made up without indicator. To suppress hydrolysis about 0.5% excess acid was added. The salt concentration was known accurately from the amount of alkali used.

The densities of several solutions of sodium butyrate were measured and it was found that the agreement with sodium acetate solutions was very close in the dilute range. Accordingly it was considered justifiable to use the same density–concentration relationship in the case of sodium propionate.

Table III gives the conductances of sodium propionate and sodium butyrate at 25°.

TABLE III

Sodium Propionate		Sodium Butyrate	
C	λ	C	λ

the contribution of carbon dioxide would be negligible.

The limiting conductances were determined by using Shedlovsky's[5] method of extrapolation, in which $1/\lambda$ is plotted against $\sqrt{C}$. This gave $\lambda_0 = 85.92$ for sodium propionate, and $\lambda_0 = 82.70$ for sodium butyrate. These values, combined with the limiting conductances for Na^+ and H^+, as determined by MacInnes, Shedlovsky, and Longsworth[20] (corrected to the Jones and Bradshaw basis) give the λ_0 values for the acids which were used in Tables I and II.

The Limitations of the Extrapolation Method

There are now sufficient accurate conductivity data to permit of a critical examination of the validity of the extrapolation method for determining conductances and ionization constants of weak electrolytes. Table IV gives a comparison of λ_0 and K values as obtained (1) from conductance measurements on the weak acid and its alkali salt, and (2) from conductance measurements of the weak acid alone, using the extrapolation method.

TABLE IV

	From acid and salt conductances		From acid conductances alone, by extrapolation	
Acid	λ_0	K	λ_0	K
Carbonic[21]	394.3	4.31×10^{-7}	424	3.65×10^{-7}
Acetic[22]	390.71	1.753×10^{-5}	395.3	1.705×10^{-5}
Propionic[23]	385.47	1.343×10^{-5}	386.34	1.337×10^{-5}
n-Butyric[23]	382.40	1.508×10^{-5}	386.05	1.475×10^{-5}
Monochloroacetic[24]	389.52	1.396×10^{-3}	389.5	1.396×10^{-3}
o-Chlorobenzoic[25]	380.07	1.197×10^{-3}	380.0	1.197×10^{-3}
Benzoic[26]	382.21	6.312×10^{-3}	382.1	6.312×10^{-3}

Table IV shows that the extrapolation method is reliable if the electrolyte is not too weak ($K \geqq 10^{-3}$), but that if the electrolyte is much weaker ($K \leqq 10^{-5}$) the method may give λ_0 and K values that are seriously in error. Therefore, the statement of some authors[1] that the extrapolation method will give a λ_0 value as accurate as the λ values is unjustified. It is obvious why the extrapolation method may fail if the electrolyte is too weak. Even if the limiting laws are obeyed exactly in the concentration range used for the extrapolation, the correct λ_0 will not be found unless the number of experimental points is very large and the distribution of experimental errors is random. Thus, in the worst case of Table IV, *i. e.*, carbonic acid, accurate extrapolation from λ's of the order of 5 to a λ_0 of 394 would require an unobtainable experimental accuracy. However, the extrapolation methods are valid for determining ionization constants if the λ_0's are known accurately.

It follows from the above that in those cases where it is impossible to measure limiting conductances by the additive principle the extrapolation method may not serve if the electrolyte, is too weak.

I wish to thank Dr. D. A. MacInnes and Dr. Theodore Shedlovsky for continued encouragement and invaluable advice during the progress of this work.

Summary

Measurements are reported on the electrical conductance of solutions of propionic acid, sodium propionate, *n*-butyric acid, and sodium butyrate in water at 25°. From these are derived limiting conductances and ionization constants.

The limitations of the extrapolation method for determining limiting conductances and ionization constants of weak electrolytes are discussed.

Optical Crystallographic Studies with the Polarizing Microscope. II. Identification of the Para-bromoanilides of Some Lower Aliphatic Acids[1]

BY W. M. D. BRYANT AND J. MITCHELL, JR.

Para-bromoanilides because of their stability and ease of preparation are excellent derivatives for the identification of organic acids by means of melting point and optical crystallographic properties. Melting points of many fatty acid *p*-bromoanilides are available in the literature[2,3] together with convenient preparative methods, but optical data are limited to those of the acetic and propionic derivatives recently studied in this Laboratory.[1] There was consequently no information available regarding the value of optical crystallographic properties for differentiating between derivatives of structurally isomeric acids. Also, the para-bromoanilides prepared by earlier investigators were confined to the unsubstituted fatty series, so that it was by no means evident that derivatives of substituted acids could be prepared with equal ease.

In the present research para-bromoanilides of nine aliphatic acids were prepared and the optical properties and melting points studied. The group consisted of the two butyric and the four isomeric valeric compounds and in addition the derivatives of methacrylic, methoxyacetic and pyruvic acids, to illustrate the effects of structural isomerism and the substitution of other functional groups for hydrogen. These crystalline derivatives are well suited for optical study. They are easily prepared and quite stable. Interference figures are distinct and usually well centered, thus facilitating the measurement of optical axial angle. This property was particularly useful in the present study because of its sensitivity to changes of composition. The measurement of optic axial angle alone is sometimes sufficient to establish the identity of an unknown acid. Optical character and axial dispersion are valuable properties of this series but are not highly specific of the individual compounds. The refractive indices α, β and γ, however, are useful criteria, and most of the weight of an identification rests upon these constants and optic axial angle. Brief descriptions of crystal habit are included, but as this property is often extremely sensitive to traces of contamination and to minor differences in preparative detail, less reliance is placed upon it and upon the related elongation, as criteria in identification.

Identification of methacrylic and three of the isomeric valeric derivatives is facilitated by the occurrence of metastable phases of considerably different optical properties in crystalline films prepared by fusion. These preparations usually revert to the stable modifications on standing. The metastable methacrylic derivative is stabilized by a trace of impurity. For example, a sample melting 3° lower than the pure substance was definitely dimorphous while under the same conditions the pure material failed to produce a metastable phase. The stable form in the contaminated preparation was scarcely distinguishable by its physical characteristics from the pure material.

It is interesting to note that the Kuehn and McElvain[3] procedure can be used to prepare *p*-bromoanilides of unsaturated acids. It was feared at first that hydrogen chloride, resulting from the action of thionyl chloride on the organic acid, would add at the double bond to form a chloroacyl chloride and give rise to the corresponding *p*-bromoanilide. Analyses of methacrylic *p*-bromoanilide for total halogen, however, have shown that no addition takes place.

Experimental

Materials.—All of the reagents used were from the Eastman Kodak Company with the exception of methacrylic acid, a du Pont product. Some batches of Eastman *p*-bromoaniline contained a purple coloring matter, most of which was removed by one recrystallization from chloroform. It was necessary to subject the *n*-valeric acid used to careful fractionation in order to obtain a sharp melting derivative. All of the remaining chemicals were sufficiently pure as received.

Preparation of the Derivatives.—The *p*-bromoanilides were prepared from the corresponding acids by the method of Robertson[2] as modified by Kuehn and McElvain.[3] Chloroform is a better solvent for the *p*-bromoanilides than benzene and advantageously can replace the latter in preparing derivatives of the lower fatty acids. The methacrylic derivative was analyzed for total halogen by a Parr peroxide bomb method.[4] The analyses showed only

the expected amount of halogen, hence contamination by the chloroisobutyryl derivative must have been negligible.

Melting Points.—Where comparisons can be made, the melting points given in Table I are in satisfactory agreement with the literature. Those of the remaining derivatives apparently have not been reported previously. In most cases there is a distinct spread between the melting points of the individual *p*-bromoanilides. Even where this fails, the distinct depression obtained on mixing two different *p*-bromoanilides of similar melting points is sufficient to remove ambiguity. For example, a mixture of equal parts by weight of the isobutyric (m. p. 155.0°) and trimethylacetic (m. p. 155.7°) derivatives melts at 147.6°, representing a depression of 8°. Similarly, a mixture of the isovaleric (m. p. 126.7°) and methylethylacetic (m. p. 122.3°) compounds melts at 112.0°.

TABLE I

MELTING POINTS OF *p*-BROMOANILIDES OF ALIPHATIC ACIDS

Derivative	M. p., °C.[a] (this research)	M. p., °C. (literature)

Methoxyacetic	85.3	
Pyruvic	167.8	

[a] Melting points determined by means of a carefully calibrated Dennis melting point bar;[1] average uncertainty ± 0.3°.

Apparatus and Technique.—A Bausch and Lomb LC petrographic microscope was used in this research. The optical equipment and methods of calibration, however, were identical with those used with the LD microscope in an earlier study.[1] The technique of optical examination was essentially the same as that previously described.[1] Both individual crystals mounted in Canada balsam and thin crystalline films prepared by fusion were examined. The pronounced birefringence and good optical quality of the latter facilitated conoscopic examination using an oil immersion system of high numerical aperture (1.25 N.A.). This technique permits direct measurement of the acute optic axial angles regardless of size, and in some cases even the obtuse angles. As previously, the quantity measured is 2H, the optic axial angle relative to cedar oil, from which 2V, the true angle within the crystal, may be calculated by means of appropriate formulas.[1] 2V was calculated from the refractive indices α, β and γ by a graphical method using tables and diagrams developed by F. E. Wright.[6]

Refractive indices were measured by the immersion method as outlined in the first paper of this series.[1] Since, however, the solubility of the present group of *p*-bromoanilides is appreciable in many of the usual organic immersion liquids, the aqueous liquids described in an earlier paper[7] were employed. This series has since been extended to n_D 1.760 in intervals of 0.005, using aqueous solutions of barium mercuric iodide. Above 1.760, the organic series was found satisfactory. The liquids of low refractive index used were standardized at 25° using an Abbe refractometer, while those above 1.650 were determined by the method of minimum deviation using a 30° capillary prism[8] suspended from the crystal adjusting device of a Hutchinson Universal Goniometer.[9] This procedure requires only a drop of the liquid and its precision compares favorably with that of the Abbe refractometer.

Optical Crystallographic Data

Optical constants of the group of nine *p*-bromoanilides of aliphatic acids are given in Table II. Comparison of measurements upon the unheated derivatives with the results obtained with preparations previously subjected to fusion has supplied conclusive evidence of the existence of metastable modifications in three of the four isomeric valeric derivatives and in a slightly contaminated sample of the methacrylic compound. The interference figures observed in the freshly prepared crystalline films were distinctly different from those of the original material as illustrated by the optic axial angle data appearing in Table II. After a few days at room temperature, the metastable crystals reverted to the corresponding stable varieties. Since the conditions suitable for the formation of isolated crystals of the metastable varieties were not known, dependable refractive index measurements could not be made. These metastable modifications are tentatively regarded as true polymorphs. Dynamic isomerism, although less likely, is not excluded.

The optical properties measured may be divided into two classes, those characteristic of the series rather than the individual compound, and exemplified by optical character[10] and axial dispersion, and those of a more specific nature including optic axial angle, the principal refractive indices and the more complex forms of dispersion. Acute bisectrix interference figures are more common than the obtuse in all but the methoxyacetic derivative. The strong inclined dispersion of

[10] The optical characters of all of the substances in Table II are positive by the usual test involving the effect of a quartz wedge upon interference figures and also by the approximate test, $\gamma - \beta > \beta - \alpha$. By the exact modification of the latter test described by Wright (*vide supra*, Ref. 6, pp. 529–532) and based on the relation, $1/\beta^2 - 1/\gamma^2 > 1/\alpha^2 - 1/\beta^2$, the *n*-butyric, *n*-valeric and isovaleric derivatives appear negative. However, changes in the refractive indices within the experimental tolerances are sufficient to restore the positive sign in two of the three cases. The optical characters of these three compounds remain in some doubt.

both the stable and metastable methylethylacetic modifications is highly specific of this compound.

Acknowledgment.—The authors thank Mr. A. N. Oemler of this Laboratory for his aid in the preparation of the derivatives and for analyses of the methacrylic derivative for halogens.

Summary

1. Optical crystallographic data and melting points of the *p*-bromoanilides of nine lower aliphatic acids have been determined.

2. Metastable crystalline modifications of the *n*-valeric, isovaleric, *d,l*-methylethylacetic, and methacrylic derivatives have been obtained from the molten material.

3. The unsaturated methacrylic derivative was successfully prepared by the regular procedure, without formation of the chloroisobutyric derivative.

The Method of Garelli and Racciu for the Preparation of Piperazine: A Criticism

BY DEAN B. ROLLINS AND H. N. CALDERWOOD[1]

With regard to a paper[2] describing a simple and inexpensive dehydration method for obtaining piperazine disulfate by heating monoethanolamine with sulfuric acid, we wish to call attention to the fact that the authors do not prove that the reaction product obtained by them is piperazine disulfate. The solubilities reported and the percentages of nitrogen and sulfate, their only analytical data for the product they designate as piperazine disulfate, hold also for β-aminoethylsulfuric acid. Their only other description, the rhombohedral crystals from dilute ethanol, is characteristic of β-aminoethylsulfuric acid,[3,4] the crystals of piperazine disulfate from dilute ethanol being monoclinic.

The interaction of monoethanolamine and fuming sulfuric acid to form β-aminoethylsulfuric acid was reported in 1918.[4] Believing that Garelli and Racciu might have developed conditions leading to the formation of piperazine disulfate, we attempted to prepare the compound according to the method sketched by them, but in twenty-three experiments, under various time and temperature conditions and with different amounts and concentrations of sulfuric acid, we were unable to obtain even a trace of piperazine, the resulting product in every case being β-aminoethylsulfuric acid.

Our reagents were monoethanolamine, 99.54% purity, from the Carbide and Carbon Chemicals Corporation, and C. P. grade sulfuric acid in concentrations from 88.3 to 20% fuming. Samples of both our crude and recrystallized products analyzed for nitrogen by the semi-micro Dumas method and for sulfur by both wet and dry oxidation gave the results recorded in Table I. These values being valid for both β-aminoethylsulfuric acid and piperazine disulfate, other properties of our purified product were compared with the corresponding properties of an authentic sample of piperazine disulfate.

TABLE I

ANALYSES OF CRUDE AND PURIFIED PRODUCTS

Material		Crude I	Crude II	Purified I	Purified II	Calcd. $C_2H_7NO_4S$
Sample, g.		0.07025	0.07753	0.07117	0.07054	
Nitrogen, %		9.96	9.94	10.13	10.05	9.93
Sample, g.		0.2710	0.2652	0.2745	0.2714	
Sulfur, %	Wet			22.40	22.48	22.68
	Dry	22.34	22.37			

Our product purified by recrystallization from dilute ethanol formed rhombohedral crystals sintering at 230°, as recorded in the literature for β-aminoethylsulfuric acid,[3,4] whereas piperazine disulfate from dilute ethanol gave white monoclinic crystals which began to darken at 325° and charred at 330°. Our purified product gave no precipitate with barium chloride, even after standing at room temperature for ten hours, nor with benzenesulfonyl chloride, whereas piperazine disulfate gave immediately after the addition of barium chloride a copious precipitate of barium sulfate, and with benzenesulfonyl chloride gave a copious white crystalline precipitate melting at 281°.[5] The molecular weight of our purified

product determined by neutralization was 141.2 and 142.5, and by cryoscopy 140.5 and 141.5, values in excellent agreement with the theoretical 141 for β-aminoethylsulfuric acid, whereas piperazine disulfate would have given values at least twice as large.

In case of a remote possibility that β-aminoethylsulfuric acid might under favorable conditions decompose to form piperazine which Garelli and Racciu[6] claim to have isolated from their product, our purified product was treated with an equivalent amount of potassium hydroxide and steam distilled. The pale yellow viscous liquid obtained by evaporating the steam distillate to dryness yielded no piperazine, contained nitrogen but not sulfur, and did not form insoluble derivatives with reagents for either amino or alcohol groups. The use of small and large excesses of potassium and sodium hydroxides failed to yield piperazine or any other definite product. With large excesses of the hydroxides steam distillation was always accompanied by a volatile imine, probably ethyleneimine.[7]

Garelli and Racciu state that they obtained the pure base as a crystalline hydrate, m. p. 44°, to which they assign a formula approximating that of the monohydrate, but incorrect, as printed, for any piperazine hydrate. Since the literature[8] reports that it is piperazine hexahydrate which melts at 44°, this statement of Garelli and Racciu is surprising. Our examination of an authentic sample of piperazine corroborated Berthelot's findings.

It would be interesting to know in detail the method by which Garelli and Racciu isolated the free base from the product which they designate as piperazine disulfate and which had the crystalline form not of piperazine disulfate but of β-aminoethylsulfuric acid, and also in detail the conditions under which they obtained piperazine hydrate, from the base so isolated, by cooling over sulfuric acid the residue obtained by evaporating to dryness on a water-bath the condensate formed in isolating the free base by steam distillation. We found that piperazine hexahydrate when stored at room temperature over sulfuric acid volatilized completely and was absorbed by the acid.

We wish to express our gratitude to Messrs. G. E. Bernard, J. M. Hogrefe, and A. L. Wilson of the Carbide and Carbon Chemicals Corporation for their interest and assistance in this investigation.

Summary

1. The only product that can be isolated from the reaction of monoethanolamine and either concentrated or fuming sulfuric acid by the method of Garelli and Racciu is β-aminoethylsulfuric acid.[9]

2. β-Aminoethylsulfuric acid does not form an insoluble derivative with benzenesulfonyl chloride.

3. Both piperazine disulfate and piperazine hexahydrate form the same insoluble derivative with benzenesulfonyl chloride.

4. From dilute ethanol piperazine disulfate forms monoclinic crystals which begin to darken at 325° and char at 330°. This crystalline form and its behavior upon heating are reported for the first time here.

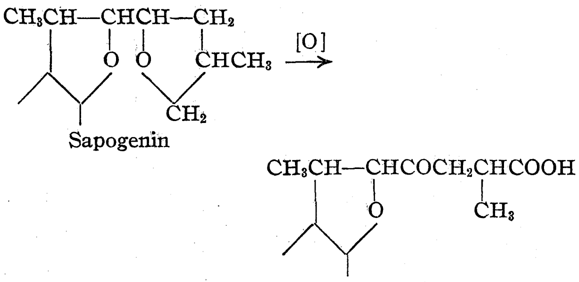
Sarsasapogenin. II. Sarsasapogenoic Acid

BY LOUIS F. FIESER AND ROBERT P. JACOBSEN[1]

The observations reported in this paper are concerned with a study of sarsasapogenoic acid, a C_{27}-acid obtained as described in Part I[2] by the oxidation of sarsasapogenin acetate with chromic acid at 60–65° and subsequent gentle saponification of the acidic fraction. Under the conditions found most favorable for the isolation of this acid, the neutral fraction contains a small amount of the acetate of the hydroxy lactone $C_{22}H_{34}O_3$, together with a substance previously regarded[2] as unchanged sarsasapogenin acetate but now recognized as consisting in large part of an isomorphous substance of higher oxygen content, possibly the acetate of a hydroxysarsasapogenin. Sarsasapogenoic acid, which probably is a stereoisomer of Tschesche and Hagedorn's[3] tigogenoic acid ($C_{27}H_{42}O_5$), displays a number of interesting if perplexing properties, and a further study of the substance was undertaken with the idea that it might hold the key to the structure of the sapogenin side chain. The extent of experimentation has been somewhat limited by the low yield of this oxidation product of the rather difficultly accessible genin, the average yield being about 5 g. of acid from 20 g. of sarsasapogenin acetate, representing the material from some 20 lb. (9 kg.) of root.[4] Farmer and Kon[5] did not encounter the acid in the mixture obtained on conducting the oxidation at the temperature of the steam-bath with a larger amount of chromic acid, and oxidation at 32–33° by the procedure found by McMillan and Noller[6] to give a good yield of chlorogenoic acid diacetate proved to be unsatisfactory for the sapogenin under consideration. A slight difference in one part of a steroid molecule often alters considerably the susceptibility to attack by chromic acid at some other site.

Tschesche and Hagedorn[3] tentatively suggested that tigogenoic acid may be a γ-keto acid arising from the opening of one of the postulated five-membered oxide rings. They were not able, however, to demonstrate the presence of a carbonyl group, the ethyl ester forming no oxime or semicarbazone under the usual conditions, and absorbing no hydrogen on attempted hydrogenation. Sarsasapogenoic acid is similarly inert to carbonyl reagents, the methyl ester, for example, being recovered unchanged after attempted oximation in boiling alcohol, and the acid yielding no semicarbazone under the usual conditions. McMillan and Noller[6] made a similar observation concerning chlorogenoic acid diacetate. On treating sarsasapogenoic acid or ester with carbonyl reagents under forcing conditions we were able to bring about reactions, but these all proved to be more profound than a simple condensation or addition involving only a carbonyl group. Thus the acid and its ester both react with two molecules of hydroxylamine at 130° and give products which appear to be unrelated but which contain two atoms of nitrogen (see chart). Paralleling the experience of Tschesche and Hagedorn, we found sarsasapogenoic acid to be very resistant to hydrogenation, but under certain conditions we were able in at least some experiments to effect a slow hydrogenation. On the above formulation one would expect to obtain a hydroxy acid or its lactone, but the substance isolated proved to be a free acid corresponding to the introduction of two or four hydrogen atoms and the loss of a molecule of water; the compound evidently is an anhydrohydro acid and not a lactone. This loss of water in some way other than by lactonization is surprising; it cannot be attributed to the presence of water of crystallization in the starting material (m. p. 193°) for this gives a normal ester, acetate and methyl ester benzoate.



(Formulation of Tschesche and Hagedorn)

The elimination of a molecule of water was observed also in a curious reaction of sarsasa-

pogenoic acid with alkali.² When heated with dilute aqueous alcoholic alkali for two hours, the sapogenoic acid ($C_{27}H_{42}O_5$) is converted into a higher melting acid $C_{27}H_{40}O_4$, designated anhydrosarsasapogenoic acid. This substance is quite reactive and, as indicated in the chart, has been converted into a number of transformation products. The presence of a carboxyl group and of the original C_3-hydroxyl group was established by the preparation of a crystalline methyl ester acetate. The anhydro acid rapidly absorbs two moles of hydrogen in the presence of platinum oxide catalyst giving a tetrahydro acid, and the same compound (VI) was obtained by reduction with sodium and *n*-propyl alcohol. The latter reaction suggested the presence of a conjugated system, and this inference was fully confirmed by a determination of the absorption spectrum kindly carried out for us by Dr. T. J. Webb at the Merck Research Laboratories. The absorption maximum at 243 mμ (Fig. 1) clearly indicates that the substance is an α,β-unsaturated ketone. The four oxygen atoms are therefore present as a hydroxyl, carboxyl, and conjugated carbonyl group, and it is clear that both of the original oxide rings of the sapogenin have been severed. A further significant inference can be drawn from the behavior of tetrahydroanhydrosarsasapogenoic acid (VI). On esterification with diazomethane followed by acetylation, this gave a crystalline methyl ester diacetate (VII), as shown by the analysis and saponification equivalent. The same substance (VII) was also obtained from the anhydro acid (V) in a different sequence: esterification, hydrogenation, and acetylation. The free acid group is thus characterized, one of the acetylated hydroxyls must be that originally present in the nucleus at C_3, and the other is a new secondary alcoholic group arising from the addition of hydrogen to the carbonyl group of the anhydro acid. When the tetrahydroanhydro acid was acetylated without prior esterification it yielded, in place of a diacetate, a lactone acetate (VIII); a lactone benzoate (IX) was similarly obtained on benzoylation. The new hydroxyl group formed in the reduction of the anhydro acid must, therefore, be in a position with respect to the carboxyl group favorable for lactone formation, and it is concluded that the carbonyl group of anhydrosarsasapogenoic acid is γ or δ to the carboxyl group.

From its composition, anhydrosarsasapogenoic acid must contain either one isolated double bond, in addition to that conjugated with the carbonyl group, or a newly formed carbon ring. The fact that the tetrahydro acid resists further hydrogenation and is saturated to permanganate points to the presence of a new ring.

The anhydro acid was altered on attempted oximation at 130° but gave a non-crystalline product, and the methyl ester acetate was attacked only slowly by chromic acid at 95° and afforded no crystalline material. The free acid, however, is oxidized smoothly and rapidly by alkaline permanganate and gives in good yield a nicely crystalline dibasic acid (X), m. p. 207°, of the composition $C_{27}H_{40}O_7$. The reaction

$$C_{27}H_{40}O_4 + 3[O] \longrightarrow C_{27}H_{40}O_7$$

involving the production of a new carboxyl group, can only be interpreted as follows

$$\left\{\begin{array}{l} -CH \\ \;\,\| \\ -C- \end{array}\right. \longrightarrow \left\{\begin{array}{l} -COOH \\ \\ >CO \end{array}\right.$$

One of the unsaturated carbon atoms carries a hydrogen atom and the other is joined to two carbon residues, and since no loss of carbon atoms occurs on severing the ethylenic linkage it is evident that the double bond is inserted in a carbon chain which is joined to the main body of the molecule on both sides of the point of unsaturation. This is perhaps a further indication of the presence of a fifth ring in the anhydro acid. For further characterization the dibasic acid X was heated with hypoiodite in dioxane–alkali, according to the haloform test of Fuson and Tullock,[7] and it yielded iodoform. The carbonyl group generated in the oxidation therefore is present in the form of an acetyl group, and the knowledge of the oxidation can be elaborated thus

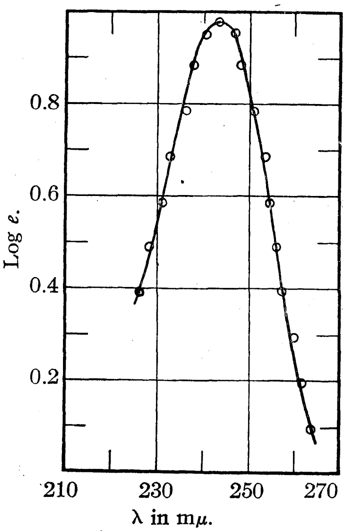

Fig. 1.—Anhydrosarsasapogenoic acid (V) in absolute alcohol.

$$\left\{\begin{array}{l} -CH \\ \;\,\| \\ -CCH_3 \end{array}\right. \longrightarrow \left\{\begin{array}{l} -COOH \\ \\ -COCH_3 \end{array}\right.$$

The conjugated carbonyl group of anhydrosarsasapogenoic acid may be attached to either of the two unsaturated carbon atoms. A further requirement is that this group must be placed γ (or δ) to the carboxyl group, and from the evidence of the absorption spectrum it appears that the carboxyl group is not conjugated with the 1,4-system. The anhydro acid, therefore, must contain one of the groupings

$$\underbrace{-C(CH_3){=}CHCO\overset{\cdot}{\underset{\cdot}{C}}\overset{\cdot}{\underset{\cdot}{C}}}COOH \text{ or}$$

$$\underbrace{-CH{=}C(CH_3)CO\overset{\cdot}{\underset{\cdot}{C}}\overset{\cdot}{\underset{\cdot}{C}}}COOH$$

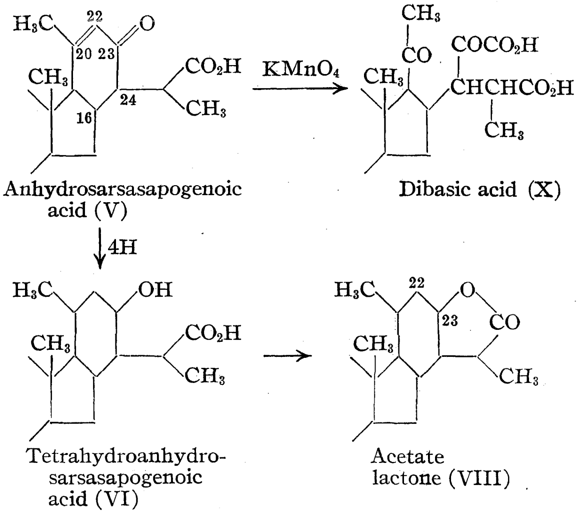
Only the first of these groupings can be accommodated to the cholesterol side chain, and it remains only to place the carbon bridge connecting the residues on the two sides of the double bond. Inspection of the possible structures shows that the choice lies between the six-ring structure indicated in the partial formula and a seven- or eight-ring structure; the six-ring formula is the more likely both from the point of view of ring size and because ring closure in this case would involve an activated position α- to the carbonyl group.

It is inferred that the anhydro acid probably has the structure shown and that it contains a new

---

[7] Fuson and Tullock, THIS JOURNAL, **56**, 1638 (1934).

ring formed by condensation between the C_{24}-position of the side chain and position 16 of Ring D. According to this formulation the dibasic acid produced on permanganate oxidation has two carbonyl groups, but since they are both subject to considerable hindrance the formula is perhaps not inconsistent with the observation that the dimethyl ester does not react with hydroxylamine at 130°. The free acid does react under these conditions and yields an anhydro-oxime. It is known only that the substance is not a β,γ-unsaturated enol lactone (negative Legal test), but with so many functional groups present any formulation, such as that shown, is purely conjectural. Uncertain also is the structure of a nicely crystalline product obtained in one small-scale hypohalite oxidation of the dibasic acid. Preliminary analyses indicate that probably two carbon atoms are lost in the oxidation and that the composition is $C_{25}H_{38}O_7$ or possibly $C_{25}H_{36}O_7$. Since a titration with a small sample (in the cold) pointed to a dibasic acid, the second structure shown is the more probable.

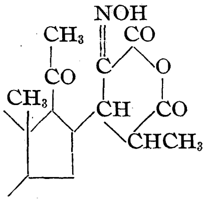


Anhydrosarsasapogenoic acid (V)

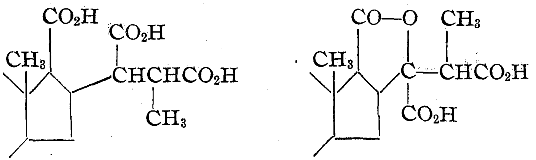
Dibasic acid (X)

Tetrahydroanhydrosarsasapogenoic acid (VI)

Acetate lactone (VIII)



Anhydro-oxime XII (?)

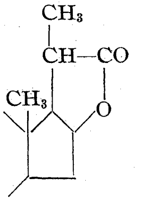


$C_{25}H_{38}O_7$ $C_{25}H_{36}O_7$

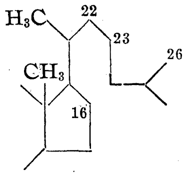
Hypohalite oxidation product (?)

While the nature of these little studied transformations is still highly uncertain, the formulation given above for tetrahydroanhydrosarsasapogenoic acid is reasonably secure; all of the functional groups have been characterized adequately, particularly by conversion to the lactone acetate and benzoate. As shown on the reaction chart, anhydrosarsasapogenoic acid was also converted in poor yield by Clemmensen reduction into a neutral product giving an acetate of the same composition as the acetate lactone VIII. The substances melt at not greatly different temperatures but show a distinct depression when mixed. The acetate resulting from the Clemmensen reduction product may be a δ-lactone with the oxygen attached at the 22-position, or, considering the opportunity for the migration of the double bond in the acid mixture, it may be a stereoisomeric γ-lactone different from VIII in the configuration at C_{23}.

With the knowledge gained of the nature of anhydrosarsasapogenoic acid, the next step is to attempt to trace the manner of its formation and the structure of this part of the sapogenin molecule. The carbonyl group at C_{23} and the terminal carboxyl group must have arisen by the rupturing of one of the original oxide linkages at C_{23} and C_{26} in the chromic acid oxidation, and the degradative experiments of Farmer and Kon[5] have established the attachment of an oxide bridge at C_{16}. The presence of a double bond in the anhydro acid between positions C_{20} and C_{22} is understandable only on the assumption that an oxide ring originally extended to one of these positions. The former position is eliminated by the observation that derivatives of the sapogenin can be oxidized to saturated C_{22}-lactones in which the carbon atom in question is not hydroxylated.[8,5] The evidence therefore indicates that the oxidic linkages of the sapogenin are joined at positions 16, 22, 23, and 26. The only structures for the



C_{22}-Saturated lactone

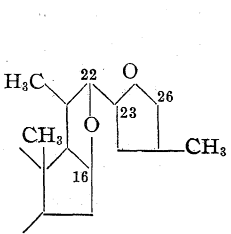


Position of oxide linkages

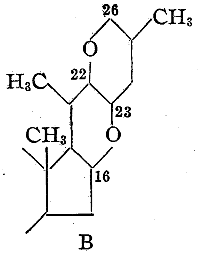
---

[8] Simpson and Jacobs, *J. Biol. Chem.*, **110**, 565 (1935).

sapogenin admissible on this basis are those shown in Formulas A and B, and only the first of these accounts for the appearance of a carbonyl group



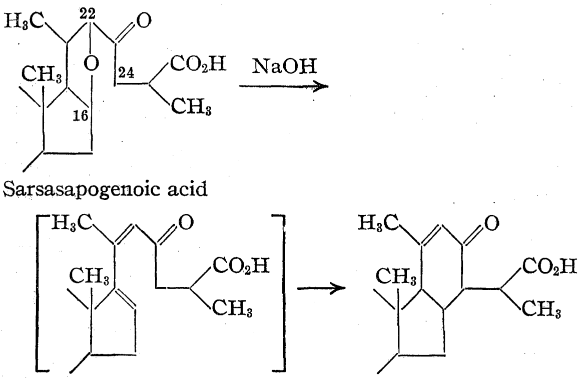
A



B

at C_{23} and a terminal carboxyl group in the oxidation, as demonstrated in the characterization of the anhydro acid. The structure A, which is the formulation tentatively suggested by Tschesche and Hagedorn,[3] thus accords best with the observations reported.

Sarsasapogenoic acid is then a γ-keto acid, corresponding also to the formulation of Tschesche and Hagedorn. The remarkable transformation brought about by the action of alkali involves elimination of the oxide bridge and a condensation between positions 16 and 24. Position 16 is a point of attachment of the oxygen atom, and the methylene group at position 24 is adjacent to an activating carbonyl group, which may account for the disposition to cyclize under the influence of alkali. The ready cleavage of the oxygen bridge may also be attributable to the activating influence of the carbonyl group adjacent to C_{22}, and the reaction possibly involves the intermediate formation of a dienone.

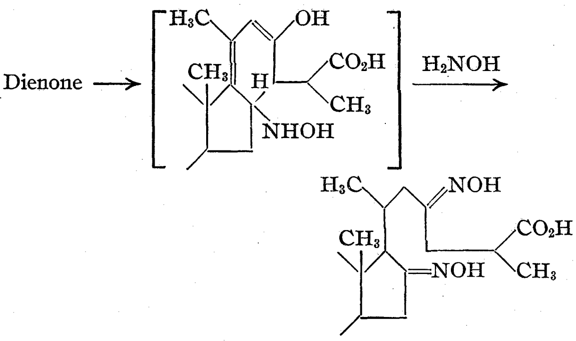


Sarsasapogenoic acid

Dienone

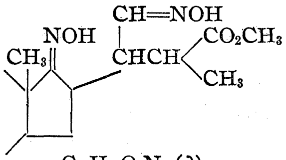
Anhydro acid

This hypothetical dienone may be an intermediate in other reactions of the sapogenoic acid, cleavage of the oxide ring occurring under the forcing conditions required to overcome the resistance of the carbonyl to additions. The inert character of this group may be associated with a hindrance arising from a special steric arrangement, although this does not seem very plausible, or to a tendency for the substance to exist in the lactol form. If the reaction with hydroxylamine at 130° involves cleavage of the oxide ring, one molecule of the reagent may add to the ends of the conjugated system of the dienone or dienone oxime giving, by a succession of ketonizations, the saturated dioxime-acid of the formula shown.



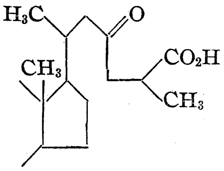
Dioxime-acid (III)

The reaction of the sapogenoic methyl ester with hydroxylamine at 130° seems to result in the loss of three carbon atoms and may follow some other course; a purely speculative formulation satisfying the present analytical data is as follows.



$C_{25}H_{40}O_5N_2$ (?)

The product obtained from sarsasapogenoic acid in some experiments in a slow hydrogenation may be either a di- or a tetrahydride; the analytical data do not distinguish between the two possibilities but agree slightly better with the tetrahydride formula. Possibly the activated oxide ring is eliminated by hydrogenolysis, or the dienone is slowly formed and saturated with hydrogen, giving in either case a saturated γ-keto acid. The substance may also be a saturated dihydride with a linkage between C_{16} and C_{24}, as in the anhydro acid.



Anhydrotetrahydrosarsa-
sapogenoic acid, $C_{27}H_{44}O_4$ (?)

While many of the new compounds described need to be characterized much more fully in order to establish the structures, the evidence regarding the structure of the anhydrosapogenoic acid is now secure and the only formulation of the sapogenin side chain consistent with this structure is that suggested by Tschesche and Hagedorn.[3]

Experimental Part[9]

Extraction of the Genin.—In working further batches of the sirupy extract from Mexican (sarsaparilla) root we followed a suggestion kindly made by Dr. J. C. E. Simpson and simplified the process by omitting the initial extraction with ligroin. The gum was defatted during the precipitation of the crude glycoside by running a 3.5-kg. portion in a thin stream into 10 l. of vigorously stirred ether. The resulting viscous gum was then processed as before,[2] centrifuging the aqueous solution of the gum prior to hydrolysis, when clarification was necessary. One batch of 18.2 kg. of crude sirup yielded 195 g. of pure sarsasapogenin, which is about the amount previously reported;[2] another lot of 20.0 kg. processed in the same way gave only 67 g. of genin. We were not able to determine the variable factor involved.

Notes on the Preparation and Characterization of Sarsasapogenoic Acid.—In studying further the oxidation of sarsasapogenin acetate,[2] material (3.8 g.), m. p. 141–145°, recovered from the neutral fraction and previously designated as "unchanged sarsasapogenin acetate" was crystallized repeatedly from acetone–chloroform to yield 2 g. of flat needles melting constantly at 165–167°. This material resembles sarsasapogenin acetate in crystalline form but melts about 20° higher. On saponification with alcoholic potassium hydroxide this gave a product crystallizing from acetone–chloroform in elongated plates, m. p. 216–218° (av. of three analyses: C, 76.09; H, 10.06). The crystals are similar in appearance to those of sarsasapogenin but the m. p. is distinctly higher. This substance on reacetylation and crystallization as above gave material, m. p. 158–160°, apparently identical with the original acetate (no depression). This was analyzed with the following results.

Anal. Calcd. for $C_{29}H_{46}O_5$: C, 73.38; H, 9.76; sapon. equiv., 475. Found: C, 73.20, 73.21; H, 9.71, 9.93; sapon. equiv., 487.

These analyses suggest that the substance is the acetate of a hydroxysarsasapogenin, but the carbon content of the saponified material is about 1% higher than that required for the normal desacetyl compound. All that can be said is that the substance recovered from the neutral fraction is definitely not pure sarsasapogenin acetate and probably is an oxidation product, or contains such a substance.

Among other attempts to improve the yield of sarsasapogenoic acid, sarsasapogenin acetate (4 g.) was oxidized by the exact procedure worked out by McMillan and Noller[6] for the conversion of chlorogenin diacetate into the sapogenoic acid diacetate in good yield (32–33°), and the precipitated material was extracted with aqueous sodium carbonate from ether. Acidification of the extract gave 2 g. of solid, but no crystalline product could be obtained from this material. After gentle saponification, as in our original procedure,[2] and crystallization from dilute acetone 0.4 g. of crude sarsasapogenoic acid was obtained, m. p. 188–190°. The neutral fraction yielded (from aqueous acetone) 0.32 g. of needles, m. p. 162–166°. On conducting the oxidation (4 g. of acetate, 6 g. chromic anhydride) initially at 35–37° and then at 45°, no crystalline sapogenoic acid could be isolated.

Trials were made of the action of chromic anhydride on sarsasapogenoic acid acetate (0.85 g.) at 60–65° and at 90–95°, but in each instance the only crystalline product isolated from the acidic fraction after saponification was unchanged sarsasapogenoic acid (0.2 g.) and there was no appreciable neutral fraction, indicating the absence of the acetate lactone $C_{24}H_{36}O_4$.

An attempted Clemmensen reduction of sarsasapogenoic acid (0.5 g.), using 20 cc. of benzene, 70 cc. of alcohol, and 20 cc. of 6 *N* hydrochloric acid with fresh additions of concentrated acid (ten hours) gave a resin which formed dense clusters of fine needles (0.3 g.) from ether–hexane, but satisfactory crystals could not be obtained free from gum. Reduction with sodium and *n*-propyl alcohol gave an even less promising product.

Heated with semicarbazide acetate in alcohol for two hours, sarsasapogenoic acid gave only non-crystalline material. When treated with hydroxylamine under similar conditions, the methyl ester was recovered unchanged. Oximation of the methyl ester at 130° for three hours gave in a poor yield a substance crystallizing from dilute methanol in fine needles, m. p. 169–171° (Found: C, 66.96, 67.21; H, 8.68, 9.30; N, 6.41, 6.49. $C_{25}H_{40}O_5N_2$ requires C, 66.92; H, 8.99; N, 6.25). Because of the very low yield, the substance was not studied further.

Dioxime-Acid (III) from Sarsasapogenoic Acid.—A mixture of 500 mg. of sarsasapogenoic acid, 0.33 g. of hydroxylamine hydrochloride, and 0.5 g. of potassium acetate in 35 cc. of absolute methanol was heated in a sealed tube at 130° for three hours. The solution was concentrated and diluted with water and the finely divided solid which separated was collected, dried, and crystallized by dissolving it in about 150 cc. of alcohol and concentrating the solution to a volume of 35 cc. The product then separated in small leaves, and after a second crystallization there was obtained 350 mg. of pure material which, when dried in vacuum at 80° over phosphorus pentoxide, melted with decomposition at 247° in a bath preheated to 235°.

Anal. Calcd. for $C_{27}H_{44}O_5N_2$: C, 68.03; H, 9.31; N, 5.76; neut. equiv., 477. Found: C, 67.86, 67.88; H, 9.18, 9.16; N, 5.89, 5.98; neut. equiv., 461.

It seems necessary to adhere strictly to the conditions specified in order to obtain the pure dioxime in satisfactory yield, for non-crystalline products were obtained when the oximation was conducted at a slightly higher temperature or for a longer time, or on varying the proportion of the reagents. Attempted hydrolysis of the dioxime acid with methyl alcoholic hydrochloric acid gave no crystalline product.

Anhydrodi-(or tetra)-hydrosarsasapogenoic Acid (IV).—One-half gram of carefully purified sarsasapogenoic acid (from aqueous acetone, m. p. 190–191°) in 40 cc. of pure

---

[9] All melting points are corrected. Analyses by Mrs. Verna R. Keevil, Dr. C. Fitz, and the Arlington Laboratories.

acetic acid was shaken with hydrogen at atmospheric pressure in the presence of 0.1 g. of Adams catalyst. Absorption of hydrogen continued slowly for fifteen to twenty hours; the apparent consumption was about 1 mole of hydrogen, but this could not be determined accurately. The solvent was partially removed in vacuum, and after dilution with water a solid product was obtained. The dried material when crystallized from 90% acetone yielded 380 mg. of short needles, m. p. 171–178°. This material was apparently nearly pure; after four more crystallizations from the same solvent the melting point range was 174–184°.

Anal. Calcd. for $C_{27}H_{42}O_4$: C, 75.31; H, 9.83. Calcd. for $C_{27}H_{44}O_4$: C, 74.96; H, 10.25. Found: C, 75.01, 74.97; H, 10.18, 10.06. Earlier analyses of a less highly purified sample gave the results: C, 75.59, 75.15; H, 9.92, 10.25.

The reduced acid is markedly less soluble in acetone than sarsasapogenoic acid. It is soluble in alkali but does not decolorize permanganate.

Although the absorption of hydrogen proceeded steadily if slowly in the above experiment, hydrogenation subsequently was accomplished only in a few of several trials with various preparations of catalyst. Even so it usually was necessary to continue shaking for a prolonged period, work up the mixture, separate a small amount of the less soluble reduced acid, and submit the recovered starting material to further hydrogenation. No reduction was observed with Raney nickel in absolute alcohol at 80° and 2000 lb. (133 atm.) pressure of hydrogen. Using Adams catalyst and glacial acetic acid, 1 g. of acid shaken with hydrogen at 90–100° and 500 lb. (33 atm.) pressure for six hours yielded 30 mg. of the acid IV, m. p. 173–183°.

Methyl Ester Acetate of IV.—Treated with diazomethane, the reduced acid IV gave an oily methyl ester mobile at −15°. On acetylation with acetic anhydride and potassium acetate this yielded a product which became crystalline on being moistened with methanol. Crystallization from aqueous methanol gave leaves melting at 64–66° with evolution of gas. After repeated crystallization from the same solvent the substance formed glistening hexagonal plates, m. p. 64–66°, dec. For analysis the sample was dried at room temperature over phosphorus pentoxide.

Anal. Calcd. for $C_{30}H_{46}O_5 \cdot {}^1/_2CH_3OH \cdot {}^1/_2H_2O$: C, 71.59; H, 9.65; solvent of crystallization, 4.89. Calcd. for $C_{30}H_{48}O_5 \cdot {}^1/_2CH_3OH \cdot {}^1/_2H_2O$: C, 71.31; H, 10.01; solvent of crystallization, 4.87. Found: C, 71.57, 71.50; H, 10.06, 9.93; loss in weight at 110° and 5 mm., 4.99, 4.97.

Methyl Ester Benzoate of IV.—The liquid methyl ester from 0.3 g. of the acid IV was heated with 1 cc. of benzoyl chloride in 4 cc. of dry pyridine for thirty minutes, and the mixture was diluted with water and extracted with ether. After washing with acid and alkali and evaporating the ether, the residue was crystallized from methanol. This gave silvery leaves, m. p. 136.5–139°, and after repeated crystallization the substance melted, when dried at 100° and 15 mm., at 138.5–140.5°.

Anal. Calcd. for $C_{35}H_{48}O_5$: C, 76.64; H, 8.87. Calcd. for $C_{35}H_{50}O_5$: C, 76.32; H, 9.15. Found: C, 76.37, 76.35; H, 9.06, 8.83.

Tetrahydroanhydrosarsasapogenoic Acid (VI). (a) **By Catalytic Hydrogenation of V.**—One-half gram of the anhydro acid (m. p. 244–246°, dec.) in 50 cc. of absolute alcohol with 0.1 g. of Adams catalyst was shaken with hydrogen at atmospheric pressure. The reaction proceeded at a regular rate and stopped with the absorption of 2 moles of gas in four to five hours. When concentrated and diluted with water the solution deposited 480 mg. of flat needles which effervesce on melting at 182°. Further crystallization from aqueous alcohol, ether–hexane, or benzene–acetone did not greatly change the decomposition point. Other preparations melted with effervescence at temperatures ranging from 179 to 188°. The product is soluble in alkali but does not decolorize permanganate.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 74.96; H, 10.25. Found: C, 74.99; H, 10.57.

(b) **With Sodium and Alcohol.**—A solution of 0.5 g. of the anhydro acid V in 20 cc. of *n*-propyl alcohol was refluxed for one hour while adding 2 g. of sodium in small portions. The solution was diluted with a large volume of water, acidified with dilute sulfuric acid, and the chalky precipitate was collected and crystallized from aqueous methanol. Needles were obtained (300 mg.) melting with effervescence at 170°. Further crystallization from aqueous methanol and from ether–hexane gave material melting at 181° with decomposition and showing no depression when mixed with the sample prepared by catalytic hydrogenation.

Methyl Ester Diacetate VII. (a) **From Tetrahydroanhydrosarsasapogenoic Acid.**—On treating 0.46 g. of the tetrahydro compound VI (prepared by catalytic hydrogenation) with diazomethane in ether there was obtained a non-crystalline residue. This was taken up in acetic anhydride (10 cc.) and heated with potassium acetate (0.1 g.). Treatment with water afforded a solid product and on crystallization from methanol this gave 380 mg. of lustrous leaves, m. p. 158–160°. Further crystallization from methanol and from ether–hexane raised the melting point (of the well-dried material) to 159.5–161°.

Anal. Calcd. for $C_{32}H_{50}O_6$: C, 72.41; H, 9.50; sapon. equiv., 177. Found: C, 72.58, 72.40; H, 9.33, 9.29; sapon. equiv., 181.

The same compound was obtained from a sample of VI prepared by reduction with sodium and alcohol; the purified substance melted at 160–162° and the mixed m. p. was 160–161.5°.

(b) **From the Methyl Ester of Anhydrosarsasapogenoic Acid.**—The oily ester prepared from V with diazomethane was hydrogenated as in (a) and the crude reaction product treated with acetic anhydride and potassium acetate. This gave material which crystallized from methanol as glistening leaves, m. p. 159–161°, and there was no depression when mixed with the first sample of diacetate described above.

Lactone Acetate VIII.—A solution of 200 mg. of tetrahydroanhydrosarsasapogenoic acid and 50 mg. of potassium acetate in 3 cc. of acetic anhydride was heated slowly to boiling during forty-five minutes; treatment with water gave 180 mg. of solid material. This crystallized from 80% methanol in flat needles, m. p. 200–203° (dried in vacuum at 80°).

Anal. Calcd. for $C_{29}H_{44}O_4$: C, 76.27; H, 9.71; sapon. equiv., 228. Found: C, 76.58, 76.11; H, 9.77, 9.51; sapon. equiv., 233.

The compound is insoluble in cold alkali, saturated to permanganate and tetranitromethane, and does not react with diazomethane.

Lactone Benzoate IX.—The tetrahydro acid VI (100 mg.) was heated at 50–55° for one hour with benzoyl chloride (1 cc.) in pyridine (3 cc.). After decomposing the excess benzoyl chloride the mixture was extracted with ether and the ether layer was washed with acid and sodium bicarbonate solution, dried and evaporated. When the oily residue was moistened with petroleum ether and allowed to stand in the cold room for several days, 50 mg. of a fine powder separated, m. p. 218–223°, dec. Repeated crystallization from acetone–hexane gave flat, bluntly tapering needles melting gradually with slight yellowing at 225–235° (well dried).

Anal. Calcd. for $C_{34}H_{46}O_4$: C, 78.72; H, 8.94. Found: C, 78.54; H, 8.86.

The benzoate is insoluble in cold alkali and does not react with diazomethane.

Clemmensen Reduction of Anhydrosarsasapogenoic Acid: Neutral Product XIII.—A mixture of 500 mg. of the acid, 20 cc. of alcohol, 2 g. of amalgamated zinc, and 5 cc. of concentrated hydrochloric acid was refluxed for five and one-half hours, with the further addition during this period of two 5-cc. portions of acid. The solution was poured into water and the finely divided solid collected and taken into ether. After washing with water the solution was extracted with sodium hydroxide solution, the alkaline extract depositing 20 mg. of solid when acidified. The ethereal solution of the neutral fraction was evaporated, and the residue yielded a crystalline product (100 mg.), m. p. 212–219°, from ether–hexane. Twice recrystallized from ether–hexane, the substance was obtained as rectangular plates (75 mg.), m. p. 226–229° (dried in vacuum).

Anal. Calcd. for $C_{27}H_{42}O_3$: C, 78.21; H, 10.21. Found: C, 78.11; H, 10.39.

Acetylation of the Neutral Product: Acetate XIV.—After heating 50 mg. of the product XIII with acetic anhydride and potassium acetate, treatment with water gave a solid. This crystallized from aqueous methanol as long, flat needles, m. p. 212.5–214°. Repeated crystallization from the same solvent brought the m. p. of well dried material to 214–216°.

Anal. Calcd. for $C_{29}H_{44}O_4$: C, 76.27; H, 9.71. Found: C, 76.32; H, 9.44.

This acetate is different from the lactone acetate VIII from tetrahydroanhydrosarsasapogenoic acid, for a mixture of the two samples began to melt somewhat below 185°.

Oxidation of Anhydrosarsasapogenoic Acid: Dibasic Acid X.—One-half gram of the anhydro acid V was suspended in 20 cc. of water and neutralized with sodium hydroxide. The solution was cooled to 0° and a 2% solution of potassium permanganate was dropped in with stirring until the color was no longer discharged, the end-point being very apparent. The solution was filtered through a thin layer of Norite to remove manganese dioxide and the nearly colorless filtrate was acidified with dilute sulfuric acid. The precipitate was dried at room temperature in vacuum over sulfuric acid and crystallized from ether–hexane, giving 350 mg. of prisms, m. p. 193–203°, dec. After two crystallizations from ether–acetone–hexane, it melted at 206–207°, dec.

Anal. Calcd. for $C_{27}H_{40}O_7$: C, 68.04; H, 8.46; neut. equiv., 238. Found: C, 68.20; H, 8.84; neut. equiv., 232.

Attempted Clemmensen reduction of the acid gave a non-crystalline product. Gas is evolved at the melting point of the dibasic acid, and this is not carbon dioxide. When heated at 235° under nitrogen the acid was converted into a brittle glass which was separated with bicarbonate into neutral and acidic fractions, but neither yielded crystals.

Dimethyl Ester XI.—The dibasic acid X (200 mg.) with excess diazomethane in ether gave a solid ester which crystallized from ether–hexane in fine, silky needles, m. p. 163.5–165°, and on recrystallization melted at 164.5–165° after thorough drying.

Anal. Calcd. for $C_{29}H_{44}O_7$: C, 69.02; H, 8.79. Found: C, 69.26, 69.01; H, 8.84, 9.12.

The ester was recovered unchanged on attempted oximation in refluxing alcohol for three hours and in methanol at 130° for two hours.

Anhydro-oxime XII from the Dibasic Acid.—The acid X (200 mg.) was heated at 135° for three hours with an excess of hydroxylamine acetate in absolute methanol. The solvent was partially evaporated and the residue treated with water. The white solid was dried and taken into ether–acetone; on long standing there was obtained 0.2 g. of crystalline material, m. p. 263–266°, dec. (effervesces and becomes dark brown). Further crystallization from methanol–acetone gave glistening microneedles (95 mg.), m. p. 268°, dec. The substance gives a negative Legal test.

Anal. Calcd. for $C_{27}H_{39}O_6N$: C, 68.47; H, 8.30; N, 2.96. Found: C, 68.32; H, 8.88; N, 3.33.

Haloform Oxidation of the Dibasic Acid X.—A solution of 0.6 g. (m. p. 204–206°, dec.) of the dibasic acid in 15 cc. of dioxane and 6 cc. of 10% sodium hydroxide was treated at 60° with iodine–potassium iodide until the color persisted for two minutes.[7] No iodoform separated on dilution with water, but a halogen-containing acid was obtained on acidification. This was redissolved in 5% alkali and warmed with iodine–potassium iodide solution on the steam-bath, and after three minutes yellow crystals of iodoform (odor) separated, m. p. 117–122°. The alkaline solution was chilled and acidified, and the dried precipitate after two crystallizations from dilute acetone yielded 50 mg. of glistening, small leaves, m. p. 212–213°, dec. (gas evolution). Preliminary analyses gave the results: C, 66.82, 67.00; H, 8.75, 8.97; neut. equiv., 233; $C_{25}H_{36}O_7$ requires: C, 66.93; H, 8.09; $C_{25}H_{38}O_7$ requires: C, 66.63; H, 8.50. On attempting to recover the material used in determining the neutralization equivalent it was found that the substance had undergone alteration (isomerization?).

Summary

From a study of a number of transformation products of sarsasapogenoic acid and anhydro-

sarsasapogenoic acid it is concluded that the latter substance is an unsaturated γ-keto acid containing the grouping shown. The sapogenin and the sapogenoic acid very probably are correctly represented by the formulas of Tschesche and Hagedorn.

Sarsasapogenin. III. Concerning Desoxysarsasapogenin and the Degradation of the C_{22}-Hydroxy Lactone

BY LOUIS F. FIESER AND ROBERT P. JACOBSEN[1]

Simpson and Jacobs[2] prepared desoxysarsasapogenin by reduction of the sapogenyl chloride with sodium and amyl alcohol, but the over-all yield from the sapogenin was only about 14% and the method was employed only after other possible methods of removing the hydroxyl group had been considered and abandoned as unsatisfactory. Attempted reduction of sarsasapogenone by the Wolff–Kishner method was unsuccessful, and Clemmensen reduction of the ketone was considered unsuitable because of the known sensitivity of the side chain to acids.[3] In our experiments on the acid cleavage of the side chain,[4] we had observed that this sensitivity is manifested particularly when acetic acid is employed as the solvent but that cleavage occurs much less readily in alcoholic solution. It therefore seemed possible that with this solvent reduction of the ketone might be accomplished at an acidity below that at which cleavage occurs. It was also thought that the addition of an immiscible solvent, as in Martin's[5] procedure, might provide added protection for the sensitive steroid. These hopes were realized, for on refluxing sarsasapogenone for five days with amalgamated zinc in a two-phase medium of alcohol, benzene, and 6 *N* hydrochloric acid, pure desoxysarsasapogenin was obtained in an over-all yield of 43.5% from sarsasapogenin.

The comparatively simple new method of preparing the desoxysapogenin may have other applications, and this consideration has prompted us to report the observation at the termination of the fellowship work of the junior author, even though the investigation of the desoxy compound has not yet reached a very advanced stage. In connection with our work on the oxidation of sarsasapogenin acetate,[4,6] we hoped to extend a brief observation of Simpson and Jacobs[2] and gain further information concerning the acidic substances resulting from the oxidation of desoxysarsasapogenin with chromic acid. Simpson and Jacobs were interested chiefly in the lactone $C_{22}H_{34}O_2$, which they obtained in 15–18% yield on conducting the reaction at 75°, but they investigated incidentally the acidic material encountered as a by-product. Neither the acidic product nor the material obtained from it on esterification yielded homogeneous crystals, but the oily ester on reaction with semicarbazide acetate gave in very small yield a pure substance having the composition of the disemicarbazone methyl ester of an acid characterized by the analyses as either $C_{27}H_{40}O_5$ or $C_{27}H_{42}O_5$. Simpson and Jacobs were inclined to accept the first formula and to regard the oxidation product as a triketo acid with one inert carbonyl group, as in I. A similar oxidation product of sarsasapogenin acetate was isolated by Farmer and Kon[7] as the methyl ester acetate, apparently of the acid $C_{27}H_{40}O_6$. We conducted the oxidation at the

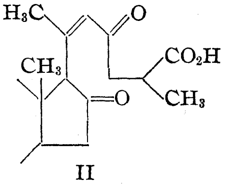
lower temperature of 60–65° and from the neutral fraction isolated the desoxy lactone $C_{22}H_{34}O_2$[8] in 13% yield. The acidic fraction afforded two crystalline products. One of these was obtained in amounts too small for thorough purification but corresponded approximately in composition to a desoxysarsasapogenoic acid ($C_{27}H_{42}O_4$).

The other substance, isolated in 20% yield as flat needles, m. p. 111°, is a monobasic acid of the formula $C_{27}H_{42}O_5$. The composition is that of a hydroxydiketo acid, and this formula was recognized by Simpson and Jacobs as an alternative possibility for the substance which they characterized as the methyl ester disemicarbazone. It is doubtful, however, that our acid is the substance which they characterized, for the behavior toward carbonyl reagents is quite different. Our acid with diazomethane gave a crystalline anhydro ester, a molecule of water being eliminated in the process, and the pure ester gave no crystalline product on prolonged refluxing with semicarbazide acetate in methanol, in contrast to the behavior of the crude ester investigated by Simpson and Jacobs. The anhydro ester liberates approximately one mole of methane in the Zerewitinoff test. Our acid was found to react with hydroxylamine at 100°, but the product proved to be an anhydro-monoxime.

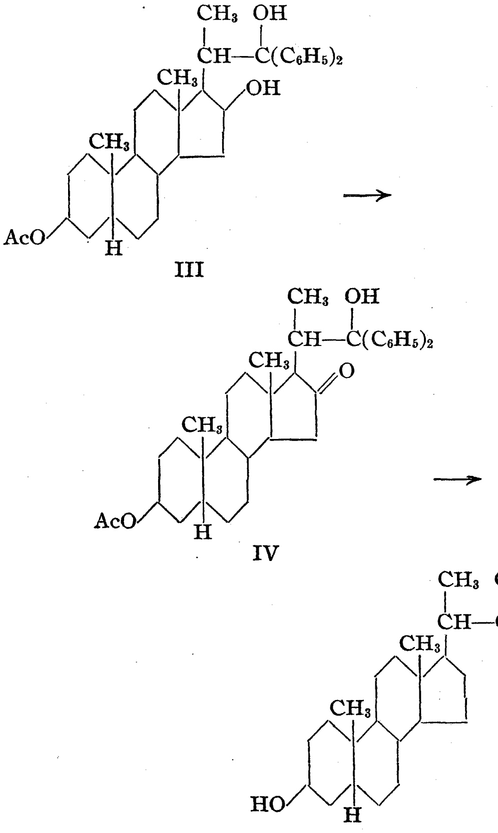
The interesting oxidation product gave no crystalline material on attempted acetylation, and was recovered unchanged after being heated with acetic–hydrochloric acid or with *o*-phenylenediamine. It decolorizes permanganate on warming, but not in the cold. The formation of an anhydro ester and an anhydro oxime may mean that the substance contains an easily eliminated hydroxyl group, but it seems unlikely that dehydration of an alcoholic group should occur on treatment with diazomethane in ether but not on refluxing with an acetic–hydrochloric acid mixture. The low-melting acid more probably is a hydrate, possibly of the unsaturated diketo acid II.



II

The behavior of the anhydro ester in the Zerewitinoff test would then be attributable to enolization, and some analogy for the failure of a carbonyl group at C_{16} to exhibit normal response to typical reagents is furnished by the results of the following series of experiments.

A Grignard degradation of the hydroxy lactone $C_{22}H_{34}O_3$ was carried in Part I[4] to the stage of a diphenylcarbinol monoacetate of the probable structure III (position of the substituent in Ring A still uncertain), only the less hindered secondary hydroxyl group at C_3 being acetylated in pyridine solution. Under controlled conditions (20–25°) it has been possible to oxidize this compound to a monoketone (IV) in good yield.



III

IV

V

This substance failed to form an oxime or semicarbazone under the usual conditions. Clemmensen reduction gave a desoxy diphenyl carbinol of the probable formula V, but the yield was so low that the degradation could not be carried further with the amount of material available.

Experimental Part[9]

Desoxysarsasapogenin.—The crude sarsasapogenone prepared from 15 g. of sarsasapogenin by the method of

---

[8] The formula was incorrectly written as $C_{22}H_{32}O_3$ in Part I,[4] p. 31.

[9] All melting points are corrected. Analyses by Mrs. G. M. Wellwood, Mrs. Verna R. Keevil, the Arlington Laboratories, and Lyon Southworth.

Simpson and Jacobs[10] was dissolved in 150 cc. of benzene and refluxed for seventy hours with 75 g. of zinc (amalgamated with 7.5 g. of mercuric chloride), 50 cc. of 6 *N* hydrochloric acid, and 50 cc. of alcohol, with the addition at five- to ten-hour intervals of 5-cc. portions of concentrated hydrochloric acid. The benzene layer was separated and combined with benzene extracts of the aqueous layer. After washing the benzene solution with water and concentrating it to a volume of about 150 cc., the reduction was continued, using 25 g. of amalgamated zinc to supplement the unused metal from the first treatment and adding fresh concentrated acid. After refluxing for fifty hours more, the benzene layer was washed and concentrated. On adding alcohol to the concentrated benzene solution, there was obtained 7.4 g. of crude desoxysarsasapogenin in the form of diamond-shaped plates, m. p. 209–216°. The mother liquors yielded only a sticky gum readily soluble in alcohol. One further crystallization of the solid product from benzene–alcohol gave 6.3 g. of material, m. p. 214–217°; yield from sarsasapogenin, 43.5%. Simpson and Jacobs[2] report the melting point 216–217°.

Anal. Calcd. for $C_{27}H_{44}O_2$: C, 80.94; H, 11.07. Found: C, 80.64; H, 10.76.

Oxidation of Desoxysarsasapogenin.—A suspension of 5.1 g. of the desoxysapogenin in 400 cc. of glacial acetic acid was stirred mechanically and treated with a solution of 4.3 g. of chromic anhydride in 75 cc. of 80% acetic acid, keeping the temperature at 60–65°. The addition was completed in one-half hour, and stirring was continued for one and one-quarter hours longer. The mixture was poured into water, and after standing overnight the gummy solid which separated was taken into ether. The ethereal solution was washed thoroughly with water and extracted with dilute sodium hydroxide solution. The alkaline extract was washed once with ether and acidified, and the precipitated solid was dried over sulfuric acid in vacuum. Crystallized from dilute acetone, this yielded 1.2 g. of small leaves of acidic material, m. p. 103–106°. When treated with cold methanol, a very small amount of amorphous solid remained undissolved. (When purified partially by crystallization from dilute acetone, this material, m. p. 218–220°, corresponded most nearly in composition to desoxysarsasapogenoic acid, calcd. for $C_{27}H_{42}O_4$: C, 75.31; H, 9.83. Found: C, 75.87; H, 9.02.) The solution was concentrated and a few drops of water added, and on cooling, the pure **desoxy acid** separated in the form of flat needles (1.15 g.), m. p. (well dried) 108–111°. There was no change in melting point after two further crystallizations from aqueous methanol. The sample for analysis was dried at 80° (18 mm.) over phosphorus pentoxide.

Anal. Calcd. for $C_{27}H_{42}O_5$: C, 72.61; H, 9.48; neut. equiv., 447. Found: C, 72.49, 72.23; H, 9.80, 9.56; neut. equiv., 447.

The acid is saturated to alkaline permanganate in the cold but rapidly decolorizes the reagent on warming. Attempted acetylation gave a gummy product. The substance was recovered unchanged after heating with *o*-phenylenediamine in alcoholic solution and also after being refluxed with acetic acid (10 cc.) and concentrated hydrochloric acid (2 cc.). It does not reduce Tollens' reagent.

The ethereal solution containing the neutral fraction was evaporated and the residue crystallized from benzene–alcohol. The first material separating was crude desoxysarsasapogenin, amounting to 0.75 g., and after this had been removed the residue from the mother liquor was dissolved in hot aqueous methyl alcoholic sodium hydroxide and heated for twenty minutes on the steam-bath. The alkaline solution was diluted with water, filtered hot through a thin layer of Norite, cooled, and acidified. The precipitated solid on crystallization from aqueous methanol gave 0.55 g. (13%) of flat needles, m. p. 125.5–127.5°, and a further crystallization raised the melting point to 127–129°. This gave no depression when mixed with the sample of the **desoxy lactone $C_{22}H_{34}O_2$**, m. p. 129.3–130.5°, prepared in our earlier work.[4]

Anhydro-methyl Ester of the Desoxy Acid.—The acid (200 mg.) was treated with excess diazomethane in ether and the crude product left on evaporation of the solvent melted at 74–76°. Crystallized from dilute methanol, this was obtained in the form of thin, glistening leaves, m. p. 78.5–79.5°.

Anal. Calcd. for $C_{28}H_{42}O_4$: C, 75.97; H, 9.57. Found: C, 75.97, 75.79; H, 9.96, 9.91.

The ester was recovered unchanged after short heating with acetic anhydride and potassium acetate. In a Zerewitinoff determination it liberated 0.63 mole of methane. In an attempt to prepare a semicarbazone the ester was heated on the steam-bath for seventeen hours with semicarbazide acetate in methanol, but no crystalline product was obtained.

Anhydro-oxime from the Desoxy Acid.—This was obtained by heating 200 mg. of the acid with hydroxylamine acetate in absolute methanol in a sealed tube at 100° for two hours. The gummy solid separating on dilution with water was dried and taken up in ether; on standing there separated 60 mg. of crystalline solid, m. p. 177–178°, dec. This material, which is very sparingly soluble in ether, was crystallized repeatedly from acetone and gave in poor yield small leaves melting with decomposition at 193–195° in a bath preheated to 188°. On rapid heating, starting with a cold bath, the substance began to turn brown at about 178° and melted at 189–191°, dec.

Anal. Calcd. for $C_{27}H_{41}O_4N$: C, 73.10; H, 9.32; N, 3.16. Found: C, 72.58; H, 9.72; N, 3.76.

Oxidation of the Monoacetate of the Diphenyl Carbinol $C_{34}H_{46}O_3$: Ketone Acetate IV.—A solution of 650 mg. of the previously described[4] monoacetate (III, m. p. 189–190°) in 50 cc. of glacial acetic acid was stirred at 20–25° and treated with 100 mg. of chromic anhydride in 10 cc. of 90% acetic acid, added in ten minutes. After ten minutes more the mixture was poured into cold water and the collected solid was washed, dried, and crystallized from ether–petroleum ether, giving 500 mg. of silky needles, m. p. 156–159°. After a further crystallization from ether–hexane the **ketone acetate** melted at 157–159° (well dried).

Anal. Calcd. for $C_{36}H_{46}O_4$: C, 79.67; H, 8.54. Found: C, 79.56; H, 8.90.

Attempts to prepare an oxime or semicarbazone were

---

[10] Simpson and Jacobs, *J. Biol. Chem.*, **109**, 573 (1935).

unsuccessful. Reduction with hydrazine according to Staudinger[11] was tried without success.

Clemmensen Reduction of the Ketone Acetate: Desoxy Diphenyl Carbinol V.—The above ketone acetate (390 mg.) was refluxed for seven hours with 1.2 g. of amalgamated zinc in 25 cc. of alcohol and 7 cc. of 8 *N* hydrochloric acid. The solid material obtained on diluting the filtered solution with water yielded no crystals and was refluxed for one-half hour with alcoholic alkali for saponification. The solid which precipitated on dilution was dried and crystallized from ether–hexane, the solution depositing glistening prisms mixed with slightly gummy, fine, felt-like needles. The prisms were separated mechanically (m. p. 224–226°) and recrystallized repeatedly from ether–hexane, giving 20 mg. of satisfactory material, m. p. 226–228° (well dried). The composition is approximately that of the desired **desoxy diphenyl carbinol.**

Anal. Calcd. for $C_{34}H_{46}O_2$: C, 83.90; H, 9.53. Found: C, 84.26; H, 9.04.

The slightly gummy needles (180 mg.) could not be freed completely from the above material by repeated crystallization from ether–hexane. Acetylation gave a resin and this on saponification gave an intractable mixture separating from methanol in clusters of small needles and soft wax-like nodules.

Summary

Conditions have been found for the reduction of sarsasapogenone to desoxysarsasapogenin in good yield by the Clemmensen method without alteration of the side chain. A preliminary account is given of a new C_{27}-acid obtained by the oxidation of desoxysarsasapogenin with chromic acid, and further observations are reported on the degradation of the hydroxy lactone $C_{22}H_{34}O_3$.

Heats of Organic Reactions. VII. Addition of Halogens to Olefins

BY JOHN B. CONN, G. B. KISTIAKOWSKY AND ELGENE A. SMITH

It has been shown in the earlier papers of this series[1] that the heats of addition of hydrogen to the olefinic bond vary in a regular manner with the constitutional make-up of the rest of the molecule. It seemed highly desirable to investigate whether these variations are specific for hydrogenations or are characteristic generally of addition reactions opening the ethylenic bond. The reaction with halogens was selected to test the question because of its convenience and the lack of accurate combustion data on dihalides. Another reaction considered, the addition of hydrogen halides, had to be discarded because we were unsuccessful in creating catalytic conditions under which this reaction occurs rapidly in the gas phase at temperatures below *ca.* 150°, the upper limit of usefulness of the present calorimeter. The results to be presented here unfortunately are neither as reliable nor as extensive as those on the heats of hydrogenation; nevertheless, even allowing for all possible errors, they are many times more accurate than the available combustion data.

Method and Compounds

The calorimeter itself and the general procedure were the same as described in the first paper of this series and only changes need to be recorded.

To avoid premature reaction, bromine or chlorine was carried to the calorimeter through a separate conduit in a stream of inert gas and mixed with excess hydrocarbon in the catalyst chamber within the calorimeter. Upon reaction and heat exchange the gases passed through a valve which directed the stream either to a cold trap for collection of a sample and tests for completeness and cleanliness of the reaction (in the fore- and after-periods), or, during the calorimetric run, to a jet where the gases were burned in excess oxygen and the halogens determined as such and as hydrogen halides.

The halogens were contained in an efficient spiral bubbler, kept at constant temperature (ice for bromine, Dry-Ice and alcohol for chlorine), through which passed a metered stream of inert gas (carbon dioxide with bromine, argon with chlorine).[2] Frequently additional inert gas was by-passed around the bubbler and added to the main gas stream to dilute the reaction mixture and so avoid the condensation of the product in the calorimeter. The hydrocarbon vapor also was metered, so that a condition of constant gas flow prevailed in the calorimeter during a run.

Several substances have been tried for their catalytic effect on the halogenation reaction, the choice being finally calcium bromide and calcium chloride for the bromination and the chlorination, respectively. Glass wool, asbestos, platinized asbestos, ferric halides, bismuth halides and activated charcoal were also experimented with but discarded either because of insufficient activity at the temperatures in question (around 100°) or because substitution reactions took place with the hydrocarbons used. The catalysts were made by evaporating a solution of cal-

[2] Nitrogen had to be avoided since nitrogen oxides are formed in the free flame used in the analytical system, and disturb the analysis.

cium halides (30%) with cleaned asbestos fibers (70%) and drying above 100°.

The conditions in the calorimeter were maintained such that a complete reaction of the halogen occurred, the exit gases being a mixture of the inert gas, the excess hydrocarbon and the dihalide. Because of this, a determination of the total halogen content of the gases sufficed to find the amount reacted. Figure 1 shows semi-schematically the analytical setup. After leaving the control valve the reacted gases entered a quartz jet and burned there in an excess of oxygen; some hydrogen was added to the combustible gases to ensure a healthier flame. The ignition was started by a spark-coil, the current being turned on a few seconds before turning the valve. Immediately surmounting the flame vessel was a quartz tube in a furnace maintained at bright red heat; this tube was filled with chips of porcelain, which ensured the combustion of the organic material and completed the conversion of the halogens to the free state or to the form of hydrogen halides. From the furnace the gases passed a trap in a Dry-Ice or ice-bath, surmounting which was a tower filled with glass beads and solid potassium iodide. Finally there was a bubbler filled with a potassium iodide solution which acted, however, merely as an indicator that absorption of halogens was complete. After the run the furnace was flushed with nitrogen and the connecting tubing flamed to distil the condensed water into the trap. The contents of the tower were then washed into the trap with potassium iodide solution and water, and the whole was made up to a liter. Aliquot parts were titrated with thiosulfate solution; the sample was then brought to boiling, cooled and potassium iodate added; a second titration with thiosulfate followed. In case of bromine the fraction present as hydrogen bromide was usually quite small (about 5%), but with chlorine the acid constituted the bulk of the product (*ca.* 95%).

Ordinarily two titrations were made on each run, but in the few cases when they disagreed by more than 0.1%, repeated titrations ensured the reliability of the result to better than that figure.

The thiosulfate solution was standardized with potassium bromate according to accepted procedure,[3] the results of repeated determinations agreeing to within 0.05%.

Before the calorimetric work was started, various tests of the analytical setup with weighed samples of pure organic halides showed that results correct to nearly 0.1% could be expected. Thereupon other preliminary work and calorimetric runs were undertaken, which occupied the fall and winter of 1937–1938. When the series of brominations was completed, the tests with weighed samples were done again, but to our considerable dismay it was discovered that losses of halogen to the extent of 0.5 to 1.0% occurred somewhere. Extensive search for sources of this error traced it finally to a coating of platinum on the porcelain chips in the furnace, which was present there from the work on hydrogenations. It is very difficult to explain why the same furnace gave satisfactory results a year earlier, the only possibility being that its temperature may have changed in the meantime. The mechanism by which the halogens are removed from the gas stream is also puzzling since the small amount of a solid distillate from the furnace was always flamed after the run to ensure its decomposition, the remainder appearing to be metallic platinum.

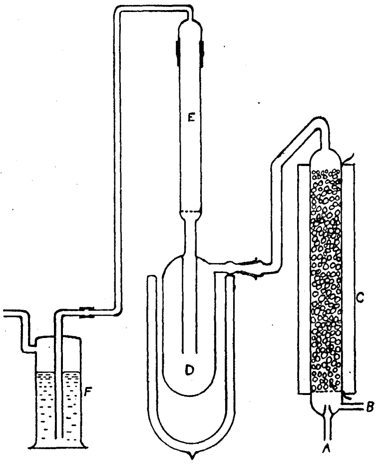

Fig. 1.—A, gas inlet; B, oxygen inlet; C, porcelain filled quartz furnace; D, cold trap; E, moist potassium iodide-glass pearl filled absorption tower; F, bubbler of 10% potassium iodide solution.

Nonetheless, whatever the precise cause of the failure of the original furnace, its repacking with clean porcelain remedied the situation, as shown in Table I, which presents the data on runs with weighed samples of organic halides and of molecular bromine. These samples were contained in sealed thin-walled glass ampoules placed in the gas stream instead of the calorimeter, and were broken after the flame was started, the rest of the procedure and the composition of the gases (except for the halogen, of course) being essentially the same as in ordinary calorimetric runs. Table I contains all runs made with sealed samples, none being discarded for "inconsistency" of the result. The runs with molecular bromine give the best agreement, then follow runs with ethylene dibromide which are also good; small losses of chlorine are noted in runs with ethylene dichloride but these, we believe, are within experimental uncertainties of the method. How-

ever, the very constant shortage of bromine in dibromobutane is outside the analytical errors and must be due to a slight impurity of the compound used for analysis (redistilled dibromide prepared for this work). This is best demonstrated by a run in which molecular bromine in the sealed ampoule and ethylene in the gas stream were used. Before the gases reached the analytical unit, the conversion of bromine to ethylene bromide was nearly complete and yet no shortage of bromine developed.

At the time of the discovery of the analytical errors, the still available quantities of pure hydrocarbons were so limited that a repetition of the entire series of brominations would have required new preparations of several of the olefins. To avoid this we have chosen to sacrifice somewhat the final accuracy of the data, making only one run on each of the olefins with the corrected combustion furnace. The average difference between the new runs and the old averages was used to correct the latter. This presumes that the furnace was misbehaving in the same manner during the entire series of brominations and thus introduces a not excessively large but nevertheless a considerable additional uncertainty.

Chlorination runs were made after the refilling of the furnace and therefore no analytical uncertainty impairs these results.

Bromine used for the reaction was Mallinckrodt analytical grade; iodimetric titration gave the correct molecular weight but no further tests or purification were undertaken.

Chlorine was distilled into the spiral bubbler directly from a used tank.

Excepting ethylene and propylene the hydrocarbons used were samples remaining from the work on hydrogenations; their description is superfluous.

Ethylene and propylene were generously presented to us by the Linde Air Products Company and were subjected by them to fractional distillations; the former is rated as 99.88% pure, the latter as 99.89% pure.

It is to be noted that in contrast to our work on hydrogenations, the method of analysis here devised is such that small amounts of saturated hydrocarbons in the material used have no effect on the results. Even the presence of minor olefinic impurities is of very small import because the heats of bromination, as will be seen presently, change only slightly with the nature of the olefin.

Results

The two important chemical sources of error in the measurement of brominations and chlorinations by the method here outlined are the incompleteness of the reaction and the occurrence of substitution. Fortunately, both are readily detected, one by introducing into the stream of exit gases a Congo Red paper, the other by introducing a paper moistened with starch–potassium iodide solution. Both these tests were applied before and after each run and were so sensitive that 0.1% of the original halogen present as such or as hydrogen halide, could have been detected readily. Only runs in which both tests were negative are reported in the following. Samples of the dihalides were collected and their refractive indices taken, but no freezing curves studied.

Table II presents a summary of the results obtained in the brominations and chlorinations. The literature values for the refractive indices are from "I. C. T." except where otherwise stated. Where more than one experiment was performed on a compound, both the rate of flow of the gases through the calorimeter and the bromine:olefin ratio were varied, but no systematic trends in the heats were observed. The deviations from the given heats of halogenation in the column of "preliminary values" represent the average deviations from the mean values; the deviations from the final values are estimated total probable errors. Deviations of the measured refractive indices from the given figures are maximum deviations of individual samples from the mean.

The experiments with ethylene extended during a period of over four months, many adjustments and minor changes of technique being made between successive runs. Undoubtedly the earlier mentioned losses of bromine did not remain quite constant, which accounts for the rather large

---

(4) Dillon, Young and Lucas, THIS JOURNAL, **52**, 1953 (1930).

deviations from the mean. It is preferable, however, to use all these runs in forming the average since no safe clue is available for a rejection of some runs.

In experiments with propylene and higher hydrocarbons a Dry-Ice trap was placed in the gas stream before it reached the Congo Red paper, since otherwise a hydrolysis of the bromide caused a change in color of the test paper. In experiments with trimethylethylene difficulty was experienced in freeing the sample of the dibromide from the unreacted olefin and the product turned purple on standing in the air, presumably due to a loss of hydrogen bromide and rearrangement to a ketone caused by the moisture of the air.

Cyclohexene and isobutene could not be brominated because in both cases substitution took place. With the latter hydrocarbon much methallyl bromide was recovered.

Propylene and higher hydrocarbons could not be chlorinated successfully because substitution took place to an extensive and variable degree. No catalyst could be found to promote the quantitative chlorination of *cis*- and *trans*-dichloroethylenes at the temperature of the calorimeter.

Table III presents the results obtained in the bromination reaction with the repacked furnace and shows the deviations of the new results from the averages of the "preliminary" column of Table II. The deviations are not very constant, but an estimation on the basis of all available data suggests that they are not outside the limits of possible accidental errors. This is demonstrated best by a comparison of the propylene and the butene-1 reactions, the products of which surely will undergo combustion in much the same manner. These two series of runs followed one another and thus the furnace should have behaved also quite similarly. And yet the variations between the earlier and the new experiments with the two compounds differ appreciably. It is therefore preferable to interpret all variations in the fourth column of Table III as accidental and take their average for the correction of the third column of Table II. The so calculated values are given in the last column of Table II.

			Mean −173

It may be noted that no more trimethylethylene and *cis*-butene-2 were available at the time of the repeat runs and therefore the average from the other hydrocarbons in Table III was used to correct the data of Table II.

Discussion of the Results

Since the heat of addition of chlorine to ethylene was measured after the alteration of the analytical furnace, no significant systematic error should be involved in the results and the error of the average is of the same order of magnitude as the mean deviation and not more than 0.3%.

The same is not true for brominations: first, the individual values show greater scattering, due no doubt to the somewhat irreproducible losses of bromine in the platinum coated furnace; second, a semi-systematic error is introduced in correcting for bromine losses. The uncertainty from the first cause can be estimated as 0.3% (except for ethylene, where a slightly larger value is used), that from the second, as not more than 0.7%; altogether, then, somewhat less than 1%.

These imperfections, fortunately, do not disfigure the results to an extent large enough to void any of the following deductions; they leave the new data decidedly superior in accuracy to values which can be derived from combustion heats. A perusal of the standard reference works reveals that extremely little has been done on combustion of dihalides derivable from olefins by addition of halogens. In fact, the only available data are on ethylene dihalides, which have been summarized by Bichowsky and Rossini.[5] Using their values, the heats of the gaseous additions are found readily

$$C_2H_4 + Cl_2 = C_2H_4Cl_2 - 40.3 \text{ kcal.}$$
$$C_2H_4 + Br_2 = C_2H_4Cr_2 - 29.2 \text{ kcal.}$$

The agreement of these values with those here reported is as good as could be expected.

The series of olefins investigated in the bromine reaction is not very extensive but it includes those essential compounds, the study of which previously led to the establishment of the regularities of the heats of hydrogenation. It is possible, therefore, to draw a rather interesting conclusion that

---

(5) Bichowsky and Rossini, "Thermochemistry of Chemical Substances," Reinhold Publishing Corp., New York, N. Y., 1936.

the trend of the heats of the two reactions is in the opposite direction when the substitution on the ethylenic group is changed; with increasing substitution the heats of hydrogenation show a very decided decrease, the heats of bromination, on the other hand, show a less pronounced increase. This is brought out very clearly in Fig. 2.

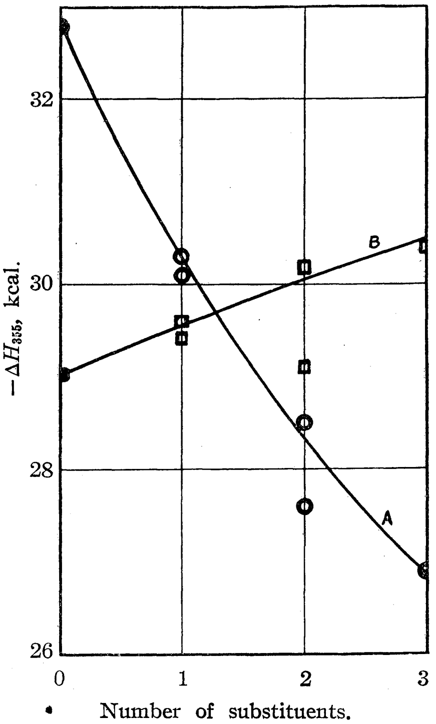

Fig. 2.—The effect of substituents on the heats of reactions: curve A, hydrogenations; curve B, brominations.

Some time ago it was suggested that the heats of iodination of olefins follow the same trend[6] as the heats of hydrogenation. This conclusion was reached, however, on the basis of rather limited and not too accurate experimental material and must be revised in view of the present findings on the heats of brominations. The iodination of butene-1 is in reality probably more exothermic than that of ethylene. This conclusion can be reconciled with the experimental data presented in the cited work; consequently the entropy changes in the two reactions are significantly different.

The opposite trends in the hydrogenation and halogenation reactions suggest that the changes themselves are due not so much to variations in the strength of the ethylenic bond as to variable bond strengths of the addenda; they must be subject to constitutional influences from the groups attached to the ethylenic system. These effects may be termed for short steric, although a naïve interpretation based on the volume requirements of the different atoms and radicals involved leads to completely wrong conclusions. Indeed, a replacement of the small hydrogen atoms by the more bulky methyl radicals in ethylene, reduces the heat of addition of the small hydrogen atoms but enhances that of the larger bromines. A qualitatively correct interpretation is offered by considerations of electrostatic induction effects. The replacement of an electropositive hydrogen atom by a more electronegative methyl radical should make the ethylenic carbon atom more electropositive and therefore favor the addition of bromine, making the addition of hydrogen less exothermic. It is very doubtful, however, whether such effects are strong enough to account for some 6 kcal./mole change in the reaction heats and, besides, another effect must be included, the direct electrostatic attraction or repulsion of the atomic groups in ethylene on the addenda. Evidently this action will cause opposite trends in the reaction heats from those just deduced and the over-all effect is in doubt.

Whatever may be the correct atomistic interpretation of the results here described, they serve admirably to explain on a thermodynamic basis the so-called Markownikoff rule, which states that normally the addition of hydrogen halides to olefins occurs so that the halogen adds to a more highly substituted carbon atom. To give this interpretation a quantitative character, it is necessary to formulate a rule which may be stated as follows. The heat of addition to the ethylenic linkage is the sum of two nearly independent terms, the heats of addition to each of the two ethylenic carbon atoms. The heats of hydrogenation provide a sound basis for this rule; they show that, except for effects of conjugation, only atoms or radicals once removed in the molecule have significant effects upon one another. Upon addition to the ethylenic bond, however, the addenda are twice removed from each other and therefore only minor interaction should be expected between them.

The lowering of the heat of hydrogenation in going from ethylene to propylene means therefore that less heat is evolved on adding hydrogen in a secondary position, the lowering being equal to the

---

[6] Cline and Kistiakowsky, *J. Chem. Phys.*, **5**, 990 (1937).

difference in observed reaction heats. On the contrary, an increase of the heat of bromination means that the addition of bromine in a secondary position is accompanied by more heat evolution than that in the primary one.

Reasoning in this manner it is possible to account for all our previous observations to about 1 kcal. accuracy, which is therefore to be considered as the accuracy of the enunciated rule.

If the rule is generally correct, then the heat of addition of hydrogen halide must be an average of the heats of addition of hydrogen and halogen, corrected by the heat of formation of the hydrogen halide. Using combustion data this comparison may be made and is shown in Table IV. The values of the first column of heat data were all derived from figures given by Bichowsky and Rossini;[5] the figures in the last column are averages of the observed heats of hydrogenation and halogenation, the heat of iodination being derived from equilibrium measurements[7] and therefore subject to a larger uncertainty. These data were converted to 25° by deducting 0.2 kcal. and corrected by the heat of formation of the hydrogen halide. The agreement of the two columns is well within the combined experimental errors, which shows that even a profound change of one of the addenda leaves unaltered the heat of addition of the other one.

TABLE IV

HEATS OF ADDITION OF HALOGEN ACIDS TO ETHYLENE

	From heats of combustion: ΔH, kcal./mole	Calculated ΔH in kcal./mole
$C_2H_4 + HCl = C_2H_5Cl$	−14.6	−15.9
$C_2H_4 + HBr = C_2H_5Br$	−17.9	−18.3
$C_2H_4 + HI = C_2H_5I$	−17.9 (?)	−21.4 (±1)

A further interesting case, which tests the rule, is the addition of hydrogen bromide to isobutene to form the tertiary bromide. The heat of this reaction has been calculated from the equilibrium measurements[8] and the value, 18.9 kcal./mole, is fairly accurate (±0.9 kcal.). The heat of addition of bromine to isobutene has not been measured but by analogy with hydrogenations it may be taken to be identical with the heat of bromination of *cis*-butene-2, *i. e.*, 30.0 kcal. at room temperature. The difference of this value from that found for ethylene (28.9) will be attributed to the addition on the tertiary carbon atom. Hence for this reaction we can write: isobutene + $^1/_2$ Br_2 (in tertiary position) = 30.0 − $^1/_2$(28.9) = 15.5 kcal. Hydrogen addition occurs in the primary position and therefore one half of the heat of hydrogenation of ethylene (16.3 kcal.) applies to this reaction. Together 31.8, and when this figure is corrected for the heat of formation of hydrogen bromide (Bichowsky and Rossini;[7] −12.4 kcal. from the gaseous elements), the result is 19.4 kcal. in excellent agreement with the directly measured figure.

The heats of addition of hydrogen chloride and hydrogen iodide to isobutene are 17.1[8] and 19.1[9] kcal., respectively. It is thus evident by comparison with Table IV that addition of chlorine or iodine in tertiary position is accompanied by an increased heat evolution similar to that discussed above for bromine.

Under normal conditions in the liquid reaction and certainly in the gas phase, the tertiary bromide is formed in preference to isobutyl bromide; this is according to the Markownikoff rule and, as we can now show, means that in the reaction the thermodynamically more stable compound results. Indeed, the heat of formation of isobutyl bromide, according to the enunciated rule, is made up of 14.4 kcal. for the addition of bromine in the primary position (as in ethylene) and 28.2 − $^1/_2$(32.6) = 11.9 for hydrogen (heat of hydrogenation of isobutene less one half the heat of hydrogenation of ethylene). Together 26.3 kcal., which, when corrected by the heat of formation of hydrogen bromide, gives 13.9 kcal. and shows that isobutyl bromide is considerably less stable than the tertiary compound, since its entropy cannot be so much larger as to overcome the exothermicity of the reaction to form the tertiary compound. In the cited work it was found that the equilibrium constant in the reaction isobutyl chloride–tertiary butyl chloride was somewhat larger than 10 at 270°. Assuming zero entropy change in the reaction between the bromides at 270°, an equilibrium constant of 10^2 is calculated in close agreement with the above value for the chlorides.[10]

On the whole it appears then that the Markownikoff rule, although it deals with the essentially kinetic problem of the relative rates of two competing reactions, can be correlated with the thermodynamic stability of the preferentially formed

(8) Kistiakowsky and Stauffer, THIS JOURNAL, **59**, 165 (1937).

(9) Jones and Ogg, *ibid.*, **59**, 1943 (1937).

(10) Similar conclusions can be drawn from the work of Brouwer and Wibaut [*Rec. trav. chim.*, **53**, 1001 (1934)] on the formation of and equilibrium between the primary and secondary propyl bromides and chlorides. See also Schjånberg, *Z. physik. Chem.*, **A172**, 197 (1935).

compound. It is obviously incorrect to postulate a close proportionality between the free energy decrease in a reaction and the rate at which it occurs, since too many exceptions to such a correlation can be cited. Nevertheless, in a series of homologous reactions a correlation of this type must frequently exist. Some cases have been discussed earlier.[11] Also in the field of catalytic reactions two instances may be cited; in the series of hydrogenations from ethylene to tetramethylethylene, studied calorimetrically, the heats of the addition decrease markedly; simultaneously the speed of the reaction on a given catalyst decreases also; thus the copper catalyst used could hydrogenate ethylene instantaneously even at 0°, but with tetramethylethylene it was ineffective even at 80° and the intermediate compounds fell in between these limits. On the other hand, the heats of bromination rise with increasing substitution; in parallel to this an increasing activity of the calcium bromide catalyst was observed.

Kharasch and others have cited instances when the Markownikoff rule breaks down, the condition apparently being that the reaction be catalyzed by oxygen or a peroxide. This effect is not noted in the gas phase reaction[8,9] and is undoubtedly due to the promotion of a chain reaction, in the course of which the peroxide or some other intermediate adds temporarily to one end of the double bond. This is then blocked for the addition of one of the atoms in the hydrogen halide and the reaction is forced to take the unnatural course.

Another instance where the rates of reaction seem to change parallel to the heat content changes in a series of analogous reactions, is the substitution of bromine in hydrocarbons. Since the reaction may be looked upon formally as a dehydrogenation, followed by addition of hydrogen bromide, the calculations discussed on the previous pages may be again employed. It is thus readily found that the substitution of bromine in a primary position is accompanied by 10.5 kcal. heat evolution, substitution in the secondary one by 13.6 and that in the tertiary one by 16.0 kcal. The increasing heat evolution in this order is wholly paralleled by the well-known kinetic tendency of bromine to replace hydrogen on the most highly substituted carbon atom of a hydrocarbon molecule.

The opposite trends of the heats of hydrogenation and bromination, so prominent in the ethylenic series, must be limited to those molecules where the changes of the reaction heats are conditioned by the interactions of the addenda with the neighboring groups. In particular, a decrease in the heat of hydrogenation due to the existence of conjugation in a diene or some other conjugated system, must be paralleled by a similar decrease of the heat of bromination, unless the now accepted theory of conjugation is incorrect and the phenomenon is not a stabilization of the double bond system by mutual interaction. There is thus offered, in the comparative study of the hydrogenation and the bromination heats, a more reliable and accurate method for a differentiation between conjugation energies and "steric" effects, than is possible from the analysis of the hydrogenation data alone; it is hoped to put this idea into practical form in the near future.

The failure to measure the heat of bromination of isobutene merits a brief comment. It has been known for some time[12] that upon addition of halogens to isobutene there is a tendency to form methallyl halide and free halogen acid. Under the conditions of bromination in the calorimeter this last reaction is thermodynamically possible, which conclusion is arrived at by comparison with the equilibrium between isobutene, hydrogen bromide and *t*-butyl bromide.[8] The noteworthy point is, however, that neither propylene nor trimethylethylene gives rise to such a reaction when brominated under *identical* conditions, although in at least one of these cases the equilibrium must be as favorable for decomposition of the dibromide as with isobutene. Thus purely kinetic factors of undetermined but highly specific nature must make the decomposition of the dibromide of isobutene occur exceptionally rapidly.

In concluding this discussion it may be pointed out that the difference of the heats of bromination of the *cis*- and *trans*-butenes-2 is quite close to the difference in their heats of hydrogenation. In the latter of these reactions the same end product is obtained, but the bromination of *cis*-butene-2 leads to the *dl*-mixture, while *trans* gives the *meso* form of the dibromide.[4] It is therefore evident that the heat content difference of these two compounds is quite small, if not zero.

Acknowledgment.—The late Professor E. P. Kohler has given us, as usual, much helpful ad-

vice and we are also grateful to Dr. J. B. Conant for his valuable suggestions. Dr. W. E. Vaughan and Dr. Ralph D. Thompson have taken part in the early stages of this work.

Summary

Certain brominations and chlorinations have been studied calorimetrically, the following being the results

$$C_2H_4 + Br_2 = C_2H_4Br_2 - 29{,}058 \pm 300 \text{ cal.}$$

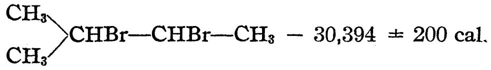
$$C_3H_6 + Br_2 = C_3H_6Br_2 - 29{,}412 \pm 200 \text{ cal.}$$

$$H_2C{=}CH{-}C_2H_5 + Br_2 = CH_2Br{-}CH_2Br{-}C_2H_5 - 29{,}585 \pm 200 \text{ cal.}$$

$$trans\text{-}H_3C{-}CH{=}CH{-}CH_3 + Br_2 = i\text{-}CH_3{-}CHBr{-}CHBr{-}CH_3 - 29{,}075 \pm 200 \text{ cal.}$$

$$cis\text{-}H_3C{-}CH{=}CH{-}CH_3 + Br_2 = dl\text{-}CH_3{-}CHBr{-}CHBr{-}CH_3 - 30{,}177 \pm 200 \text{ cal.}$$

$$(CH_3)_2C{=}CH{-}CH_3 + Br_2 =$$



$$(CH_3)_2CBr{-}CHBr{-}CH_3 - 30{,}394 \pm 200 \text{ cal.}$$

$$C_2H_4 + Cl_2 = C_2H_4Cl_2 - 43{,}653 \pm 120 \text{ cal.}$$

All heats of reaction refer to 355°K. and gases at one atmosphere total pressure.

The most notable conclusion to be drawn from these data is that substitution on the ethylenic group results in increased heat evolution on addition of bromine, while previously it was found to decrease the heat of hydrogenation.

It is pointed out that the observed trends give a thermodynamic basis to the so-called Markownikoff rule and to the trend of bromine to replace hydrogen on the most substituted carbon atom of a saturated hydrocarbon. A rule is formulated which makes possible a calculation of quite accurate heats of addition of hydrogen halides and of substitution of bromine.

The Solubility of Carbon Dioxide in Deuterium Oxide at 25°[1]

BY JAMES CURRY AND C. L. HAZELTON

In the course of measuring the first ionization constant of deuterio-carbonic acid, it was found necessary to determine the solubility of carbon dioxide in deuterium oxide. This measurement is of interest in itself since, up until the present, no values for the solubility of gases in deuterium oxide have appeared in the literature.

Experimental

Apparatus.—The apparatus used was of the Ostwald type[2] and the measurements were carried out by means of the "dry method." The buret, which was surrounded by a water jacket, had a volume of 10 cc. and was graduated in 0.05 cc. The absorption vessel had a volume of approximately 7 cc. The buret and the absorption vessel were connected by a flexible piece of copper tubing 1.5 meters long and 1 mm. internal diameter. In order to fasten the copper tubing to the glass, short pieces of 7-mm. glass tubing were sealed to the three-way capillary stopcocks which were at the top of the buret and the absorption vessel. The copper tubing was inserted to a depth of about 3 cm. into the glass tubing and the joints were then made fast with picein. In order to minimize breakage the copper tubing was held by a brass clamp at a point near the picein joint at the buret stopcock. This clamp in turn was fastened to the ringstand which held the buret. Another type of brass clamp, acting as a splint, strengthened the other copper–picein–glass joint at the absorption vessel. This mode of connection permitted a vigorous shaking of the absorption vessel but when necessary it was very simple to disconnect the latter.

Materials.—The carbon dioxide came from a commercial tank. It was analyzed by absorption in a potassium hydroxide solution and was found to be 99.8% pure.

The deuterium oxide was from a commercial source and at the beginning of the measurements was 99.9% D_2O. It was purified by distillation from alkaline permanganate, then from phosphoric anhydride and finally carried through a distillation without any reagents in a still especially reserved for this purpose. Before use the deuterium oxide was refluxed in order to remove any dissolved gases. During this operation it was protected from the atmosphere by means of a soda lime–calcium chloride tube. After the solubility measurements were completed the deuterium oxide was used for ionization constant determinations and when these were finished the analysis was 99.1% D_2O.

Measurements.—These were carried out in the usual manner except that a few slight modifications were necessary because the quantities of deuterium oxide used were relatively small and deuterium oxide is hygroscopic. During a measurement the absorption vessel was shaken in a thermostat adjusted to 25.00 ± 0.01°. The absorption vessel contained a short piece of 1-mm. copper wire which moved about during the shaking and thus aided in

---

[2] Just, *Z. physik. Chem.*, **37**, 342 (1901).

lessening the time required to reach equilibrium. The amount of water in the absorption vessel was obtained from the weight of the dry vessel and the weight of the vessel plus contents at the end of the measurements, allowance being made for the weight of the carbon dioxide present.

Equilibrium was established in about ten minutes. The vessel was then allowed to stand for fifty minutes in contact with the carbon dioxide and was then shaken for a few minutes. No additional absorption was ever noted.

Results

In order to test the apparatus, measurements were also made on the solubility of carbon dioxide in ordinary water. The experiments were carried out in exactly the same way except that H_2O was used in place of D_2O. Thus if any errors were present while one kind of water was being used they also would be present during the measurements with the other kind of water. The experimental data and the calculated results are given in the table.

SOLUBILITY OF CARBON DIOXIDE IN H_2O AND D_2O AT 25°

The total volume of the absorption vessel was 6.811 cc. except in the first experiment with H_2O, where it was 8.868 cc.

There is no general agreement as to the best method for expressing the solubility of gases in liquids. We have chosen the Ostwald coefficient, λ, *i. e.*, the volume of gas (measured at experimental conditions) absorbed by unit volume of liquid, because it is often used in theoretical discussions.

In order to determine the partial pressure of the carbon dioxide in the absorbing vessel it was necessary to know the vapor pressures of the two waters at 25°. For deuterium oxide the value 20.7 mm. was used.[3]

As mentioned previously, the composition of the deuterium oxide changed slightly during the experiment. The average composition was taken as 99.8% D_2O. Thus in calculating the above results $d^{25}{}_4$ was taken as 1.1042. In the calculations correction was made for the slight amount of impurities in the carbon dioxide.

Discussion

Shedlovsky and MacInnes[4] have made the most recent determination of the solubility of carbon dioxide in H_2O. The value they obtained was 0.03372 mole per liter per atmosphere. In terms of the Ostwald coefficient this corresponds to $\lambda = 0.825$. Our value agrees with theirs well within our experimental error, which is less than 1%, so we can conclude that our results are fairly reliable. It should be pointed out that the precision obtainable in solubility measurements is largely determined by the quantities of water used. With the present high cost of D_2O it is necessary to make some sacrifice in precision.

Thus, from our data, it is apparent that the values for the Ostwald coefficient for carbon dioxide in H_2O and D_2O are the same within less than 1%. Consequently on a molal basis (moles/1000 g. of water) carbon dioxide is less soluble in D_2O than in H_2O, the respective solubilities being 0.0304 and 0.0337 molal when the partial pressure of carbon dioxide is one atmosphere.

This result is about what one would expect from theory. It has been known for a long time that there usually is at least a qualitative relationship between solubility of a gas and surface tension of the solvent. Uhlig[5] has been one of the latest to attempt a quantitative expression. Early workers reported a difference of about 7% in the surface tension of the two kinds of waters but this result has not been substantiated. Jones and Ray[6] found that the surface tensions were the same within 0.054%. Thus one would expect no great difference in the solubility of a gas, such as carbon dioxide, in the two waters, particularly since, in addition, the values for the dielectric constants are the same within 1%.[7]

We are indebted to the Class of 1900 Fund for a

grant which enabled us to purchase the deuterium oxide used in this work.

Summary

The solubility of carbon dioxide in 99.8% D_2O at 25° has been measured relative to its solubility in H_2O at the same temperature. In terms of the Ostwald coefficient the solubilities are the same within less than 1%. On a molal basis this means that carbon dioxide is 0.902 times as soluble in D_2O as in H_2O.

The First Thermodynamic Ionization Constant of Deuterio-carbonic Acid at 25°[1]

BY JAMES CURRY AND C. L. HAZELTON

Introduction

Since carbon dioxide plays an important role in many physiological processes and the effect of deuterium oxide on living matter has been studied extensively, it is of importance to determine the strength of deuterio-carbonic acid. From the standpoint of chemical theory the strength of this acid is also of interest.

The method used in this work followed that of Korman and La Mer[2] very closely. In this paper it was shown that heavy water studies could be made using a quinhydrone electrode in cells without transference of the type developed by Harned and Ehlers.[3] On account of the cost of deuterium oxide the measurements were limited to a relative determination of the first thermodynamic ionization constants of proto- and deuterio-carbonic acid in dilute solutions. No extrapolation to infinite dilution was attempted.

Measurements were made using the following cells

$$\text{Pt, Q, QH}_2\text{, H}_2\text{CO}_3\text{, KHCO}_3\text{, KCl, AgCl, Ag} \qquad \text{(I)}$$

$$\text{Pt, Q, QD}_2\text{, D}_2\text{CO}_3\text{, KDCO}_3\text{, KCl, AgCl, Ag} \qquad \text{(II)}$$

As is well known, the potential of cell I is given by

$$E = E_0 - \frac{RT}{F} \ln m_{\mathrm{H}} m_{\mathrm{Cl}} - \frac{RT}{F} \ln f_{\mathrm{H}} f_{\mathrm{Cl}} \qquad (1)$$

where the E_0 term includes the standard electrode potential for the quinhydrone and the silver–silver chloride electrodes in H_2O, m is the concentration in molal terms and f is the activity coefficient of the quantities indicated by the subscripts.

The primary dissociation of proto-carbonic acid may be written in the following manner

$$CO_2 + H_2O \rightleftarrows H_2CO_3 \rightleftarrows H^+ + HCO_3^-$$

The first thermodynamic ionization constant for proto-carbonic acid is accordingly

$$K_{\mathrm{H}} = \frac{m_{\mathrm{H}}\, m_{\mathrm{HCO_3}}}{m_{\mathrm{CO_2}}} \cdot \frac{f_{\mathrm{H}}\, f_{\mathrm{HCO_3}}}{f_{\mathrm{CO_2}}} \qquad (2)$$

where $m_{\mathrm{CO_2}}$ represents the total concentration ($CO_2 + H_2CO_3$) of dissolved carbon dioxide in molal terms.[4] A similar expression would hold for the thermodynamic ionization constant of deuterio-carbonic acid, K_{D}.

Replacing m_{H} in (1) by its value from (2) we obtain for the e. m. f. of cell I

$$E = E_0 - \frac{RT}{F} \ln \frac{m_{\mathrm{Cl}}\, m_{\mathrm{CO_2}}}{m_{\mathrm{HCO_3}}} - \frac{RT}{F} \ln K_{\mathrm{H}} - \frac{RT}{F} \ln \frac{f_{\mathrm{Cl}}\, f_{\mathrm{CO_2}}}{f_{\mathrm{HCO_3}}} \qquad (3)$$

In order to determine K_{H} this expression may be put into a somewhat more convenient form. In an aqueous solution, in the region of a partial pressure of 760 mm., carbon dioxide obeys Henry's law so we may say that $m_{\mathrm{CO_2}} = hp_{\mathrm{CO_2}}$ where h is a constant. Using this expression and rearranging (3) we obtain

$$\log K_{\mathrm{H}} = \frac{E_0 - E}{0.0591} - \log \frac{m_{\mathrm{Cl}}}{m_{\mathrm{HCO_3}}} - \log h - \log p_{\mathrm{CO_2}} - \log \frac{f_{\mathrm{Cl}}\, f_{\mathrm{CO_2}}}{f_{\mathrm{HCO_3}}} \qquad (4)$$

The similar expression which holds for cell II is

$$\log K_{\mathrm{D}} = \frac{E_0' - E}{0.0591} - \log \frac{m_{\mathrm{Cl}}'}{m_{\mathrm{DCO_3}}'} - \log d - \log p_{\mathrm{CO_2}} - \log \frac{f_{\mathrm{Cl}}'\, f_{\mathrm{CO_2}}'}{f'_{\mathrm{DCO_3}}} \qquad (5)$$

The prime terms refer to the values for D_2O and d corresponds to h except that it refers to the solubility of carbon dioxide in D_2O.

Since carbon dioxide is a neutral molecule its activity will be unaffected by ions in dilute solutions so we may put $f_{\mathrm{CO_2}} = f_{\mathrm{CO_2}}' = 1$.[5] If the

[3] Harned and Ehlers, *ibid.*, **54**, 1350 (1932).

[4] For a discussion of this expression see MacInnes and Belcher, *ibid.*, **55**, 2630 (1933).

[5] This statement is not absolutely true due to the salting-out effect of the electrolytes on the carbon dioxide. The influence of this factor will be considered later.

molal concentration of potassium chloride is about the same as that of potassium bicarbonate, then in dilute solutions, since they are both uni-univalent electrolytes, their respective activity coefficients will be practically equal, so in (4) and (5) the last logarithmic term on the right-hand side will be almost zero and consequently may be neglected. This will be true for both the H_2O and D_2O solutions. Even if these terms do not vanish completely they should be the same in H_2O and D_2O solutions of the same molal concentrations since the dielectric constant of H_2O is nearly identical with that of D_2O. Therefore, in order to determine the ratio of ionization constants it is only necessary to determine K_H and K_D at one and the same ionic strength. The measurements should be carried out in dilute solutions which have been made up so that m_{Cl} and m_{HCO_3} (or m'_{Cl} and m'_{DCO_3}) are about equal. A discussion of the remaining quantities in equations (4) and (5) will be given later.

Experimental

Materials.—The carbon dioxide was obtained from a commercial tank and was 99.8% pure. The deuterium oxide was purified as previously described[6] and at the end of the measurements was 99.1% D_2O. Eastman Kodak Co. quinhydrone was used without further purification. The potassium bicarbonate was purified by the method of MacInnes and Belcher[4] (p. 2633) and the potassium chloride was recrystallized twice from distilled water and dried at 120°. A semi-micro balance was used in making up the D_2O solutions.

Electrodes.—The silver–silver chloride electrodes were prepared by the method of Brown.[7] Pairs showing a potential difference of not more than 0.05 mv. were used in each experiment. The platinum electrodes were of the spiral type and were kept in cleaning solution when not in use. They agreed with each other better than 0.05 mv. Before insertion into the cells, both types of electrodes were well rinsed with the appropriate solution. This required about 1.6 cc. per electrode.

Cells.—Two identical cells (A and B) were used and all measurements were carried out in duplicate. Each cell was shaped like the letter H. The two side arms had an inside diameter of 8 mm. and a length of 8 cm. and were of course closed at the bottom. The top of each arm was widened out so that it would take a no. 2 rubber stopper. The two side arms of a cell were connected by means of a stopcock which had a 1.5-mm. bore. The connection tubes were sealed in just where the side arms started to widen out and the stopcocks were greased only at the top and bottom. Each rubber stopper carried an electrode, an inlet tube for the introduction of carbon dioxide and an outlet tube. The total amount of solution needed for each cell was about 6 cc. The cells were immersed in a thermostat adjusted to 25.00 ± 0.01°.

Before the carbon dioxide entered the cell it was saturated with water vapor by allowing it to bubble through a trap immersed in the thermostat and filled with the appropriate water. After bubbling through the cell solution the carbon dioxide escaped into the air through a tube which dipped just under the surface of some paraffin oil.[8] Thus the pressure of carbon dioxide over the solution was essentially equal to the atmospheric pressure minus the vapor pressure of water in the cell. The gas connections were arranged so that the pressure was the same in all four compartments. It should be pointed out that carbon dioxide was bubbled through both the quinhydrone and the silver–silver chloride electrode compartments. This was done in order to eliminate the possibility of any liquid junction potential.

Experimental Procedure.—Measurements were made with a Leeds and Northrup type K potentiometer and a type R galvanometer. The standard cell was checked against one calibrated by the Bureau of Standards. Measurements were made first with H_2O and then with D_2O. Reproducible results were obtained without resorting to a vacuum technique to remove oxygen. In making measurements the appropriate solution was first saturated with carbon dioxide and then part of it was put in cell A and part in cell B. Quinhydrone was then added, the stoppers inserted tightly and carbon dioxide bubbled through the cells with the stopcocks closed. A gentle flow of gas was maintained except when e. m. f. measurements were actually being made. Equilibrium was established in about thirty minutes and the potential of any one cell remained constant within 0.2 mv. for a period of two to three hours. After equilibrium was established the e. m. f. values were the same whether or not the stopcocks were open.

Results and Discussions

In order to test the method, apparatus and materials the thermodynamic ionization constant for acetic acid in H_2O was determined using the above method except that acetic acid and potassium acetate were used instead of carbon dioxide and potassium bicarbonate. At an ionic strength of 0.06132 the ionization constant was found to be 1.75×10^{-5}, which is in good agreement with the value in the literature.[9]

Table I lists our experimental data and the calculated results.

Several of the quantities in equations (4) and (5) require further discussion. E_0 was obtained from Harned and Wright's[10] data for the quin-

(8) With this technique it is conceivable that the cell solution became supersaturated with carbon dioxide. If such an effect did occur it must have been small because, as will be pointed out later, our value for K_H agrees well with careful measurements made by other workers. Even if supersaturation did occur it should be practically the same in H_2O and D_2O and accordingly have no appreciable effect on K_H/K_D.

$K_H/K_D = 2.68$

hydrone electrode and the silver–silver chloride electrode. The term E_0' is made up of the standard electrode potential of quinhydrone in D_2O and the standard electrode potential for the silver–silver chloride electrode in D_2O. The quinhydrone potential was obtained from the work of La Mer and Korman,[11] and is equal to -0.7341 v. The standard electrode potential of the silver–silver chloride electrode should be the same in D_2O as in H_2O since there is no theoretical reason for thinking that f_{Cl} and f'_{Cl} differ, provided the molal concentrations of the chloride ions are the same in the two kinds of water.

The terms h and d are the Henry's law constants for the molal solubility of carbon dioxide in H_2O and D_2O when the partial pressure of this gas is expressed in mm., and these, or rather their logarithms, have been calculated from some previous work done by us.[6] In very exact work the salting out effect of the electrolytes on the carbon dioxide should be considered but this often is neglected. At the ionic strengths we used, if this correction were made the values of K_H and K_D recorded above would have to be increased by about 0.7%. This correction would certainly be practically the same for both kinds of water and accordingly would not affect the K_H/K_D ratio given above.

No account has been taken of the secondary dissociation of carbonic acid. This is allowable since it is very small ($K_{II} = 7 \times 10^{-11}$) compared to the first dissociation. It also should be pointed out that the solution actually used for cell II was made up using $KHCO_3$ but exchange must take place very rapidly and at the concentrations used the equilibrium point should be far over on the $KDCO_3$ side.

In order to establish the reliability of our measurements it is necessary to compare our values for K_H with those recorded in the literature. Up until a few years ago it was thought that K_H was equal to 3.5×10^{-7} at 25°. Recently, however, MacInnes and associates redetermined K_H using two methods; with a glass electrode[4] they found K_H equaled 4.5×10^{-7}, and by conductivity methods[12] to be 4.3×10^{-7}.

Our value of 4.5×10^{-7} agrees very well with that of MacInnes and Belcher at the same ionic strength. Of course we used a potentiometric method also but ours differed considerably from theirs in respect to details.

The heavy water used in determining the above K_H/K_D ratio was at least 99.1% D_2O. To a first approximation the curve $K_H/K_D - N_{D_2O}$ is linear and this would mean that for 100% D_2O the ratio would be greater but certainly not more than 1% higher. Since this is less than the precision of our measurements this correction will not be applied.

It is of interest to compare our results with those of other workers. Rule and La Mer,[13] making very careful measurements on five acids, found that the K_H/K_D ratio increases as the strength of the acid decreases. This is in accordance with the prediction of Lewis and Schutz and the theory of Halpern.[14] From the Rule–La Mer data one might expect for carbonic acid a ratio of 3.6.

---

(12) Shedlovsky and MacInnes, *ibid.*, **57**, 1705 (1935).

(13) Rule and La Mer, *ibid.*, **60**, 1974 (1938).

(14) Lewis and Schutz, *ibid.*, **56**, 1913 (1934); Halpern, *J. Chem. Phys.*, **3**, 456 (1935).

Our value, 2.68, is 25% smaller, and this difference is much greater than our experimental error which is about 2%. However, it should be remembered that carbonic acid is a peculiar acid in that the proton (or deuteron) must come exclusively from the water. Thus the hydration equilibrium plays an important role and it probably will not be the same in H_2O and D_2O. This factor may account for the difference mentioned above.

We are indebted to the Class of 1900 Fund for a grant which enabled us to purchase the deuterium oxide used in this work.

Summary

The ratio of the first thermodynamic ionization constants of proto- and deuterio-carbonic acid has been determined potentiometrically using a cell without transference in which the electrodes were quinhydrone and silver–silver chloride. Using 99.1% D_2O the ratio, K_H/K_D, has been found to be 2.68 at 25°.

Conductivities of Concentrated Mixtures of the Nitrates of Some Uni-, Di-, and Trivalent Cations in Aqueous Solution

BY PIERRE VAN RYSSELBERGHE AND GOON LEE

As a further step in our investigation of the conductivity of concentrated mixtures of strong electrolytes[1] we have studied a number of nitrates of uni-, di-, and trivalent cations at different total concentrations ranging from 1 to 5 *N*. All possible types of binary mixtures have been included: two univalent cations, one uni- and one divalent cation, two divalent cations, one uni- and one trivalent cation, one di- and one trivalent cation, two trivalent cations. The method was essentially the same as in our previous work. The conductivities of the pure salts were found to be in close agreement with the existing standard data (I. C. T.; L. B. R.), except in three cases [$LiNO_3$, $Mg(NO_3)_2$, $Cr(NO_3)_3$] for which the standard data seem to be somewhat in error. Moreover, some conductivities of pure salts are reported here for the first time. Others have been obtained for the first time at 25°. The results are recorded in Table I in which we give the conductivities of twenty types of mixtures arranged in series corresponding to the same total equivalent concentration. We represent by x and $1-x$ the fractions of the total equivalent concentration corresponding to salts 1 and 2, salt 1 being the first in the title of the series. For each solution we give the specific and the equivalent conductivity and the difference $\Delta\Lambda$ between the measured conductivity and that calculated from the simple, uncorrected mixture rule:

$$\Lambda = x\Lambda_1 + (1 - x)\Lambda_2$$

Two series of mixtures (19 and 20) contain nitric acid as one of the components, the maximum amount of nitric acid present being in both cases half the total normality.

Discussion

In all the mixtures, except those of chromium nitrate with cadmium nitrate and of chromium nitrate with aluminum nitrate, the conductivity calculated according to the mixture rule is larger than the measured conductivity. As previously observed with other types of mixtures, the maximum difference between measured and calculated conductivities in a series of given total equivalent concentration follows the same trend as the difference between the conductivities of the pure salts. This is shown in Table II where the various groups of mixtures are classified according to the value of the difference λ between the conductivities of the pure salts, $\Delta\Lambda$ being the largest departure from the mixture rule in the series. If one excludes the mixtures of chromium nitrate with cadmium and aluminum nitrates and those containing nitric acid, Table II could be combined with the corresponding tables of our previous papers. We note, however, that $\Delta\Lambda$ for 1 N mixtures of $KNO_3 + NaNO_3$ is larger than for the 1 molal mixtures previously studied.

TABLE II

N	Mixtures	λ	$-\Delta\Lambda$
2	$HNO_3 + Cd(NO_3)_2$	241.94	8.97
2	$HNO_3 + KNO_3$	210.43	6.95
2	$KNO_3 + Cr(NO_3)_3$	43.30	1.88
3	$KNO_3 + Cd(NO_3)_2$	33.80	2.32
3	$KNO_3 + Al(NO_3)_3$	33.24	1.89
2	$KNO_3 + Cd(NO_3)_2$	32.12	1.94
1	$KNO_3 + Cd(NO_3)_2$	30.06	2.11
3	$KNO_3 + Cu(NO_3)_2$	28.10	1.95
2	$KNO_3 + Cu(NO_3)_2$	26.32	1.47
3	$KNO_3 + Zn(NO_3)_2$	25.24	0.66
1	$Al(NO_3)_3 + Cr(NO_3)_3$	20.04	− .77
1	$KNO_3 + NaNO_3$	16.69	.85
3	$KNO_3 + NaNO_3$	16.58	.48
2	$KNO_3 + NaNO_3$	16.15	.65
5	$LiNO_3 + Cd(NO_3)_2$	12.96	.79
2	$Al(NO_3)_3 + Cr(NO_3)_3$	12.56	−1.17
4	$LiNO_3 + Al(NO_3)_3$	12.23	0.40
2	$Cd(NO_3)_2 + Cr(NO_3)_3$	12.21	− .78
3	$LiNO_3 + Cd(NO_3)_2$	12.04	.28
4	$Zn(NO_3)_2 + Cd(NO_3)_2$	8.43	.25
5	$Mg(NO_3)_2 + Cd(NO_3)_2$	8.25	.92
3	$Zn(NO_3)_2 + Al(NO_3)_3$	8.00	1.04
3	$Mg(NO_3)_2 + Cd(NO_3)_2$	7.13	0.26
5	$NaNO_3 + LiNO_3$	5.83	.39
2	$Cu(NO_3)_2 + Cd(NO_3)_2$	5.65	.08
3	$Cu(NO_3)_2 + Cd(NO_3)_2$	5.58	.04
3	$LiNO_3 + Mg(NO_3)_2$	4.63	.15
4	$LiNO_3 + Zn(NO_3)_2$	4.32	.08
4	$Al(NO_3)_3 + Cr(NO_3)_3$	2.18	−1.54
4	$Cd(NO_3)_2 + Cr(NO_3)_3$	1.42	−1.06
4	$Cd(NO_3)_2 + Al(NO_3)_3$	0.52	0.09

The behavior of the $Cr(NO_3)_3 + Cd(NO_3)_2$ and $Cr(NO_3)_3 + Al(NO_3)_3$ mixtures seems abnormal, particularly in 4 N solutions where some mixtures exhibit larger conductivities than those of the two pure salts. We have noticed that the slope of the conductivity curve of $Cr(NO_3)_3$ is, at least in the range of concentrations here studied, appreciably smaller than the slopes for the other nitrates, these being all nearly equal. When the conductivities of $Cr(NO_3)_3$ and of the other salt in the mixture are nearly equal, there is a positive $\Delta\Lambda$ due to this difference in the slopes. When the conductivities are quite different, as in the 2 N mixtures with KNO_3, $\Delta\Lambda$ is negative because the effect of this difference is larger than that of the difference in the slopes.

On account of the very large difference between the conductivity of pure nitric acid and that of KNO_3 or $Cd(NO_3)_2$ we would expect $-\Delta\Lambda$ to be much larger than is observed. We found in our previous work that, with salts, a difference of 100 in Λ corresponds to a $\Delta\Lambda$ of 14 to 16. The abnormal behavior of mixtures containing acids was pointed out in one of our papers and is evidently connected with the peculiar mechanism of proton conductivity. A common ion effect on the degree of ionization of nitric acid would tend to increase the lowering of the conductivity with respect to the mixture rule. Such an effect is to be expected, whether we accept Rao's[2] claim that nitric acid, alone among all nitrates, is incompletely dissociated, or whether we make the less drastic and more reasonable assumption that, at these high concentrations, nitric acid is less completely dissociated than the salts. The corresponding effect on the conductivity of mixtures containing nitric acid apparently is overshadowed to a certain extent by an effect in the opposite direction due to the adjustment of mobilities.

Strong evidence for the incomplete dissociation of nitrates is provided by Davies'[3a] recent analysis of Van Rysselberghe and Nutting's data[3b] on the conductivity of mixtures of KNO_3 with NaCl and of $NaNO_3$ with KCl. Davies gives a striking explanation for the fact that the calculated Λ's are smaller than the experimental values in the former group of mixtures, and larger in the latter. On the basis of dissociation constants previously obtained for KNO_3 and $NaNO_3$ he is able to calculate $\Delta\Lambda$ values in excellent agreement with the experimental ones.

Summary

1. Conductivities of twenty groups of binary mixtures of nitrates of uni-, di-, and trivalent cations have been measured at total equivalent concentrations ranging from 1 to 5 N.
2. All mixtures studied, except those of chromium nitrate with cadmium and aluminum nitrates, exhibit conductivities lower than the values calculated from the simple mixture rule. The departure from the mixture rule is the larger the larger the difference of the conductivities of the pure salts.
3. The behavior of mixtures containing chromium nitrate and of those containing nitric acid is briefly discussed.

Heats of Solution and Heats of Reaction in Liquid Ammonia. V.[1] The Alkali and Alkaline Earth Metals

BY FREDERIC C. SCHMIDT, FRANK J. STUDER AND JOSEPH SOTTYSIAK

In earlier papers in this series a liquid ammonia calorimeter has been described and results of measurements of heats of solution and reaction in liquid ammonia have been published.[2] In the present work, the heats of solution of the alkali and alkaline earth metals have been studied over a fairly wide range of concentrations. Kraus and Schmidt previously measured the heat of solution of metallic sodium in this solvent[2] and found it to have a negative heat of 1385 cal. Metallic lithium also has been studied, but only at quite low concentrations. In this paper the results of the heats of solution of lithium at higher concentrations are reported, as well as those of calcium, barium and strontium, and they show a markedly large change in the atomic heat effect with a change in concentration. Atomic heats of solution of the metals, potassium, rubidium and cesium have also been measured.

Experimental Details

A new calorimeter made of "Nonex" glass was used in these experiments. This instrument was the same in all details as the one described by Kraus and Schmidt.[2] The calorimeter constant was determined experimentally by introducing a known amount of heat into water in the calorimeter and noting the difference in the heat introduced and that taken up by the water at 20°. Allowing for the change in the specific heat of the glass with the temperature, this reduces to 9.16 cal. per degree at the boiling point of liquid ammonia. Uncertainties in this value do not affect the precision of the results, as the temperature changes are, for the most part, very small. The radiation constant of the calorimeter was determined and found to be 0.10 cal. per degree per minute. This correction was generally insignificant, due to the short duration of the determinations. The amount of ammonia used in all the determinations was 29.80 g., which was corrected for the ammonia vaporized due to the heat evolved. The following constants were employed: specific heat of ammonia at the boiling point 1.067 cal./deg.,[3] heat of vaporization 327.7 cal./g.[4] In the case of the metals potassium, rubidium and cesium, whose heat effects were zero, the current in the battery circuit of the Queen potentiometer was diminished by means of a resistance so as to spread out the scale readings and catch any small temperature change that might have occurred. The temperature change in all of these measurements was zero to an accuracy of 0.005°.

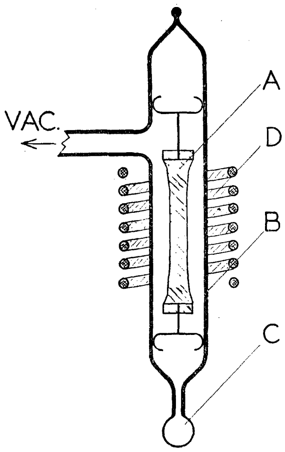

Fig. 1.

Preparation of the Metals.—The metals rubidium and cesium were reduced from their respective chlorides by granulated metallic calcium in the apparatus shown in Fig. 1. Twenty-five grams of the chloride was quickly and thoroughly mixed in an atmosphere of dry air with approximately 5% more than an equivalent of the calcium and put into a pure nickel tube (A), the ends of which were folded over. The charged tube was introduced into the apparatus at (B) and supported by nickel wire springs. The apparatus was then sealed off at the top and immediately evacuated. The glass was heated with a hand torch during the evacuation so as to degas the interior as thoroughly as possible. Coil (D) from an induction furnace was used to heat the nickel tube to red heat in order to initiate the reaction. Sufficient heat was maintained by the reaction to carry the reduction to completion. Both rubidium and cesium distilled and exuded from the seams of the nickel tube, free from unreacted salts and calcium chloride, and ran down into the fragile bulb (C) which was then sealed off. The metals were then redistilled into weighed fragile bulbs to be used for the heat measurements. Yields ranging from 35 to 45% were obtained in the case of both metals. Chemical examination of these metals showed no impurities. The potassium used was twice distilled. The lithium and the alkaline earth metals were better than 99.5% pure. In an atmosphere of dry hydrogen, these metals were cut into as large pieces as were permitted by the size of the capillary tubes on the fragile bulbs. The metals were free of their respective nitrides and oxides.

Experimental Results

The heats of solution of lithium, potassium, rubidium and cesium are presented in Table I, and those of the alkaline earth metals, calcium, barium and strontium, in Table II.

Discussion

As will be noted upon examination of Figs. 2 and 3, the atomic heats of solution of lithium and the alkaline earth metals vary regularly over the range of concentrations measured, decreasing with a decrease in concentration. The high heats of solution of these metals are due, in part, to a heat of reaction to form an ammoniated metal ion. The other metals measured, potassium, rubidium and cesium, do not form solvated ions. The atomic heats of solution of lithium and calcium in liquid ammonia were calculated by Kraus from vapor pressure measurements and found to be 8698 and 10,230 cal., respectively, for their saturated solutions at 0°.[5] Our measurements of these metals were made at the boiling point of the solvent and in the concentrated region agree very well in magnitude with the calculated values at the higher temperatures.

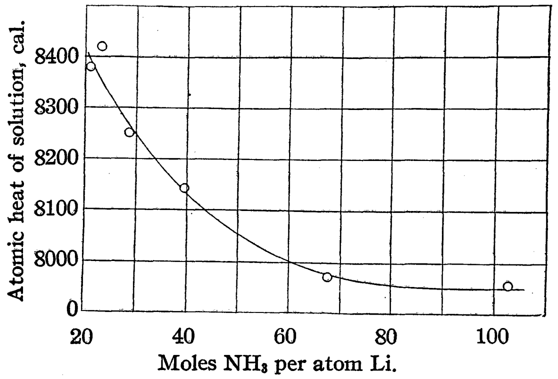

Fig. 2.—Atomic heats of solution of lithium in anhydrous liquid ammonia.

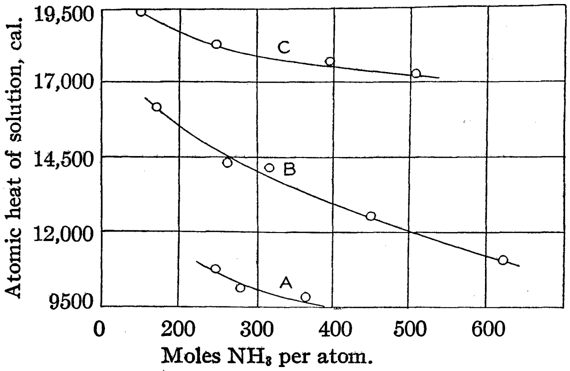

Fig. 3.—Atomic heats of solution of calcium, barium, and strontium.

In the case of the solution of metallic calcium in anhydrous liquid ammonia two phases are formed, one of which is quite dilute and one of which is quite concentrated.[5] There are no data regarding such happening in the case of the metals barium and strontium, but in all probability similar two phase systems are formed. It would seem that such a phenomenon would show as a break in the atomic heat of solution–concentration curves of these metals. Examination of these curves in Fig. 3 shows that apparently such is not the case in the region of the concentrations studied.

Summary

A method is described for the extraction of pure rubidium and cesium from their respective halides in good yields.

---

(5) C. A. Kraus, THIS JOURNAL, **30**, 653 (1908).

The atomic heats of solution of potassium, rubidium and cesium have been measured over a fairly wide range of concentrations and found to be zero.

The atomic heats of solution of metallic lithium, calcium, barium and strontium have been measured over a range of concentrations and have been found to have a negative heat of dilution.

The Kinetics and Mechanism of α-Aminoisobutyronitrile Formation

BY T. D. STEWART AND CHOH-HAO LI

Introduction

The α-amino nitriles are generally obtained by the reaction of equimolecular proportions of an alkali cyanide and an amine salt with an aldehyde or ketone in aqueous or aqueous alcoholic solution,[1] or by the reaction between equimolecular proportions of a cyanohydrin and an amine.[2] The main reaction is

$$R_2C(OH)CH + R_2NH \rightleftharpoons R_2C(NR_2)CN + H_2O \quad (1)$$

This equation implies that the oxygen is removed from the cyanohydrin and is replaced by the amino group directly; but in view of the following argument this path is extremely unlikely.

When a cyanohydrin is placed in an alkaline medium, such as a solution of an amine, the following equilibria are rapidly established

$$R_2C(OH)CN \rightleftharpoons R_2CO + HCN \quad (2)$$

$$HCN + R_2NH \rightleftharpoons R_2NH_2CN \rightleftharpoons R_2NH_2^+ + CN^- \quad (3)$$

The rapid appearance of cyanide ion demonstrates an apparent high reactivity of the carbon–cyanide bond in the cyanohydrin and shows the improbability of the hydroxyl group being dissociated or exchanged in alkaline solution. Ultee[3] showed that this reactivity was not a property of the cyanohydrin as such, because in acidic medium prussic acid was not formed.

The mechanism[4] of the dissociation in alkali can be expressed

$$R_2C(CN)OH + OH^- \rightleftharpoons R_2C(CN)O^- + H_2O \quad (4)$$

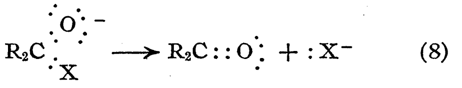
$$R_2C(CN)O^- \rightleftharpoons R_2CO + CN^- \quad (5)$$

in which both reactions are rapid and reversible. Equations (4) and (5) are of particular interest inasmuch as a similar effect of alkali has been noted in other cases, namely, aldehyde bisulfite and formocholine dissociations.

$$C_6H_5CH(SO_3)OH^- \xrightleftharpoons{-OH^-} C_6H_5CH(SO_3)O^= \longrightarrow C_6H_5CHO + SO_3^= + H_2O \quad (6)$$

$$(CH_3)_3\overset{+}{N}CH_2OH \xrightleftharpoons{-H^+} CH_3)_3\overset{+}{N}CH_2O^- \longrightarrow (CH_3)_3N + CH_2O \quad (7)$$

In each case[5] the rate of appearance of cyanide ion, sulfite ion or trimethylamine, respectively, is proportional to the hydroxide ion concentration which in turn governs the concentration of the intermediate ion. In each case the intermediate takes the form



$$R_2C\overset{:\ddot{O}:^-}{\underset{\cdot X}{:}} \longrightarrow R_2C::\ddot{O}: + :X^- \quad (8)$$

in which the electron pair bonding the radical X is replaced by an unshared electron pair of the charged oxygen; the dissociation is therefore a substitution reaction and not an ionization in the ordinary sense, and as such would be a relatively rapid reaction.[6] The alkaline catalysis of sugar mutarotation as well as alkaline catalysis of diacetone alcohol dissociation[7] may be represented similarly. It is clear that in an acidic medium the concentration of the intermediate ion would be reduced and hence the rate of dissociation inhibited; in alkali neither the cyanohydrin as such nor the intermediate ion could be expected to dissociate hydroxyl or react to replace it by the amine group.

A clue as to the path by which the oxygen (Eq. 1) is removed is given by the known reactions of the α-amino alcohols and their ethers. Lapworth and his co-workers[8] have pointed out

the capacity of the hydroxyl and alkoxyl groups in these substances to dissociate

$$R_2C(NR_2)OH + H^+ \rightleftharpoons R_2C{=}N^+R_2 + H_2O \quad (9)$$

The reaction conforms to the generalized intramolecular substitution reaction presented in Equation 8, and, unlike the cyanohydrin case, both the oxygen and nitrogen systems are susceptible to dissociation. It is evident that in the α-amino alcohols a means is to be found by which the oxygen of a ketone may be removed readily. We may therefore superimpose upon the system represented in Equations 2 and 3 the further reactions

$$R_2C{=}O + R_2NH \rightleftharpoons R_2C(OH)NR_2 \quad (10)$$

$$R_2C(OH)NR_2 + HCN \rightleftharpoons R_2C(CN)NR_2 + H_2O \quad (11)$$

$$R_2C(OH)NR_2 + R_2C(OH)CN \rightleftharpoons R_2C(CN)NR_2 + R_2C(OH)_2 \quad (12)$$

showing how the hydroxyl of the cyanohydrin is formally replaced by the amine group. Evidence favoring this viewpoint is presented below.

Experimental Results

The Rate Law in Acetone as a Solvent.—The rate of the reaction

$$(CH_3)_2C(OH)CN + (C_2H_5)_2NH \longrightarrow (CH_3)_2C(CN)N(C_2H_5)_2 + H_2O$$

was determined to be proportional to the concentration of each of the reactants in acetone solution. Tables I and II present typical data; *a* and *b* represent the concentration of acetonecyanohydrin and diethylamine, respectively, and k'' is the specific reaction rate constant as normally calculated for a second order reaction. In Table II the rate constant was calculated for each interval of time and shows no trend up to 65% of the total reaction, showing that the equilibrium lies far to the right in this solvent.

Catalysis by Tertiary Amines.—When triethylamine or tri-*n*-propylamine is added to the reacting mixture of acetonecyanohydrin and diethylamine in acetone, the rate of the reaction is increased in proportion to the concentration of tertiary amine present, as shown in Fig. 1. If k''_t is the over-all bimolecular specific reaction rate constant we may write

$$k'' = k'' + mk''_c$$

where *m* is the molarity of the tertiary amine, k''_c the specific reaction rate constant of the catalyzed reaction, and k'' that of the uncatalyzed reaction. The rate law becomes

$$\text{Rate} = k''(a)\,(b) + k''_c(a)\,(b)\,(m)$$

as an expression of two independent rate determining steps. The data are summarized in Table III.

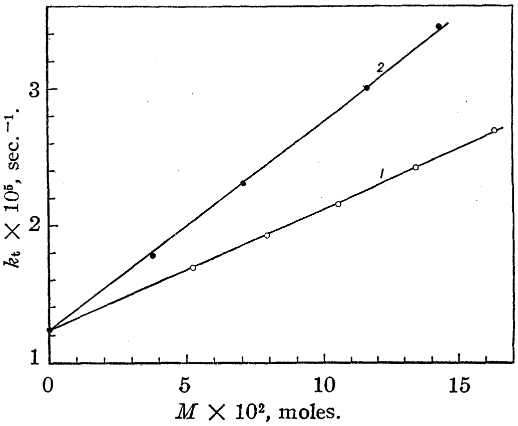

Fig. 1.—The catalytic effect of tertiary amines: 1, tri-*n*-propylamine; 2, triethylamine.
