The Synthesis of Dipeptides from α-Keto Acids[1]

BY DAVID SHEMIN AND ROBERT M. HERBST

The classical peptide syntheses of Emil Fischer, and the elegant methods of Bergmann have proved to be of great value both practically and theoretically. However, the possibility of synthesizing peptides from α-keto acids appeared attractive since biological materials other than amino acids could be utilized. The methods developed in this report are primarily of theoretical interest, although their further development in some specific instances may prove to be of practical value.

The conversion of α-keto acids into the corresponding amino acids has been accomplished in a variety of ways. The oximes of α-keto acids have been reduced to amino acids either with tin and hydrochloric acid,[2] or with sodium amalgam.[3] Knoop and Oesterlin[4] have succeeded in reducing α-keto acids to amino acids catalytically with hydrogen in the presence of ammonia. Herbst and Engel[5] have been able to convert α-keto acids into the corresponding amino acids by interaction with another α-amino acid, a reaction which has been accomplished recently in biological systems.[6,7] Of biochemical interest are the reduction of the oxime of pyruvic acid to *dl*-alanine by actively fermenting yeast,[8] the synthesis of alanine from pyruvic acid and ammonia by liver tissue slices,[9] and the formation of *l*-aspartic acid from oxalacetic acid and hydroxyl-

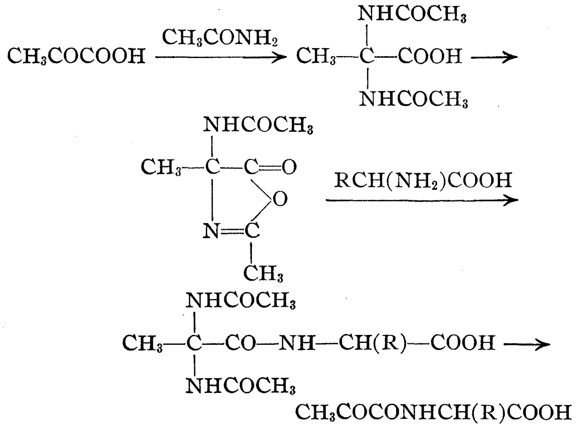
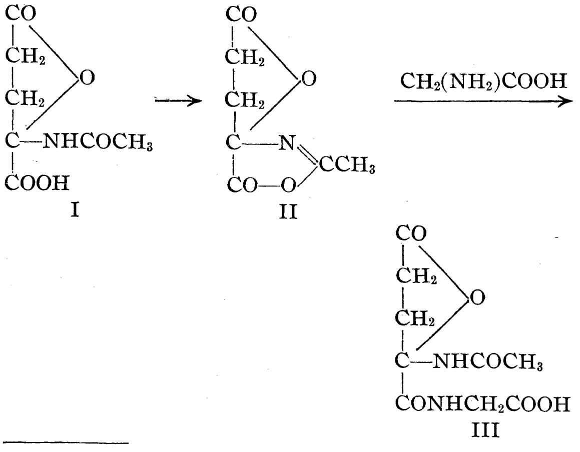
amine by the root nodules of leguminous plants.[10]

Bergmann and Grafe[11,12] have synthesized pyruvyl derivatives of α-amino acids by the following series of reactions



Two methods of converting the pyruvylamino acids into the corresponding dipeptides were tried, the second proving the more satisfactory: (a) catalytic reduction in the presence of ammonia, and (b) catalytic reduction of the oximes of the pyruvylamino acids. Preliminary experiments with the oximes of pyruvic and phenylpyruvic acids, under conditions similar to those employed for simple oximes by Hartung,[13] demonstrated its feasibility for the preparation of amino acids. By this procedure the reduction of the oximes of pyruvylglycine, pyruvylalanine and pyruvylphenylalanine was accomplished. In some cases it was found advantageous to work with the oxime esters.

Application of this synthesis to α-ketoglutaric acid was attempted. Condensation of this keto acid with acetamide led to the formation of the lactone of α-acetamino-α-hydroxyglutaric acid (I). This compound with acetic anhydride formed an azlactone (II) which was coupled with glycine to form the lactone of α-acetamino-α-hydroxyglutarylglycine (III).



The possibility of preparing glutamyl and glutaminyl peptides from the last named compound has not been explored.

Experimental

The melting points, yields and analyses of all compounds prepared are reported in Table I. With three exceptions the yields given are for the reaction leading directly to the product in question; for example, the yield of alanine is for the reduction of pyruvic acid oxime to alanine. The yields of pyruvylglycine oxime ethyl ester, pyruvylalanine ethyl ester and pyruvylphenylalanine oxime are over-all yields based on the amounts of the α,α-diacetaminopropionyl derivatives of glycine, alanine and phenylalanine used, since no intermediates were isolated.

Pyruvylamino Acids.—Pyruvylglycine and pyruvylphenylalanine were prepared as described by Bergmann and Grafe.[12] Pyruvylalanine was prepared by a similar procedure. The mixture obtained by the hydrolysis of α,α-diacetaminopropionylalanine was evaporated to dryness and extracted with dry acetone, from which pyruvylalanine, possessing the properties recorded by Bergmann and his collaborators,[14] was secured on concentration to a small volume and recrystallizing from acetone or ether–petroleum ether.

Ethyl Esters of Pyruvylamino Acids.—Solutions of the pyruvylamino acids, obtained by extracting the above residues with absolute ethyl alcohol instead of acetone, were saturated with hydrogen chloride and boiled under reflux for about half an hour. After the removal of the solvent as completely as possible under reduced pressure, pyruvylglycine ethyl ester was converted into the oxime without further purification; pyruvylalanine ethyl ester was purified by distillation in high vacuum.

Preparation of Oximes.—The oximes of keto acids and pyruvylamino acids were prepared in aqueous solution, those of the ethyl esters of pyruvylamino acids in 50% alcoholic solution by treatment with about one and a half equivalents of hydroxylamine hydrochloride and three equivalents of sodium acetate. The reactions were allowed to proceed for twelve to twenty-four hours at room temperature. The products either crystallized from the reaction mixture before or after acidification to Congo red or were isolated by extraction with ether. Purification was effected either by crystallization from hot water or from ether by addition of petroleum ether or by distillation in high vacuum.

Reduction of Oximes.—The oximes were reduced in alcoholic or aqueous alcoholic solution in the presence of Adams platinum oxide catalyst[15] with hydrogen under 2–3 atmospheres pressure. In some cases, especially with the

[a] The authors wish to thank Mr. William Saschek for the micro analyses reported in the table. [b] All melting points are corrected. [c] Amino nitrogen, determined according to Van Slyke. [d] Low values for the oximes were obtained by the micro Dumas technique. The micro Kjeldahl process was, of course, not directly applicable. [e] Fischer[16] reports the melting point of carbethoxyalanylglycine ethyl ester as 67.5° and that of carbethoxyalanylglycine as 122°, both corrected. [f] During the preparation of carbethoxyalanylglycine ethyl ester it is partially hydrolyzed to carbethoxyalanylglycine.[16] The combined yield of the two products, obtained in one experiment, amounted to 68%. [g] Distils at 95° bath temperature under 0.4 mm. pressure. [h] Distils at 160–170° bath temperature under 0.7–0.9 mm. pressure.

esters of the pyruvylamino acid oximes, it was found advantageous to carry on the reduction in solutions acidified with a small amount of hydrochloric acid.[13] Free amino acids and dipeptides were isolated from the reduction mixtures by evaporation to dryness after removal of chloride ions, and were purified by crystallization from water by the addition of alcohol. The dipeptide esters obtained by the reduction of the esters of the pyruvylamino acid oximes were isolated as carbethoxy derivatives following the technique of Fischer.[16,17] Phenylalanine was obtained without difficulty by reduction of the oxime of phenylpyruvic acid. However, when the oxime of pyruvylphenylalanine was reduced under the same conditions, alanylcyclohexylalanine was formed. From the latter, cyclohexylalanine was obtained by hydrolysis with dilute hydrochloric acid and isolated as the benzoyl derivative,[18] the identity of which was established by analysis and by mixed melting point determinations.

Lactone of α-Acetamino-α-hydroxyglutarylglycine, (III).—A suspension of 3 g. of α-acetamino-α-hydroxyglutaric lactone (I),[19] in 60 cc. of acetic anhydride was heated on a boiling water-bath until all the material had dissolved. About ten or fifteen minutes were required, during which time the solution became orange-yellow. After removal of the excess acetic anhydride *in vacuo*, the crude azlactone (II), a yellow viscous oil, was suspended in 30 cc. of acetone and treated immediately with a solution of 1.12 g. of glycine in 15 cc. of normal sodium hydroxide. The mixture, containing a trace of undissolved material, was shaken for thirty minutes, neutralized with 15 cc. of normal sulfuric acid, evaporated to dryness *in vacuo*, and extracted thoroughly with cold 95% alcohol. The alcoholic solution was evaporated to dryness; the residue was taken up in a small amount of water and decolorized with charcoal. The aqueous solution was then evaporated to dryness and the residue washed with cold alcohol. The insoluble portion, weighing 1.3 g., was recrystallized by suspension in hot alcohol and dropwise addition of water until solution took place. On cooling 0.7 g. of product separated from the solution.

On direct titration with 0.01 *N* sodium hydroxide, using phenolphthalein as the indicator, the substance immediately consumed somewhat more than one equivalent of alkali, and thereafter behaved like a lactone. The equivalent weight (calcd. 122; found 116, 128) was determined by back-titration with hydrochloric acid after treatment with a slight excess of alkali.

Summary

1. The possibility of synthesizing amino acids and dipeptides from α-keto acids has been demonstrated.

2. The oximes of pyruvic and phenylpyruvic acids were converted into the corresponding amino acids by catalytic reduction.

3. The pyruvyl derivatives of glycine, glycine ethyl ester, alanine, and alanine ethyl ester were converted into the corresponding dipeptides by catalytic reduction of their oximes. In the case of pyruvylphenylalanine oxime, reduction led to alanylcyclohexylalanine.

4. The azlactone of α-acetamino-α-hydroxy-

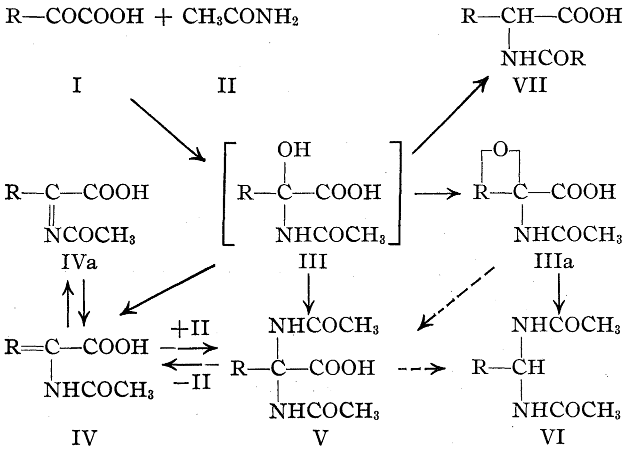
The Condensation of α-Keto Acids and Acetamide[1]

BY DAVID SHEMIN AND ROBERT M. HERBST

In order to extend the dipeptide synthesis described in the preceding paper, it was necessary to prepare α,α-diacetamino derivatives from α-keto acids other than the pyruvic acid studied by Bergmann and Grafe.[2] The results obtained in the reaction of α-ketoglutaric acid with acetamide made desirable a more extensive study of this condensation, with a view to obtaining clearer insight into its mechanism.

The results obtained with the several α-keto acids studied are summarized in the following scheme



When α-ketoglutaric acid (I, R = $COOHCH_2CH_2$—) was condensed with acetamide (II) at 70°, the main product was the lactone of α-acetamino-α-hydroxyglutaric acid (IIIa, R = —$COCH_2CH_2$—). If the reaction was carried out at a higher temperature, or if IIIa was heated at a higher temperature with acetamide, a second product, γ,γ-diacetaminobutyric acid (VI, R = $COOHCH_2CH_2$—) was obtained. Whether V is an intermediate in this reaction, as indicated by the dotted arrows, or whether IIIa is decarboxylated, must remain an open question, but the opening of the lactone ring of IIIa by addition of acetamide appears to be a new reaction.

These results suggested that the formation of the diacetamino compounds proceeds in two steps, (a) addition of acetamide to the carbonyl group of the keto acid with the formation of an α-hydroxy-α-acetamino compound (III), and (b) replacement of the hydroxyl group of III by an acetamino group. This hypothesis seemed reasonable in view of the fact that benzaldehyde, on treatment with acetamide under suitable conditions, forms benzylidene-diacetamide.[3,4] However, it should be pointed out that in the preparation of α,α-diacetaminopropionic acid (V, R = CH_3—) from pyruvic acid and acetamide, a small amount of α-acetaminoacrylic acid (IV, R = CH_2=) is always formed.[2] If α-acetamino-α-hydroxypropionic acid (III, R = CH_3—) is formed as the first step in the reaction, loss of water from this intermediate readily explains the formation of α-acetaminoacrylic acid. In the case of α-ketoglutaric acid the intermediate (III) is stabilized by the formation of the lactone (IIIa). On the basis of the above hypothesis α-acetaminoacrylic acid would appear to be a by-product, but the possibility that it is an intermediate must be considered.

To test this point α-acetaminoacrylic acid (IV, R = CH_2=) was heated with acetamide. Surprisingly, almost quantitative conversion to α,α-diacetaminopropionic acid (V, R = CH_3—) resulted, so that α-acetaminoacrylic acid cannot be excluded as an intermediate. In this connection it should be recalled that α-aminoacrylic acid derivatives may be considered as tautomeric substances[2,5] capable of reacting in the forms IV or IVa. Acetamide may therefore add onto either the carbon–carbon double bond of IV or the car-

---

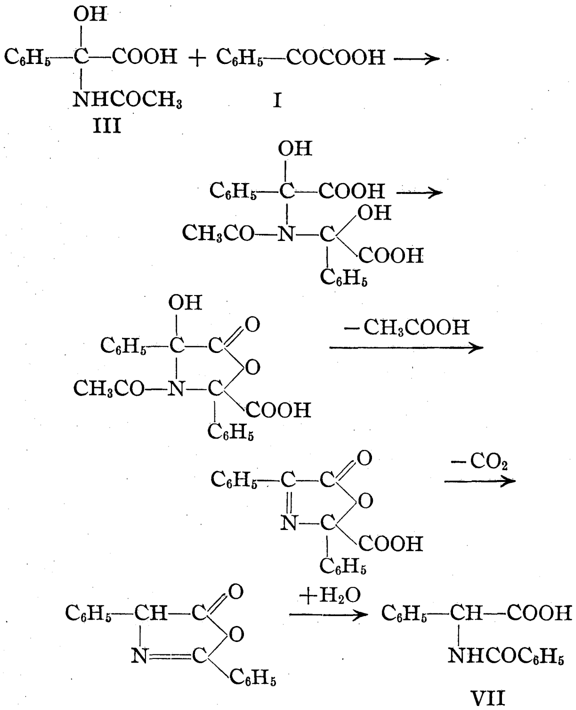
bon–nitrogen double bond of IVa.[6] Our data permit no definite conclusion as to the mode of addition of acetamide to α-acetaminoacrylic acid. The only other examples tried, cinnamic acid and α-acetaminocinnamic acid, showed no tendency to react with acetamide. However, the side chain double bond of cinnamic acid is notoriously unreactive, and the presence of the benzene ring may elicit a similar condition in the case of acetaminocinnamic acid. This is supported by the observation that when phenylpyruvic acid was heated with acetamide, α-acetaminocinnamic acid was formed in excellent yield.

The condensation of benzoylformic acid with acetamide was also studied. In this case an intermediate of type IV cannot form, although IVa is still a possibility. Actually α,α-diacetaminophenylacetic acid (V, R = C_6H_5—) was formed in good yield, together with small amounts of α-benzoylaminophenylacetic acid (VII, R = C_6H_5—) and benzylidene diacetamide (VI, R = C_6H_5—). The latter probably resulted from the interaction of acetamide with benzaldehyde, formed by decarboxylation of benzoylformic acid. Attempts to decarboxylate α,α-diacetaminophenylacetic acid were unsuccessful.

The experimental results are best explained by the assumption that the first step in the reaction between α-keto acids and acetamide is the addition of acetamide to the carbonyl group of the keto acid with the formation of an α-acetamino-α-hydroxy derivative. The second step involves replacement of the hydroxyl group by another acetamino group either directly or through an unsaturated intermediate of the Schiff base type.

The formation of the α-benzoylaminophenylacetic acid resembles that of N-phenacetylphenylalanine from α-benzoylaminocinnamic acid or phenylpyruvic acid and aqueous ammonia,[7] and that of N-acetylalanine from ammonia and pyruvic acid.[8] Du Vigneaud and Irish[9] have recently demonstrated the significance of this reaction in the biological synthesis of amino acids. The following scheme is suggested to account for the conversion of III into VII (R = C_6H_5—).



Attempts to isolate the azlactone postulated in the above scheme were unsuccessful, and it was impossible to find evidence of a similar reaction in the case of any of the other α-keto acids studied.

Both the Erlenmeyer and the de Jong reactions can be explained by an analogous mechanism, ammonia being substituted for acetamide and water split out instead of acetic acid at the appropriate point. The formation of the amide of phenacetylphenylalanine in the Erlenmeyer reaction can be best explained by the assumption of an azlactone as a precursor, especially since Bergmann and collaborators[10] have shown that the azlactones of acylamino acids are converted into the respective amides by aqueous ammonia.

Experimental

α-Ketoglutaric Acid with Acetamide

α-Acetamino-α-hydroxyglutaric Lactone (IIIa, R = —$COCH_2CH_2$—).—α-Ketoglutaric acid (13.5 g.), prepared according to Neuberg and Ringer,[11] was treated with 6 g of acetamide at 70–75° under 10–15 mm. pressure for ten hours. The partially crystalline reaction mixture was extracted with four 50-cc. portions of hot ethyl acetate. The insoluble fraction (9.5 g.) was recrystallized from acetone–ether, from which it separated as colorless prisms which, on rapid heating, melted with decomposition at 196° (corr.). The substance was also soluble in water and alcohol, and crystallized from the latter on addition of ether. Opening of the lactone ring and esterification (see below) occur on prolonged boiling in alcoholic solution. The material was dried for analysis at 76° at 5 mm.

---

[6] Dr. R. E. Steiger very kindly called our attention to the latter possibility.

Anal. Calcd. for $C_7H_9O_5N$: C, 44.9; H, 4.9; N, 7.5. Found: C, 45.1; H, 4.7; N, 7.5.

On direct titration with standard alkali the substance behaved like a lactone. The equivalent weight determined by back-titration after dissolving in a slight excess of alkali was 88, calculated for $C_7H_9O_5N$, 93.5. No reaction took place with bromine in aqueous solution.

On hydrolysis with normal hydrochloric acid, a 95% yield of α-ketoglutaric acid was obtained, isolated as the 2,4-dinitrophenylhydrazone, m. p. 217° (corr.) with decomposition, and showing no depression when mixed with an authentic specimen.

Glutamic Acid Hydrochloride.—α-Acetamino-α-hydroxyglutaric lactone was boiled with absolute ethyl alcohol for three hours. The resultant unsaturated ester was hydrogenated in the presence of a platinum catalyst and hydrolyzed with normal hydrochloric acid, when glutamic acid hydrochloride was obtained.

Anal. Calcd. for $C_5H_9O_4N \cdot HCl$: N, 7.6; NH_2-N, 7.6. Found: N, 7.9; NH_2-N, 7.7.

γ,γ-Diacetaminobutyric Acid (VI, R = COOHCH$_2$-CH$_2$—).—A mixture of 18 g. of α-ketoglutaric acid and 15 g. of acetamide was heated at 110 ± 5° for eight to nine hours at 10–15 mm. pressure. The reaction mixture was then dissolved in 400 cc. of cold ethyl acetate. An oil separated which crystallized on standing in the refrigerator. The crystals were filtered off and washed with cold ethyl acetate and cold absolute alcohol. Recrystallization was effected by boiling a suspension of the material in hot absolute alcohol and adding water dropwise until solution was complete. On standing in the refrigerator the substance crystallized in the form of needles, m. p. 197° (corr.), in a yield of 3.5 g. The melting point was markedly depressed when the material was mixed with α-acetamino-α-hydroxyglutaric lactone.

Anal. Calcd. for $C_8H_{14}O_4N_2$: C, 47.5; H, 6.9; N, 13.9; equiv. wt., 202. Found: C, 47.6; H, 7.0; N, 13.6; equiv. wt., 203.

γ,γ-Diacetaminobutyric acid was also formed when the lactone of α-acetamino-α-hydroxyglutaric acid (1.87 g.) was heated with acetamide (1.8 g.) at 110°. By similar methods of isolation, 900 mg. was obtained, m. p. 197° (corr.), and showing no depression when mixed with the product described above.

Anal. Calcd. for $C_8H_{14}O_4N_2$: N, 13.9. Found: N, 13.7.

The constitution was determined by hydrolysis in aqueous acid solution to the semi-aldehyde of succinic acid, isolated as the *p*-nitrophenylhydrazone, m. p. 179.5° (corr.), in a yield of 55%. The melting point showed no depression when mixed with an authentic specimen.[12]

α-Acetaminoacrylic Acid with Acetamide

α,α-Diacetaminopropionic Acid (V, R = CH$_3$—).—α-Acetaminoacrylic acid was prepared from α,α-diacetaminopropionic acid according to Bergmann and Grafe.[2]

Anal. Calcd. for $C_5H_7O_3N$: N, 10.9. Found: N, 10.7.

α-Acetaminoacrylic acid (4.75 g.) was heated with acetamide (10 g.) at 110–115° under 10–15 mm. pressure for three hours. The fraction insoluble in ethyl acetate was recrystallized from hot 95% ethyl alcohol. The yield of pure α,α-diacetaminopropionic acid was 4.5 g., m. p. 189–190° (corr.) with decomposition. It did not take up bromine in aqueous solution.

Anal. Calcd. for $C_7H_{12}O_4N_2$: N, 14.9. Found: N, 14.9.

α-Acetaminocinnamic Acid with Acetamide

In an attempt to condense α-acetaminocinnamic acid with acetamide under comparable conditions, 94 per cent. of the α-acetaminocinnamic acid was recovered as such.

Phenylpyruvic Acid with Acetamide

α-Acetaminocinnamic Acid (IV, R = C$_6$H$_5$CH=).—A mixture of 12 g. of phenylpyruvic acid[13] and 12 g. of acetamide was heated for three hours at 110–115° under 10–15 mm. pressure. On recrystallization from boiling water with norite, the reaction mixture yielded 7.1 g. of pure α-acetaminocinnamic acid, m. p. 193° (corr.) with decomposition.

Benzoylformic Acid with Acetamide

α,α-Diacetaminophenylacetic Acid (V, R = C$_6$H$_5$—).—Benzoylformic acid (10 g.) was heated with acetamide (10 g.) for one hour at 110–115° under 10 mm. pressure. The initially clear melt solidified during the course of heating. Crude α,α-diacetaminophenylacetic acid (9.3 g.) remained after the reaction mixture was thoroughly extracted with ether (see below) and washed with cold alcohol. On recrystallization from 70–80% alcohol α,α-diacetaminophenylacetic acid separated in the form of microscopic crystals, containing one mole of water of crystallization, m. p. 201–202° (uncorr.) with foaming. The material was dried for analysis at 110° *in vacuo* over phosphorus pentoxide.

Anal. Calcd. for $C_{12}H_{14}O_4N_2 \cdot H_2O$: H_2O, 6.7. Found: H_2O, 6.5. Calcd. for $C_{12}H_{14}O_4N_2$: C, 57.6; H, 5.6; N, 11.2. Found: C, 57.4; H, 5.6; N, 11.2.

On boiling with normal hydrochloric acid, α,α-diacetaminophenylacetic acid yielded benzoylformic acid, identified as the 2,4-dinitrophenylhydrazone, m. p. 196° (uncorr.) with decomposition, and showing no depression when mixed with an authentic specimen.[14]

α-Benzoylaminophenylacetic Acid (VII, R = C$_6$H$_5$—).—The ether-soluble fraction of the above reaction product of benzoylformic acid and acetamide, on recrystallization from hot water, gave 220 mg. of α-benzoylaminophenylacetic acid, m. p. 175° (corr.) showing no depression when mixed with an authentic sample.[15]

Benzylidene Diacetamide (VI, R = C$_6$H$_5$—).—During the reaction of benzoylformic acid with acetamide variable amounts of benzylidene diacetamide were formed. This substance was separated from the diacetaminophenylacetic acid by its ready solubility in hot absolute alcohol, from which it crystallized in the form of long needles, m. p. 250° (uncorr.) with decomposition.

Anal. Calcd. for $C_{11}H_{14}O_2N_2$: N, 13.6. Found: N, 13.7.

When α,α-diacetaminophenylacetic acid was heated with acetamide under the above conditions for as long as five hours, no evidence of decarboxylation could be obtained, and only the starting material could be isolated from the reaction mixture.

Summary

1. The condensation of the following α-keto acids with acetamide has been studied: pyruvic, phenylpyruvic, α-ketoglutaric, and benzoylformic acids.

2. The condensation takes place in the following steps: (a) addition of acetamide to the carbonyl group of the keto acid with the formation of an α-acetamino-α-hydroxy acid, and (b) replacement of the hydroxyl group by a second acetamino group, either directly or by dehydration followed by addition of acetamide to the unsaturated intermediate.

3. Phenylpyruvic acid forms only α-acetaminocinnamic acid, and the latter does not add acetamide to its double bond under the experimental conditions chosen.

4. The opening of a lactone ring by addition of acetamide was observed with the lactone of α-acetamino-α-hydroxyglutaric acid.

5. In the condensation of benzoylformic acid with acetamide a secondary reaction analogous to the Erlenmeyer-de Jong reaction was observed. A mechanism is suggested to explain the formation of α-acylamino acids from α-keto acids by this reaction.

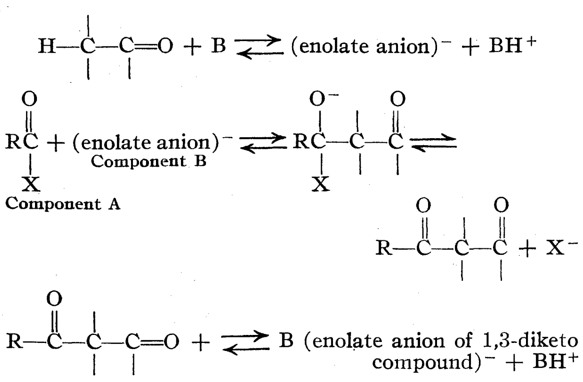
Condensations Brought about by Bases. III. The General Course of the Claisen Type of Condensation

BY CHARLES R. HAUSER

The equations proposed recently[1] for the Claisen condensation of ethyl esters may be generalized to include other carbon-carbon condensations in which a metallic enolate condenses with a compound of the general type RCOX, where X is an atom or group that is removed as an anion during the reaction. The general course for this type of condensation may be represented by the following ionic equations, in which B represents a base.



$$\mathrm{H{-}\underset{|}{\overset{|}{C}}{-}\underset{|}{C}{=}O} + \mathrm{B} \rightleftharpoons (\text{enolate anion})^- + \mathrm{BH}^+$$

$$\underset{\text{Component A}}{\mathrm{R\overset{\overset{O}{\|}}{\underset{\underset{X}{|}}{C}}}} + \underset{\text{Component B}}{(\text{enolate anion})^-} \rightleftharpoons \mathrm{R\overset{\overset{O^-}{|}}{\underset{\underset{X}{|}}{C}}{-}\overset{|}{\underset{|}{C}}{-}\overset{\overset{O}{\|}}{\underset{|}{C}}} \rightleftharpoons \mathrm{R{-}\overset{\overset{O}{\|}}{C}{-}\overset{|}{\underset{|}{C}}{-}\overset{\overset{O}{\|}}{\underset{|}{C}}} + \mathrm{X}^-$$

$$\mathrm{R{-}\overset{\overset{O}{\|}}{C}{-}\overset{|}{\underset{|}{C}}{-}\underset{|}{C}{=}O} + \rightleftharpoons \mathrm{B}\ (\text{enolate anion of 1,3-diketo compound})^- + \mathrm{BH}^+$$

The first equation represents an acid-base reaction in which a new acid and a new base (the enolate anion) are formed. The second equation represents a carbon-carbon condensation between the enolate anion, designated component B, and a compound of the type RCOX, which is designated component A.[2] This reaction gives an intermediate organic anion, which releases X as anion, forming the 1,3-diketo compound. The last equation represents another acid-base reaction in which the 1,3-diketo compound is converted into its enolate anion. This reaction can occur, of course, only if the 1,3-diketo compound contains an enolizable hydrogen, and if a sufficiently strong base is present.

A number of apparently diverse condensations, as, for example, the condensation of two molecules of an ethyl ester in the presence of a base, and the condensation of a molecule of acetoacetic ester (as enolate) with a molecule of an acid chloride are represented by these general equations. It is proposed that any reaction that is represented by the above equations be classified as a Claisen type of condensation.

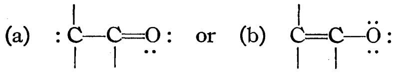
While there is little doubt that the general mechanism of the Claisen type of condensation involves the formation of a metallic enolate as an active intermediate, the detailed mechanism by which this enolate condenses with a compound

---

[1] (a) Hauser and Renfrow, THIS JOURNAL, **59**, 1823 (1937); (b) Renfrow and Hauser, *ibid.*, **60**, 463 (1938).

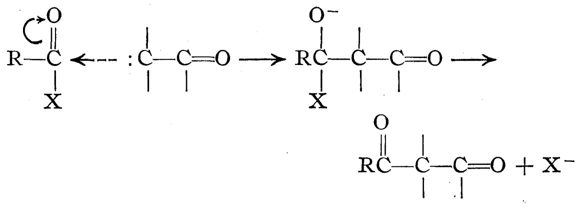
[2] In this connection see Arndt and Eistert, *Ber.*, **69**, 2383 (1936).

of the type RCOX is not entirely clear. Metallic enolates are capable of reacting as if their anions possessed either of the resonance forms

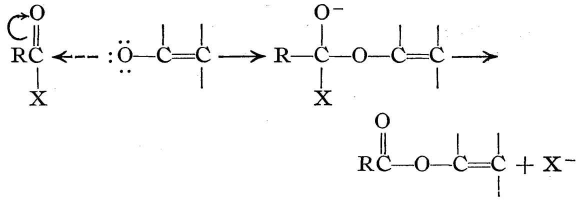


$$(a)\ :\overset{|}{\underset{|}{C}}-\underset{|}{C}=\ddot{O}:\quad \text{or}\quad (b)\ \overset{|}{\underset{|}{C}}=\underset{|}{C}-\ddot{O}:$$

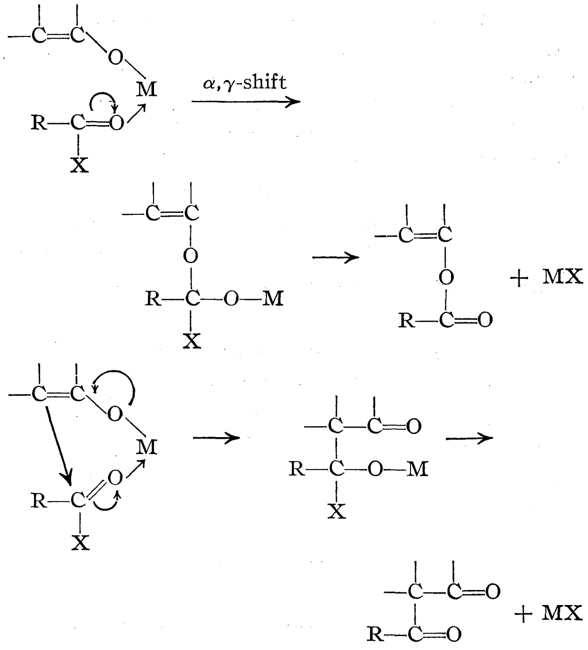
giving both carbon and oxygen derivatives. The carbon–carbon condensation represented by the above equations may be considered to involve an attack of resonance form (a) of the enolate anion on the potentially positive carbon atom of the carbonyl group in component A, thus



An oxygen–carbon condensation may be considered to involve a reaction of resonance form (b) of the enolate anion, thus



This simple representation, however, does not indicate the effect that component A may have on the course of the condensation as exhibited, for example, in the reactions of the sodium enolate of acetoacetic ester with certain acid chlorides; this enolate with acetyl or benzoyl chloride gives mainly the carbon derivative, but with chloroformic ester, mainly the oxygen derivative.[3] In the similar phenomena of oxygen- and carbon-alkylation of metallic enolates Johnson[4] assumes that a coördination complex is first formed: an α,γ-shift leads to oxygen ethers, and a cyclic mechanism leads to carbon alkylation. On the basis of these ideas the alternative courses of reaction of metallic enolates (especially those that would not be ionized appreciably) with compounds of the type RCOX might be represented as follows[5]



Whether or not further data will support these mechanisms remains to be determined. At the present time the ionic point of view of the Claisen condensation seems preferable. It is not only simpler but at least certain metallic enolates appear to be ionized; certain other enolates which may not be ionized appreciably, may be regarded as possessing potential ions. It is possible that a coördination complex between component A and the metallic enolate might lead to the transient formation of resonance structures (a) or (b). Regardless of the intimate mechanism, however, a carbon–carbon condensation between a metallic enolate and a compound of the type RCOX may be classified as a Claisen type of condensation.

The types[6] of component A of the condensation include esters, anhydrides,[7] acid chlorides,[7] and N-diphenylacetamide,[8] where X is OR, OOCR, Cl, and $(C_6H_5)_2N$, respectively. The types[6] of component B include the enolate anions of esters, aldehydes, ketones, N-diphenylacetamide,[8] and 1,3-diketo compounds.[9] Component B could also be the enolate anions of other types of compounds. A general formula for compounds whose anions might function as com-

---

[4] See Gilman, "Organic Chemistry," John Wiley and Sons, Inc., New York, N. Y., 1938, p. 1651.

[5] The general formula $-\overset{|}{C}=\overset{|}{C}-O-M$ represents a metallic enolate. The enolic form of the enolate is shown because this, rather than the ketonic form, probably more nearly approximates the structure of the compound.

[6] It should be pointed out that not all of these types of components A and B have been condensed with each other.

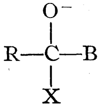
[7] See Hudson, Dick and Hauser, THIS JOURNAL, **60**, 1960 (1938).

[8] Chelintzev and Osetrova, *Ber.*, **69B**, 374 (1936).

[9] The reaction of the enolate of a 1,3-diketo compound, such as acetoacetic ester, with an acid chloride (component A) will form a triketo compound of the type $RCOCH(COR)\underset{|}{C}O$.

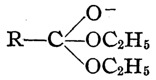
ponent B is represented by the system $\text{H—}\overset{|}{\underset{|}{\text{C}}}\text{—}\underset{|}{\text{A}}\text{=X}$, where A is carbon or nitrogen and X oxygen or nitrogen. It should be pointed out also that the condensation of many basic anions or of Grignard reagents with a compound of the type RCOX may follow a course similar to that represented above, but it is probably best to classify as examples of the Claisen type of condensation only those reactions in which a carbon–carbon condensation occurs, and in which a metallic enolate or its anion serves as component B.

The types of base B that may be used to effect the Claisen condensation include the anions, $^-OC_2H_5$, $^-NH_2$, and $(C_6H_5)_3C^-$, and certain Grignard reagents.[10] The base that will effect a condensation between a particular set of components A and B is limited by several factors. In the first place, the base B, as well as the enolate anion, may condense with the carbonyl group of component A, giving the intermediate anion



$\text{R—}\overset{\text{O}^-}{\underset{\text{X}}{\text{C}}}\text{—B}$;

the latter on decomposition may form RCOB and X^-. This competing reaction should be expected especially when the equilibrium of the first equation above is on the left side (*i. e.*, when there is a high concentration of the base B), and when X of component A corresponds to a weaker base than B. In the common condensations of ethyl esters effected by sodium ethoxide the equilibrium of the first step is probably on the left side, but here the base B, which is ethoxide ion, is the same group as X of component A; consequently, any anion of the type



$$R\text{—}C\begin{cases}O^- \\ OC_2H_5 \\ OC_2H_5\end{cases}$$

that might be formed by reaction of ethoxide ion with component A, would on decomposition regenerate the original component A (ethyl ester) and original base B (ethoxide ion). On the other hand, if X of component A is chlorine, the ethoxide ion probably would convert most of the acid chloride into the corresponding ethyl ester and chloride ion. The very low yield of acetoacetic ester obtained from ethyl acetate in the presence of sodamide[11] is probably due to the predominance of a similar competing reaction between the amide ion $(NH_2)^-$ and the carbonyl group of the ester. In certain cases it is possible to minimize the competing reaction of the base B with component A by first converting the system $\text{H—}\overset{|}{\underset{|}{\text{C}}}\text{—}\underset{|}{\text{C}}\text{=O}$ into its enolate anion, and then allowing this anion to react with component A. Esters may be enolized by sodium triphenylmethyl,[12] and ketones by sodamide.[13] β-Keto esters, such as ethyl acetoacetate,[9] are commonly enolized by sodium ethoxide.

Other factors that limit the type of base B that may be used to effect a Claisen condensation are not well understood at the present time. One of the requirements appears to be that a weaker base must be formed than the one used to initiate the reaction. In all known condensations of ethyl esters by sodium ethoxide the β-keto ester that is formed is converted into its enolate; it should be noted that in this way only can a base (enolate anion) be formed that is weaker than the one (ethoxide ion) used to initiate the reaction. On the other hand, when sodium triphenylmethyl is used in condensations of ethyl esters it is not necessary[1b] for the β-keto ester that is formed to be converted into its enolate, because a weaker base, the ethoxide ion, is formed during the reaction. It should be pointed out, however, that condensation does not always occur even when it appears possible to form a weaker base.[14] Solubility relationships or perhaps other factors may play an important role in these condensations.

Summary

1. The general course of the Claisen type of condensation is outlined.

2. It is proposed that any reaction that involves the carbon–carbon condensation of a metallic enolate with a compound of the type RCOX, where X is an atom or group that is removed as an anion, be classified as a Claisen type of condensation.

3. Certain aspects of this type of condensation are discussed.

[14] Roberts and McElvain [THIS JOURNAL, **59**, 2007 (1937)] have shown that ethyl isovalerate and ethyl *t*-butylacetate are not condensed by sodium ethoxide even though the β-keto esters that would be formed have hydrogen on the α-carbon atom.

[Contribution from the Chemistry Department of Duke University]

Condensations Brought about by Bases. IV. The Condensation of Ethyl Isobutyrate with Benzoyl Chloride, Benzoic Anhydride and Phenyl Benzoate as Examples of the Claisen Type of Condensation[1]

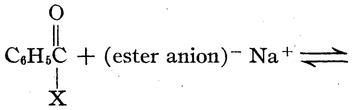
By B. E. Hudson, Jr., R. H. Dick and Charles R. Hauser

The general course of the Claisen type of condensation has been outlined in the third paper of this series.[2] It was pointed out that any reaction involving the condensation of a metallic enolate with a compound of the type RCOX, where X is an atom or group that is removed as an anion, may be classified as a Claisen type of condensation.

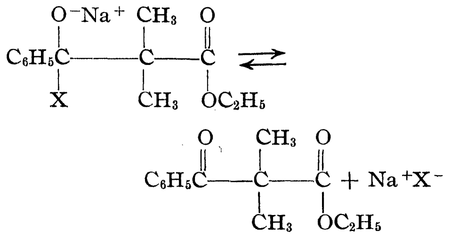
The purpose of this paper has been to investigate the possibility of condensing the simple esters, ethyl acetate, ethyl propionate and ethyl isobutyrate, with a series of compounds of the type C_6H_5COX, using sodium triphenylmethyl as the base. In order to minimize the competing reaction of sodium triphenylmethyl with RCOX, it seemed expedient first to convert the ester into its enolate by means of the sodium triphenylmethyl and then allow the enolate to condense with RCOX, but this procedure has been satisfactory only with ethyl isobutyrate.

Ethyl isobutyrate was added to an ether solution of sodium triphenylmethyl, and, after eight to ten minutes, benzoyl chloride,[3] benzoic anhydride, or phenyl benzoate was added. These reactions gave good yields (50–55%) of the carbon–carbon condensation product, ethyl benzoyldimethylacetate. No oxygen derivative was isolated. These carbon–carbon condensations, as well as the one between ethyl isobutyrate and ethyl benzoate,[4] are regarded as examples of the Claisen type of condensation. They may be represented by the following equations, where X of component A is chlorine, benzoate, phenoxide or ethoxide.

$$(CH_3)_2CHCOOC_2H_5 + (C_6H_5)_3C^-Na^+ \rightleftharpoons (\text{ester anion})^-\,Na^+ + (C_6H_5)_3CH$$



$$C_6H_5\underset{X}{\overset{\overset{O}{\|}}{C}} + (\text{ester anion})^-\,Na^+ \rightleftharpoons$$



$$C_6H_5\underset{X}{\overset{O^-Na^+}{C}}-\underset{CH_3}{\overset{CH_3}{C}}-\underset{OC_2H_5}{\overset{\overset{O}{\|}}{C}} \rightleftharpoons C_6H_5\overset{\overset{O}{\|}}{C}-\underset{CH_3}{\overset{CH_3}{C}}-\underset{OC_2H_5}{\overset{\overset{O}{\|}}{C}} + Na^+X^-$$

It should be pointed out that in order to obtain ethyl benzoyldimethylacetate when X is ethoxide it is necessary to acidify the reaction mixture within a short time,[5] because on standing in the presence of ethoxide ion (which is formed in the condensation), this β-keto ester is converted into ethyl benzoate and ethyl isobutyrylisobutyrate.[6]

The condensation of ethyl acetate or ethyl propionate with compounds of the type RCOX is difficult to control, first because these esters, in the presence of sodium triphenylmethyl, undergo self condensation very rapidly,[7] and, second, because the β-keto esters which result also are capable of condensing with many compounds of the type RCOX. When ethyl acetate or ethyl propionate is added to an ether solution of sodium triphenylmethyl the deep-red color of the latter changes quickly to a lighter color (orange or yellow) even at 0°; and at room temperature a good yield (43%) of ethyl acetoacetate[8] is obtained from ethyl acetate when the reaction is stopped by acidification within three minutes.[7]

It has not been possible to isolate a good yield of the primary condensation product from the reaction of ethyl acetate or propionate with a compound of the type RCOX. The addition of

[2] Hauser, This Journal, **60**, 1957 (1938).

[3] This reaction serves as perhaps the best method for the preparation of ethyl benzoyldimethylacetate. Previously, it has been carried out on a small scale by Scheibler and Stein, *J. prakt. Chem.*, **139**, 105 (1934).

[4] Renfrow and Hauser, This Journal, **60**, 463 (1938).

[5] Ethyl benzoyldimethylacetate has been obtained from ethyl isobutyrate and ethyl benzoate by stopping the reaction after thirty minutes.[4] The yield of β-keto ester that could be isolated in this case, however, was only about one-third of that obtained from the condensation of ethyl isobutyrate with benzoyl chloride.

[6] Further details of this conversion will be published shortly.

[7] It should be pointed out that ethyl isobutyrate likewise undergoes self-condensation in the presence of sodium triphenylmethyl, but at a slower rate. See Hauser and Renfrow, This Journal, **59**, 1823 (1937).

[8] That the enolate of ethyl acetate is an intermediate in this condensation is indicated by the fact that when the ester is added to sodium triphenylmethyl, followed by the addition of iodine, ethyl iodoacetate is obtained (25% yield); Muller, Gawlick and Kreutzmann, *Ann.*, **515**, 109 (1934).

ethyl propionate to an ether solution of sodium triphenylmethyl at 0°, followed immediately by the addition of benzoyl chloride, gave only high boiling products, which were assumed to be benzoylated β-keto esters. The addition of a mixture of ethyl propionate and phenyl benzoate to sodium triphenylmethyl gave a very small yield of a product which apparently was the primary condensation product, ethyl benzoylmethylacetate, but in this case also a considerable amount of higher boiling material was obtained. Low yields of ethyl benzoylacetate[9] and ethyl benzoylmethylacetate (primary condensation products) have been obtained by adding mixtures of ethyl acetate and ethyl benzoate, and of ethyl propionate and ethyl benzoate, to solutions of sodium triphenylmethyl.

Experimental

Preparation of Sodium Triphenylmethyl.—For the condensations studied in this paper ether solutions of sodium triphenylmethyl were prepared by shaking together 63 g. of triphenylchloromethane, 2100 g. of 1% sodium amalgam and 1500 cc. of dry ether as described previously.[10] In some preparations 1500 g. of 1% sodium amalgam to 63 g. of triphenylchloromethane has been used. It is advisable to stop the shaking with the appearance of the deep-red color, and cool the reaction bottle with a wet towel; the shaking should then be continued for about thirty minutes longer. The ether solution of sodium triphenylmethyl may be analyzed as follows. A 50-cc. aliquot of the solution is run into 25 cc. of water in a separatory funnel. The water is drawn off and the ether solution extracted with three additional 25-cc. portions of water. The water is boiled to expel the ether, cooled and titrated with 0.2 *N* sulfuric acid using methyl red as indicator. It has been found that when a good grade of triphenylchloromethane is used the yield of sodium triphenylmethyl is almost quantitative.

Results with Ethyl Isobutyrate.—To the solution of sodium triphenylmethyl was added 25 cc. of ethyl isobutyrate, and the mixture shaken and allowed to stand at room temperature for eight to ten minutes. To the solution of enolate was added with shaking a solution of 21.5 cc. of a good grade of benzoyl chloride dissolved in 50 cc. of ether. The mixture became warm and a white precipitate of sodium chloride separated immediately. After standing at room temperature for several hours the mixture was distilled on a water-bath until the volume was reduced to 300–400 cc. A solution of 5 cc. of acetic acid in 300 cc. of water was added and the mixture shaken in a separatory funnel until two homogeneous layers were obtained. The aqueous layer was drawn off, the ether layer shaken with 10% sodium carbonate solution and dried over "Drierite." The ether solution was filtered from the Drierite and distilled on a water-bath until most of the ether was removed. The residue was cooled in a refrigerator and the precipitate of triphenylmethane filtered off and washed with several portions of ether. The filtrate after further removal of ether was distilled at 15 mm. and all material boiling up to 180° collected. The distillate was redistilled at 15 mm., collecting liquid boiling at 120–160°. A final distillation was carried out at 15 mm. and the fraction boiling at 146–148° taken as ethyl benzoyldimethylacetate.[3] The yield was 20.5–22.5 g. (50–55% of the theoretical amount). The isoxazolone prepared as described previously[4] melted at 69–70°.

Anal.[11] Calcd. for $C_{11}H_{11}O_2N$: N, 7.40. Found: N, 7.40, 7.54.

The condensations of ethyl isobutyrate with benzoic anhydride[12] and with phenyl benzoate were carried out in a similar manner. The yield of ethyl benzoyldimethylacetate obtained with benzoic anhydride was approximately the same as when benzoyl chloride was used; the yield obtained with phenyl benzoate was slightly less.

Results with Ethyl Acetate.—To the ether solution of sodium triphenylmethyl was added at room temperature 16 g. of ethyl acetate, and the solution shaken. The color changed in less than a minute from deep red to orange, and further addition of a little ethyl acetate produced no further color change. After standing for three minutes at room temperature 20 cc. of glacial acetic acid was added. The ether solution was washed with dilute sodium carbonate and dried with "Drierite." Most of the ether was distilled from a water-bath through a fractionating column. The remaining solution was cooled and the triphenylmethane which precipitated filtered off. On fractionation a little ethyl acetate was recovered, and 5 g. of ethyl acetoacetate (43% of the theoretical amount) boiling at 73–76° at 14 mm. was obtained.

A mixture of 17 g. of ethyl acetate and 29 g. of ethyl benzoate was added to the ether solution of sodium triphenylmethyl. After standing for several hours the products were isolated in the usual manner. Some ethyl benzoate was recovered and ethyl acetoacetate was obtained. A small fraction (2.9 g.) of ethyl benzoylacetate boiling at 164–168° at 15 mm. was obtained. This is the approximate boiling point reported in the literature.[13] The isoxazolone melted at 151–152° (corr.) which is in agreement with the melting point reported in the literature.[14]

Results with Ethyl Propionate.—Similar to ethyl acetate, ethyl propionate quickly changes the color of sodium triphenylmethyl.

Eighteen grams of ethyl propionate was added to a rapidly stirred ether solution of sodium triphenylmethyl at 0°, followed immediately by the addition of 25 g. of benzoyl chloride. No ethyl benzoylmethylacetate could be isolated. Mixed with triphenylmethane high boiling products were obtained which were assumed to be benzoylated products. These were not further investigated, since we were interested in the primary condensation products.

---

[9] A better yield of ethyl benzoylacetate has been obtained from ethyl acetate and ethyl benzoate in the presence of sodium ethoxide; Claisen and Lowman, *Ber.*, **20**, 653 (1887).

[10] Hauser and Renfrow, THIS JOURNAL, **59**, 1825 (1937).

[11] Micro-Dumas by R. L. Peck.

[12] This experiment has been carried out by W. B. Renfrow, Jr.

[13] Claisen, *Ann.*, **291**, 71 (1896); see ref. 9.

[14] Moureu and Lazennec, *Compt. rend.*, **144**, 1281 (1907); Uhlenhuth, *Ann.*, **296**, 38 (1897).

A mixture of 17 g. of ethyl propionate and 35 g. of phenyl benzoate was added to the ether solution of sodium triphenylmethyl at room temperature. After standing overnight the products were isolated in the usual manner. Only a little ethyl propionate and phenyl benzoate were recovered. Similar to the experiment with benzoyl chloride, the triphenylmethane was contaminated with high boiling oils. A small fraction (1.5 g.) boiling at 153–156° at 11 mm. which was apparently ethyl benzoylmethyl acetate was isolated.

A mixture of 17 g. of ethyl propionate and 26 g. of ethyl benzoate was added to the ether solution of sodium triphenylmethyl at room temperature. After fifteen minutes the mixture was acidified with acetic acid, and the products isolated in the usual manner. Some ethyl benzoate was recovered, and ethyl propionylmethylacetate was obtained. Four grams of ethyl benzoylmethylacetate boiling at 154–156° at 11 mm. was isolated. Hope and Perkin[15] give 162–163° as the boiling point at 18 mm. The isoxazolone melted at 120.5–121.5° (corr.). Haller and Bauer[16] give 123–124° as the melting point of the isoxazolone after many recrystallizations.

Summary

1. The enolate of ethyl isobutyrate has been condensed with benzoyl chloride, benzoic anhydride, and phenyl benzoate to give good yields of ethyl benzoyldimethylacetate.

2. Ethyl acetate in the presence of sodium triphenylmethyl gives a good yield of ethyl acetoacetate within three minutes.

3. Ethyl acetate and ethyl propionate condense with ethyl benzoate in the presence of sodium triphenylmethyl but only low yields of ethyl benzoylacetate and of ethyl benzoylmethylacetate have been obtained.

4. These reactions are regarded as examples of the Claisen type of condensation.

The Kinetics of the Hydrolysis of Ethyl Orthoformate in D_2O–H_2O Mixtures

BY FRANK BRESCIA AND VICTOR K. LA MER

Introduction

Recent work[1] on acid catalysis in heavy water has led to the general criterion that an increase in the rate in D_2O, over that in H_2O, is evidence that an equilibrium is maintained in the first stage of the reaction mechanism whereas a decrease in rate would indicate that the rate-determining step is a proton transfer in the first stage. In the case of a specific hydrogen-ion catalyzed reaction, the rate in H_2O–D_2O mixtures should be proportional to the relative concentration of D^+ and H^+, if these are the ionic species involved in the equilibrium. This was found to be the case for sucrose inversion,[2] which has been studied[3] over the range of H_2O–D_2O mixtures. We shall subject this hypothesis to further test by investigating the hydrolysis of ethyl orthoformate. This reaction,[4] which is specifically catalyzed by hydrogen ion, has been investigated carefully in H_2O for secondary salt[5] and solvent medium[6] effects. Recently, Hornel and Butler[7] have reported two measurements in a water of high deuterium content to determine the effect of deuterium substitution upon the dissociation constant of cacodylic acid.

Since the reaction is exceedingly sensitive to the concentration of hydrogen ions, acetic acid–sodium acetate buffers are well adapted for kinetic study. The thermodynamic and conductive properties of acetic acid have been studied carefully for the entire range of H_2O–D_2O mixtures.[8] The hydrolysis is accompanied by a relatively large volume change and therefore can be studied dilatometrically—a desirable characteristic when dilution must be avoided.

The velocity constant for a constant buffer ratio decreases steadily as the deuterium content of the solvent increases. This is contrary to the principle that the rate of a H^+ ion catalyzed reaction should increase. At the same time, however, the dissociation constant of acetic acid decreases 3.3-fold on passing from H_2O to D_2O so that it is possible that the rate when referred to the actual concentration of H^+ or D^+ ions increases.

Experimental Procedure

1. **The Apparatus.**—To carry out measurements on limited quantities of heavy water, it was necessary to construct a semi-micro dilatometer (Fig. 1), whose capacity (10 cc.) is about 1/20 of the customary macro apparatus, by reducing the area of the capillary proportionately. The radius of the capillary bore is 0.1277 mm.; its uniformity, determined with a comparator, shows an average deviation of 0.3% the largest single deviation being 0.6%; it is sensitive to a volume change of 0.001% since a change of 0.02 cm. can be read easily (with experience readings can be made to ± 0.01 cm.). The expansion produced by 10 cc. of 0.05 *M* ethyl orthoformate is about 4 cu. mm., which corresponds to a change in height of about 8 cm.

The difficulty of leaking stopcocks was overcome effectively by the use of spring collars and mercury seals. Leakage was tested for by raising the mercury column in the capillary above that in the reaction chamber. The column remained constant at any fixed height over a period of time, long compared to the time needed to complete a run. No difficulty due to sticking was experienced; nevertheless a buzzer was attached at the top of the capillary. A lubricant was unnecessary. The entire dilatometer was immersed in a thermostat at 25.050 ± 0.002°, determined with a B. of S. calibrated platinum resistance thermometer.

2. **Materials.**—Merck C. P. acetic anhydride was redistilled and the middle fraction, 138–139°, collected.

Kahlbaum analytical grade sodium acetate was recrystallized below 80°, dried and pulverized. It was dehydrated between 45–50° for twelve hours and dried completely at 110° for twenty-four hours.

Eastman ethyl orthoformate was shaken several times in a separatory funnel with an aqueous sodium carbonate solution to decompose ethyl formate and neutralize formic acid. The ethyl orthoformate layer was separated, dried over calcium chloride, filtered and distilled. The fraction of b. p. 145–145.5° was retained.

H_2O–D_2O Mixtures.—Waters of 95–99% deuterium content from Norsk Hydro were treated as follows: (a) atmospheric pressure distillation from alkaline permanganate, (b) atmospheric pressure distillation from acid dichromate, (c) slow vacuum distillation. The reaction products, ethyl formate and ethyl alcohol, cannot be removed by distillation. The following technique proved satisfactory for the recovery of the solvent: (a) refluxed for about twelve hours with acid dichromate and distilled at atmospheric pressure; (b) refluxed with alkaline permanganate below the boiling point for twenty-four hours; (c) slow vacuum distillation. The chromate test for alcohol gives a negative result. The densities of the waters were determined in a 10-ml. pycnometer.

3. **Procedure.**—In the early experiments, the buffered solutions were prepared directly in a weight buret which may be connected to the dilatometer by a mercury-sealed glass ground joint. When larger quantities of deuterium oxide became available, 30 cc. of a reactant solution was prepared in a flask. Five cc. of acetic acid was freshly prepared for each experiment by adding acetic anhydride to the water. Several drops were then added to sodium acetate dissolved in water of the same D content. Fifteen cc. of the prepared buffer solution was pipetted into the dilatometer. When temperature equilibrium was established, 0.125 cc. of ethyl orthoformate was added and the mixture stirred with a motor. Suction was applied to the mercury reservoir and the solution followed into the reaction chamber; stopcocks were closed, suction turned off and the buzzer turned on. Readings were taken every two minutes. The elapsed time from the addition of reactant to first readings was about five minutes. The remaining portion of the solution, used within two days to check the first run, was kept in a refrigerator.

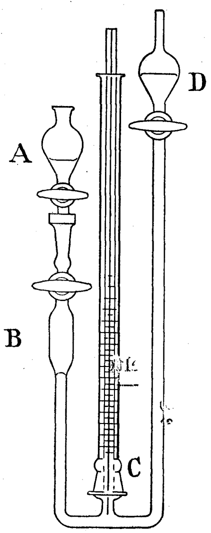

Fig. 1.—A, weight buret; B, reaction chamber; C, capillary; D, mercury reservoir. Approximately one-sixth actual size.

For a long period of time we were troubled with inability to obtain a constant end-point. The hydrolysis of ethyl orthoformate is complete within four hours, yet a very slow expansion of the solution continued over a period of two weeks. We first suspected hydrolysis of ethyl formate as a consecutive reaction. Investigation, however, established that this reaction produces no perceptible volume change. Dr. J. C. Hornel informs us that some previous investigators have corrected their end-point for drifts on the assumption that ethyl formate hydrolyzes slowly.

We observed that scrupulously cleaned apparatus yielded a satisfactory end-point but that on successive filling with duplicate solutions, the end-point reading continued to increase progressively with each refilling, until eventually refilling with water alone yielded a continuous slow expansion. We suspected bacterial decomposition. When the apparatus was sterilized with dilute nitric acid, washed with sterile water, and all buffer solutions preserved on ice, the difficulty entirely disappeared. With the technique described, we now achieve a final reading within six hours which remains constant to within ± 0.01 cm. for at least twenty-four hours.

The velocity constants were calculated by the usual first order formula

$$k = \frac{2.303}{t_2 - t_1} \log \frac{V_\infty - V_{t_1}}{V_\infty - V_{t_2}} \qquad (1)$$

where V_∞ and V_t are the dilatometer readings at time = ∞ and time = *t*; and also by Roeser's method of least squares for equal intervals.[9] The agreement between the two methods was always within 1%; the agreement between duplicate experiments was within 2%. A typical experiment is given in Table I, which shows the absence of drifts and freedom from sticking in the unusually narrow capillary.

k by least square = 0.0317 = 0.0313

For comparison of the rate constants of different experiments, k is corrected to the rounded buffer ratio of 0.001000 M Ac_2O/0.1000 M NaAc.

$$\text{Thus } k_c = (0.0315)\,\frac{(0.09732)}{(0.001010)}\,\frac{(0.001)}{(0.1)} = 0.0304$$

The Specific Catalytic Coefficient of H_3O^+.—The specific catalytic coefficient $k_{H^+} = k/C_{H_3O^+}$. At a given ionic strength

$$C_{H_3O^+} = KC_{HAc}/C_{Ac^-}$$

$K = 2.87 \times 10^{-5}$ at $\mu = 0.1$ and 2.60×10^{-5} at $\mu = 0.05$, obtained by Harned and co-workers[10] in sodium chloride solutions, are used since the corresponding values for sodium acetate solutions are unknown.

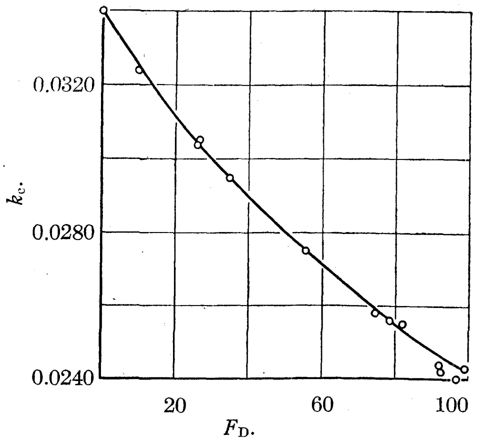

Fig. 2.

TABLE II

SPECIFIC CATALYTIC COEFFICENT OF H_3O^+

Molarity HAc	Molarity NaAc	Expts.	Av. k	$10^{-4}\,k_{H^+}$
0.0008918	0.08814	2	0.0171	6.02
.001422	.1434	1	.0185	6.03
.001312	.06573	2	.0311	5.81
.001989	.09941	2	.0336	5.85
.001926	.09616	2	.0341	5.98
.002255	.1128	2	.0348	5.92
.002444	.1214	1	.0358	5.95

Av. $k_{H^+} = 5.93 \times 10^4$; a. d. = 0.07

The average value $10^{-4}\,k_{H^+} = 5.93$ shown in Table II is in excellent agreement with the value of 6.0 reported by Harned and Samaras,[6] who employed a macro dilatometric method.

The experimental results for constant buffer ratio in mixtures of D_2O–H_2O are given in the first two columns of Table III, and are plotted against F_D in Fig. 2. The data exhibit the characteristic negative deviation from linearity.[11]

The specific catalytic coefficient of D_3O^+, k_{D^+}, is calculated from the value $k_C = 0.0242$ for $F_D = 100$, which is obtained by a short extrapolation from $F_D = 98$ in Fig. 2. C_{D^+} is obtained from

$$K_{DAc} = \frac{C_{D_3O^+}\cdot C_{Ac^-}}{C_{DAc}} = \frac{K_{HAc}}{3.3}$$

substituting 0.002 for C_{DAc}, 0.1 for C_{Ac^-}, and 2.87×10^{-5} for K_{HAc}. Hence, $k_{D^+} = 1.39 \times 10^5$ and the ratio of specific catalytic coefficients is

$$\frac{k_{D^+}}{k_{H^+}} = \frac{1.39 \times 10^5}{5.93 \times 10^4} = 2.35$$

This ratio is not in good agreement with the value 2.05 reported by Hornel and Butler.[7] Part of the discrepancy arises from the fact that these authors employed the value K_{HAc}/K_{DAc} 2.77 calculated from kinetic measurements. Our value 3.3 for the ratio of the dissociation constants is to be preferred since this value is obtained independently from e. m. f. and from conductance measurements.[8] Using 3.3, Hornel and Butler's k_{D^+}/k_{H^+} becomes 2.44, which is in better agreement.

Discussion

The concentration of protium and of deuterium ions in the mixtures of the oxides may be calculated from the kinetic data on the basis of the following considerations. The dissociation constants of acetic acid and of deuteroacetic acid are assumed to be independent of the deuterium content of the solvent water. This assumption is

---

(10) Harned and Robinson, *ibid.*, **50**, 3157 (1928); Harned and Owen, *ibid.*, **52**, 5079 (1930).

(11) *Cf.* Refs. (2) and (4); La Mer and Greenspan, *Trans. Faraday Soc.*, **33**, 1266 (1937).

justified since the dielectric constants and the activity coefficients at constant ionic strength are practically independent of the D content of the solvent. That is

$$K_{HAc} = C_{H^+}C_{Ac^-}/C_{HAc} \qquad (2)$$

and is constant in any mixture of D_2O–H_2O at constant ionic strength. Similarly

$$K_{DAc} = C_{D^+}C_{Ac^-}/C_{DAc} \qquad (3)$$

in mixtures of D_2O–H_2O.

Twice the concentration of acetic anhydride equals the sum of the concentrations of acetic and deuteroacetic acids formed or

$$C_{HAc} + C_{DAc} = 2C_{Ac_2O} \qquad (4)$$

On the assumption that the velocity in D_2O–H_2O mixtures is proportional to C_{H^+} and C_{D^+}

$$k = k_{H^+}C_{H^+} + k_{D^+}C_{D^+} \qquad (5)$$

where k_{H^+} and k_{D^+} are the catalytic coefficients determined above and k, the measured rate constant in a water of deuterium content F_D.

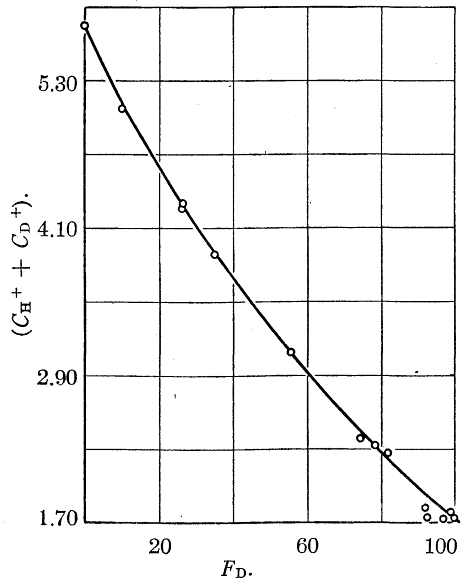

Fig. 3.

Dividing equation (2) by (3) and substituting C_{D^+} from (5), C_{DAc} from (4), and C_{HAc} from (2) gives

$$K = \frac{K_{HAc}}{K_{DAc}} = \frac{k_{D^+}}{k - k_{H^+}C_{H^+}}\left(\frac{2C_{Ac_2O}K_{HAc}}{C_{Ac^-}} - C_H^+\right) \qquad (6)$$

from which

$$C_{H^+} = \frac{k_{D_+}2C_{Ac_2O}K_{HAc}}{C_{Ac^-}(k_{D^+} - Kk_{H^+})} - \frac{Kk}{k_{D^+} - Kk_{H^+}} \qquad (7)$$

Hence, C_{H^+} can be calculated since all quantities on the right are known. k is the rate constant for buffer ratio 0.001 *M* Ac_2O/0.1 *M* NaAc denoted as k_c in Table III. Knowing the value of C_{H^+}, equation (5) yields C_{D^+}, and hence $(C_{H^+} + C_{D^+})$ and F_{D^+}, the fraction of deuterium ions. The sum $(C_{H^+} + C_{D^+})$ divided into k_c gives the specific catalytic coefficient, k_m, for each of the waters used, which is identical with k_{H^+} for H_2O and with k_{D^+} for D_2O.

A sample calculation of the typical experiment is given. Using equation (6)

$$3.3 = \frac{1.39 \times 10^5}{0.0304 - 5.93 \times 10^4\, C_{H^+}}\left(\frac{2(0.001)\,(2.87 \times 10^{-5})}{0.01} - C_{H^+}\right)$$

and solving, $C_{H^+} = 3.62 \times 10^{-7}$. Solving equation (5)

$$0.0304 = (5.93 \times 10^4)\,(3.62 \times 10^{-7}) + (1.39 \times 10^5)C_{D^+}$$

$$C_{D^+} = 6.40 \times 10^{-8}$$

$$C_{H^+} + C_{D^+} = 4.26 \times 10^{-7}$$

$$F_{D^+} = \frac{0.64}{4.26} \times 100 = 15.02 \text{ and}$$

$$k_m = \frac{0.0304}{4.26 \times 10^{-7}} = 7.13 \times 10^4$$

The results of similar calculations are summarized in columns (3) to (7) in Table III.

TABLE III

100	(.0242)	0	1.74	1.74	100	13.9

The results are plotted in Figs. 3 and 4.

Figure 3 shows that $(C_{H^+} + C_{D^+})$ plotted against F_D gives a sagging curve similar to Fig. 2. k_m plotted against F_{D^+} (Fig. 4) gives a straight line in agreement with the results of the hydrogen ion catalyzed sucrose hydrolysis. This, however, is not a proof since in calculating the C_{D^+} we use equation (5) which is based on the assumption that the rate is proportional to F_{D^+}. But we do have sufficient data to check this assumption by calculating the dissociation constant, $K_{H,D}$, for a weak acid in H_2O–D_2O mixtures and comparing with values determined by La Mer and Chittum from conductance data. $K_{H,D}$ is de-

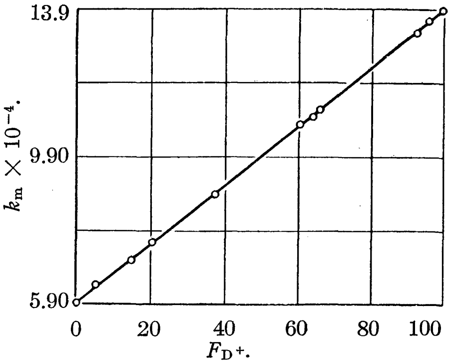

Fig. 4.

fined as $(C_{H^+} + C_{D^+})C_{Ac^-}/(C_{HAc} + C_{DAc})$. Substituting the values for $(C_{H^+} + C_{D^+})$, yields the results summarized in Table IV and plotted against F_D in Fig. 5. La Mer and Chittum's results[8] are represented by filled circles. Since the value 2.87×10^{-5} has been used for the dissociation constant of acetic acid for an ionic strength $\mu = 0.1$ and La Mer and Chittum report 1.84×10^{-5} for $\mu = 0$, we multiply their values by 1.56 for direct comparison. The kinetic results are in substantial agreement with those from conductance. This means that if we had not been able to calculate C_{H^+} and C_{D^+} from our kinetic data but were obliged to use the conductance data, the results would be substantially the same, *i. e.*, k_m plotted against F_{D^+} would yield a straight line, conforming to the basic assumption.

TABLE IV

The Rate-Determining Step.—The theory of intermediate complex formation offers two possibilities for the rate-determining step in an acid catalyzed reaction. The general scheme[12] may be represented as

$$\text{Substrate} + \text{HA} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \text{A}^- + (\text{Substrate, H}^+) \xrightarrow{k_3} \text{Products}$$

Adopting the usual assumption that in the stationary state the probability of disappearance of the complex is unity, the velocity of the reaction may be written as

$$V = -\frac{dC_S}{dt} = kC_SC_{HA} = \frac{k_1k_3}{k_2 + k_3}\,C_SC_{HA}$$
$$\text{or } k = k_1k_3/(k_2 + k_3)$$

Previous researches and discussions[13] have led to the general conclusion that the rate-determining step in a specific hydrogen-ion catalyzed reaction is the rate of decomposition of the complex (k_3), which when multiplied by the equilibrium constant of the reaction: reactants $\rightleftarrows$ complex, yields the rate of the reaction. Then, for the ratio of the rates in D_2O and in H_2O

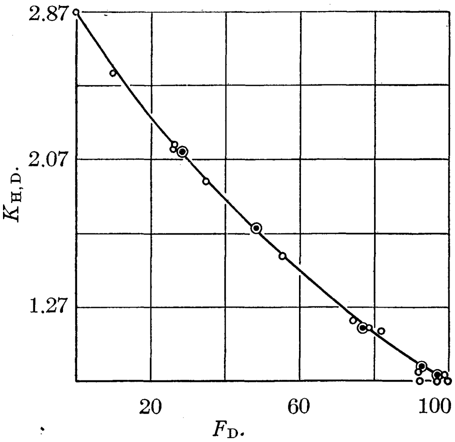

Fig. 5.—Results of La Mer and Chittum, ◉.

$$\frac{k_{D^+}}{k_{H^+}} = \frac{k_{3SD^+}\,K_{SD^+}}{k_{3SH^+}\,K_{SH^+}}$$

where K_{SD^+} and K_{SH^+} are the equilibrium constants involving the heavy and light complexes, respectively. From experiment, the ratio $k_{D^+}/k_{H^+} = 2.35$. If we assume the equilibrium in D_2O is shifted in favor of formation of SD^+ and if the rates of decomposition of SD^+ and SH^+ are

assumed to be equal to kT/h on the basis of Eyring's theory,[14] then $K_{SD^+}/K_{SH^+} = 2.35$.

The increase in the rate on passing to the deutero catalyst is thus explained as the result of a shift in the equilibrium in favor of the heavy complex. We must, however, note that although Urey and Rittenberg[15] have calculated that the equilibrium constant for the reaction $H_2 + 2DCl = 2HCl + D_2$ is shifted in favor of DCl, the reverse was found for $H_2 + 2DI = 2HI + D_2$. The position of the equilibrium $CH_3COCH_3 + HDO = CH_3COCH_2D + H_2O$ was measured by Halford, Anderson and Bates[16] and they found that the equilibrium constant is about two in favor of formation of heavy acetone.

Conclusions

1. The kinetics of the hydrogen-ion catalyzed hydrolysis of ethyl orthoformate in acetic acid–sodium acetate buffers of constant ratio has been investigated over the entire range of H_2O–D_2O mixtures.

2. The specific catalytic constant for D_3O^+ ion is 2.35 times greater than for H_3O^+.

3. A semi-micro dilatometer was constructed for the kinetic measurements which yields results in excellent agreement with the macro results of Harned and Samaras in H_2O.

4. An equation, from which the concentration of hydrogen and deuterium ions can be calculated, is derived.

5. The rate constant for constant acid/salt ratio decreases with increasing D content and shows a negative deviation from linearity. The sum $(C_{H^+} + C_{D^+})$ follows a similar curve. The specific rate constant or catalytic coefficient increases with increasing D content, and is linear with respect to the fraction of deuterium ions.

6. The calculated dissociation constants of a weak acid in H_2O–D_2O mixtures, defined as $(C_{H^+} + C_{D^+})C_{A^-}$/Total undiss. acid, are in substantial agreement with values obtained from the conductance method.

7. The greater catalytic effect of D^+ ion is explained as a shift in the equilibrium $S + H^+ \rightleftarrows SH^+$ in favor of the deutero complex in agreement with Bonhoeffer's treatment.

The Temperature Coefficients of the Base Catalyzed Decomposition of Nitramide in Deuterium Oxide

BY SILVESTER LIOTTA AND VICTOR K. LA MER

The basic decomposition of nitramide ($H_2N_2O_2$) to nitrous oxide and water is catalyzed by the presence of any molecule, for example, water or the anions of weak acids, which possesses the property of associating a proton; *i. e.*, by basic molecules in the Brönsted formulation. The molar catalytic constant, k, is related to the dissociation constant, K_A, of the acid, conjugate to the catalyst base, by the well-known empirical formula $G = kK_A^{\alpha}$. For carboxylic anions in water, $\alpha = 0.83$, indicating a high sensitivity of the substrate to changes in K_A. Since deuterium substitution always reduces the value of K_A by a factor of 2 to 4, depending upon the strength and type of the acid, it becomes of interest to investigate the effect of deuterium substitution upon the rate of anion catalysis by determining the effect upon the constant G and the sensitivity index α.

It is also one of the purposes of this investigation to study in how far the rate depressing action of deuterium substitution arises from a displacement of the energy of activation and of the entropy of activation.

When proto nitramide is dissolved in D_2O at least one and presumably both protons are exchanged instantaneously for deutons, producing deutero-nitramide as the effective substrate.[1] In their investigation of the effect of deuterium substitution upon the *solvent catalysis*, La Mer and Greenspan[2] found that the substitution of deuterium for protium in the solvent produced a 5.21-fold decrease in rate.

There are two possible mechanisms. The first, suggested by Brönsted and supported by Peder-

sen and by Marlies and La Mer, postulates that the rate-determining step is the rate of transfer of the proton from the substrate to the catalyst base. The slower rate in D_2O on this mechanism would be ascribed to the slower rate of donation and of acceptance of deutons as compared to protons.

The second, based upon the transition state theory of kinetics, would ascribe the difference in rate on passing from the proto to the deutero systems to a shift in the equilibrium between reactants and critical complex with the additional possibility of a differential rate of decomposition of the proto and deutero complexes.

If one employs anions like acetate, benzoate and salicylate rather than the solvent as the effective catalyst base, the problem becomes somewhat simplified since the hydrogens attached to carbon do not exchange and the base remains unchanged regardless of the D content of the solvent. For a more detailed treatment of the general problem of isotopic exchange and the effects of deuterium substitution for hydrogen upon the properties of conductance, e. m. f. and acid-base catalysis the reader is referred to current reviews and symposia.[3]

The difficulty of obtaining sufficiently large quantities of water with high deuterium content when this investigation was initiated (1935) led to the development of a gas evolution apparatus[4] applicable to a precision study on a semi-micro scale. The apparatus, which requires only 10 cc. of solution, yields results which are even more precise than those obtained with the macro-types employing 60–100 cc. of solution.

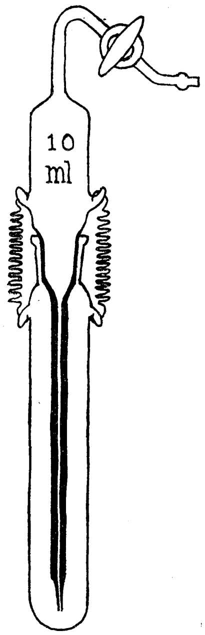

Fig. 1.—Special weight pipet.

Preparation of Materials

Nitramide was prepared by the improved method of Marlies and La Mer.[5]

Heavy water was initially purified by distillation at atmospheric pressure from alkaline permanganate, from acid chromate and finally vacuum distilled in an all-glass Pyrex still with a receiver cooled with solid carbon dioxide–alcohol mixture. The water was recovered by vacuum distillation after neutralization of excess acid with solid sodium hydroxide. After each cycle of use, neutralization and distillation, the deuterium content diminished by only 0.2%.

Sodium acetate was recrystallized from distilled water, and dried *in vacuo* over calcium chloride at 40° for three days. Complete dehydration was achieved in two days at 115° following a gradual elevation of temperature to prevent fusion of the hydrate. The purity of the reagents was established by kinetic comparisons with the values of $k_{\text{Ac}-}$ and $k_{\text{H}_2\text{O}}$ obtained in H_2O by previous investigators.

Acetic acid was prepared by adding acetic anhydride directly to the H_2O–D_2O solvent. The anhydride was triply distilled in a Pyrex Vigreux fractionating column, retaining as the final fraction the distillate boiling at 139.0 ± 0.1°.

Sodium benzoate and sodium salicylate were recrystallized twice from distilled water; **benzoic acid** twice from alcohol; **salicylic acid** twice from chloroform. All salts were dried in a vacuum desiccator.

The solutions were made up just before use by weighing acid, salt and solvent in the same container. Acetic anhydride and sodium acetate were added with a special weight pipet (Fig. 1). The latter was added in the form of a concentrated solution of known composition.

Apparatus and Experimental Procedure

The semi-micro apparatus contains a number of specific improvements which have been described in detail elsewhere. Four such instruments were immersed in a thermostat maintained within ± 0.004° at 15°, ± 0.002° at 25° and ± 0.003° at 35°, and checked against a B. S. standardized platinum resistance thermometer.

Since the decomposition yields only a few milligrams of H_2O and N_2O as the sole products, the composition of the solution is changed only by a small calculable decrease in D content and should, therefore, be available for successive runs without removal from the apparatus or variation in the concentration of the catalyst. This procedure was highly satisfactory in the previous work where hydrochloric acid solutions were involved but failed in the case of the sodium acetate solutions.

The conflicting reports in the literature on isotopic exchange with acetate ion naturally suggested that we were observing the effects of slow exchange of H by D on the carbons of the acetate ion. Specially designed experiments, however, established that no exchange takes place at 25° over two weeks' time since the densities of the recovered waters in these experiments remained constant to within five parts in 100,000.[6] The disturbance was finally traced to the instability of dilute sodium acetate–acetic acid buffers,[7] very likely through bacterial decomposition. This conclusion was confirmed by measuring the change in conductance with time, of a representative solution of 0.01 *M* sodium acetate and 0.04 *M* acetic acid with the following results

Time, days	0	1	2	3	5
Resistance, ohms	683	681	679	678	675

When the buffer solutions were prepared and used immediately thereafter, reproducible results were always obtained, which procedure was accordingly adopted.

Methods of Calculation

The anion catalyzed decomposition follows accurately the first order law in heavy water mixtures. Since the final pressure is proportional to the initial concentration (C_0) and the instantaneous concentration (C_1) is proportional to the difference between the final and instantaneous pressures

$$k^* = (1/t) \ln (p_\infty - p_0)/p_\infty - p) \qquad (1)$$

$$\text{or } \log (p_\infty - p) = \text{const.} - kt \qquad (2)$$

where $k = 0.4343\, k^*$.

The units of time and concentration are minutes and moles per liter, respectively. The graphical determination of k from $\log (p_\infty - p)$ *versus* t plots is too cumbersome and not sufficiently precise to warrant its use. An especially simple analytical method based on the principles of least squares, if the observations are separated by equal time intervals, suggested by Roeser,[8] has been found satisfactory by Marlies and La Mer.[9] This method gave the best agreement between independent experiments.

Unless the reaction requires an exceedingly long time for completion, p_∞ should be the most accurate measurement of the series since the readings can be repeated. Practically, however, the possibility of leaks in the apparatus or of side reactions like the decomposition of the buffer, require the use of the Guggenheim method[10] when the end-point cannot be determined more precisely than the running values of p. We found this method to be better for the exceedingly slow spontaneous decomposition at 15°.

The molar catalytic constant k is obtained from the relation $k = (k_{\text{obsd.}} - k_0)/C$, where k_0 is the velocity of the spontaneous decomposition due to the solvent and C is the concentration of the catalyst in moles per liter. When 0.01 M hydrochloric acid is used, $k_{\text{obsd.}}$ yields k_0 directly. The hydrochloric acid serves to eliminate the presence of hydroxyl ion and since at that concentration the acid catalysis is negligible, the rate is entirely due to the basic properties of the solvent. In this work we were obliged to use water of D content = 91.5% rather than 100% D_2O so that the respective catalytic constants are made up of two factors, the major part due to the 91.5% D_2O and a small part to the 8.5% H_2O.

Experimental Results

The values obtained for $k_{\text{obsd.}}$ and k are given in Table I. Variation in anion and acid concentration produced no variation in molar catalytic constant k. The values of the temperature coefficients for 15–25°, the energies of activation E and the frequency factor B in the integrated form of the Arrhenius equation

$$\log k = B - \frac{E}{2.3RT} \qquad (3)$$

are given in Table II. The values for H_2O were obtained by Baughan and Bell,[11] who use a least square treatment over a range of temperature. In Table III are listed the values of k at 15 and 25° as well as their ratios in the two solvents.

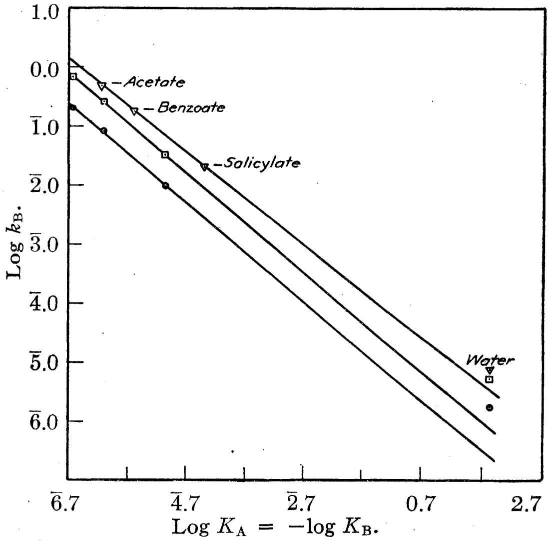

Fig. 2.—The relation between the logarithms of the velocity constants (ordinates) and dissociation constants (abscissas): ▽, H_2O at 15°; □, D_2O at 25°; ○, D_2O at 15°.

Discussion

Rate and Equilibrium Constants.—Brönsted's equation for generalized base catalysis

$$\log k_B = \log G - \alpha \log K_A \qquad (4)$$

is tested at F_D = 91.5% in Fig. 2 by plotting $\log k_B$ against $\log K_A$. The three anion bases chosen extend over a range of 1.4 units in $\log k$ and 1.6 units in $\log K_A$. Since the acidic dissociation constants in D_2O at 15° were not all

[a] Using Greenspan's more precise value for $k_0^{25°} = 1266 \times 10^{-6}$, then $k_{\text{H}_2\text{O}}/k_{\text{D}_2\text{O}} = 4.12$.

available, the use of values of K_{A} measured at 25° may account for the minor discrepancies from linearity on the 15° curve.

In heavy water as well as in light water, the point representing the catalytic properties of the solvent acting as a base lies above the continuation of the line obtained with the anion bases. This is consistent with Pedersen's theory[12] that for bases of the same strength the catalytic effect increases in the series $B^- < B^0 < B^+$ provided the substrate is uncharged. The difference may also arise from the fact that H_2O is a base of a different chemical type from the carboxylic anions.

Since the Brönsted relation holds equally well for a mixed deuterium water as for pure H_2O, a plot of $\log k_{D_2O}$ *versus* $\log k_{H_2O}$ should yield a straight line, provided $\log K_{D_2O}$ *versus* $\log K_{H_2O}$ exhibits the same linear relationship. That this conclusion is valid may be demonstrated as follows.

Figure 3 shows that the $\log k_{D_2O}$ points adhere closely to the linear equation

$$\log k_{D_2O} = x \log k_{H_2O} + C \qquad (5)$$

at both temperatures.

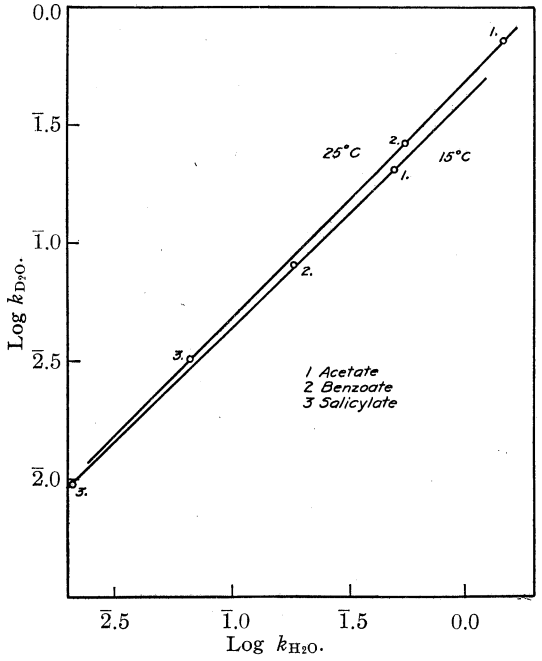

Fig. 3.—The logarithmic relation between the velocity constants in water and deuterium oxide at 15 and 25°: 1, acetate; 2, benzoate; 3, salicylate.

For light and heavy waters, respectively

$$\log k_{D_2O} = \log G_{D_2O} - \alpha' \log K_{D_2O} \qquad (6)$$

$$\log k_{H_2O} = \log G_{H_2O} - \alpha'' \log K_{H_2O} \qquad (7)$$

combining (5), (6) and (7) yields

$$\log K_{D_2O} = \frac{x\alpha''}{\alpha'} \log K_{H_2O} - \frac{x \log G_{H_2O} - \log G_{D_2O} + C}{\alpha'} \qquad (8a)$$

which is of the form

$$\log K_{D_2O} = y \log K_{H_2O} + C_0 \qquad (8b)$$

Substituting the kinetic data in equation (5): $x = 0.967$; $C = 9.611–10$ (Fig. 3); $\log G_{H_2O} = 5.792–10$; $\log G_{D_2O} = 4.998–10$; $\alpha' = 0.832$; $\alpha'' = 0.83$ (Table IV); yields $y = 0.965$ and $C_0 = -0.60$.

A plot of $\log K_{H_2O}$ *versus* $\log K_{D_2O}$ obtained from e. m. f.[13] data yields a straight line of slope $y = 0.972$ which is within 1% of the predictions, and $C_0 = -0.30$. The disagreement of 0.30 unit between the observed and calculated values of C_0 may arise from the uncertainty in executing the graphical solution, and in the accumulation of errors originally present in the constants obtained from equations (5), (6) and (7).

The studies of Brönsted and co-workers[14] on the decomposition of nitramide in *m*-cresol and H_2O furnish further data for testing this relation. Equation (4) holds in both solvents. The plot of the dissociation constants, $\log K_{\text{cresol}}$ *versus* $\log K_{H_2O}$ yield a linear relation with unit slope. In the case of velocities (Fig. 4) when the log k_{cresol} values of Brönsted, Nicholson and Del-

[12] Pedersen, *J. Phys. Chem.*, **38**, 581 (1934).

[13] Schwarzenbach, Epprecht and Erlenmeyer, *Helv. Chim. Acta*, **69**, 1292 (1936). Some of these data will require revision in the light of researches in progress in this Laboratory since the measurements involve galvanic cells with junction potentials. See Rule and La Mer, THIS JOURNAL, **60**, 1974 (1938).

[14] (a) Brönsted, Nicholson and Delbanco, *Z. physik. Chem.*, **169**, 379 (1934); (b) Brönsted, Delbanco and Tovberg-Jensen, *ibid.*, **169**, 361 (1934); (c) Brönsted and Duus, *ibid.*, **117**, 299 (1925); (d) Brönsted and Vance, *ibid.*, **A163**, 240 (1933).

banco are plotted against the log k_{H_2O} values of Brönsted and Duus, a straight line of slope $x = 1.11$ is also obtained. Since $\alpha_{H_2O} = 0.75$ and $\alpha_{m\text{-cresol}} = 0.84$, the calculated value for y in the equation corresponding to (8b) is $y = 0.99$, in excellent accord with the value of unity reported in reference (14b). A linear relation also obtains for the data of Brönsted and Vance[14d] using isoamyl alcohol as solvent (line A of Fig. 4).

Although several authors have shown that the logs of the dissociation constants in different solvents are related linearly when the solvents are as diverse as water, concentrated sulfuric acid and benzene,[15] no one appears to have called attention to the linear relationship between the logs of the velocity constants of a reaction obeying the Brönsted relation in two solvents.

The Arrhenius and Brönsted Equations.—Table IV summarizes the values of α and G in the Brönsted eq. (4). The decreases in rate arising either from a decrease in temperature or substitution of deuterium in the substrate and solvent are reflected almost exclusively in G and not in α. G may be interpreted as the rate for a hypothetical acid–base system K_A = unity. It appears that temperature and deuterium substitution operate primarily upon the fundamental kinetic properties of the substrate in the case of anion catalysis rather than upon the acid-base properties of the catalytic system.

TABLE IV

COMPARISON OF THE VALUES OF α AND G FROM THE BRÖNSTED EQUATION IN 91.5% D_2O WITH THOSE IN H_2O

Temperature, °C.		15	25
Present authors (D_2O)	α	0.832	0.845
	G	9.95×10^{-6}	2.94×10^{-5}
Baughan and Bell[11] (H_2O)	α	0.794	0.758
	G	8.44×10^{-5}	3.69×10^{-4}
Brönsted and Pedersen[16] (H_2O)	α	0.83	
	G	6.2×10^{-5}	

Baughan and Bell[11] report α equal to 0.76 at 25, 35 and 45°, but consider that the 4% increase to 0.79 at 15° is a real effect. Our data in D_2O do not support this view. Where comparisons can be made our data are in better agreement with those of Brönsted and Pedersen[16] than with those of Baughan and Bell.

In equation (3), $B = \log \frac{kT}{h} + \frac{\Delta S^*}{2.3R}$ where ΔS^* is Eyring's[17] entropy of activation which includes the contributions of all degrees of freedom (translational and internal) and kT/h is a pure frequency (ν) equal to $10^{14.6}$ (min.$^{-1}$) at 25°. In the collisional form of the statistical theory of kinetics,[18] kT/h is replaced by $Z°$, the collision frequency, which is equal to approximately $10^{12.2}$ (min.$^{-1}$) at 25°. In the notation of the English school, $B = \log A = \log PZ$; hence $\log P = S_{\text{act.}}/2.3R$. Here the entropy of activation, $S_{\text{act.}}$, as defined by La Mer,[18] does not contain the entropy contributions of the two translational degrees of freedom involved in the collision process. These contributions are contained in $Z°$.

Before the concept of entropy of activation was stressed[18] it was generally assumed that a catalyst effected an increase in rate solely by lowering the potential barrier (energy of activation). In Table V, we have decomposed $\Delta \log k = \Delta F^*/2.3RT$, where ΔF^* is the free energy of activation,

TABLE V

Catalyst referred to the "spontaneous" decomposition (H_2O) (11)	$\Delta \log k_{25}$	$\Delta \log A = \Delta B$	$-\Delta E/2.3RT$
Trimethylacetate	3.274	1.59	1.67
Acetate	3.082	1.97	1.10
Benzoate	2.652	1.61	1.04
Formate	2.318	1.33	0.96
Salicylate	1.735	1.28	.44
Monochloroacetate	1.579	1.01	.54
o-Nitrobenzoate	1.135	2.30	−1.20
Dichloroacetate	0.290	2.45	−2.19
Catalyst referred to the "spontaneous" decomposition (D_2O)			
Acetate	3.379	4.64	−1.28
Benzoate	2.939	2.99	−0.08
Salicylate	2.033	2.84	−0.83
Data in H_2O referred to D_2O for same catalyst			
Acetate	0.308	−1.55	1.85
Benzoate	.318	−0.26	0.59
Salicylate	.307	−0.44	.75
Spontaneous	.605	+1.12	− .52

R. P. Bell informs us (July 7, 1938) that the values in Baughan and Bell's Table IV[11] should be corrected to read

Monochloroacetic $A = 1.19 \times 10^{-13}$; $E = 19{,}640$
Dichloroacetic $A = 2.35 \times 10^{-14}$; $E = 23{,}160$

This produces a corresponding change in our Table V to read

	$\Delta \log k$	ΔB	$-\Delta E/2.3RT$
Monochloroacetate	1.574	0.80	0.77
Dichloroacetate	0.285	2.09	−1.81

These changes do not affect our conclusions.

---

into its component entropy and energy factors B and $E/2.3RT$, respectively. The data show that $\Delta \log k$, representing the catalytic effects of the anions referred to the solvent decomposition as a standard, is dominated more by an increase in the entropy of activation $\Delta B = \Delta S^*/2.3R$, than by a decrease in the energy of activation. This is particularly true of our data in 91.5% D. The only exception in H_2O is Baughan and Bell's result for trimethylacetate ion.

In their studies on the mutarotation of glucose, Hamill and La Mer[19] found that the increased catalysis of H^+ over that of the solvent decomposition, $\Delta \log k = 1.47$, was due to an increase in B of 3.48 units which was more than sufficient to overshadow the rate depressing effect of an increase of 1.95 units in $E/2.3RT$. Recently, Smith and Smith[20] report that the energy of activation of this reaction varies but very little with a series of catalysts. The marked changes in rate are due almost exclusively to a variation in $\log P$, *i. e.*, in the entropy of activation. From their data, B varies approximately as the square root of the acid dissociation constant K, a relation which Smith[21] had suggested previously for the acid–base catalyzed acetone–iodine reaction. The greater importance of entropy of activation is *not* confined to proton transfers but is illustrated also in the primary salt catalysis of ionic reactions. The Debye–Hückel limiting law requires that B increase with the square root of the ionic strength three times as rapidly as $E/2.3RT$.[22]

When the same anion catalyst operates in H_2O and in D_2O, we find (Table V) an almost constant difference in the free energy of activation ($\Delta RT \log k$), irrespective of the anion. The entropy and energy factors, however, appear to be specific to the anion, with the latter exercising a more predominant effect than the former.

Although equation (4) is a well-established empirical relation, which is obeyed closely in the nitramide decomposition and acetone–iodine reactions, no satisfactory theoretical derivation has been forthcoming. Brönsted[23] offered what he termed "a plausible (but) not absolutely cogent" development. Horiuti and Polanyi[24] "derive" equation (4) by assuming for a series of homologous reactions that

$$\log K = \Delta H/RT + \text{const.} \qquad (9)$$

$$\log k = E/RT + \text{const.} \qquad (10)$$

Equation (9) is an approximation which is not valid for the dissociation of weak acids over a range of temperature and does not hold for different acids since a change in the free energy of ionization between two acids is not generally followed by a corresponding change in the heat of ionization.[25] Horiuti and Polanyi's assumption that $\log k$ varies from catalyst to catalyst solely from changes in activation energy E is certainly not permissible in the light of the data discussed above. Any derivation which yields the Brönsted relation without consideration of entropy factors achieves the result by some fortunate cancellation which is not clear from the premises and the development.

Summary

1. Precision measurements of the anion catalysis of the decomposition of nitramide have been extended to waters of 91.5% deuterium content at 15 and 25°.

2. The velocity of anion catalysis is decreased approximately 2.3 fold at 15° and 2.0 fold at 25° for the bases, acetate, benzoate and salicylate ions on passing from H_2O to 91.5% D_2O.

3. The Brönsted equation $G = kK_A^\alpha$ relating velocity and dissociation constants holds accurately in D_2O. The exponent α characterizing the sensitivity of the substrate to basic catalysis is not perceptibly affected by temperature or by isotopic substitution. Most of the rate depressing effect of deuterium substitution is reflected in the constant G since K_A is also reduced.

4. Although the difference in the free energy of activation between proto and deutero forms is practically constant for these anion catalysts at 25°, the corresponding entropy and energy differences do not remain constant.

5. For a given solvent (H_2O) or (D_2O) the entropy factor is predominant in determining the rate for a series of anions, whereas for the same anion catalyst the energy of activation is the more important factor in deuterium substitution.

6. The spontaneous water reaction is of a different mechanism from the anion catalyzed process as judged by the influence of temperature and deuterium substitution.

7. The interdependence of the rates of a base catalyzed reaction and the dissociation constants of the catalysts on passing to new media is discussed in the light of the Brönsted equation. Attention is called to a linear relation between the logarithms of the rate constants in the two media.

Dissociation Constants of Deutero Acids by E. m. f. Measurements

By C. K. Rule and Victor K. La Mer

Although the dissociation constants of weak acids are decreased by a factor of two- to four-fold on passing from H_2O to D_2O, there is disagreement regarding the underlying theory. One school holds that the ratio of the dissociation constants of the proto and deutero forms of an acid is a function of the strength of the acid; the second that the ratio is constant for acids of a given type; a third,[1] that the ratio is uniformly three regardless of type.

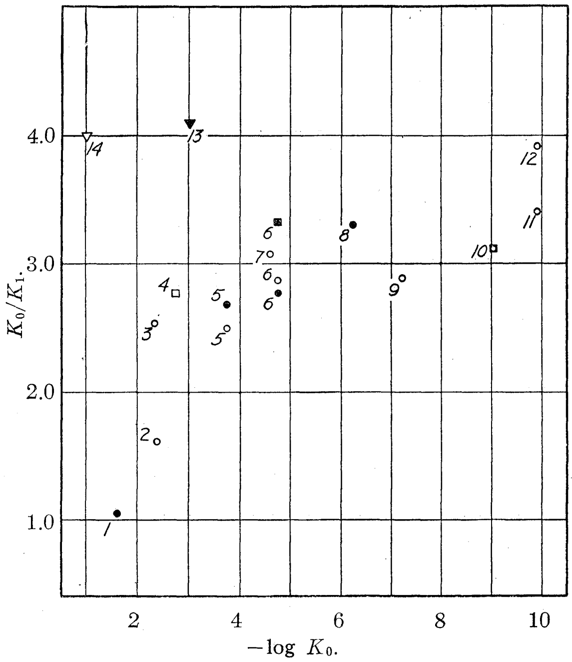

Fig. 1.—Dissociation constant ratios. Acids and references: 1 oxalic,[1a] 2 phosphoric (first),[3] 3 glycine,[3] 4 chloroacetic,[2] 5 formic,[1a,3] 6 acetic,[1a,4,23] 7 aniline hydrochloride,[3] 8 cacodylic,[1a] 9 phosphoric (second),[3] 10 ammonium chloride,[2] 11 glycine hydrochloride,[3] 12 trimethylamine hydrochloride,[3] 13 salicylic,[4] 14 picric.[1b] Methods of measurements: ● catalytic, ○ potentiometric with transference, □ conductimetric, ▽ distribution coefficient, ▼ potentiometric (approximate), ▣ conductimetric and potentiometric without transference.

Lewis and Schutz[2] predicted that the ratio will depend on the strength of the acid—being larger the weaker the acid. They assumed that the potential field is unchanged by the substitution of a deuteron for a proton. Then the deutero acid will have a lower zero point energy and will be less dissociated, the difference increasing with decreasing strength of the acid. They mention that the difference in the extent of dissociation of the proto and deutero acids will depend also on the difference between their entropies of dissociation.

On the other hand, Schwarzenbach[3] concludes from measurements on cells with liquid–liquid junctions that the ratio is a function of the type of the acid, being smaller for carboxylic acids than for amine hydrochlorides.

A critical consideration of the data in the literature shows that there is little accurate work upon which to base a decision between these conflicting theories. These data are shown in Fig. 1. The ratios of the dissociation constants of the proto to those of the deutero acids are plotted against the logarithm of the dissociation constants of the proto acids. The differences of 15 and 20% between the ratios reported by different investigators for acetic acid are an indication of the inaccuracy of the data.

When accurate measurements are required, the uncertainty introduced by the presence of liquid–liquid junctions between H_2O and D_2O should be avoided in potentiometric studies. Korman and La Mer[4] have demonstrated the suitability of the quinhydrone electrode for measurements in H_2O–D_2O mixtures. We have accordingly reinvestigated their cells

Apparatus and Experimental Procedure

Accurate measurements with the silver–silver chloride electrode require the exclusion of oxygen and liberal washing with the cell solution.[5] A semi-micro cell, Fig. 2, was devised which avoided waste of solution, exposure to air, or contact of the solution with any surfaces except Pyrex which had been steamed. The relatively higher ratio of glass and electrode surfaces to the volume of solution in the micro as compared to the macro technique demands special care in cleaning apparatus and eliminating contact with foreign gases.

Solutions were made up in a 50-cc. flask fitted with a ground glass cap, stopcock and a small ground glass joint. The solvent was run directly from the pycnometer into the flask; solids were added contained in micro weighing bottles; liquid solutes were added from weight burets. The flask containing the solution was attached to the vacuum and nitrogen gas lines and air was removed from the solution by repeated evacuation and shaking followed by the admission of nitrogen. Account was taken of the loss of water by evaporation.

The cell with electrodes in place was connected to the vacuum line. The flask containing the solution was connected directly to the cell through a ground glass joint. Having evacuated the cell, small amounts of solution were admitted to wash the silver–silver chloride electrodes. The wash solution was kept in contact with the electrodes for some ten minutes, was drawn off into a trap, and the washing was either repeated or the entire cell filled. No difference was observed between the potentials of cells in which the electrodes were rinsed twice and those in which they were rinsed only once. Each solution of 16 cc. sufficed to fill two cells, allowing for rinsing.

A Leeds and Northrup type K-II potentiometer was used with two Bureau of Standards Weston cells. The thermostats were maintained at 5, 25 and 45 ± 0.02° as determined by a B. of S. platinum resistance thermometer. No hysteresis was observed when the cells were transferred back and forth from one thermostat to another. Distillation of solvent was prevented by filling the cells completely. The potentials of the duplicate silver–silver chloride electrodes against the duplicate quinhydrone electrodes were recorded every ten minutes. Equilibrium was assumed when the potentials remained constant within 0.1 millivolt for an hour. No drift of potential was observed in the use of the quinhydrone electrode at 45° except when the cell contained a buffered solution of dihydrogen phosphate.

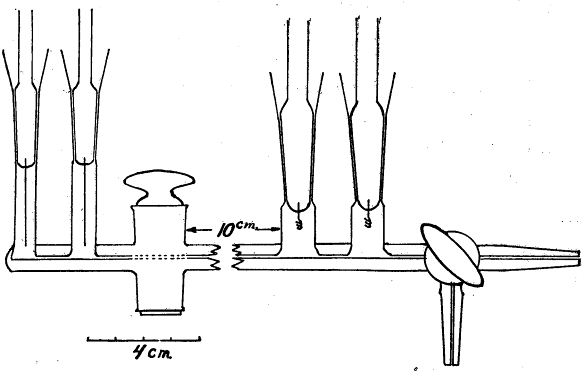

Fig. 2.

Purification of Materials.—Three preparations of quinhydrone were used—one made by the method of Biilman and Lund.[6] The others were Eastman, one of which was purified by recrystallization from conductivity water in an atmosphere of carbon dioxide. All gave the same potentials. Silver–silver chloride electrodes were made as described by Rule and La Mer,[7] the silver chlorate having been prepared from silver carbonate and chloric acid free from other halogens, and twice recrystallized.

Bureau of Standards benzoic acid was used. Sodium benzoate was recrystallized from alcohol and was neutral to phenolphthalein. Potassium dihydrogen phosphate was recrystallized three times and dried at 110°. Its loss of weight on ignition was 13.16% (theory 13.23%). When titrated against sodium hydroxide using phenolphthalein indicator, its molecular weight was found to be within 0.3% of the theoretical. $Na_2HPO_4 \cdot 2H_2O$ was a sample of special purity prepared for work with enzymes. It was exposed to the atmosphere until it had reached constant weight. Loss on ignition was 25.29% (theory 25.30%). Analysis for phosphate, by precipitation as $MgNH_4PO_46H_2O$ and weighing as $Mg_2P_2O_7$, showed 53.29% (theory 53.36%).

Sodium chloride was recrystallized by La Mer and Kamner.[8] Potassium chloride was recrystallized once. They were dried at 110°.

$H_2O–D_2O$ mixtures were recovered from previous experiments. The quinhydrone was oxidized by alkaline potassium permanganate in a flask kept at 80° for thirty-six hours or until permanganate was no longer reduced. The water was distilled *in vacuo* and redistilled *in vacuo* from an alkaline solution. Its density and conductivity were determined in a combined pycnometer and conductivity cell whose volume was 16 cc. The water was forced through a glass tube directly from the pycnometer into the flask in which the solution was made up. Water having a specific conductivity greater than 2.10^{-6} ohm^{-1} was not used.

Constant boiling hydrochloric acid was prepared according to Bonner and Titus.[9]

Nitrogen gas was freed from oxygen by passage through a tower containing copper spirals bathed with a solution of ammonium hydroxide saturated with ammonium chloride.[10] Ammonia and water were removed subsequently by means of two absorption towers filled with sulfuric acid solutions, followed by two traps cooled to −78°.

Methods of Calculation

The ratio of the dissociation constants of hydroquinone in H_2O and D_2O can be calculated from the difference of the electromotive forces of cell I when H_2O is replaced by D_2O.[11] Silver and silver chloride are solids whose activities are unity by definition whether the electrode be immersed in H_2O or in D_2O.[12]

Hence, the standard electromotive force of cell I is

$$E_0^0 = \frac{RT}{2F} \ln \frac{(QH_2)_0}{(Q)_0(HCl)_0} \tag{1}$$

when the solvent is H_2O, and is

$$E_1^0 = \frac{RT}{2F} \ln \frac{(QD_2)_1}{(Q)_1(DCl)_1} \tag{2}$$

when the solvent is D_2O.[14]

Subtracting E_0^0 from E_1^0

$$E_1^0 - E_0^0 = \frac{RT}{2F} \ln \frac{(QD_2)_1(Q)_0(HCl)_0^2}{(QH_2)_0(Q)_1(DCl)_1^2} \tag{3}$$

Introducing K_0 and K_1, the geometric mean of the first and second dissociation constants of hydroquinone and hydroquinone-d_2, respectively

$$E_1^0 - E_0^0 = \frac{RT}{2F} \ln \frac{(Q)_0(Cl^-)_0^2(Q^=)_1K_0^2}{(Q_1)(Cl^-)_1^2(Q^=)_0K_1^2} \tag{4}$$

The relative free energies of chloride ions and of quinone ions in H_2O and in D_2O not being known, we must assume that the factor $(Q)_0(Cl^-)_0^2(Q^=)_1/(Q)_1(Cl^-)_1^2(Q^=)_0$ is unity. Eq. (4) becomes

$$E_1^0 - E_0^0 = \frac{RT}{F} \ln \frac{K_0}{K_1} \tag{5}$$

Using this equation, the ratios of the dissociation constants of hydroquinone and hydroquinone-d_2 can be calculated from the difference of the standard electromotive forces of cell I when the solvent is D_2O and when it is H_2O.

On the other hand, the equilibrium constant, K_2, of the exchange reaction $QH_2 + 2DCl \rightleftarrows QD_2 + 2HCl$ can be calculated on the assumption that quinone has the same activity in D_2O as in H_2O. Equation (3) then reduces to

$$E_1^0 - E_0^0 = \frac{RT}{2F} \ln \frac{(QD_2)_1(HCl)_0^2}{(QH_2)_0(DCl)_1^2} = \frac{RT}{2F} \ln K_2 \tag{6}$$

The dissociation constants of other acids in H_2O–D_2O mixtures can be determined from the e. m. f. of cell II following the methods of Harned and co-workers[15] and Korman and La Mer,[4] who first applied the method to deutero acids. The e. m. f. of cell II for an H_2O–D_2O mixture in which the mole fraction of deuterium is *n*, is[16]

$$E_n = E_n^0 - \frac{RT}{2F} \ln \frac{(QH_2 + QD_2)_n}{(Q)_n(H^+ + D^+)_n^2(Cl^-)_n^2} \tag{7}$$

For low ionic strengths where the salt effect of the quinhydrone electrode is negligible $(QH_2 + QD_2)_n = (Q)_n$ and

$$E_n = E_n^0 - \frac{RT}{F} \ln \frac{1}{(H^+ + D^+)_n(Cl^-)_n} \tag{8}$$

In this equation E_n is the e. m. f. of cell II and E_n^0 is the standard e. m. f. of cell I when the fraction of deuterium in the solvent is the same for both cells. Defining the dissociation constant of an acid in an H_2O–D_2O mixture as[17]

---

(10) Van Brunt, THIS JOURNAL, **36**, 1448 (1914).

(11) La Mer and Korman, *ibid.*, **57**, 1511 (1935).

(12) Drucker[1] has attempted to show, by measuring the cells

$Ag–AgCl\ |^1\ DCl(D_2O)\ |^2\ KCl(satd., H_2O)\ |^3\ KCl(H_2O)\ |\ HgCl–Hg$ A

$Ag–AgCl\ |^4\ HCl(H_2O)\ |^5\ KCl(satd., H_2O)\ |^6\ KCl(H_2O)\ |\ HgCl–Hg$ B

that the difference in the e. m. f. arises from the difference in the solubilities of silver chloride in H_2O and in D_2O. Brodsky[13] and Schwarzenbach[3] hold similar views.

This cannot be correct. It is well recognized that the silver–silver chloride electrode operates by virtue of the fact that the activities of silver and silver chloride in solution are independent of the solvent since they are in equilibrium with a solid phase of fixed activity. The magnitude of the solubility, so long as it does not change the ionic strength appreciably, cannot influence the electromotive force.

The difference of e. m. f. between cells A and B arises in fact from the liquid–liquid junction potentials 2 and 5.

(13) Brodsky, *Trans. Faraday Soc.*, **33**, 1180 (1937).

(14) In this paper symbols in parentheses represent activities. The symbol E^0 represents the standard electromotive force of cell I. The subscript 0 is used when the solvent is H_2O; and the subscript *n* when the solvent is an H_2O–D_2O mixture in which the mole fraction of deuterium is *n*.

(15) Harned and Owen, THIS JOURNAL, **52**, 5079 (1930); Harned and Ehlers, *ibid.*, **54**, 1350 (1932); **55**, 652 (1933).

(16) $(H^+ + D^+)$ in these equations means the sum of the activities of all the hydrogen and deuterium ions whether hydrated or not.

(17) That it is permissible thermodynamically to write the sums $(QH_2 + QD_2)_n$ and $(H^+ + D^+)_n$ in defining cell processes and dissociation constants in H_2O–D_2O mixtures can be shown as follows. When the quinhydrone electrode is used in an H_2O–D_2O mixture there will be two oxidation–reduction systems; one is composed of quinone and hydroquinone

$$E_a = E_a^0 - \frac{RT}{2F} \ln \frac{(QH_2)_n}{(Q)_n(H^+)_n^2}$$

and the other of quinone and hydroquinone-d_2

$$E_b = E_b^0 - \frac{RT}{2F} \ln \frac{(QD_2)_n}{(Q)_n(D^+)_n^2}$$

At equilibrium the potentials of the two systems are equal. Introducing into equation (7) the fraction, α, of hydroquinone-d_2 and the fraction, β, of deuterium ion and omitting the chloride ion we obtain either

$$E_n = E_n^0 - \frac{RT}{2F} \ln \frac{(QH_2 + QD_2)_n(1 - \alpha)}{(Q)(H^+ + D^+)_n^2(1 - \beta^2)}$$

or

$$E_n = E_n^0 - \frac{RT}{2F} \ln \frac{(QH_2 + QD_2)_n\,(\alpha)}{(Q)(H^+ + D^+)_n^2\,(\beta)^2}$$

Hence the normal potential of the quinhydrone electrode as defined

$$K_n = \frac{(\mathrm{H}^+ + \mathrm{D}^+)(\mathrm{A}^-)}{(\mathrm{HA} + \mathrm{DA})}$$

we substitute for $(\mathrm{H}^+ + \mathrm{D}^+)$ in equation (8)

$$E_n = E_n^0 = \frac{RT}{F} \ln \frac{(\mathrm{A}^-)_n}{(\mathrm{HA} + \mathrm{DA})(\mathrm{Cl}^-)_n K_n}$$

simplifying

$$\log K_n = \frac{E_n - E_n^0}{2.3RT/F} - \log \frac{(\mathrm{HA} + \mathrm{DA})_n(\mathrm{Cl}^-)_n}{(\mathrm{A}^-)_n}$$

Introducing the activity coefficients and the molal concentrations m_1, m_2 and m_3 of the acid, of its ion and of the chloride ion, respectively

$$\log K_n = \frac{E_n - E_n^0}{2.3RT/F} - \log \frac{m_1 m_3}{m_2} - \log \frac{f_1 f_3}{f_2} \quad (9)$$

In the case of acids whose anions have unit charge, the last term is the ratio of the activity coefficients of two univalent ions and, being sensibly unity, can be neglected. The error introduced will be particularly small when the ratio of the dissociation constants in H_2O and in D_2O is considered.

In the case of the dissociation of dihydrogen phosphate, the anion formed is a divalent ion and the last term in equation (9) becomes appreciable, requiring extrapolation of the data to infinite dilution. We set

$$\log f_1 f_3/f_2 = 2A\sqrt{\mu} + B\mu$$

where A is the theoretical constant of the Debye–Hückel limiting law and B is an empirical constant. Replacing the last term in equation (9) by these functions and transferring the term B to the left-hand side

$$\log K_n + B\mu = \frac{E_n - E_n^0}{2.3RT/F} - 2A\sqrt{\mu} - \log \frac{m_1 m_3}{m_2} \quad (10)$$

The data of Nims[18] on this system indicate that a plot of the right-hand side of equation (10) against the ionic strength, μ, gives a straight line at least to an ionic strength of 0.17. The intercept at zero ionic strength gives the logarithm of the thermodynamic ionization constant.

Experimental Results

In Table I are the observed potentials E_n^m for cell I, and the normal potentials, E_n^0.

TABLE I

ELECTROMOTIVE FORCE OF CELL I

Each recorded potential is the mean of measurements with two cells filled with the same solution. Each cell contained duplicate quinhydrone and duplicate silver–silver chloride electrodes.

Unpublished data of Noonan and La Mer employing the cell Pt D_2/ DCl / AgCl–Ag indicate that the interionic activity coefficients of HCl and DCl do not differ appreciably. The molal potential of cell I was therefore calculated from the observed potentials, E_n^m, by subtracting the e. m. f. of the cell

$$\mathrm{H_2/HCl}\ (m=1)\mathrm{/AgCl\text{–}Ag\text{–}AgCl/HCl}\ (m)\mathrm{/H_2}$$

The e. m. f. of this cell was calculated from the data of Harned and Ehlers.[19]

The differences of the molal potentials for cell I when the solvent is an H_2O–D_2O mixture and when it is H_2O are plotted in Fig. 3 against the mole fraction, n, of deuterium in the solvent. A number of measurements were made in the neighborhood of 5% D_2O, where evidence for a minimum had been reported previously.[4] No minimum was found, the differences being an almost linear function of the fraction of deuterium in the solvent. The least squares equation of the curve, obtained from the data at 25°, is

$$E_n = E_0 + 0.02975n + 0.00985n^2 - 0.00301n^3 \quad (11)$$

The same equation fits the data equally well at 45 and at 5°, though additional data are desirable at the latter temperature. The temperature coefficient of the e. m. f. is consequently the same in H_2O, in D_2O and in their mixtures at

---

by equation (7) differs from the normal potential E_a^0 only by the factor

$$\frac{RT}{2F} \ln \frac{(1-\alpha)}{(1-\beta)^2}$$

and from the potential E_b^0 by the factor

$$\frac{RT}{2F} \ln \frac{\alpha^2}{\beta}$$

These factors are constants for an H_2O–D_2O mixture containing a fixed fraction of deuterium.

(18) Nims, THIS JOURNAL, **55**, 1946 (1933).

(19) Harned and Ehlers, *ibid.*, **55**, 2179 (1933).

temperatures between 5 and 45°. The average deviation of the data from equation (11) is 0.2 mv.

Using equations (5) and (6), the exchange constant, K_2, and the ratios of the dissociation constants of hydroquinone and hydroquinone-d_2 were calculated and are shown in Table II.

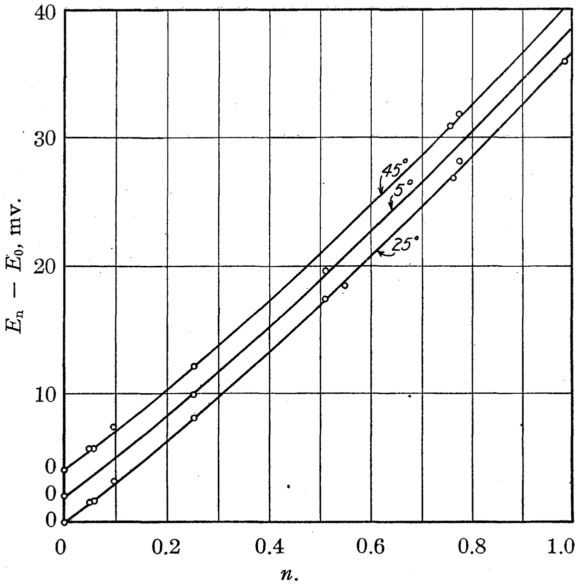

Fig. 3.—The molal potential of cell I as a function of the mole fraction of deuterium in the solvent. The curves for 5 and 45° have been displaced upward by 4 and 8 millivolts, respectively.

Table II

Temp., °C.	5	25	45
K_2	19.1	15.6	13.0
K_0/K_1	4.61	4.16	3.80

Since the temperature coefficient of the electromotive force is zero, the difference between the free energies of dissociation of hydroquinone and of hydroquinone-d_2 is the same as the difference in the heats of dissociation. The difference in the entropies is zero within 0.4 entropy unit.

In Table III are the data on the composition of the benzoic acid buffer solutions used in cell II, the e. m. f. data and the dissociation constants calculated from equation (9). The ratios K_n/K_0 are plotted in Fig. 4 against the mole fraction of deuterium in the solvent. K_n is the dissociation constant in an H_2O–D_2O mixture and K_0 is the dissociation constant in H_2O. The short extrapolation to D_2O was made using the equation

$$\frac{K_n}{K_0} = \frac{\left((H_2O) + M(HDO) + N(D_2O) + \frac{\sqrt{(D_2O)^3}}{\sqrt{(H_2O)^3}}\frac{1}{\sqrt{L}}\right)\sqrt{(H_2O)}\sqrt{L}}{\left(\sqrt{(H_2O)}\sqrt{L} + \frac{K_0}{K_1} - (D_2O)\right)\left((H_2O) + (HDO) + (D_2O)\right)} \qquad (12)$$

This is analogous to the equation employed by Gross, Steiner and Suess[20] and Orr and Butler.[21]

The significance of the constants L, M and N is shown by the equations

$$\sqrt{L} = \frac{(H_3O^+)}{(D_3O^+)}\frac{\sqrt{[D_2O]^3}}{\sqrt{[H_2O]^3}}$$

$$\frac{1}{M} = \frac{(H_3O^+)}{(H_2DO^+)}\frac{[HDO]}{[H_2O]}$$

$$\frac{1}{N} = \frac{(H_3O^+)}{(HD_2O^+)}\frac{[D_2O]}{[H_2O]}$$

In these equations, symbols in brackets represent moles per liter and symbols in parentheses represent activities.

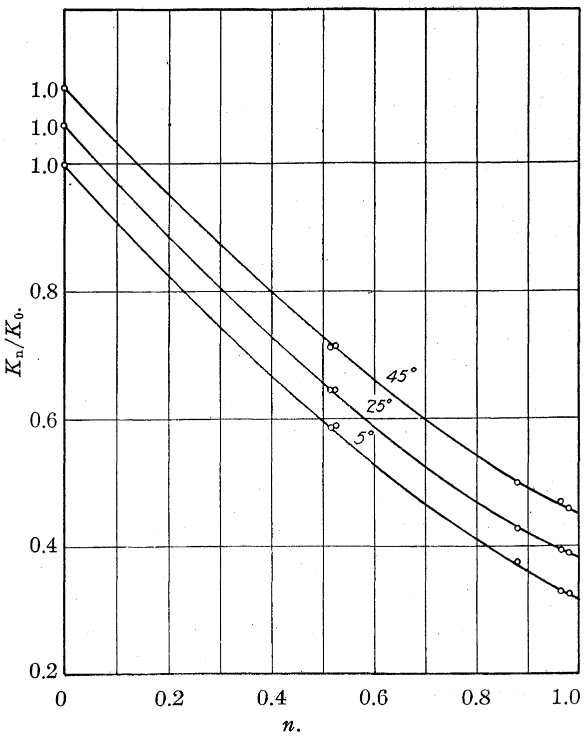

Fig. 4.—Dissociation constant ratios for benzoic acid as a function of the mole fraction of deuterium in the solvent. The curves for 25 and 45° have been displaced upward by 0.06 and 0.12 unit, respectively.

L can be calculated from the equation[3]

$$\log L = \frac{2F\Delta E}{2.3RT} + \log K_3$$

K_3 is the equilibrium constant of the reaction $D_2 + H_2O \rightleftarrows H_2 + D_2O$, calculated from the data of Farkas and Farkas for the equilibrium

$H_2O + HD \rightleftarrows HDO + H_2$, of Urey and Rittenberg for the equilibrium $H_2 + D_2 \rightleftarrows 2HD$, and of Topley and Eyring for the equilibrium $H_2O + D_2O \rightleftarrows 2HDO$[22]. ΔE is the difference between the e. m. f. of the cell $H_2 \mid HCl \mid AgClAg$ when the solvent is D_2O and when it is H_2O. We are indebted to Mr. Evan C. Noonan for permission to use his data for ΔE before publication. The constants ΔE, K_3, and L are given in Table IV.

TABLE IV

CONSTANTS FOR EQUATION (12)

Temp., ° C.	5	25	45
ΔE	0.0041	0.0042	0.0049
K_3	11.6	8.70	6.45
L	16.3	12.04	9.21
M	0.97	1.04	1.12
N	1.03	1.15	1.28

The constants M and N were obtained by fitting equation (12) to the data for the dissociation constant ratios for hydroquinone in H_2O–D_2O mixtures calculated by means of equations (5) and (11) (see Fig. 5). The constants M and N are given in Table IV and at 25° agree closely with the values 1.05 and 1.10 obtained by Orr and Butler.[21]

The ratios K_0/K_1 for benzoic acid, obtained by the extrapolation in Fig. 4, together with the differences of heats, entropies, and free energies of dissociation are shown in Table V.

TABLE V

DIFFERENCE OF MOLAL HEATS, FREE ENERGIES, AND ENTROPIES OF DISSOCIATION FOR BENZOIC ACID

°C.	K_0/K_1	$R \ln K_0/K_1$	H_1-H_0 cal.	F_1-F_0 cal.	S_1-S_0 cal./deg.
5	3.16	2.29	−9	636	−2.3
25	3.13	2.27	175	676	−1.7
45	3.04	2.21	379	703	−1.0

Subscript 1 refers to benzoic acid-*d;* subscript 0 to protobenzoic acid.

At 25° the heat of dissociation of benzoic acid-*d* is 175 cal. greater than that of protobenzoic acid and the entropy of dissociation is −1.7 calories per degree less.

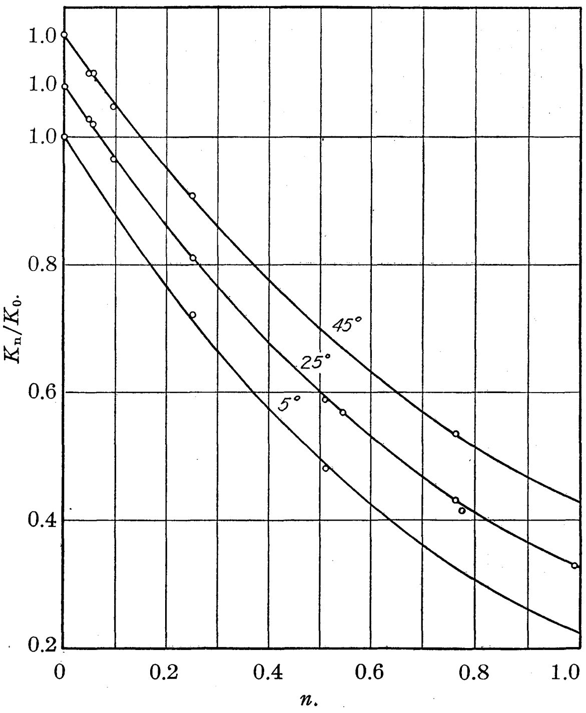

Fig. 5.—Dissociation constant ratios for hydroquinone as a function of the mole fraction of deuterium in the solvent. The curves for 25 and 45° have been displaced upward by 0.08 and 0.16 unit, respectively.

The composition of the phosphate buffer solutions used in cell II in the determination of the dissociation constant of $H_2PO_4^-$ at 25° and the e. m. f. data are given in Table VI. In Fig. 6 the dissociation constant data were extrapolated to infinite dilution employing equation (10). The extrapolated values are given in Table VII.

Equation (12) was employed in making the extrapolation to pure D_2O. The ratio K_0/K_1 is 3.62.

Discussion

In Fig. 7 the ratios K_0/K_1 for benzoic acid, hydroquinone, and $H_2PO_4^-$ are plotted against log K_0. The length of the lines in the figure shows the estimated probable error of the dissociation constant ratio. In view of the fact that the dissociation constants of the proto and of the deutero acids were determined by exactly the same method, any constant errors of the method tend to cancel when their ratios are considered. The average deviation of the ratio should therefore be a fair measure of the probable error.

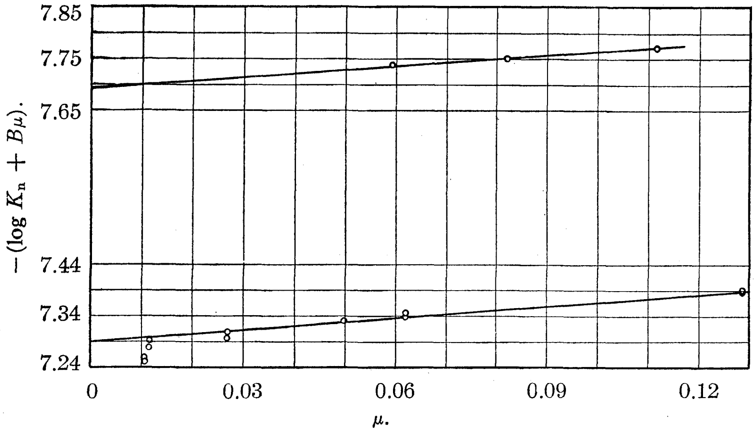

Fig. 6.—The secondary dissociation of phosphoric acid in H_2O–D_2O mixtures at 25° as a function of ionic strength. The lower curve refers to data obtained with H_2O. The upper curve refers to data obtained with 90.6% D_2O.

For benzoic acid, the average deviation of the data from the curve in Fig. 4 is 1%. For $H_2PO_4^-$, the necessity of extrapolating first to infinite dilution and afterward to pure D_2O increases the uncertainty of the result and 2% is a better estimate. For hydroquinone the assumptions underlying equation (5) introduce an error which cannot be estimated. On the basis of the average deviation of the e. m. f. data (0.2 mv.), the average deviation for the ratio K_0/K_1 is 1.6%.

The ratios for acetic acid (from the closely agreeing conductance and e. m. f. data of La Mer and Chittum[23] and of Korman and La Mer[4]) and for chloroacetic acid (from the conductance data of Lewis and Schutz[2]) are also plotted in Fig. 7. The data for acetic acid fit a curve similar to that for benzoic acid with an average deviation of about 1%. The precision of the data for chloroacetic acid cannot be estimated, for Lewis and Schutz do not report the exact fraction of deuterium in their H_2O–D_2O mixture. The dissociation constant for chloroacetic acid-*d*, is being redetermined in this Laboratory by Mr. James Yates.

The curve in Fig. 7 passes through or very near all the points and is consistent with an extrapolated ratio equal to unity at log K_0 = 1.75, or K_0 = 55, the dissociation constant of H_3O^+. The ratio decreases as the strength of the acid increases; for acids approaching the strength of H_3O^+, the dissociation constants may be the same in H_2O and in D_2O.

It should be noted that of all the data in the literature on the dissociation constants of deutero

acids, these are the only ones which have been obtained by modern conductimetric methods or by potentiometric methods employing cells without liquid–liquid junctions between H_2O and D_2O. We have pointed out the difficulty of interpreting the cell reactions and therefore the dissociation constant data obtained from cells with liquid junctions.

Summary

The cell Pt | QQH_2–QQD_2 HCl–DCl(H_2O–D_2O) | AgCl–Ag was reinvestigated at 25° and the measurements were extended to 5 and 45°. No minimum was found at 5% deuterium, the e. m. f. being an almost linear function of the deuterium content of the solvent. The temperature coefficient of the e. m. f. is the same in H_2O and in D_2O. The cell

$$\mathrm{Pt}\left|\ \mathrm{QQH_2\text{–}QQD_2}\ \begin{matrix}\text{Benzoic acid}\\ \text{Sodium benzoate } (\mathrm{H_2O\text{–}D_2O})\\ \text{Sodium chloride}\end{matrix}\ \right|\ \mathrm{AgCl\text{–}Ag}$$

was studied at 5, 25 and 45°. The heat of dissociation for benzoic acid d_1 is 175 calories greater than for protobenzoic acid at 25°. The difference in the entropies of dissociation is 1.7 calories per degree. The cell

$$\mathrm{Pt}\left|\ \mathrm{QQH_2\text{–}QQD_2}\ \begin{matrix}\mathrm{KH_2PO_4}\\ \mathrm{Na_2HPO_42H_2O}\ (\mathrm{H_2O\text{–}D_2O})\\ \mathrm{KCl}\end{matrix}\ \right|\ \mathrm{AgCl\text{–}Ag}$$

was studied at 25°.

The ratio of the dissociation constants for the deutero acid referred to, the proto acid for hydroquinone, $H_2PO_4^-$ and benzoic acid are compared with the ratios for acetic and chloroacetic acids as determined by other investigators using both thermodynamic and conductivity methods. The ratios decrease as the strength of the acid increases and may become unity for acids as strong as H_3O^+.

The Catalytic Interaction of Hydrogen and Deuterium with Ethylene and Deutero-ethylenes on Copper

By G. Joris,[1] H. S. Taylor[2] and J. C. Jungers[3]

Numerous efforts have been made to elucidate the detailed mechanism of the catalytic hydrogenation of ethylene by studies of the kinetics of interaction of ethylene with hydrogen and deuterium.[4] The possibility of a more penetrating analysis of the problem presented itself to us in the preparation of ethylene-d_4 and various deuterium-substituted ethylenes, permitting therefore catalytic studies in which the effect of the substitution of the unsaturated partner in the hydrogenation process could be tested independently with both hydrogen and deuterium as the addition agents.

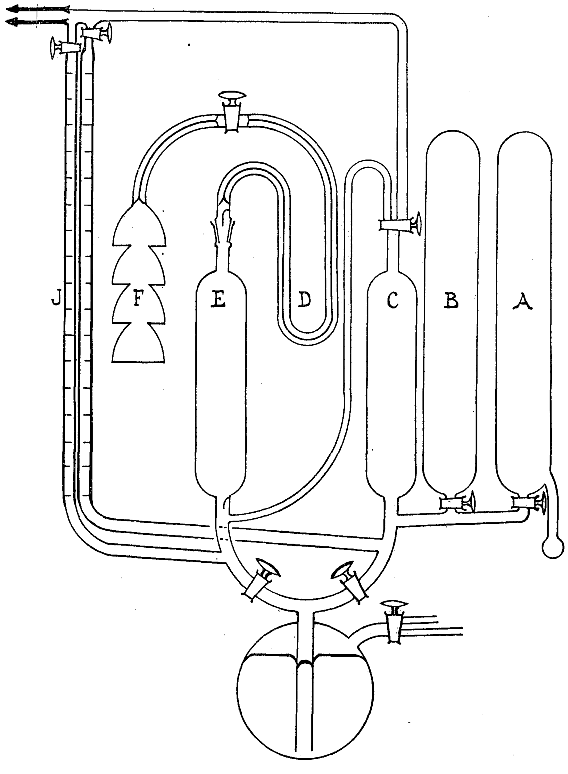

Fig. 1.

Experimental Details

Gases. Ethylene was obtained by the interaction of ethyl alcohol and sulfuric acid. The gas was freed from ether and acid fumes in the usual way and purified by liquefaction and fractionation. It was stored in a reservoir in the reaction system (Fig. 1) in which the process of condensation and removal of volatile impurities could be repeated at intervals if necessary.

Ethylene-d_4 was obtained by the action of zinc on ethylene dibromide-d_4 prepared by interaction of acetylene-d_2 and deuterium bromide. The acetylene-d_2 was prepared by interaction of 99.6% deuterium oxide with a high grade calcium carbide, freed from water by heating at 500° for several hours. The deuterium bromide was prepared by the hydrolysis of resublimed phosphorus pentabromide with 99.6% deuterium oxide. The ethylene-d_4 was purified by vacuum distillation and the middle fraction (6 liters) was admitted to a reaction reservoir, A, the walls of which had been covered with molten sodium to eliminate traces of bromine compounds which might have survived the purification process. Raman spectra observations of this product indicate that it is 90–95% C_2D_4 or better than 97.5% deuterium content of the hydrogen of the hydrocarbon.

Ethylene-d_2 was obtained by catalytic exchange between ethylene and deuterium oxide on an active nickel catalyst at 150° during several days. The central fraction of 6 liters from the purification process showed, by Raman spectra, that its D-content was slightly greater than 50%, and that it was composed predominantly of symmetrical *cis-* and *trans*-$C_2H_2D_2$, with much smaller amounts of the unsymmetrical $CH_2{=}CD_2$ and C_2H_3D and C_2HD_3.

The hydrogen and deuterium were obtained by electrolysis of appropriate solutions of NaOH and NaOD. The gases were purified over hot copper, dried over phosphorus pentoxide and liquid air and stored in receptacles of Type B. Some hydrogen used was further purified by adsorption on and desorption from charcoal.

Catalysts.—The copper catalyst employed was prepared by dehydration and reduction of a co-precipitated mixture of magnesium hydroxide–copper hydroxide in the molecular ratio 4:1 whose catalytic characteristics have been described already by Taylor and Joris.[5] In many of the experiments only 0.5 g. of catalyst, corresponding to 0.11 g. copper, was employed. In some of the last experiments 4 g. of the catalyst was used.

Apparatus.—The reaction vessel F (85-cc. volume) shown in Fig. 1 was of a shape which permitted the distribution of the catalyst on the horizontal areas of the several "stories," thus providing greater accessibility of catalyst to gas mixture. Gas mixtures were prepared in E, from the storage reservoirs, A and B, via the vessel C. The gases were introduced into the reaction vessel by raising the

mercury level in E, the gases passing through the trap D cooled in solid carbon dioxide–acetone mixtures to minimize access of mercury vapor to the catalyst system. During reaction, the mercury level was maintained at the glass point near the entrance to the capillary tubing, pressures, at constant volume, being read on the manometers J, through which, also, the apparatus could be evacuated. Between experiments, the catalyst was evacuated to a pressure of 10^{-4} mm. at the temperature of the succeeding experiment if above that of the preceding.

Procedure.—Experiments have been performed at −20, 0, 20 and 40°. The gas ratios studied were 1:1, 2:1 and 1:2, the unit pressure being 5 cm. for each component, 10 cm. for the constituent in excess in the non-stoichiometric mixtures.

Experimental Results

With the smaller amount of catalyst first used a small drift was noted in catalyst activity. The data have been presented graphically in Figs. 2–6, in small groups covering a particular variable to be investigated and in a sequence such that any variation due to the observed fatigue of the catalyst would be minimized in its effect on the conclusions to be drawn.

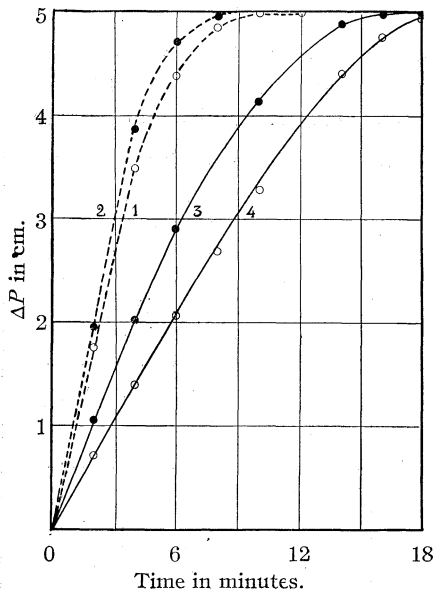

Fig. 2.—Experiments at 40° (5 cm., 5 cm.): 1, $C_2H_4 + H_2$ (40° 3); 2, $C_2D_4 + H_2$ (40° 2); 3, $C_2D_4 + D_2$ (40° 2); 4, $C_2H_4 + H_2$ (40° 3).

Note on Figs. 2–8.—Dotted lines indicate hydrogenation; full lines indicate deuterization. Circles indicate C_2H_4; dots indicate C_2D_4.

In Fig. 2 are presented the data on stoichiometric mixtures of the four gases taken in pairs in the order shown, reacting at 40°. These experiments show unquestionably (a) that ethylene-d_4 hydrogenates more rapidly than ethylene and (b) that the rate of reaction of both with deuterium is approximately one-half that with hydrogen. This latter result confirms that of Pease and Wheeler[4c] on a different but active copper catalyst.

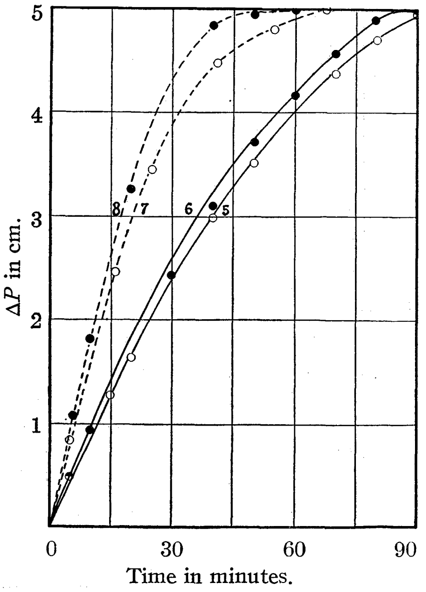

Fig. 3.—Experiments at 20°: 5, $C_2H_4 + D_2$; 6, $C_2D_4 + D_2$; 7, $C_2H_4 + H_2$; 8, $C_2D_4 + H_2$.

The data of Fig. 3 confirm both these conclusions for stoichiometric pairs of gases at 20°. The data with hydrogen are comparable with those at 40°. With deuterium the spread between the two ethylenes is less than at 40° but this is probably largely experimental error and, even in this case, ethylene-d_4 is still a faster reactant than ethylene.

Experiments 11–14 at 40° in Fig. 4 once more confirm these results and supply data on varying rate with varying concentration. The reaction is faster than that of the stoichiometric mixture in presence of excess deuterium and markedly slower with excess of the ethylenes. In the latter cases, also, the change in rate with time is much greater than with the stoichiometric mixtures. This is also shown by the data of Experiments 15–17 in Fig. 5, the rates of 16 and 17 again pointing to a reaction with deuterium somewhat less than half that with hydrogen.

The data of Experiments 20–23 at 40° presented in Fig. 6 show that the 50% D-substituted ethylene reacts at a rate intermediate to that of ethyl-

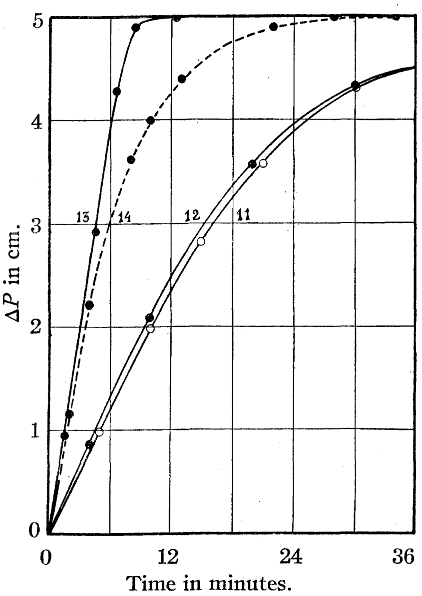

Fig. 4.—Experiments at 40°: 11, $2C_2H_4 + D_2$ (10 cm. C_2H_4 + 5 cm. D_2); 12, $2C_2D_4 + D_2$ (10 cm. C_2D_4 + 5 cm. D_2); 13, $C_2D_4 + 2D_2$ (5 cm. C_2D_4 + 10 cm. D_2); 14, $2C_2D_4 + H_2$ (10 cm. C_2D_4 + 5 cm. H_2).

ene and ethylene-d_4. A comparison of Experiments 20 and 23 gives an indication of the degree of reproducibility attainable in separated runs. At 0° the same influence of extent of deuterium substitution on the velocity is found.

To test the effect of catalyst deterioration on the results obtained, a new series of experiments was carried out with 4 g. of the copper oxide–magnesium oxide mixture as source of catalyst mass. In Fig. 7 are presented the data of the first experiments, Nos. 1, 2 and 3 on the new catalyst at 20° with stoichiometric mixtures of hydrogen and C_2H_4, $C_2(HD)_2$ and C_2D_4, respectively. It

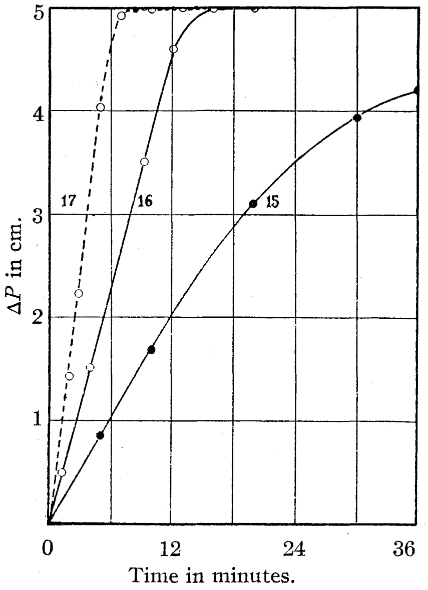

Fig. 5.—Experiments at 40°: 15, 10 cm. $C_2D_4 + D_2$; 16, 5 cm. $C_2H_4 + 2D_2$; 17, 5 cm. $C_2H_4 + 2H_2$.

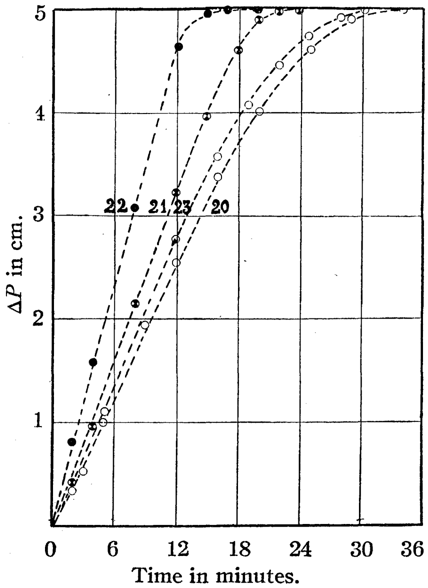

Fig. 6.—Experiments at 40°: 20, $C_2H_4 + H_2$; 21, $C_2(DH)_2 + H_2$; 22, $C_2D_4 + H_2$; 23, $C_2H_4 + H_2$.

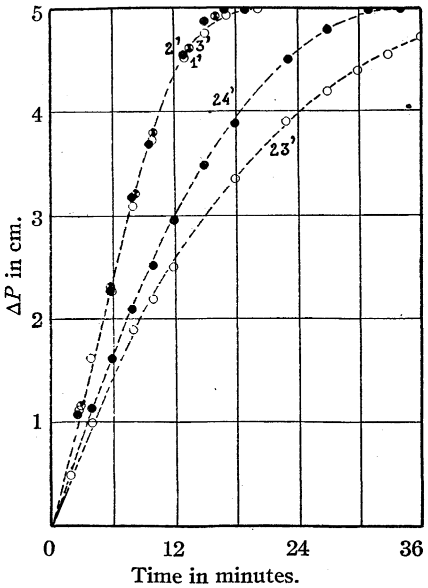

Fig. 7.—At 20°, influence of deterioration P, 5 cm.: 1′, $C_2H_4 + H_2$; 2′, $C_2(HD)_2 + H_2$; 3′, $C_2D_4 + H_2$; 23′, $C_2H_4 + H_2$; 24′, $C_2D_4 + H_2$.

will be noted that, initially, within the experimental error, all three ethylenes show the same rate of reaction. During the succeeding twenty experiments the activity of the catalyst showed a slow but progressive deterioration, which was accompanied by a progressive increase in the differences of hydrogenation rate between C_2H_4 and C_2D_4, as shown by Experiments 23 and 24 on the same diagram. With ethylene the half life has increased from six to twelve minutes, while that of ethylene-d_4 has changed from six to nine and one-half minutes. Since Experiment 24 with C_2D_4 succeeds Experiment 23 with C_2H_4 and still shows a faster reaction rate although catalyst activity is slowly decreasing, it is evident that the differences in rates observed with the deteriorating catalyst are a function of the two gases and not wholly to be ascribed to the deterioration process.

This is true also of the data presented in Fig. 8 for the effect of temperature in the range -20 to $+40°$ with the stoichiometric mixtures of C_2H_4 and C_2D_4 with hydrogen. The sequence of temperatures studied was -20, $+20$, 0 and 40°. In every case C_2D_4 was studied after C_2H_4 and except at $-20°$ is, in every case, the faster process. At 0, 20 and 40° the times for one-quarter reaction are, respectively, $T_{1/4}$ = 24, 20, 5.3, 4.6, 1.5 and 1.4 minutes. These data correspond to apparent activation energies of hydrogenation $E_{\text{obsd.}}(C_2H_4) = 11.8$ kcal. and $E_{\text{obsd.}}(C_2D_4) = 11.3$ kcal. In this temperature range, therefore, the differences between C_2H_4 and C_2D_4 decrease with increasing temperature. The differences are real but their trend with temperature may well be within the error of experiment. Since, in this temperature range, the influence of varying gas ratios (Fig. 4) points to a unimolecular reaction with respect to hydrogen, inhibited by ethylene, the observed activation energy $E_{\text{obsd.}}$ is related to the true activation energy E_t by the equations

$$E_{\text{obsd.}(C_2H_4)} = E_{t(C_2H_4)} - \lambda_{H_2} + \lambda_{C_2H_4}$$
$$E_{\text{obsd.}(C_2D_4)} = E_{t(C_2D_4)} - \lambda_{H_2} + \lambda_{C_2D_4}$$

where the λ's refer to the respective heats of adsorption. The small difference in observed activation energies (0.5 kcal.) is divided in some indeterminate manner between the true activation energies and the heats of adsorption of the two ethylenes. Since, in general, one would expect $\lambda_{C_2D_4}$ to be somewhat larger than $\lambda_{C_2H_4}$, it would follow that the true activation energy for the reaction between C_2H_4 and hydrogen would be somewhat more than 0.5 kcal. greater than the true activation energy in the hydrogenation of C_2D_4. As might be expected from this reasoning the rate of hydrogenation of C_2D_4 is actually greater than that of C_2H_4 and the intermediate case, $C_2H_2D_2$, is intermediate between these two extremes. Why the true activation energy should be greater for ethylene than for ethylene-d_4 is not apparent.

We can avoid these difficulties of detailed mechanism by stating the observed facts, quite generally, in terms of the concept of the activated complex. At a given ratio of hydrogen to any of the ethylenes, the rate indicates that the concentration of the activated complex $(C_2H_xD_{6-x})^*$ on the surface is greater, the greater the D-concentration of the complex.

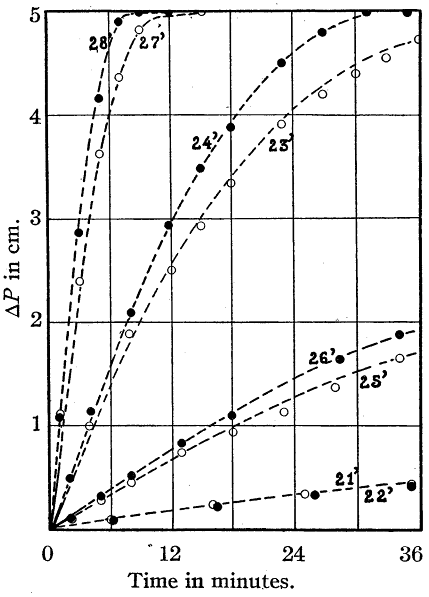

Fig. 8.—Influence of temperature on $H_2 + C_2H_4$ and C_2D_4 (5 cm.): 21' and 22' at $-20°$; 25' and 26' at 0°; 23' and 24' at 20°; 27' and 28' at 40°.

This same factor must also be operative in the reactions which involve the comparative rates of reaction between ethylene or ethylene-d_4 and hydrogen or deuterium. With either unsaturated hydrocarbon the velocity of reaction with deuterium is only one-half that with hydrogen. On surfaces largely covered with the unsaturated hydrocarbon, collision rates of hydrogen and deuterium with the free surface would introduce a factor of 1.4 in favor of the hydrogen reaction. What we have termed the concentration of activated complex would, as we have seen, favor more rapid reaction of deuterium by an amount of the order of 10%. It is therefore evident that a definite part of the difference in rates of reaction with hydrogen and with deuterium, approximately one-third of the total difference in rate, is to be ascribed to factors associated with zero-point energy differences of the hydrogen and deuterium, in their interactions with catalyst and substrate. In actual amount these are small, an energy difference of $\Delta E = 250$ cal. being sufficient, together with the collision factor and the concentration of complex, to account for the two-fold difference in velocity observed.

These considerations cannot be decisive in the experiments at −20° (Nos. 21 and 22) where the slow and approximately equal rates with C_2H_4 and C_2D_4 point to the availability of empty spaces for hydrogen adsorption as the rate-determining process.

Since the slow deterioration of the catalyst with time occurs progressively with any of the three ethylenes prepared by three different methods, we cannot ascribe it to impurities in the gases employed. Rather must it be ascribed to progressive irreversible reactions of the ethylenes themselves on the active catalysts which we have employed, leading to carbonaceous deposits on the most active centers, the deposits being retained during the evacuation procedures intervening between experiments. Such deterioration has been well established previously with nickel catalysts, but has not generally been noted hitherto with copper catalysts. The catalysts here used are, as we have already established,[5] very much superior in activity to copper catalysts hitherto studied. It is evident, from the data, that the rate-determining factors change with changes in the active centers studied, the differences between the rates of hydrogenation of C_2H_4, $C_2(HD)_2$ and C_2D_4 being negligible on the most active centers, and definite but relatively small on centers of lesser activity. This again illustrates the observation frequently made that the kinetics of a given heterogeneous surface reaction can vary widely with variation in the surface activity.[6]

Acknowledgment.—We wish to express our indebtedness to Professor Marc de Hemptinne who so kindly placed at our disposal the supplies that we have used of deuterium and of the various deutero-ethylenes.

Summary

1. The rates of addition of hydrogen and of deuterium to ethylene, ethylene-d_2 and ethylene-d_4 on active copper catalysts have been studied in the temperature range −20 to +40°.

2. The addition of deuterium occurs at a rate approximately one-half that of hydrogen on the several ethylenes.

3. Initially, on catalysts of high activity, no differences are observed in the rates of hydrogenation of the several ethylenes.

4. A slow deterioration of the catalyst, ascribed to irreversible reactions of ethylene leading probably to carbonaceous depositions, progressively occurs.

5. With decreasing activity due to this poisoning, small differences in the rates of hydrogenation of the ethylenes are observed, the more highly deuterized ethylenes reacting more rapidly.

6. Collision rates of hydrogen and deuterium with the surface are inadequate to account for the relative rates of addition observed. Zero-point energy differences are also involved.

7. The apparent activation energies of these reactions average 11.5 kcal. in the temperature range studied.

The System Ammonium Selenate–Magnesium Selenate–Water at 30°[1]

BY RALPH W. LAWRENCE AND G. BROOKS KING

Relatively few ternary systems of the type selenate–selenate–water have been investigated. Meyer and Aulich[2] studied the following systems at 25°: Na_2SeO_4–$MgSeO_4$–H_2O; K_2SeO_4–$MgSeO_4$–H_2O; K_2SeO_4–$CaSeO_4$–H_2O; Na_2SeO_4–$CaSeO_4$–H_2O; and K_2SeO_4–Na_2SeO_4–H_2O. It was of interest to study further salt pairs of this type and to compare these with the corresponding sulfate systems. The purpose of the present investigation was to study solubility relationships in the system $(NH_4)_2SeO_4$–$MgSeO_4$–H_2O. Although the double salt $(NH_4)_2SeO_4 \cdot MgSeO_4 \cdot 6H_2O$ has been reported, solubility data in this system appear to be entirely lacking.

Experimental

Materials and Apparatus.—The preparations of selenic acid and ammonium selenate have been described previously.[3] Magnesium selenate was prepared by dissolving magnesium carbonate in selenic acid and recrystallizing the salt.

An electrically controlled thermostat was employed, allowing the temperature to be maintained at 30 ± 0.05°.

Methods of Analyses.—The ammonium selenate was determined by distilling the ammonia from an alkaline solution into standard acid and the excess acid determined by titration with sodium hydroxide. The magnesium selenate was determined by precipitation of the magnesium as magnesium ammonium phosphate and subsequent ignition to the pyrophosphate. Both determinations were checked by using samples of known magnesium and ammonium content. Water was determined by difference. The results of duplicate determinations varied no more than three parts in one thousand.

Solubility Determinations.—Various mixtures of ammonium selenate, magnesium selenate hexahydrate, and water were weighed out approximately and placed in 6-inch (15 cm.) Pyrex test-tubes. Each of these tubes was closed by a cork through the center of which passed a glass stirrer, surmounted by a small air turbine. None of the samples were dissolved by heating because of the danger of hydrolysis of ammonium selenate.

The tube contents were stirred continuously for at least twelve hours before samples were taken for analysis. In order to ensure equilibrium, samples of the solutions were removed at intervals and analyzed. Analysis showed that in all cases equilibrium conditions were reached in less than twelve hours. Samples were removed from the solution by means of a small pipet equipped with a cotton filter, the pipet being pre-heated to slightly above the temperature of the thermostat. The solutions were weighed in glass-stoppered bottles. The tube and its content of wet residue was stoppered, the outside of the tube dried, and the tube and wet residue weighed. The residue was then transferred to a 100-ml. volumetric flask. Aliquot portions were taken for analysis.

The solubility of magnesium selenate was determined by removing samples at intervals of four hours until concordant results were obtained. A similar procedure was followed for ammonium selenate. Solubility determinations of samples of pure magnesium selenate made up at different times by different individuals gave concordant results. The same is true for ammonium selenate.

Results

The compositions of solutions and residues are given in Table I and are shown graphically in Fig. 1. Solid phases were determined by the method of Schreinemakers.[4]

of concentrations. The solubility curve for $(NH_4)_2SeO_4$ was not experimentally realizable.

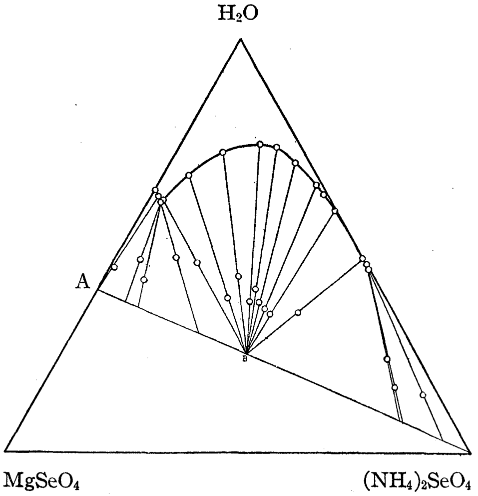

Fig. 1.—The isotherm at 30°: A represents $MgSeO_4 \cdot 6H_2O$; B represents $MgSeO_4 \cdot (NH_4)_2SeO_4 \cdot 6H_2O$.

Weston[5] investigated the corresponding sulfate system and found that the solubility curves of both $MgSO_4 \cdot 7H_2O$ and $(NH_4)_2SO_4$ could not be realized. The selenate and sulfate systems are analogous in nearly every respect.

It should be noted that the solubilities given here for both magnesium selenate and for ammonium selenate do not agree with previous determinations.[2,6] For the former, Meyer and Aulich give 31.2 wt. per cent. and for the latter, Tutton gives 57.9 wt. per cent. Tutton does not state his method for determining the solubility.

Approximate solubility determinations at 60° have been made. It was found that the same phases are present at that temperature as at 30°, the solubility of each phase increasing with increased temperature.

Acknowledgment.—Hydrogen peroxide used in the preparation of selenate salts was furnished by E. I. du Pont de Nemours and Company. This kindness is gratefully acknowledged.

Summary

1. The solubility relations in the system ammonium selenate–magnesium selenate–water have been determined at 30°.

2. The system is analogous to the corresponding sulfate system.

Maleic Acid Production—Vapor Phase Oxidation of Five-Carbon Olefinic Acids[1]

BY W. L. FAITH AND M. F. YANTZI

It has been shown that maleic acid may be produced by the catalytic oxidation of crotonic acid, or the corresponding aldehyde.[2,3] The purpose of the present work was to study the catalytic vapor phase oxidation of several five-carbon olefinic acids under similar conditions. The major objective of the study was to determine whether the chief product of such oxidation would be maleic acid or a five-carbon unsaturated dicarboxylic acid.

Three acids were chosen for the work: 2-pentenoic acid, $CH_3CH_2CH{=}CHCOOH$; 3-pentenoic acid, $CH_3CH{=}CHCH_2COOH$; tiglic acid, $CH_3CH{=}C(CH_3)COOH$.

It was felt that the results of the study might aid research on the catalytic vapor phase oxidation of olefin hydrocarbons.

Preparation of the Acids.—The 2-pentenoic acid was prepared by the method of Boxer and Linstead.[4] The acid boiled at 103–111° under 19 mm. pressure.

The 3-pentenoic acid was prepared by the method of Linstead, Noble and Boorman.[5] This acid boiled at 90–92° under 10 mm. pressure.

Tiglic acid was prepared by the method of Michael and Ross.[6] The crystals melted at 64°.

Method and Apparatus.—The apparatus used for the oxidation of the 2- and 3-pentenoic acids was essentially the same as that previously described.[3] In the oxidation of the tiglic acid, a preheater for the primary air was added to prevent deposition of tiglic acid crystals in the tube leading from the vaporizer to the catalyst chamber.

The bath surrounding the vaporizer was maintained at

a constant temperature of 71.1° for the runs on the 2- and 3-pentenoic acids, and raised to 80.3° for those on tiglic acid. The catalyst, vanadium pentoxide deposited on a carrier of aluminum balls, also was prepared as before.

Analytical Methods

In most runs, 1 to 2 cc. of acid to be oxidized was introduced at a constant rate for a period of two hours.

Carbon dioxide was determined by passing a known portion of the exhaust gases through a gas-scrubbing bottle containing barium hydroxide solution for a period of twenty minutes during the run. The barium carbonate thus obtained was filtered, redissolved in hydrochloric acid and determined as barium sulfate in the usual manner.

The only acid product which formed in any quantity was maleic acid, and it was determined as the barium maleate monohydrate, using the same procedure as that described previously.[3] Check analyses on known mixtures of 2-pentenoic acid and maleic acid were accurate within 2%.

The purity of the barium maleate monohydrate was proved by the quantitative conversion to barium sulfate in the usual manner.

Anal. Calcd. for $C_4H_2O_4Ba \cdot H_2O$: Ba, 50.98. Found: Ba, 50.85, 50.86.

Further proof that the solid product was maleic acid (or anhydride) was shown by its conversion to fumaric acid under the influence of light in the presence of bromine.

In the case of known mixtures of 3-pentenoic acid and maleic acid, check analyses were accurate within 1.5%. Again the purity was proved by conversion to barium sulfate.

Anal. Calcd. for $C_4H_2O_4Ba \cdot H_2O$: Ba, 50.98. Found: Ba, 50.80, 50.81.

The acid was also converted to fumaric acid as above.

Check analyses on mixtures of maleic acid and tiglic acid were accurate within 2%, but since no maleic acid was found in the oxidation products of tiglic acid, a purity test was not made.

Aldehyde was determined by the neutral sodium sulfite method.[7] Maleic acid was found to offer no interference under the conditions of this test.

Discussion and Results.—Typical results obtained by oxidation of the three acids are shown in Table I. The 2- and 3-pentenoic acids showed little difference in their oxidation characteristics. Maximum maleic acid conversions were obtained at 450° with both acids. In all cases more carbon dioxide was produced than could be accounted for by the reaction

$$CH_3CH_2CH{=}CHCOOH + 3O_2 \longrightarrow HOOCCH{=}CHCOOH + CO_2 + 2H_2O$$

With both acids, maleic acid conversions increased with increasing molar air–acid ratios. No maleic acid was found in the products of tiglic acid oxidation.

A mixture of aldehydes was found in the products of all runs. No single aldehyde was identified. Tests for malonic, acetic, oxalic, glutaconic and citraconic acids were negative. It should be noted that conversions to carbon dioxide in excess of that accompanying maleic acid formation varied considerably. Apparently total oxidation increases with the age of the catalyst, although no difference could be detected in maleic acid conversions.

Summary

The catalytic vapor phase oxidation of 3 five-carbon olefinic acids was studied using a vanadium pentoxide catalyst.

2-Pentenoic acid was oxidized to maleic acid; a maximum conversion of 38.8% was obtained. 3-Pentenoic acid yielded maleic acid with a maximum conversion of 42.5%. Tiglic acid yielded only carbon dioxide and unidentified acids and aldehydes.

The Two-Step Oxidation–Reduction of Lapachol, Lomatiol and Related Compounds

BY EDGAR S. HILL

A number of quinones, both naturally occurring and synthetic, have been found to oxidize and reduce in alkaline solution in two steps, with the formation of an intermediate compound, or semiquinone. Among these are the anthraquinonesulfonates,[1] β-naphthoquinone,[2] phenanthrenequinonesulfonate,[3] and phthiocol.[4] Phthiocol is a substituted hydroxynaphthoquinone and related to it by structure are a large number of hydroxynaphthoquinone derivatives, which, depending on the experimental conditions, form reversible oxidation–reduction systems. Some of these hydroxynaphthoquinones occur in a wide variety of plant materials, making their study of more than theoretical interest.

The author has been able to study successfully a number of these compounds by potentiometric methods and has found that their behavior in alkaline solution is similar to that of the quinones mentioned above. The compounds studied were lapachol, lomatiol, hydrolomatiol, hydroxyhydrolapachol, iso-β-lapachol, α-lapachone, β-lapachone, chlorohydrolapachol, bromo-β-lapachone, juglone and lawsone. The first five of these were found to be sufficiently stable in strongly alkaline solution to permit a thorough potentiometric study, and the remainder, although too unstable in alkaline solutions for similar study, were believed to oxidize and reduce in a similar way, on the strength of their structural relationship and on colorimetric experiments.

Fieser[5] has reported the normal potentials of lapachol, iso-β-lapachol, chlorohydrolapachol, hydroxyhydrolapachol, lomatiol, α-lapachone and β-lapachone, working only in 50% alcohol, 0.1 *N* in hydrochloric acid and 0.2 *N* in lithium chloride, using titanous chloride as reducing agent. No titrations were made in alkaline solution. Ball[6] has reported the normal potentials of several of these compounds for *p*H values ranging from 1.1 to 12.6, but obtained his values by the method of mixtures. Ball, working independently, recently has found[7] by titration methods that lapachol, in alkaline solutions, exhibits two-step oxidation and reduction, similar to phthiocol. The normal potentials of juglone have been reported by Conant and Fieser,[8] working again in alcoholic acid solution, and those of both juglone and lawsone by Friedheim,[9] working over a considerably wider *p*H range, who found that rapid decomposition in alkaline solution prevented the obtaining of titration curves reliable enough for analysis. Fieser and Fieser[10] were able to titrate lawsone (2-hydroxy-1,4-naphthoquinone) satisfactorily over the range *p*H 0.33–12.92.

Solutions of the quinones were titrated reductively over a *p*H range from 7.1 to 14.3. The technique of potentiometric titration was the usual one and the concentration of the oxidants used was 0.0005 *M* throughout. All potentials were measured at 30° and have been corrected to the hydrogen standard, and those values obtained in sodium hydroxide solutions have been corrected for liquid junction potentials. The buffers used are tabulated with the potential values.

The compounds successfully titrated were lomatiol, hydrolomatiol, lapachol, hydroxyhydrolapachol and iso-β-lapachol. Since there is little difference in the normal potentials of the various systems (the maximum difference between any two being only 4 to 6 mv.), only one compound, lomatiol, will be discussed in detail and the others but briefly.

Lomatiol is 2-(δ-hydroxy-β-isopentenyl)-3-hydroxy-1,4-naphthoquinone and occurs in the seeds of the Australian plants, *Lomatia ilicifolia* and *Lomatia longifolia*. The coloring matter is the same in both species and was first isolated by Rennie[11] and its constitution, synthesis, relation to and conversion into the other hydroxynaphthoquinone derivatives studied by Hooker.[12] Solutions of lomatiol were titrated reductively over a

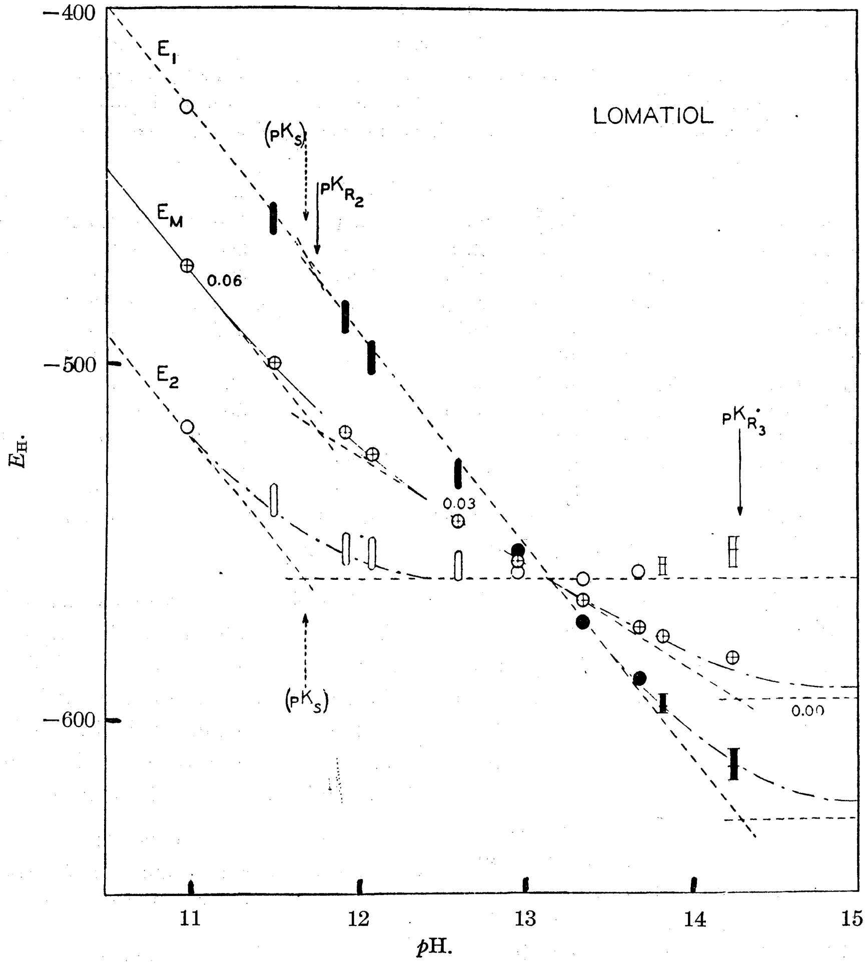

Fig. 1.—The three normal potentials, referred to the normal hydrogen electrode at 30°, of lomatiol, plotted against *p*H: E_m, normal potential of the system fully oxidized–fully reduced form; E_1, that of the system semiquinone form–fully reduced form; E_2, that of the system totally oxidized form–semiquinone form.

*p*H range from 7.1 to 14.3, and it was found from an analysis of the titration curves that the separation of the two steps begins a little above *p*H 9.0 and is more distinct in more alkaline regions.

A summation of the data for lomatiol is shown graphically in Fig. 1, giving the normal potentials plotted against *p*H. The separation never becomes so great as to produce a jump of the potential at 50% of the whole titration. The slopes of the titration curves varied all the way from 14.5 mv. at the lower limit to 36 mv. at about *p*H 14.24(3 *M* sodium hydroxide). Table I shows the variations in the slopes (E_i) and the attending variations in the formation constant, *K*, of the semiquinone and in the maximum ratio, *M*, of semiquinone to total material. The two steps always overlap so much that, at the most, about 61% of the total material in the form of the semiquinone is in equilibrium with the other forms. The curve (Fig. 1) shows a second dissociation constant of the reductant at about *p*H 11.74, which is in agreement with the findings of Ball,[6] and possibly a third in the neighborhood of *p*H 14.3, although titration data at this *p*H (3 *M* sodium hydroxide) are not too reliable on account of badly drifting potentials and the high liquid junction potentials involved. The separation of the two component systems is small and the precise location of the dissociation constant of the semiquinone is a bit uncertain. It is very close to the second dissociation constant of the reductant, possibly in the neighborhood of *p*H 11.68–11.7. The points on the E_1 and E_2 curves in this region are drawn elliptically to show possible variations; slight variations in the *S* value in this region will cause rather large varia-

$K = (76.63S - 2)^2$, (13) $E_2 - E_1 = 0.06 \log K$, (14) $M = \sqrt{K}/(\sqrt{K} + 2)$. (3)

tions in the value of $E_2 - E_1$. The largest value for K was found to be 10. The fact that the titration curves were smooth, with no jump in the middle, is in keeping with the mathematical interpretations of Michaelis and Schubert,[3] which allow for no lateral points of inflection unless K is greater than 16.

The color changes are worthy of comment. In all lomatiol solutions above *p*H 8.0, the fully oxidized form is cherry-red. Between *p*H 10.0 and 12.6, the intermediate color is brownish-orange with a bluish tinge appearing as the *p*H increases. Above *p*H 13.0 the semiquinone color is brownish-violet and almost pure purple at *p*H 14.24. The completely reduced form is pale yellow below *p*H 13.0 and greenish-yellow above this point.

Parallel investigations on hydrolomatiol, lapachol, hydroxyhydrolapachol, and iso-β-lapachol resulted in potential values almost identical with those of lomatiol, and with only minor variations in the amount of semiquinone formation (Table II). All of these compounds have been described by Paternò, Hooker, Fieser, *et al.* Hydrolomatiol[12] is prepared by the hydrogenation of lomatiol. Lapachol[15–17] is 2-(γ,γ-dimethylallyl)-3-hydroxy-1,4-naphthoquinone and is found in the grain of a number of South American woods. Hydroxyhydrolapachol[15,16] can be prepared by the action of potassium hydroxide on β-lapachone. Iso-β-lapachol[18,5] is isomeric with lapachol, and differs only in color from the other compounds of this series. Solid iso-β-lapachol is brick-red, while the other compounds mentioned are yellow. In alkaline solution, it is intensely purple, the intermediate reduction stage is brownish-red and the completely reduced form is greenish-yellow.

TABLE II

COMPARISON OF THE VALUES OF K, THE SEMIQUINONE FORMATION CONSTANT

All of these compounds gave stable potentials during titration in all of the alkaline buffers except the strong sodium hydroxide solutions. Here, the quinones undergo decomposition and irreversible changes, causing drifting potentials. It is due to this instability that the values for E_2 in the range of *p*H 13.6–14.24 deviate from the

base line (Fig. 1). Table II shows a comparison of the maximum ratios of semiquinone to total material for all of the quinones. The E_1 and E_2 curves all intersect the E_0' curves in the neighborhood of pH 13.1–13.2. The values of pKr_2 agree closely with those of Ball,[6] and the values of E_0' vary but slightly. The E_0':pH curve for these compounds is about 10–12 mv. more positive than that of phthiocol. These quinones are extremely insoluble in acid solution, but titrations in alcoholic acid buffers failed to show any step formation in this region.

α-Lapachone, β-lapachone, chlorohydrolapachol and bromo-β-lapachone were not titratable in alkaline solution due to their rapid decomposition. α-Lapachone, first obtained by Games Paternò[15] by the action of nitric acid on lapachol, and later described by Hooker,[16] decomposes rapidly in alkali. The same is true of β-lapachone,[15,16] its ortho isomer. Both of these compounds are insoluble in alkalies in the cold, but are dissolved gradually by a boiling 1% solution of sodium hydroxide, and in so doing undergo change. Bromo-β-lapachone[15,16] can be obtained by treating lapachol with hydrogen bromide gas in chloroform solution, and is also extremely insoluble. The bromine of bromo-β-lapachone is easily displaced from the molecule by alkalies and the substance reverts to β-lapachone, making it useless for titration. Chlorohydrolapachol[16] is a product of the direct addition of hydrogen chloride to lapachol. In contact with dilute alkalies, chlorohydrolapachol is converted into a mixture of lapachol, hydroxyhydrolapachol, α-lapachone and β-lapachone, the latter two of which crystallize out, all of these complications making it impossible to study the compound potentiometrically. The similarity in structure of these compounds with the ones successfully titrated, coupled with the fact that slow reduction in test-tube experiments gives rise to similar intermediate color changes, seem to indicate that they too possess the ability to form semiquinones.

For the opportunity to study potentiometrically these compounds of the lapachol group, the author is greatly indebted to Dr. Louis F. Fieser, who kindly placed at his disposal pure samples of these materials left by the late Dr. Samuel C. Hooker, whose exhaustive study of hydroxynaphthoquinone chemistry is unique in the literature of organic chemical research.

The potentials of the naturally occurring hydroxynaphthoquinones, juglone and lawsone, were reinvestigated. Lawsone is 2-hydroxy-1,4-naphthoquinone and occurs in the leaves of the henna plant (*Lawsonia inermis*) and juglone, the coloring matter contained in the husks of walnuts, is 5-hydroxy-1,4-naphthoquinone. Friedheim[9] reported an irregularity in the slopes of titration curves obtained with these substances at pH 7 and above, and suggested that this irregularity pointed toward semiquinone formation. This possibility was not pursued, due to the instability of the pigments in alkaline media. On reinvestigating these compounds, the author also found it impossible to obtain reliable titration curves with juglone and lawsone at pH greater than 7.0 due apparently to the decomposition of these compounds in alkaline buffers. In the case of lawsone, which was extracted from henna leaves by the method of Tommasi,[19] the fault probably lay in the purity of the material used, since Fieser and Fieser,[10] working with a completely pure substance, were able to titrate this compound successfully in buffers as alkaline as pH 12.92. It is the intention of the author to reinvestigate the potentials of lawsone, using a thoroughly pure synthetic sample. The juglone used was prepared synthetically by oxidation of 1,5-dihydroxynaphthalene with chromic–sulfuric acid mixture, according to Bernthsen and Semper.[20] Test-tube experiments seemed to show intermediate colors when these quinones were oxidized and reduced, and, since they are so similar in structure to phthiocol, lomatiol, *et al.*, it might be suggested, pending further work, that these pigments be included among anionic semiquinone formers. On comparing juglone with lawsone and the aforementioned hydroxynaphthoquinones, one might draw the conclusion that substitution of the benzene ring containing the quinone oxygens has considerable to do with potentiometric stability.

Conclusion

Semiquinone formation by lomatiol, lapachol, and other hydroxynaphthoquinones has been investigated. The two-step character of the oxidation–reduction becomes evident at about pH 9.5 and becomes more distinct as the solution becomes more alkaline. The ratio of semiquinone to total material reaches a maximum of 0.61 at pH 14.24. It corresponds to an index potential of 36 mv. and a formation constant of 10. The

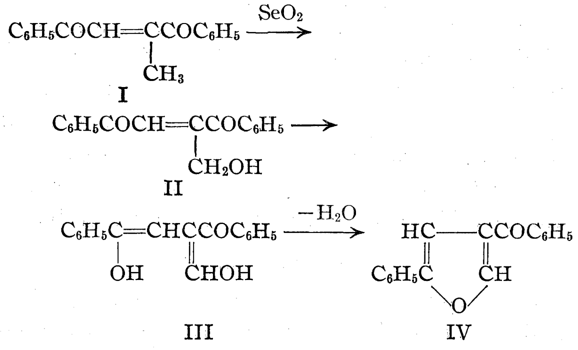
2-Phenyl-4-benzoylfuran

BY REYNOLD C. FUSON, C. L. FLEMING AND ROBERT JOHNSON

Very few β-keto furans are known and of these none has an unsubstituted α-position. 2-Phenyl-4-benzoylfuran (IV) is, therefore, unique. In the study of the application of the principle of vinylogy to ketones we chanced to prepare this furan and noted that its properties reflected its unusual structure. This observation led us to examine these properties in some detail.

The furan was made by treating 1,2-dibenzoyl-1-propene (I) with selenium dioxide. Since the diketone is a vinylog of acetophenone it was expected that the methyl group would be attacked. Evidently this group is oxidized and the furan is formed by rearrangement and subsequent loss of water. Of especial interest in this connection is the observation that only one-half mole of selenium dioxide is required to convert one mole of the diketone (I) to the furan (IV). This corresponds to the amount of oxidation necessary to form the hydroxy compound (II). The latter could rearrange to the dienol (III) by a 1,5- or a double 1,3-shift. The dienol would be expected to lose water to form the furan.



This mechanism suggests that the method might be general for ketones of the type $RCOC{=}C{-}CH_3$. To test this idea we subjected 2,3-dibenzoyl-2-butene (V), dypnone (VI) and crotonophenone (VII) to a similar treatment. Only dypnone yielded a furan; the other two ketones were recovered unchanged even after long treatment with the oxidizing agent. This indicates that this method of preparing furans is highly specific. It should be mentioned that 2,4-diphenylfuran (VIII), the product obtained from dypnone, had been prepared in low yields by the oxidation of dypnone with nitrobenzene.[1]

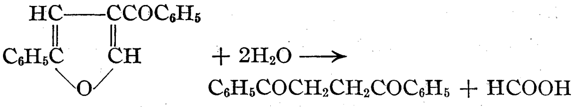
VIII

The most striking property of 2-phenyl-4-benzoylfuran is the ease with which it reacts with alkalies, ammonia or aniline. This appears less extraordinary if we consider that the compound is vinylogous with benzoic esters and might, therefore, be expected to be sensitive to hydrolytic and ammonolytic agents. Aqueous alkalies hydrolyze it rapidly to 1,2-dibenzoylethane and formic acid



Ammonia and aniline convert the furan, respectively, into the pyrrole (IX) and the anil (X) of the expected phenylpyrrole.

[1] Engler and Dengler, *Ber.*, **26**, 1446 (1893); *cf.* Delacre, *Bull. soc. roy. Belg.*, [3] **26**, 534 (1893).

Hydrolysis transforms the latter into the N-phenylpyrrole (XI) and aniline. It is of interest to note that the benzoylpyrrole (IX) does not show the sensitiveness to alkalies that characterizes the benzoylfuran (IV).

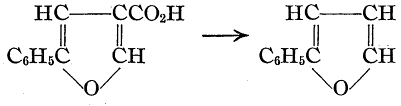
The furan was remarkably stable to acids. Long treatment with hot alcoholic hydrochloric acid partially transformed it into a high-melting derivative which appeared to be trimolecular. Its structure was not investigated further.

The behavior of the benzoylfuran under alkaline and acidic conditions is in distinct contrast with the usual reactions of the furan nucleus. In general this nucleus is characterized by stability to alkalies and extreme sensitiveness to acids, whereas the converse is true of the present furan. However, this is in harmony with the view already mentioned that β-keto furans are vinylogs of esters.

A number of reactions were carried out which affected only the carbonyl group. Oximes were prepared of the benzoylfuran (IV), the pyrrole (IX) and the N-phenylpyrrole (XI). Reduction of the furan gave a carbinol (XII) which was characterized by the formation of a benzoate and a *p*-nitrobenzoate. Attempts to effect differential oxidation were unavailing. Sodium chlorate in the presence of vanadium pentoxide gave only benzoic acid. Ozonolysis led to a similar result.

Confirmation of the structure of the benzoylfuran (IV) was obtained by degrading it to 2-phenylfuran (XIV). The furan formed an oxime which underwent the Beckmann rearrangement to give the corresponding anilide. The latter was hydrolyzed to 2-phenyl-4-furoic acid (XIII) which in turn was converted to 2-phenylfuran (XIV) by heating.

IV ⟶ oxime ⟶ anilide ⟶



XIII XIV

In contrast to the benzoylfuran (IV) the furoic acid (XIII) was very resistant to the attack of reagents. The ring was not attacked by alkalies or ammonia and decarboxylation could be effected only with difficulty.

Experimental

1,2-Dibenzoyl-1-propene (I).—This compound was prepared from mesaconyl chloride and benzene by a modification of the method described by Lutz and Taylor.[2] The following is a typical procedure. Twenty-five grams of mesaconyl chloride, prepared by the method of Meyer,[3] was added, with stirring, to an ice-cold suspension of 45 g. of aluminum chloride in 150 cc. of benzene. Fifteen minutes was required for the addition of the acid chloride. Stirring was continued for fifteen minutes after completion of the addition; the mixture was cooled in an ice-bath during the entire reaction period.

The reaction mixture was then hydrolyzed and worked up in the usual way. The solution was concentrated and cooled; a yellow solid separated and was collected on a filter. Two crystallizations from alcohol gave 32.0 g. of 1,2-dibenzoyl-1-propene; m. p. 52.0–52.5°. The yield was 85% of the theoretical amount. It was found necessary to work up the reaction mixture as rapidly as possible after hydrolysis. If this was not done the product was contaminated with a green oil which greatly retarded the separation of a crystalline product.

2-Phenyl-4-benzoylfuran (IV).—The oxidation was carried out in the usual way, using 60 cc. of dioxane, 2 cc. of water, 5.6 g. (0.05 mole) of selenium dioxide and 25.0 g. (0.10 mole) of the diketone. After eight hours the selenium was collected on a filter and washed with hot dioxane. The filtrate was poured into water; the brown solid which separated was collected on a filter and air dried. After crystallization from ether there was obtained 15.5 g. of 2-phenyl-4-benzoylfuran; the yield was 63% of the theoretical amount.

Anal. Calcd. for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87; mol. wt., 248. Found: C, 82.69, 82.31; H, 4.96, 5.15; mol. wt., 249, 254.

The furan is sparingly soluble in ether, from which it separates as colorless needles which melt at 113.7–114.0°. It is moderately soluble in alcohol and glacial acetic acid. It reduces a potassium permanganate solution readily and decolorizes a carbon tetrachloride solution of bromine with the evolution of hydrogen bromide.

Dypnone.—This ketone was made by the method of Calloway and Green.[4] The oxidation of 22.3 g. (0.10 mole) of dypnone with 5.6 g. (0.05 mole) of selenium dioxide was carried out in the usual way. No crystalline material could be isolated from the tarry product and so it was distilled *in vacuo*. The 2,4-diphenylfuran (VIII) distilled at about 200° under 3 mm. pressure and solidified in the side-arm. After two crystallizations from alcohol there was obtained 2.3 g. of colorless plates; m. p. 110.7–111.0°. A solution of the pyran in concentrated sulfuric acid exhibited an intense violet fluorescence; this was reported also by Engler and Dengler.[1] The furan changed on standing, in the solid state or in solution, to an insoluble colorless powder which did not melt below 250°; this change was also noted by Delacre.[1]

Crotonophenone and 2,3-Dibenzoyl-2-butene.—Each of these compounds was recovered unchanged after long treatment with selenium dioxide.

Reactions of 2-Phenyl-4-benzoylfuran

Cleavage with Alkali.—A solution of 2.5 g. of the furan, 75 cc. of alcohol and 30 cc. of a 10% sodium hydroxide solution was heated under reflux for forty-five minutes. The resulting mixture was steam distilled; no product

other than alcohol was found in the distillate. The residue was acidified with phosphoric acid and again steam-distilled; the clear distillate was acidic.

This distillate was neutralized with sodium hydroxide and evaporated to dryness. An aqueous solution of this salt reduced a solution of potassium permanganate immediately. A portion of the dry salt was heated with *p*-bromoaniline; after crystallization from dilute alcohol the product melted at 115.8–116.8°. A mixture of the product with an authentic specimen of *p*-bromoformanilide also melted at 115.8–116.8°.

The solid residue which remained in the flask after the steam distillation was collected on a filter and recrystallized from alcohol. There was thus obtained 0.7 g. of colorless needles; m. p. 145.2–146.2°. A mixture of this product with an authentic specimen of 1,2-dibenzoylethane also melted at 145.2–146.2°.

The same products were formed when the furan was treated with potassium carbonate under similar conditions.

Reaction with Hydrochloric Acid.—A solution of 1.0 g. of the furan, 20 cc. of concentrated hydrochloric acid and 50 cc. of alcohol was heated under reflux for eighty hours. The solution was diluted with water and cooled; a solid product separated. This material was collected on a filter and purified by recrystallization from alcohol. A portion of the product was insoluble in boiling alcohol and was removed. The solid which separated when the filtrate was cooled was isolated by filtration; there was obtained in this way 0.5 g. of unchanged starting material.

The insoluble product separated above was purified by several recrystallizations from aqueous acetone; it becomes brown at 211.5° and melts with decomposition at 214.8–215.8°.

Anal. Calcd. for $C_{51}H_{34}O_5$: C, 84.28; H, 4.72; mol. wt., 727. Found: C, 84.24, 84.10; H, 4.73, 4.65; mol. wt. (Rast), 686.

The compound separates from dilute acetone as colorless fluffy needles. It is insoluble in dilute acids and bases and forms a green solution in concentrated sulfuric acid. It does not contain chlorine.

The same product was formed by treating the furan with a methyl alcoholic solution of dry hydrogen chloride.

Reaction with Ammonium Hydroxide.—A mixture of 1.0 g. of the furan, 5 cc. of concentrated ammonium hydroxide and 10 cc. of alcohol was heated at 130–140° for eighteen hours. The reaction was carried out in a stainless steel bomb. A solid product was isolated from the reaction mixture by filtration and washed with water. This material was then extracted several times with boiling alcohol; the extract was discarded. After two crystallizations of the residue from dilute acetone there was obtained 0.5 g. of 2-phenyl-4-benzoylpyrrole (IX) in fine yellow needles which melted at 213.7–215.5°.

Anal. Calcd. for $C_{17}H_{13}ON$: C, 82.57; H, 5.30; N, 5.66; mol. wt., 247. Found: C, 82.73; H, 5.51; N, 5.42, 5.59; mol. wt. (Rast), 256.

The pyrrole is sparingly soluble in alcohol and readily soluble in ether and benzene. It is insoluble in dilute acids and bases; it forms an orange solution in concentrated sulfuric acid. It reduces a potassium permanganate solution readily and decolorizes a bromine solution with the evolution of hydrogen bromide. It was recovered unchanged after treatment with sodium hydroxide under conditions similar to those used in the cleavage of the parent furan. It forms an **oxime** which separates from dilute alcohol as fine, faintly pink needles which soften at 171° and melt with decomposition at 188.5–191.5°.

Anal. Calcd. for $C_{17}H_{14}ON_2$: N, 10.68. Found: N, 10.89.

Reaction with Aniline.—A solution of 5.0 g. of the furan in 50 cc. of dry aniline was heated under reflux for seventy-two hours. The solution was then cooled and concentrated under a pressure of 3 mm.; absolute alcohol was added to the residue. The solid product which separated was collected on a filter, washed with absolute alcohol and recrystallized from a mixture of dry benzene and petroleum ether (b. p. 60–90°). There was thus obtained 2.3 g. of a solid in the form of clumps of colorless needles. After further crystallization the anil (X) melted at 230.5–231.0°.

Anal. Calcd. for $C_{29}H_{22}N_2$: C, 87.40; H, 5.57; N, 7.03. Found: C, 87.59; H, 5.61; N, 7.08.

The anil is readily soluble in benzene and moderately so in absolute alcohol. In contact with concentrated sulfuric acid it turns yellow but does not dissolve.

The hydrolysis of the anil was carried out by adding 20 cc. of dilute hydrochloric acid to a suspension of 1.5 g. of the anil in 75 cc. of alcohol. A yellow color appeared instantly and the mixture became slightly warm. The reaction mixture was allowed to stand at room temperature for forty-eight hours and then was diluted with water. The solid product was isolated by filtration, dried and recrystallized from ethyl acetate. There was obtained in this way 0.8 g. of 1,2-diphenyl-4-benzoylpyrrole (XI) which melted at 240.0–241.0°. Further crystallization did not alter the melting point.

Anal. Calcd. for $C_{23}H_{17}ON$: C, 85.42; H, 5.30; N, 4.33. Found: C, 85.68, 85.87; H, 5.58, 5.37; N, 4.53.

The pyrrole (XI) separates from ethyl acetate or from a benzene–petroleum ether (b. p. 60–90°) mixture as colorless silky needles. It is practically insoluble in alcohol, sparingly soluble in acetone, ether or ethyl acetate and moderately soluble in benzene. It forms a straw-yellow solution in concentrated sulfuric acid. The **oxime** of the pyrrole was prepared in the usual way; it separates from dilute alcohol as colorless needles which melt at 215.5–218.5°.

Anal. Calcd. for $C_{23}H_{18}ON_2$: N, 8.28. Found: N, 8.13.

Reduction to the Carbinol.—A solution of the furan in ethyl acetate was treated with hydrogen in the presence of a nickel catalyst.[5] The solid residue obtained by evaporating the solution to dryness was crystallized from alcohol. The **carbinol** was thus obtained as colorless needles which melted at 128.1–129.1°.

Anal. Calcd. for $C_{17}H_{14}O_2$: C, 81.57; H, 5.64. Found: C, 81.82; H, 5.62.

The carbinol is readily soluble in ethyl acetate and in ether. It forms a wine-colored solution in concentrated sulfuric acid.

The benzoate, prepared in pyridine solution, separates from alcohol as colorless needles which melt at 123.1–124.1°.

---

(5) Covert and Adkins, THIS JOURNAL, **54**, 4116 (1932).

Anal. Calcd. for $C_{24}H_{18}O_3$: C, 81.32; H, 5.12. Found: C, 81.11; H, 5.15.

The **p-nitrobenzoate** separates from alcohol as rosets of colorless needles which melt at 109.5–109.8°.

Anal. Calcd. for $C_{24}H_{17}O_5N$: N, 3.51. Found: N, 3.49.

Conversion to 2-Phenylfuran.—The oxime of 2-phenyl-4-benzoylfuran was prepared in absolute alcohol solution in the presence of pyridine. It is readily soluble in the common organic solvents and separates from dilute alcohol as colorless needles which melt at 149.0–149.4°.

Anal. Calcd. for $C_{17}H_{13}O_2N$: C, 77.55; H, 4.98; N, 5.32. Found: C, 77.70; H, 5.13; N, 5.46, 5.40.

The Beckmann rearrangement was carried out by adding phosphorus pentachloride to a solution of the oxime in absolute ether. After crystallization from alcohol with the aid of Norite the **anilide** of 2-phenyl-4-furoic acid was obtained as colorless plates which melted at 192.0–193.0°.

Anal. Calcd. for $C_{17}H_{13}O_2N$: N, 5.32. Found: N, 5.44.

The anilide was hydrolyzed with alcoholic potassium hydroxide; it was necessary to heat the solution under reflux for twenty-four hours to cause complete reaction. The aniline was separated by steam distillation and identified as 1-phenylazo-2-naphthol, m. p. 128–129°. The residue was treated with Norite and acidified. Crystallization from alcohol produced colorless needles of **2-phenyl-4-furoic acid** which melted at 208.0–209.0°.

Anal. Calcd. for $C_{11}H_8O_3$: C, 70.25; H, 4.25; neut. equiv., 188. Found: C, 70.20; H, 4.49; neut. equiv., 191, 190.

The acid is readily soluble in acetone, moderately soluble in alcohol, sparingly soluble in benzene, xylene, ether and chloroform. It forms a yellow solution in concentrated sulfuric acid.

The acid was not converted to the corresponding pyrrole when treated with ammonium hydroxide in a bomb at 180°. Decarboxylation did not occur when it was subjected to the following treatments:

1. A mixture of the acid and copper bronze was heated to 250°.
2. A mixture of the acid and copper bronze in quinoline was heated at 225° in a stream of nitrogen.
3. A mixture of the acid and copper bronze in benzylmethylaniline was heated at 280° for one hour.
4. A mixture of the sodium salt of the acid and soda-lime was heated for two hours at 375° under a pressure of 10 mm.

The reaction was finally carried out by heating the acid overnight at 275° in a high-pressure bomb. The **2-phenylfuran** obtained in this way had the following properties: b. p. 107–108° (18 mm.); $n^{20}{}_D$ 1.5968; $d^{20}{}_4$ 1.083. These data are in agreement with those found for a sample prepared by the method described by Kondo and Suzuki.[6]

Summary

1,2-Dibenzoyl-1-propene is transformed into 2-phenyl-4-benzoylfuran by treatment with selenium dioxide. The furan is readily hydrolyzed by aqueous alkalies to give 1,2-dibenzoylethane and formic acid. Ammonia and aniline react to give the corresponding pyrroles. By a series of reactions the benzoylfuran was degraded to the known 2-phenylfuran.

URBANA, ILLINOIS RECEIVED MAY 31, 1938

NOTES

The Structure of Cholesteryl Chloride

BY ERNST BERGMANN

In work with cholesteryl chloride, as carried out in various laboratories and also in this Institute, certain conflicting evidence has accumulated with regard to its usual formula (I). The main point is the following one: while the two epimeric cholestyl chlorides react with sodium acetate under Walden inversion,[1] cholesteryl chloride has been found in our laboratory to give the same cholesteryl acetate which is obtained by direct acetylation of cholesterol.[2] Recently, Marker and co-workers[3] have reported that 7-oxocholesteryl chloride, the constitution of which follows from the characteristic absorption band at 270 mμ of α,β-unsaturated ketones[4] behaves "normally" toward sodium acetate, giving an acetate under configurational inversion. Besides that, Marker and his co-workers have pointed out that cholesteryl chloride reacts under much less drastic conditions than the other chlorides mentioned.[5]

Reactions of halogenides with acetate ions are

---

[1] Marker and co-workers, THIS JOURNAL, **57**, 1755, 2358 (1935).

[2] That cholesterol and cholesteryl chloride have identical configuration, has been discussed in *Helv. Chim. Acta*, **20**, 590 (1937).

[3] Marker and co-workers, THIS JOURNAL, **59**, 619 (1937).

[4] Unpublished results from our laboratory (Miss F. Goldschmidt); compare for 7-oxocholesteryl acetate, Eckhardt, *Ber.*, **71**, 461 (1938).

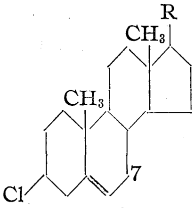
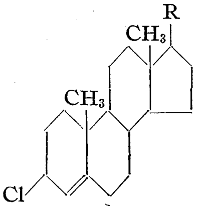
now generally accepted to occur with Walden inversion,[2,6] with one exception, if the halogenide belongs to the allyl derivatives. In this case the possibility of allylic rearrangement prevents any prediction of the steric course taken by a substitution reaction. Therefore, the above difficulty would be overcome if cholesteryl chloride were able to react in the form (II),[7] deriving from *allo*-cholesterol.[8] The reaction of form (II) with sodium acetate would be accompanied by a shift of the double bond.[9] In the case of 7-oxocholesteryl chloride the conjugation with the carbonyl group would stabilize the C=C— double bond in the "classical" 5,6-position.

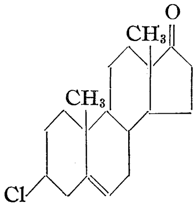
It is interesting to note that similar conditions have been observed by Linstead and Rydon[10] in the case of buten-(1)-ol-(4), which is converted by a mixture of sulfuric and hydrobromic acids partly into 4-bromobutene-(1), and partly into 4-bromobutene-(2). On the basis of Juvala's[11] results, the high substitution velocity, too, of cholesteryl chloride would be understood more easily.



I



II



III

Analogous considerations apply to the case of chloroandrostenone (III), which in contrast with the corresponding saturated chloroandrosterone is able to react with sodium benzoate without configurational inversion. This behavior may again be due to the possibility of III reacting in an allylic form.

Finally, it may be mentioned that this possibility is not necessarily limited to (I) and (III), but may apply to corresponding derivatives of other strong acids as, *e. g.*, toluenesulfonic acid.[12]

Racemization During Esterification by Diazomethane

BY ERNST BERGMANN AND YAÏR SPRINZAK

In the course of experiments on Walden inversion, we had to prepare optically active methyl bromosuccinate. While esterification with methyl alcohol in the presence of concentrated sulfuric acid[1] gave satisfactory results, a series of experiments carried out with diazomethane gave invariably a racemic ester.

(–)-Bromosuccinic acid (1.5 g., rotation in acetone: c 3.000; l 9.9 cm.; α_D $-2.18°$, hence $[\alpha]_D$ $-72.7°$), finely pulverized, was added at zero temperature to a solution of diazomethane, prepared from ethyl nitrosomethylcarbamate (5 g.) and 25% methyl-alcoholic potash solution (7 cc.) in ether (30 cc.). The acid disappeared quickly; after thirty minutes of standing, the yellow solution was evaporated and the remaining racemic methyl bromosuccinate distilled *in vacuo;* b. p. 87° (2.5 mm.); yield 1.4 g. (Calcd. for $C_6H_9O_4Br$: Br, 35.5. Found: Br, 35.4).

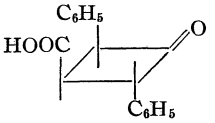
As check experiments, a sample of the same (–)-bromosuccinic acid was kept for thirty minutes with a mixture of ether and methyl alcohol (6:1) and the optically active methyl ester in contact with diazomethane solution, prepared as above, for two hours. In both cases, no changes in optical rotation were observed.

Therefore we are inclined to assume that the racemization is connected in some way with the esterification mechanism. An analogous observation has been made incidentally by Stoermer and Starck[2] in the case of the optically active acid

---

[1] Holmberg, *Ber.*, **59**, 125 (1926).

[2] Stoermer and Starck, *ibid.*, **70**, 479 (1937).



which is racemized too in the course of esterification by diazomethane.

Furthermore, the observation reported by Schlenk and Bergmann[3] may be recalled, that fluorene-9-carboxylic acid behaves—at least to a certain extent—abnormally toward diazomethane, giving dimethyl dibiphenylenesuccinate.

Remark on the Mechanism of the Fittig Reaction

BY O. BLUM-BERGMANN

(1) Bachmann and Clarke[1] have shown, some years ago, that the by-products formed in the biphenyl synthesis from boiling chlorobenzene and sodium metal indicate the intermediary formation of free phenyl radicals. Analogous results are obtained at room temperature, working in benzene solution.

To bromobenzene (50 g.), dissolved in benzene (50 g.) in a Schlenk tube,[2] sodium slices (10 g.) were added in nitrogen atmosphere, reaction starting quickly and causing a marked rise in temperature. When this first reaction ceased, the mass was shaken for two days, diluted with benzene (100 cc.) and separated by decantation from the excess sodium metal. Water was added, the benzene solution washed several times with water, dried and evaporated *in vacuo* and the residue fractionated at 13–15 mm. (a) B. p. 123–129°. This fraction crystallized completely; it consisted of pure biphenyl; m. p. 69–71°; yield 6.8 g. (b) B. p. 165–200°. The yellowish oil solidified almost quantitatively, on trituration with methyl alcohol; yield 2.1 g. From methyl alcohol, stout prisms, m. p. 56–57°, which according to their physical properties and the analysis proved to be *o*-phenyl-biphenyl, described before by Bachmann and Clarke.[1] (Calcd. for $C_{18}H_{14}$: C, 93.9; H, 6.1; mol. wt., 230. Found: C, 93.5; H, 6.0; mol. wt. (camphor), 241, 236.) (c) B. p. 200–250°, yellowish oil, which crystallized on trituration with light petroleum (b. p. 80–100°) (yield 0.26 g.) and was purified from the same solvent. Long needles of triphenylene; m. p. and mixed m. p. with an authentic sample, 195° (Calcd. for $C_{18}H_{12}$: C, 94.7; H, 5.3; mol. wt., 228. Found: C, 94.6; H, 5.3; mol. wt. (camphor), 257, 255).

(2) Theoretically free phenyl radicals may occur either in the formation from sodium and bromobenzene of phenylsodium[3] or in the interaction between the latter compound and a second bromobenzene molecule or in both processes. Horn and Polanyi[4] showed that, on interaction with dilute sodium vapor, bromobenzene forms biphenyl, undoubtedly via phenyl radicals. On the surface of metallic sodium, on the other hand, it will be expected that a second sodium atom will always be near enough for phenylsodium formation when the first metal atom has removed the halogen from the C-Hal bond,[5] although, obviously, temporary radical formation cannot be excluded. Therefore it is more likely that the reaction of the alkylsodium compound with bromobenzene involves the intermediary production of the radicals. In favor of this, the observation may be reported that phenylsodium, on interaction with bromobenzene, gives triphenylene $(C_6H_4)_3$ too, indicating formation of phenyl radicals and their disproportionation into benzene and phenylene radicals C_6H_4.[6]

Diphenylmercury (6 g.) was shaken in benzene solution with sodium slices (10 g.) for two days;[7] the phenylsodium containing mass was then separated by decantation from the excess metal, and bromobenzene (7 cc.) (twice the theoretical amount) added. The mixture was kept at 70° for forty-eight hours and poured out into water. Treatment as above gave (besides some bromobenzene) (a) biphenyl, b. p. 120–160° (22 mm.), m. p. 65°, yield 1.45 g.; (b) triphenylene, b. p. 200–220° (13 mm.) after trituration of the crude product (1 g.) with light petroleum and recystallization from the same solvent, m. p. 194–195.5°.

Hydrogenation of Ethylene and Partially Deuterized Ethylene on Catalytic Metal Surfaces

BY G. G. JORIS AND J. C. JUNGERS

The hydrogenation on catalytic copper of ethylene, ethylene-d_4 and partially deuterized ethylene (50%D) has been measured and found to be faster for the heavy compound.[1] To gain further information on this reaction and establish that this was not due to accidental circumstances, the hydrogenation of ethylene and partially deuterized ethylene was carried out on nickel, cobalt and platinum surfaces. The rates measured for mixtures of 5 cm. of ethylene and 7.5 cm. of hydrogen are given in the table and show

---

Some Phenacyl and *p*-Substituted Phenacyl Esters

BY R. V. LUNDQUIST

Some phenacyl and *p*-substituted phenacyl esters of organic acids have been prepared for the identification of those acids. They were prepared by the method of Judefind and Reid.[1]

Heptylic Acid.—The phenacyl ester was a liquid.

Dichloroacetic Acid.—The phenacyl ester was a liquid; the *p*-bromophenacyl ester, observed m. p. 98.2 to 99.3°; the *p*-chlorophenacyl ester, observed m. p. 93.0 to 93.8°.

α-Bromo-*n*-butyric Acid.—The phenacyl ester was a liquid; the *p*-phenylphenacyl ester, observed m. p. 103.5 to 104.0°.

Acetylsalicylic Acid.—The phenacyl ester, observed m. p. 105.0 to 105.5°.

The esters were obtained in excellent yield and the solid esters were purified easily to a constant melting point.

Acid Dissociation Constants in Dioxane–Water Mixtures. A Correction of the Dissociation Constant of Benzoic Acid

BY CECIL C. LYNCH AND VICTOR K. LA MER

Professor Martin Kilpatrick and Dr. L. John Minnick of the University of Pennsylvania kindly called our attention to the fact that the dissociation constants of benzoic acid as given in the "International Critical Tables," Vol. VI, p. 279, are in error by a factor of ten and that this had led to an unnecessary restriction of statement in our paper of the above title.[1] When the most recent value for 25°[2] is plotted in our Fig. 8 instead of the erroneous "I. C. T." value (6.15×10^{-4}), the anomalous behavior of benzoic acid as compared with acetic, propionic and butyric acids disappears. Log K_{benzoic} becomes a linear function of the reciprocal of the dielectric constant between $D = 78$ and 21, and now conforms closely to the behavior of the three aliphatic acids. In Table III, p. 1257, K_{acetic} ($D = 34.3$) should read 5.62×10^{-7} instead of 5.01×10^{-7} and the second datum for propionic acid ($D = 21.0$) should read 5.33×10^{-9} instead of 5.30×10^{-9}.

The Hydrolysis of Methyl Iodide

BY RICHARD A. OGG, JR.

The hydrolysis of methyl iodide in pure water[1] has been shown to be kinetically first order with respect to methyl iodide, and unretarded in rate by the resulting hydriodic acid. Essentially similar results have been found by the author in a brief study of methyl iodide hydrolysis in a mixture of equal volumes of anhydrous methanol and water. The solutions (some 0.02–0.08 molar in methyl iodide) were heated in sealed nitrogen-filled tubes. Reaction was followed by titration of the resulting hydriodic acid. The last stages of the reaction were complicated by formation of considerable iodine (Moelwyn-Hughes found only traces)—undoubtedly as a result of the side reaction $CH_3I + H_3O^+ + I^- \longrightarrow CH_4 + I_2 + H_2O$. (The solutions containing most iodine gave off inflammable gas on opening the tubes.) Displacement of the equilibrium

$$CH_3OH + H_3O^+ + I^- \rightleftarrows CH_3I + 2H_2O$$

to the right by the large concentration of methanol in the solvent explains the importance of the side reaction—as contrasted to the results in pure aqueous solution.

Very good first order rate constants were obtained up to some 60% completion of the reaction (iodine formation then became troublesome). At 100 and 55° the rate constants were found to be, respectively, some 3×10^{-4} (average from

(1) E. A. Moelwyn-Hughes, *Proc. Roy. Soc.* (London), **A164**, 295 (1938).

three runs, with following respective sets of constants corresponding to successive time intervals—3.1, 2.9, 3.0, 3.1, 3.2, 3.1, 3.0, 3.1; 2.9, 3.0, 2.8, 3.0) and 3.2×10^{-6} sec.$^{-1}$ (average from two runs, with following respective sets of constants—3.3, 3.4, 3.2, 3.1; 3.1, 3.0, 3.2, 3.1). The corresponding values found by Moelwyn-Hughes for the reaction in aqueous solution are 4.47×10^{-4} and 4.9×10^{-6} sec.$^{-1}$. The effect of replacing a portion of the solvent water by methanol is thus to diminish the rate of methyl iodide hydrolysis. Comparison of the figures at the respective temperatures indicates that the activation energy is but slightly affected, if at all. These results are entirely similar to the effects of solvent change on the rates of hydrolysis of secondary and tertiary alkyl halides in mixtures of ethanol and water.[2] It would appear that the hydrolyses by *neutral water* of methyl halides are kinetically similar to the corresponding reactions of secondary and tertiary halides, and that an identical intimate mechanism obtains for all of these reactions.

A New and Direct Method for the Determination of Creatine. I. Preliminary Report

BY CHARLES F. SCHAFFER

Investigations on the origin and significance of the excretion of creatine in the urine have received no general acceptance. The reason for this uncertainty is that creatine is not determined directly, but by difference. The preformed creatinine is determined by Folin's colorimetric method, and then the urine is heated with acid which converts the creatine to creatinine. The creatinine is then redetermined. The difference between this total creatinine value and that of the preformed creatinine is called creatine. The fallacies of such an analytical procedure are obvious; especially when considering that the quantitative determination of creatinine itself is made by measuring its reducing action. In fact it has been pointed out independently by Arnold,[1] Emden,[2] Hurtley,[3] Greenwald[4] and confirmed by Graham and Poulter,[5] that acetoacetic acid is capable of showing a false presence of creatine.

In attempting to formulate a copper reagent that would eliminate entirely the effect of reducing nitrogenous substances, but still retain its maximum ability to be reduced by sugars, Folin and Svedberg[6] developed one which is reduced by nitrogenous substances such as uric acid, creatine, creatinine and allantoin, but is not affected by sugar.

It was the use of this reagent which enabled Larson[7] to promulgate his colorimetric method for the determination of allantoin.

The subsequent use of this procedure for the determination of added allantoin in urine of man resulted in the recovery of excessive amounts. On investigation it was found that the substance responsible for this greatly increased reducing action was creatine.

Aware of the negligible amounts of allantoin present in human urine, it was decided that an earnest endeavor to utilize this procedure for the determination of creatine warranted investigation. It was soon discovered that by increasing the alkalinity of the copper solution, creatine demonstrated reducing properties which varied directly as its concentration and could be measured quantitatively.

Larson's procedure, slightly modified for its adaptation to creatine, is used. The determination is made by treating a portion of the filtrate of the test sample in a Folin–Wu[8] sugar tube with the ammoniacal copper solution; the alkalinity is increased by the addition of sodium hydroxide solution, and immediately it is placed in a rapidly boiling water-bath for ten minutes, cooled and the blue color, developed after the addition of acid molybdate, compared with a 1-mg. creatine standard similarly treated.

Reagents Required

Phospho-24-tungstic Acid.—It is essential that the phosphotungstic acid used be pure. Larson obtained inconsistent results in the precipitating power of eight different lots of C. P. phosphotungstic acid procured from four leading manufacturers and the results have been substantiated in this Laboratory. Basic lead acetate;[9] 5% (by weight) sulfuric acid solution; Folin ammoniacal cop-

per reagent;[10] 20% sodium hydroxide solution; acid molybdate reagent;[11] creatine standard: dissolve 100 mg. of creatine in water and dilute to 100 cc.

Technique.—Place 1.5 g. of phosphotungstic acid in a large Pyrex tube, 30- to 50-cc. capacity, and dissolve in 6 cc. of water. With the aid of a pipet add 4 cc. of urine sample and centrifuge until clear. Add 4 cc. of the basic lead acetate solution and centrifuge again.[12] When clear, add 6 cc. of 5% sulfuric acid and recentrifuge. Transfer 2 cc. of the resultant, clear filtrate to a Folin–Wu sugar tube. Add 2 cc. of ammoniacal copper solution and 1 cc. of 20% sodium hydroxide. Place in a vigorously boiling water-bath for ten minutes, cool, add 2 cc. of acid molybdate reagent, dilute to mark and compare immediately with a 1-mg. creatine standard similarly treated.

Observations

The phosphotungstic acid precipitates the proteins and some of the other interfering substances while the addition of lead acetate removes the excess phosphotungstic acid and the remaining interfering substances. The subsequent use of sulfuric acid precipitates the excess lead completely.

The optimum alkalinity of the medium required for the creatine to exert its most efficient reducing action necessarily detracts from the non-sugar reducing properties of the copper solution.

Normally, urine contains traces of glucose which are so minute that the error introduced by such amounts is negligible. However, when sugar is present in any appreciable amounts it must either be removed by the brief fermentation process described by Folin and Svedberg[6] and designed for use on filtrates, or the quantitative sugar determinations of Folin–Wu[11] run in conjunction with the determination of creatine. This latter method is preferred as the fermentation procedure must be regulated rather too exactly, otherwise the reducing powers are increased rather than decreased.

Recovery of Creatine Added to Urine.—Urine that had no reducing action on the copper solution or at best produced only a slight coloration which was impossible to read colorimetrically was selected and varying amounts of a standard creatine solution added.

Filtrates of these various specimens were then prepared as described above, and the determination proper performed on the filtrates.

From a series of twenty-eight different determinations recoveries ranging from 90 to 110% were obtained in contrast to recoveries of 82 to 92% employing the method of Folin.

The accompanying protocol shows a comparison of the values for creatine recovery, obtained by both the Folin and the suggested colorimetric method, when added to urine.

PROTOCOL

COMPARISON OF CREATINE RECOVERIES AFTER THE ADDITION OF A DEFINITE AMOUNT TO URINE

Urine no.	Creatine present, mg. per cc.	Recovery Folin method, mg. per cc.	Percentage error	Recovery Colorimetric method, mg. per cc.	Percentage error
1	2.6	2.5	− 3.9	2.6	0
2	3.6	3.2	−11.2	3.4	−5
3	4.6	3.8	−17.4	4.45	−3
4	1.0	0.92	− 8.0	0.97	−3
5	2.0	1.83	− 8.4	2.1	+5
6	3.0	2.57	−14.3	3.12	+4
7	1.0	0.88	−12.0	0.97	−3
8	2.0	1.74	−13.1	1.92	−4.2
9	3.0	2.38	−20.7	3.13	+4.5
10	0.6	0.49	−17.7	0.6	0

Conclusion

A preliminary report on a direct method for the determination of creatine in urine is presented. The full report is to be submitted on completion of the work.

(12) Prior to the addition of the basic lead acetate, Larson recommends refrigerator incubation of the tube for one-half hour to minimize the time required for complete phosphotungstate precipitation. This procedure may be omitted as the results obtained, on final analysis of the filtrate, show very little variation.

The Common Basis of Intramolecular Rearrangements. IV.[1] A Correction: The Benzilic Acid Rearrangement

BY FRANK C. WHITMORE

Since the formulation of the working hypothesis used in this Laboratory, no facts have been found contrary to the assumption of the basis of molecular rearrangement as due to a carbon with an open sextet of electrons. However, the extreme extension of the hypothesis to include the benzilic acid rearrangement involving the addition of a proton to benzil to form a positive ion, cannot be supported. Ingold[2] has proposed the existence of an intermediate negative ion produced by the addition of hydroxyl ion to benzil and indi-

cated the importance of an alkaline medium in the transformation.[3] The reaction rate study conducted by Westheimer[4] indicated the existence of a bimolecular reaction between benzil and hydroxyl ion which can best be explained by the formation of the same negative ion. Recent investigation by Roberts and Urey[5] on the oxygen interchange of benzil with water of a higher concentration of H_2O^{18} indicates a more rapid exchange in alkaline than in neutral solution which is explained by the rapid, reversible addition of hydroxyl ion to form a negative ion with benzil, followed by rearrangement.

COMMUNICATIONS TO THE EDITOR

THE SALT EFFECT IN THE PARAMAGNETIC CONVERSION OF *p*-HYDROGEN

Sir:

In 1934 Sachsse [*Z. physik. Chem.*, **B34**, 429 (1934); *Z. Elektrochem.*, **40**, 531 (1934)] reported that the rate constants for the conversion of *p*-hydrogen by solutions of paramagnetic ions were independent of the concentrations of these ions if the change in solubility of hydrogen with changing ionic strength were taken into account. To this is now added the fact that these rate constants are also independent of the concentration of added diamagnetic salts. The measurements were made by shaking the solutions with p-H_2 at a shaking speed in the range at which the conversion rate was independent of the shaker speed. The ratio of gas volume to solution volume was known and kept constant. The apparent rate was independent of hydrogen pressure.

Some representative data are given in the following table for which the solution volume is always 100 cc., the gas pressure *ca.* 100 mm., the concentration of manganous chloride 0.02 *M*, at room temperature.

Expt.	Molality of diamagnetic salt	$k'_{0.02} \times 10^3$	l(Ostwald)	$k(l, m^{-1}, \text{min.}^{-1})$
1	0	3.03	0.0198	7.9
2	0.3 *M* $CaCl_2$	2.75	.0173	8.2
3	0	2.15	.0198	8.0
4	1 *M* $NaNO_3$	1.65	.0158	7.7
5	2 *M* $NaNO_5$	1.41	.0127	8.2
6	0.6 *M* $BaCl_2$	1.56	.0151	7.7

In experiments 1 and 2 the gas volume is 45.1 cc.; in expts. 3 to 6 the gas volume is 64 cc. k' is the observed first order rate constant calculated by $k'_{0.02} = \frac{1}{t} \log \frac{(p\text{-}H_2)_0}{(p\text{-}H_2)_t} - k'_w$ where t is the time in minutes, $(p\text{-}H_2)_0/(p\text{-}H_2)_t$ is the rate of the initial p-H_2 concentration to that at the time t and k'_w is the correction for the conversion by pure water under the same conditions and calculated in the same way. For expts. 1 and 2 $k'_w = 0.07 \times 10^{-3}$ and for expts. 3 to 6 $k'_w = 0.05 \times 10^{-3}$. k is the velocity constant reduced to unit Mn^{++} ion concentration and corrected for the gas not in solution by the relation $k = \frac{V_g \times 2.303}{V_s \times l \times M_{MnCl_2}} \times k'$ where V_g is the gas volume, V_s the solution volume, l the Ostwald solubility of H_2 (from Seidell's "Solubilities") and M_{MnCl_2} the molality of the manganous chloride.

Thus the rate of conversion of $p\text{-}H_2 \longrightarrow o\text{-}H_2$ by Mn^{++} can be expressed by

$$\frac{-d(p\text{-}H_2)}{dt} = k(Mn^{++})\,(p\text{-}H_2)$$

where (Mn^{++}) and $(p\text{-}H_2)$ are the concentrations of Mn^{++} ion and p-H_2, respectively. There is no need to introduce any activity factor of Brönsted $f_{Mn^{++}}f_{H_2}/f_{Mn^{++}\cdot H_2}$, although the concentration of the diamagnetic salts was carried as high as 4 *M* $NaNO_3$ and 2.4 *M* $CaCl_2$ in 0.02 *M* manganous chloride. If it is incorporated it must be a constant and this is not unreasonable since the two reactants completely retain their independent identities throughout the reaction.

The effectiveness of the inhomogeneous magnetic field of the ion is independent of the ionic environment of the paramagnetic ion. This is in agreement with the observation of Sachsse that solutions of manganous sulfate and manganous chloride give the same rate constant.

THE CATALYTIC CONDENSATION OF GRIGNARD REAGENTS WITH HYDROCARBONS

Sir:

Meyer and Tögel [*Ann.*, **347,** 55 (1906)] observed that the addition of water during the formation of the Grignard reagent from bromobenzene resulted in the formation of large amounts of biphenyl. It is also well-known that phenylmagnesium bromide does not react with bromobenzene to yield biphenyl. These facts suggested to us the possibility that this reaction might be due to the formation of free phenyl radicals, and that under suitable conditions these might condense with certain reactive molecules. This assumption was strengthened when the above reaction was carried out in the presence of a large excess of mesitylene; only a trace of biphenyl and a 13% yield of 2,4,6-trimethylbiphenyl were obtained.

We have now extended our study of this new condensation reaction to include several Grignard reagents and hydrocarbons and we are able to draw the following tentative conclusions. (1) The reaction involves the already-formed Grignard reagent. (2) *The presence of both water and metallic magnesium is necessary.* (3) Catalytic quantities of water and magnesium are sufficient, indicating that these agents serve only to initiate chain reactions. (4) A minimum amount of ether should be employed. (5) The reaction is applicable to a variety of Grignard reagents and hydrocarbons.

The following preparation of diphenylmethane from benzylmagnesium chloride and benzene is representative of the procedure now in use: 0.3 g. of magnesium turnings is allowed to react completely with 2.0 g. of benzyl chloride in 0.10 mole of ether in the usual manner. Then 1.5 moles of benzene and enough magnesium to make a total of 0.25 mole are added, followed by slow addition over a period of two hours of a mixture of one mole of benzene and enough benzyl chloride to make a total of 0.25 mole. The temperature rises to about 45° during the addition of the mixture and stirring is continued for another hour. 0.025 to 0.3 mole of water is then added (the mixture contains a little unreacted magnesium) and the mixture is stirred for another hour. The amount of water, or the rate, or the temperature at which it is added, has no marked effect on the yield. The products are isolated by standard procedures.

The following yields of condensation products have been obtained:

Grignard reagent	Hydrocarbon	Products found		Yield on basis of halide used, %
$C_6H_5CH_2MgCl$	Benzene	Diphenylmethane		29
		Dibenzyl		18
$C_6H_5CH_2MgCl$	*m*-Xylene	2,4-Dimethyldiphenylmethane		17
$C_6H_5CH_2MgCl$	Mesitylene	2,4,6-Trimethyldiphenylmethane		20
$C_6H_5CH_2MgCl$	Cyclohexane	Benzylcyclohexane		None
C_6H_5MgBr	Toluene	4-Methylbiphenyl	estimated	10
		Biphenyl		20
C_6H_5MgBr	*m*-Xylene	Dimethylbiphenyl		9
C_6H_5MgBr	Chlorobenzene	Chlorobiphenyl		5
		Biphenyl		39
C_6H_5MgBr	Cyclohexane	Biphenyl		39
		Phenylcyclohexane		None
CH_3MgI	Benzene	Toluene		0.06
		p-Xylene		.03

Further work on the problem is actively under way and we hope to publish soon the results of our findings.

THE ACTIVITY OF CERTAIN NICOTINIC ACID DERIVATIVES AS GROWTH ESSENTIAL FOR THE DYSENTERY BACILLUS

Sir:

Recent evidence indicates that nicotinic acid or its amide is of wide biological significance. The compound has been shown to be a part of Warburg's coenzyme, important in the treatment of human pellagra and canine black tongue, and essential for the growth of staphylococci, the diphtheria bacillus and the dysentery bacillus.

In a previous report [Koser, Dorfman and Saunders, *Proc. Soc. Exptl. Biol. Med.*, **38,** 311 (1938)] the authors have shown that 0.004 microgram per cc. will cause growth of certain members of the dysentery group in a synthetic medium otherwise unable to support growth. The essential role of nicotinic acid was demonstrated by the use of a synthetic culture medium consisting of fifteen amino acids, dextrose, and several inorganic salts. In such a medium many dysentery strains fail to grow. Upon the addition of nicotinic acid, however, development of the organisms took place. In order to test the relationship between biological activity and chemical structure we have tested a series of compounds related to nicotinic acid. The solutions were tested in decimal dilutions of molar concentration.

Pyridine-2-sulfonic acid, trigonelline, 6-methylnicotinic acid, nipecotic acid, isonicotinic acid, β-acetylpyridine, β-picoline, and pyridine were completely devoid of growth-promoting activity. The following substances showed 3+ growth (comparable to veal infusion broth) in the dilutions indicated: nicotinic acid, nicotinamide, methyl nicotinate $M \times 10^{-7}$, trigonelline amide, ethyl nicotinate, nicotinuric acid, ethyl nicotinoacetate $M \times 10^{-6}$, nicotinic acid N-methyl amide $M \times 10^{-5}$, nicotinonitrile $M \times 10^{-4}$. Picolinic acid and quinolinic acid showed activity at a dilution of $M \times 10^{-4}$ but there is some possibility that these two preparations may be contaminated with traces of nicotinic acid. They are being synthesized by reactions which will exclude the possibility of any contamination and the results of tests of their growth-promoting activity will be reported later.

We are grateful to Dr. Frank M. Strong for samples of a number of compounds tested.

This investigation was aided by a grant from the Committee of Scientific Research of the American Medical Society.

THE CHEMILUMINESCENCE OF THE CHLOROPHYLLS, AND OF SOME OTHER PORPHYRIN METAL COMPLEX SALTS

Sir:

Recently, Helberger [*Naturwiss.*, **26,** 316 (1938)] reported a case of chemiluminescence, found in experimenting with the complex magnesium salt of phthalocyanin, and of substances with related chemical structure.

It is of considerable interest to study the chemiluminescence of porphin and of *meso* tetrasubstituted porphins, which are now synthetically accessible [Rothemund, THIS JOURNAL, **57,** 2010 (1935); **58,** 625 (1936)], and of the chlorophylls, especially with regard to the problem of photosynthesis.

We found that upon adding pure chlorophyll *a* to tetrahydronaphthalene ("Tetralin"), heated to about 125°, the red chemiluminescence is just perceptible. The intensity of the phenomenon increases with increasing temperature, exhibiting a beautiful red glow between 160 and 190°, diminishes then, and disappears, when the solution is boiled for a few minutes. Addition of more chlorophyll *a* to the hot solution causes the chemiluminescence to reappear. Chlorophyll *b* shows the same behavior. The magnesium and the zinc complex salts of porphin as well as of α,β,γ,δ-tetraphenylporphin react in the same manner, and with the same color of luminescence. The free porphyrins, porphin, and α,β,γ,δ-tetraphenylporphin, or their hemins, copper, nickel, cobalt, or silver complex salts react negative. When one adds, however, magnesium filings to a solution of α,β,γ,δ-tetraphenylporphin in tetralin, and allows the mixture to stand for some time, the chemiluminescence can be observed upon heating. No change of color or intensity of the glow takes place, if one bubbles oxygen or carbon dioxide through the hot solution. The following substances show the phenomenon, when used as solvents for porphyrin magnesium or zinc complex salts: tetrahydronaphthalene, xylene, *p*-cymene, and bromocyclohexane.

After the reaction, the solution differs spectroscopically from the unheated solution; the investigation of the reaction products from the above mentioned substances in the different solvents is in progress.

THE STRUCTURE OF THE INSULIN MOLECULE

Sir:

On the basis of the Cyclol hypothesis, a structure C_2 was proposed for the insulin molecule.[1] C_2 is a cage structure consisting of a fabric carrying side chains, bent over a truncated tetrahedral framework. The only metrical parameter, *a* (a mean between C-C and C-N bond lengths), taken as 1.5 Å., defines the dimensions of C_2. C_2 molecules with axes parallel fit the rhombohedral cell of the insulin lattice given by an x-ray analysis. They can be arranged with any orientation α in the corresponding hexagonal cell, and α was necessarily left undetermined.[1] Further data, namely, Patterson–Harker diagrams, have now become available.[2]

It has been stated that these diagrams are in-

---

[1] Wrinch, *Trans. Faraday Soc.*, **33**, 1368 (1937).

[2] Crowfoot, *Proc. Roy. Soc.*, (London) **164A**, 580 (1938).

compatible with the structure I proposed for insulin.[2] I have therefore made a study of the Patterson–Harker diagrams given by C_2. The skeleton of C_2 is a truncated tetrahedron with six slits whose centers give an octahedron of side $l = 8\sqrt{6a}$. All the vectors between points on its framework lie on or within a truncated octahedron of side $2l = 16\sqrt{6a} = 33.9$ Å. Postulating concentrations of atoms near these six octahedral points of the C_2 we obtain Patterson–Harker peaks for a molecule at O which lie at the corners and midpoints of the sides of the octahedron $2l$ with center at O. The figure shows the projection on the c-plane of these 18 peaks giving a hexagon with center at O, with side length 33.9 Å. There are six at its corners, six at the midpoints of its sides, and six at the midpoints of lines joining alternate corners, indicated for convenience as A, B, and C, respectively.

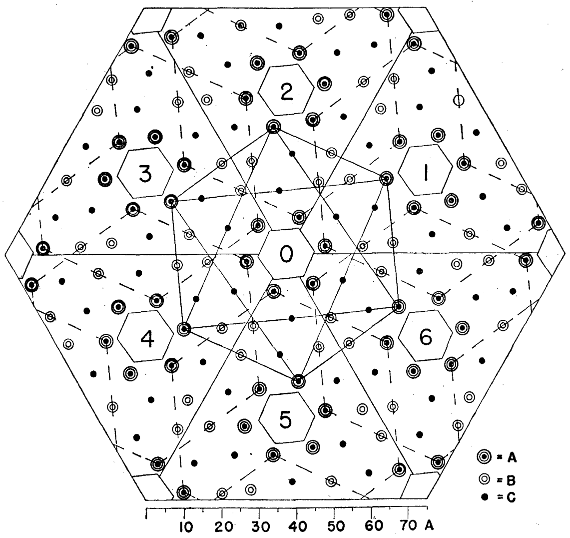

Fig. 1.—The c-plane projection of the Patterson–Harker map of the six slits of the C_2 molecule, superposed upon the corresponding projection obtained from the X-ray analysis of insulin.

We now notice that Crowfoot's c-plane projection also gives 18 peaks per molecule, reproduced in Fig. 1, which fall into a pleasing pattern of hexad, triad, and dyad sets. Superposing the C_2 hexagon on this diagram, we turn this hexagon about its center, through an increasing angle α until any of its points fall upon a Crowfoot peak. We find with $\alpha = 6°$ that all A peaks fit on A peaks, B peaks on B peaks, and C peaks on C peaks, as shown in Fig. 1.

This procedure allocates to the molecule at O, one A peak in each of the hexad sets surrounding the points 1, 2, 3, 4, 5, 6; the most remote B peak of each neighboring triad set; the nearer C peak of each neighboring dyad set. Drawing corresponding hexagons around other molecules, all the A, B, and C peaks are filled in. The six nearest A and B peaks around O are contributed, one each, by the molecules associated with the positions 1, 2, 3, 4, 5, 6, and none of them by the molecule at O.

So far the details of the skeleton and the positions of the side chains attached to the C_2 molecule have been left out of account. Nevertheless, the 18 peaks per molecule in Crowfoot's c-plane projection are given in the correct positions, on the assumption that there are concentrations of atoms at the six slits.

The full investigations will shortly be published.

NEW BOOKS

Chemical Principles, with Particular Application to Qualitative Analysis. By JOHN H. YOE, Ph.D., Professor of Chemistry, University of Virginia. John Wiley and Sons, Inc., 440 Fourth Ave., New York, N. Y., 1937. ix + 311 pp. 29 figs. 15.5 × 23.5 cm. Price, $2.75.

A Laboratory Manual of Qualitative Analysis. By JOHN H. YOE, Ph.D., Professor of Chemistry, University of Virginia. John Wiley and Sons, Inc., 440 Fourth Ave., New York, N. Y., 1938. ix + 219 pp. 7 figs. 15.5 × 23.5 cm. Price, $2.50.

This text is a good example of the modern Leftist tendency in Qualitative Analysis. It offers the student, in a compass of 300 pages, a comprehensive and somewhat amplified review of most of the theoretical material in General Chemistry: fundamental laws, definitions and principles, chemical change, kinetic theory, states of matter, solutions, homogeneous and heterogeneous equilibrium, precipitation theory, complex ions and coördination, *p*H, oxidation–reduction, kinetics of reactions, thermo-, electro-, and photo-chemistry, atomic structure, colloids. The presentation of each topic is of necessity very brief, with a minimum of mathematics and derivations, but seems satisfactory for general review; the sections on atomic heats, the early periodic table, the gas laws, solubility and washing of precipitates, and osmotic pressure would benefit by revision and a slightly different mode of treatment. The book will provide a substantial basis for a review of chemical fundamentals, but will be criticized by some instructors as containing very little about Qualitative Analysis, being largely a repetition of the student's earlier work, and not offering any appreciable advance in chemical theory for the well-grounded student ready for a course in physical chemistry.

The accompanying Laboratory Manual supplies the basis for a large but flexible course of experimental work, with many preliminary tests in addition to the regular schemes. The method of cation analysis is a composite of the well-known Fresenius and Noyes methods, while the anion identification schemes are based on the groups of volatile, barium, silver, and soluble radicals. The use of organic reagents and spot tests is encouraged and there is a section on Dry Methods of Analysis.

ALLEN D. BLISS

Qualitative Chemical Analysis. Revised edition. By LOUIS J. CURTMAN, Professor of Chemistry, City College, The College of the City of New York. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1938. xii + 514 pp. 44 figs. 15 × 22 cm. Price, $3.75.

A review of the first edition of this text was published in THIS JOURNAL in March, 1932 (Vol. **54**, page 1257). The second edition resembles the first edition but has been rewritten more nearly completely than most revised texts. The book consists of the usual prefaces, introduction and appendix and five major parts. The first major part, "Theory," occupies 115 pages and includes discussions of structure of atoms, valence, coördination theory, dipole moments, Brönsted's theory of acids and bases, Kohlrausch's law of independent migration, the complete ionization theory of Debye and Hückel, activity coefficient, ionic strength and all of the other topics usually discussed by texts in qualitative analysis. These ideas are made an integral part of the text, and their applications to analysis are shown. The second and fifth parts of the text furnish information regarding the metal ions and acids or anions, respectively. They include 105 and 48 pages. Besides colors of compounds and their solubilities in water, many applications of theory are made at appropriate points. For instance, solubilities of sulfides are discussed: ZnS in HCl by union of $S^=$ with H_3O^+; CuS in HNO_3 by oxidation of $S^=$ by NO_3^-; HgS in aqua regia by oxidation of $S^=$ and also formation of $HgCl_4^=$. Part three deals with problems which would occur in volumetric quantitative analysis. It includes only sixteen pages but part one contains an abundance of problems and exercises based on the other topics treated in the text. Part four, sixty pages, gives directions for preliminary experiments and a systematic analysis for metal ions. Directions for micro analysis and for setting up a system of individual reagents are included in the text. The sixteen-page table of analytical constants included in the first edition has been omitted. The subject matter is well chosen for a year's work in qualitative analysis. The arrangement is logical and the descriptions and explanations as clear and simple as truth permits. References to other books and to journals are frequent. The print is clear and errors are few. It is an improvement on the former edition as well as a modernization and a revision.

F. E. BROWN

Spectroscopy in Science and Industry. Edited by GEORGE R. HARRISON. Proceedings of the Fifth Summer Conference in Spectroscopy and its Applications. Held in Massachusetts Institute of Technology, Cambridge, Massachusetts, July 19–22, 1937. The Technology Press: John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1938. vii + 134 pp. 60 figs. 19 × 25.5 cm. Price, $3.00.

This conference, held at the Massachusetts Institute of Technology in July, 1937, was probably the largest gathering of practical spectroscopists ever assembled. Thirty-six papers, twenty-nine of which appear in the present volume, comprise discussions of the most varied applications of spectroscopy. The main emphasis, quite understandably, is upon apparatus and method. A spectacular achievement in metallurgical analysis is the posting of a complete quantitative analysis for five impurities in iron by two operators within seven minutes. Absorption measurements, in the visible and in the infrared, serve for rapid analysis of mixtures difficult to separate and identify chemically; to evaluate degrees of polymerization, molecular arrangements, and reaction rates; and as aids in the solution of biochemical problems in great variety.

Unfamiliarity with modern spectroscopic methods promises to be especially disadvantageous to analysts, but the same will be true, in varying degrees, for workers in other branches of science.

GEORGE S. FORBES

Über die Bildung und den chemische Bau der Kohlen. (The Formation and Chemical Structure of Coal.) By PAUL ERASMUS, Ohlau. Verlag von Ferdinand Enke, Hasenbergsteige 3, Stuttgart W, Germany, 1938. viii + 121 pp. 16.5 × 25.5 cm. Price, RM. 10.

This is the twelfth volume of publications in the field of fuel geology, edited by Prof. W. Gothan. The author, Paul Erasmus, who was a colleague of Bergius, was killed in a laboratory accident in 1936, and the purpose of this publication, as stated by the editor in a foreword, is partly to give expression to the interesting points of view of the author, and partly to honor his memory.

That part of the work which has to do with the chemical structure of coal and which will be of greater interest to the chemist, comprises nineteen pages; the balance is devoted to a discussion of investigations of coal formation in nature.

In the part devoted to chemical structure there appear sections on the nature of hydrogen in coal, the oxygen, on the effects of hydrolysis, on the unitary character of coal, and on artificial coal. The greatest part of the chemical investigations upon which these sections are based, are stated to have been carried out in Bergius' laboratory in 1926–1930.

The point of view developed is that coal is a tridimensional polymer of relatively small aromatic and hydroaromatic units, ten carbon atoms each, linked through linear and cyclic ether oxygen bonds, and that the principal mass of the coal is essentially unitary in character. Resins, waxes, coloring materials, cuticles, and so forth, are specifically excluded from the discussion, and the findings are stated to apply chiefly to the bright coals as opposed to the durains.

In discussing the different methods of attack, solvent degradation of bright coal is stated to result in extract fractions of hydrogen–carbon ratios varying from 0.8 to 1.0, but in constant carbon–oxygen ratios of 10.0. The idea that solvent degradation may be due to partial hydrogenation is rejected. By fractional vacuum distillation of the extracts from bright coals it is said to be possible to recover 12.5% of the weight of the pure coal as a substance of composition $C_{10}H_{14}O$.

By primary hydrogenation of bright coals at 360°, a stoichiometric, easily reproducible reaction is said to take place and on the basis of twenty carbon atoms, sixteen are always found in liquid and solid products and four in the form of gases, while half the oxygen remains in organic combination and half is found as water. Based on sixteen carbon atoms the series of products formed contain from twelve to twenty-four hydrogen atoms, but the carbon–oxygen ratio is constant at sixteen to one.

Durain is looked upon as the primary hydrogenation product of bright coal and because of its higher hydrogen content, its particular value as raw material for commercial hydrogenation is pointed out.

In the section dealing with the nature of oxygen in coal, it is said that up to 50% of the oxygen in the extracts from low rank bituminous coals can be identified as carboxyl by phenylhydrazine. In the degradation products of high temperature alkali treatment, by which yields of 50% of simple products are obtained from natural and artificial bituminous coals, a large part of the oxygen is found as hydroxyl, characterized by acetylation. Hydrolysis is looked upon as taking place in two steps, the first being the opening of the oxygen-containing cycles to form hydroxyl groups, without any considerable change in molecular weight, and the second, the hydrolysis of the linear ether linkages with consequent degradation to small units. This second step is incomplete, conversions are usually 30–40% and in exceptional cases 60–80%, due to the tridimensional structure of the coal as compared with a simple linear polymer like cellulose. Crystalline bodies were obtained by the bromination of the water-soluble hydrolytic products, but no compounds were isolated.

The second part of the book, comprising ninety-four pages, is a comprehensive review of our knowledge of coal formation in nature. There are four broad headings: Humoliths, Saproliths, Fusains, and Anthracite and Graphite. Under the Humoliths are discussed decay, peat formation, the chemistry of the humic acids, moors and the transformation of various kinds of peat to brown and bituminous coals. Under Saproliths are treated the origins of the dull coals, oil shales, bitumens and petroleum, only a few pages being devoted to the last three. The usual view as to the origin of the Fusains, from forest fires, is accepted. The temperature of transformation of bituminous coals to anthracite is placed at 380° or above.

This book will be of very great interest to fuel geologists and to all those working in the field of coal chemistry. The part dealing with chemical structure is very poorly documented, and important statements and conclusions are inadequately supported by experimental data. Editor Gothan apologizes for this in a foreword, and points out that had the author lived, the experimental data would no doubt have been presented in the scientific journals. Apparently neither author nor editor had knowledge of recent American contributions in the field of the chemistry of coal.

HENRY C. HOWARD

Aanvullingen der Thermostatica. (Supplement to Thermostatics.) By Prof. Dr. J. E. VERSCHAFFELT, University of Ghent, De Sikkel, Antwerp, Belgium. 160 pp. 16 × 24.5 cm.

Instead of preparing a revised edition of his "Thermostatics" [reviewed in THIS JOURNAL, **55,** 5065 (1933)], the author has preferred to edit an appendix with corrections, in which the same division into chapters and sections is maintained as occurs in the 1933 edition of "Thermostatics." The system of symbols and the nomenclature originally proposed by the Institut International du Froid is still adhered to, although no general agreement among chemists and physicists in different countries has been attained. The significant contributions to physical sciences of the past decade have been incorporated under new section headings and some space is devoted to familiar topics previously omitted, *e. g.*, the Donnan membrane relationships. In striking contrast to the prevailing tendency of the present day toward specialization, the writer has tried to maintain a proper balance between the physical and the chemical aspects of his subject. Nevertheless, there can be no doubt that Thermostatics and its Supplement will appeal more to physicists than to chemists.

H. S. VAN KLOOSTER

Analytische Chemie der Sauerstoffsäuren des Schwefels. (Analytical Chemistry of the Oxygen Acids of Sulfur.) By Prof. DR. ALBIN KURTENACKER, German Technical Institute, Brünn. Ferdinand Enke Verlag, Hasenbergsteige 3, Stuttgart-W, Germany, 1938. ix + 216 pp. 8 figs. 16.5 × 25 cm. Price, RM. 18; bound, RM. 19.60.

This book is a very satisfactory compilation of the information that is to be had on the analytical chemistry of the oxygen acids of sulfur. Methods for the determination of sulfates, thiosulfates, sulfites, sulfides, polythionates, hyposulfites, persulfates and monopersulfates are described and in many cases these are critically discussed. Considerable space is devoted to the determination of the various types of compounds in the presence of one another, and particular attention is given to the interference of one compound in the determination of another. The effects of other substances are also discussed.

The plan of the book is to give qualitative tests for the identification of the different classes of acids of sulfur first, and then to describe quantitative methods of determination. In general, the quantitative discussion includes gravimetric and volumetric methods; in special cases, colorimetric, nephelometric, gasometric and microanalytical methods are also given.

The book carries a good subject index, and is especially rich in references to the literature, some 822 being given. It is a distinct addition to texts that deal with chemical analysis, and should find good use in any laboratory that must analyze for the oxygen acids of sulfur.

G. E. F. LUNDELL

The Analytical Chemistry of Tantalum and Niobium (Columbium). The Analysis of their Minerals and the Application of Tannin in Gravimetric Analysis. By W. R. SCHOELLER, Ph.D. Foreword by G. ROCHE LYNCH. Nordemann Publishing Company, Inc., 215 Fourth Avenue, New York, N. Y., 1937. xvi + 198 pp. 14.5 × 22.5 cm. Price, $5.50.

This monograph welds into a comprehensive analytical scheme the analytical methods developed by Doctor Schoeller and his co-workers during the past twenty years, and which have been described in some 33 original papers under the general title: "Investigations into the Analytical Chemistry of Tantalum, Niobium, and their Mineral Associates." In the welding, the old has been liberally fluxed with new material, the scope of which is by no means confined to earth acid analysis.

Of the three parts into which the monograph is divided, the first deals with primary considerations such as tantalum and niobium compounds of analytical importance, the chemical composition of tantalum and niobium minerals, alkaline and acid fluxes, the tartaric acid method for the analysis of tantaloniobate minerals, the hydrofluoric acid method for the analysis of titanoniobate minerals of the rare earths, and other methods.

The second covers quantitative separation methods involving tantalum, niobium, titanium, zirconium, tungsten, thorium, rare earths, uranium, beryllium, aluminum, and iron.

The third contains a discussion of the use of tannin as a reagent, and methods of separation and determination based on its use in the presence of mineral acid, acetate, tartrate, oxalate or ammonia. In addition to the elements just listed, these methods cover vanadium, chromium, manganese, copper, zinc, gallium, tin, and uranium. The monograph concludes with chapters on the detection of tantalum and niobium in minerals, and on the literature dealing with earth-acid analysis.

The monograph brings to fruition the work of a master in the field of earth-acid analysis. It will be found indispensable by anyone who is working in this difficult field, and will be a very worthwhile addition to the library of anyone who is interested in inorganic chemical analysis.

G. E. F. LUNDELL

Hydrophobic Colloids. Symposium on the Dynamics of Hydrophobic Suspensions and Emulsions, under the Auspices of the Colloidchemistry Section of the "Nederlandsche Chemisch Vereeniging." Held at Utrecht on the 5th and 6th of November, 1937. Reprinted from "Chemische Weekblad," 1938. Published by D. B. Centen's Uitg. Mij. N. V., Amsterdam, Holland, 1938. 180 pp. 15.5 × 23.5 cm. Price, Dutch florins 4.

The opening address of the Symposium was made by Dr. J. H. De Boer, President of the Committee on Arrangements. Professor H. R. Kruyt then gave a general introduction in which he pointed out that hydrophobic colloids had been selected for discussion at this Symposium because they are, at least ideally, the simplest of all colloids and offer an opportunity to study advantageously three important types of problems appertaining to all colloidal systems: 1. Why do the particles of a mere suspension tend to adhere to each other? (questions of attraction); 2. what must be done to prevent this? (questions of peptization); 3. what promotes coalescence? (question of flocculation).

The papers were as follows: The first, by Dr. Hamaker, described an ingenious graphical method for the study of the attractive and repulsive forces; the second, by Professor Rutgers, dealt with the electric double layer and its behavior in an external electric field; the third, by Dr. Verwey, on the double layer and stability of lyophobic colloids; the fourth, by Professor Tendeloo, on counter ion exchange with lyophobic colloids; the fifth, by Dr. Voet, on lyotropic effects in lyophobic systems; the sixth, by Dr. Overbeek, on the protective and sensitizing action of hydrophilic colloids on hydrophobic sols; the seventh, by Dr. van der Minne, consisted of (I) general remarks on emulsions, and (II) emulsification with lyophobic colloids, and the eighth, by I. H. Eilers, dealt with technical applications of base materials in the emulsified state.

After each address there is a printed discussion, often of decided interest.

The account of this Symposium, published in English, will be of great value to students of colloid chemistry, since it represents the most recent work and ideas of an active and progressive group of Dutch investigators.

ARTHUR B. LAMB

A Textbook of Qualitative Chemical Analysis. By ARTHUR I. VOGEL, D.Sc. (Lond.), D.I.C., F.I.C., Head of Chemistry Department, Woolwich Polytechnic. Longmans, Green and Company, 114 Fifth Avenue, New York, N. Y., 1937. xi + 383 pp. 14.5 × 22.5 cm. Price, $3.00.

Qualitative Analysis. By H. V. ANDERSON, B.Ch.E., M.S., Associate Professor of Chemistry, Lehigh University, and T. H. HAZLEHURST, A.B., Ph.D., Assistant Professor of Chemistry, Lehigh University. Second revised edition. Prentice-Hall, Inc., 70 Fifth Avenue, New York, N. Y., 1937. xiii + 280 pp. Illustrated. 14.5 × 21 cm. Price, $2.25.

An Elementary Course in Qualitative Analysis. By WILLIAM LLOYD EVANS, JESSE ERWIN DAY and ALFRED BENJAMIN GARRETT, The Ohio State University. Ginn and Company, 15 Ashburton Place, Boston, Massachusetts, 1938. vii + 234 pp. 21 × 27 cm. Price, $2.00.

The scope of the first of these textbooks of Qualitative Analysis is indicated by the following statement in the preface: "The ultimate object was to provide a textbook at moderate cost which can be employed by the student continuously throughout his study of the subject."

The material is divided into the following sections: The Theoretical Basis of Qualitative Analysis; Analytical Operations; Reactions of the Cations; Reactions of the Anions; Systematic Analysis of Inorganic Substances; Modification of the Systematic Analysis for Phosphate, etc.; Reactions of some Rarer Elements. The theoretical treatment is somewhat more extensive than usual, including the interionic attraction theory, some mention of the proton theory of acids and bases, electrode potentials, calculation of the electromotive force of cells, indicators, and their use for determining hydrogen ion concentrations. This treatment is in general adequate for the purpose, with the minor criticism that in some few cases reactions are explained by mechanisms which seem unnecessary at present. The descriptive material covers the reactions of most importance in qualitative analysis; a considerable number of organic reagents are included. The system of analysis for the cations is, in general, conventional; the procedures are presented in tabular form so that the manipulative directions are somewhat brief. Additional details in regard to the limitations of the methods of separation and the sensitivity of the reactions would be advantageous in a book of this scope. The acidic analysis is confined to certain group tests followed by individual confirmatory tests. The treatment of the rarer elements is brief, the reactions of some thirteen elements being covered in twenty pages.

The text by Anderson and Hazlehurst is a revision of the previous edition by Long, Anderson and Hazlehurst. In the preface to this edition the authors state that they have felt justified in making but few changes in the experimental part of the book; in consequence this review will be largely restricted to the new material. The theoretical presentation has been largely rewritten, has been separated from the related experimental procedures and is now collected in the first hundred pages; in spite of this the treatment appears to be pedagogically effective.

Acids and bases are defined as proton donors and acceptors and an analogy is drawn between the neutralization process and the electron transfer in oxidation–reduction reactions; however, the older viewpoint of the partial ionization of salts is retained. There may be in some cases too great a tendency toward over-simplification for the purpose of clarity of presentation to the student. The physical phenomena of the precipitation process are treated in considerable detail.

A few statements of chemical fact are questioned: for example, the mercurous ion is represented as being monoatomic, while both this text and that of Vogel imply that the cuprous ion is di-atomic, formulas such as $K_2Cu_2(CN)_8$ being given.

An attempt to maintain the interest of the student is made by numerous references to the industrial application of the elements and their reactions. In general, the text appears to be well worthy of consideration for elementary courses where it is not desired to emphasize the more quantitative features of either theory or laboratory practice.

It is stated in the preface that the text by Evans, Day and Garrett is designed for those students for whom elementary qualitative analysis is an integral part of their first or second year study of chemistry. It is more elementary in its approach and more distinctly a laboratory manual than the two preceding books; both the material and procedure of the course are given in considerable detail.

The cation analysis is introduced by a lecture demonstration of the group separations with tabular forms being provided wherein the student is to record his observations. Following this, experiments on the reactions of the cations are given. These are divided into Precipitation and Separation Reactions, Confirmatory Reactions, and Supplementary Reactions. These are followed by the systematic analysis which is shown by tabular outlines carrying the procedures, and by flow sheets. The procedures used are evidently designed more for simplicity of performance than analytical exactness. The anions are presented similarly and some twenty-seven constituents are included. The anion analysis consists essentially of group tests and identification of the individual constituents by separate confirmatory tests.

The theoretical material is collected in the last fifty pages of the book, and the reviewer is pleased to observe that it appears to be designed to explain the experimental phenomena which have gone before, rather than an exposition of the entire field of chemistry. This book should appeal to teachers who feel that the proper approach to qualitative analysis is through demonstration experiments and laboratory work.

The book has flexible cardboard covers and a two-ring-perforated sheet type of binding.

E. H. Swift

Combustion, Flames and Explosions of Gases. By Bernard Lewis, Ph.D., U. S. Bureau of Mines Experiment Station, and Guenther von Elbe, Ph.D., Coal Research Laboratory, Carnegie Institute of Technology, Pittsburgh, Pennsylvania. Cambridge University Press: The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1938. xv + 415 pp. 79 figs. 14.5 × 22.5 cm. Price, $5.50.

It is twenty-five years since Bodenstein first demonstrated, in the hydrogen–chlorine combination, the existence of a chain reaction. That concept has been among the most fruitful in the domain of reaction kinetics in the intervening years not only in pure science but also in the applications of science in industrial life. The present volume is an excellent exemplification of the application of the chain concept to the general field of combustion and in particular to that of hydrogen, carbon monoxide and the hydrocarbons. After a discussion of the theoretical foundations of the chain theory in Chapter 1, three chapters are devoted to the chain reactions of oxidation of the gases just mentioned. One is amazed at the complexity of phenomena revealed by the detailed analysis of processes still largely formulated in the elementary texts by simple stoichiometrically balanced equations of the type $2H_2 + O_2 = 2H_2O$. The multitude of detailed mechanisms which such an equation hides is revealed in Chapter 2. Even this oxidation is relatively simple compared with the oxidation of even the simplest hydrocarbon. The authors rightly observe that, with these latter, "there is considerably less assurance of discovering unique solutions to the various problems. In any kinetic treatment...at the present time, a certain amount of speculation is unavoidable and it is not surprising to find divergencies of opinion among investigators." The reader should not expect finality in this volume, but may well feel a deep indebtedness to the authors for their incorporation, in the first 125 pages, of the results of their own penetrating and mature consideration, over a period of years, of a great complex of material that has accrued from researches vigorously prosecuted in many important laboratories principally in Russia, Germany, England and the United States. To the assembly of those data a great mass of experiment and excellent technique has been contributed.

The remaining 250 pages of the book, however, have an equally compelling appeal. Emission spectra and ionization, ignition by sparks, the propagation of flames, the influence of vessel shape and motion variables on these flames, stationary and diffusion flames, the theory of burning velocity and detonation, these are among the chapters incorporated in Part II. Beautiful illustrations are employed to clarify the text; see especially pp. 153, 186, 189, 191, 259. Part III discusses the state of the burnt gas with important thermodynamic features properly stressed. Part IV discusses problems in technical combustion including industrial heating and internal combustion engines. It is hard to see how the mind of any chemist, physicist or engineer could not be enormously enriched and enlarged by this presentation of a subject which has always been rich in fascination to the enquiring mind from the days of the remote ancestors who made the first fires to those who daily put combustion to use either with the Bunsen flame or at the turn of the ignition key in modern motor transportation. Alternatively, the book may be read as an excellent illustration of penetrating scholarship illuminating a by no means elementary field of research.

Hugh S. Taylor

Numerical Problems in Advanced Physical Chemistry. By Dr. J. H. Wolfenden. Oxford University Press, 114 Fifth Avenue, New York, N. Y., 1938. 227 pp. Price, $2.75.

This reviewer has never before discovered any set of exercises for students that was even mildly exciting to read through, but here is one that provides very interesting reading indeed. The idea behind this unique book is to give the student of advanced physical chemistry a set of problems each of which is taken from some recently published investigation. In other words, instead of trivial exercises that are obviously merely exercises, these are problems to which some one has actually wanted to know the answers.

There are one hundred and thirty-three problems in the book, covering a very wide range of topics such as Fundamental Constants, Stoichiometry, Gaseous Equilibrium, Heterogeneous Equilibria, Thermochemistry and Thermodynamics, Conductivity of Solutions, Equilibria in Solution, Electrochemistry, Photochemistry, Molecular Structure, Crystal Structure and Radioactivity. References to the original papers from which the data for the problems were taken are given, as well as references to the appropriate parts of certain standard textbooks. In addition, each problem has a footnote containing suggestions and related information. The answers are listed at the end of the book.

Some of the problems are simple enough for use in an elementary physical chemistry course, but probably most of them are more suitable for somewhat more advanced students. They appear to be well chosen and should be of great value to graduate students and advanced undergraduates in physical chemistry.

E. Bright Wilson, Jr.

A Text-book on Crystal Physics. By W. A. Wooster, M.A., Ph.D., Lecturer in the Department of Mineralogy and Petrology, University of Cambridge. Cambridge University Press: The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1938. xxii + 295 pp. 107 figs. 14.5 × 22.5 cm. Price, $4.00.

In this book the author attempts to present the field of classical crystal physics in a form suitable for students having only an elementary knowledge of physics, mathematics and crystallography.

Tensors are introduced in the first chapter and the restrictions imposed upon the tensor components due to the invariance under symmetry operations are discussed. Much space could have been saved in the succeeding chapters if the author had included a little of the algebra of tensors. For instance reciprocal tensors are used implicitly in several sections of the book, and ought to have been defined in this first chapter.

The following chapters discuss in turn homogeneous deformation, conduction, induction, optics, piezo-electricity, pyro-electricity and elasticity.

In keeping with the assumed deficient knowledge of the reader the presentation is held on an elementary level. As a consequence the treatment is mainly descriptive, and the mathematical formulations, if given, are often sketchy and lack rigor. A discussion of Born's lattice theory was naturally outside the scope of a book of this kind. In a series of tables the author gives, however, qualitative, empirical correlations between observed properties and the atomic arrangement.

The material given in the book is well chosen and organized. While the book is not suited for students who have some knowledge of theoretical physics, it may be warmly recommended to the type of students for which it is written.

The Catalytic Dehydrogenation of Sugar Alcohols[1]

BY J. W. E. GLATTFELD AND SOLOMON GERSHON

The preparation of aldoses by the oxidation of the corresponding sugar alcohols has been accomplished with varying degrees of success by several investigators. The published methods have not given encouraging results when applied to the preparation of some of the rare and more expensive aldoses. *l*-Galactose and *dl*-erythrose are sugars which might be made available for study if a method for accomplishing the dehydrogenation of the alcohols in a sufficiently convenient and inexpensive manner could be devised. A catalytic dehydrogenation process in which platinum is the catalyst was considered to have possibilities in this direction and the dehydrogenation of mannitol and dulcitol was attempted to test it.

Dehydrogenation of mannitol should give but one aldohexose, *d*-mannose, and one 2-ketohexose, *d*-fructose. This consideration together with the fact that the phenylhydrazone of mannose is particularly easy to separate in good yield makes mannitol an ideal alcohol for study. Fischer[2] treated mannitol with dilute nitric acid and isolated mannose phenylhydrazone and phenylglucosazone. Since then the presence of aldoses and ketoses in solutions obtained by oxidative treatment of hexitols has been verified on numerous occasions. In the case of dulcitol the aldohexoses and 2-ketohexoses theoretically possible as dehydrogenation products are *d*-galactose, *l*-galactose, *d*-tagatose, and *l*-tagatose.

With the possibilities outlined above in mind, the catalytic dehydrogenation of the two hexitols by the use of platinic oxide monohydrate as the catalyst source was undertaken. The course of the reaction and the effect of changes in the possible variants were studied first. Mannitol was used exclusively as the alcohol in this study; the data obtained are reported below under the head "Dehydrogenation Study." Procedures for the isolation of the aldoses produced from the alcohols were then investigated; the data here accumulated are reported under the head "Isolation Study." Finally the experimental work which yielded the data discussed under these two heads is reported under the head "Experimental Part."

Dehydrogenation Study

The preliminary data on the course of the reaction were obtained by analysis of the dehydrogenated mannitol solutions for total reducing material (Benedict titration), for aldose content (iodometric titration), and for acid content (titration with alkali). In order to determine the extent of oxidation of the primary products of hexitol dehydrogenation and the nature of their oxidation products, *d*-mannose and *d*-fructose were subjected to catalytic oxidation under the conditions that prevailed during the oxidation of mannitol. The data accumulated are given in Table I. In each case the dehydrogenation was carried out on a sample of 10 g. of substance in 200 cc. of water solution.

Dehydrogenation of *d*-Mannose.—The data in Table I indicate that *d*-mannonic acid was the

only oxidation product of *d*-mannose in the early stages of the oxidation (the loss in reducing power 32.8%, twelve hours oxidation, coincided fairly well with the gain in hexonic acid content, 33.8%). Furthermore, the only reducing material present during this period was unchanged *d*-mannose (the amount of aldohexose present, as determined by iodometric titration, coincided with the total amount of reducing material present as determined by Benedict titration). As the dehydrogenation proceeded, however, the situation became more complex. A consideration of all the facts supports the conclusions that the second step in the oxidation process was the formation of *d*-mannuronic acid from *d*-mannonic acid and the third step the formation of *d*-mannosaccharic acid from *d*-mannuronic acid. The discussion below provides the basis for these conclusions.

A few of the theoretically possible primary oxidation products of *d*-mannonic acid (I) are indicated by the given formulas. *d*-Mannuronic acid (II) is a reducing alduronic acid. 2-Keto-*d*-mannonic acid (III) and 5-keto-*d*-mannonic acid (IV) are reducing keturonic acids. *d*-Mannuronic acid reduces both Benedict's solution and iodine solution whereas the two keturonic acids reduce the former but the latter only slightly, if at all. The reducing power of alduronic acids as measured by Benedict's solution is generally less than that of an equivalent weight of aldohexose[3] whereas the amount of iodine consumed in the two cases is the same. Hence, if alduronic acid were present with *d*-mannose an iodometric analysis would show more aldose, calculated as *d*-mannose, than would be indicated by a total reduction method. If keturonic acids were present with *d*-mannose, the iodometric analysis would show less aldose than would be obtained by a total reduction method. The per cent. aldose actually found by iodometric titration in the solution of *d*-mannose which had been oxidized for twenty-four hours or more

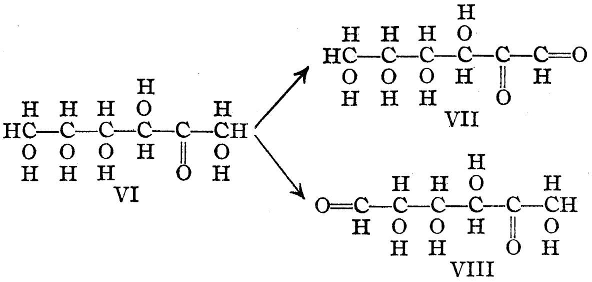
was greater than that found by Benedict's titration (Table I). This is best explained on the assumption that *d*-mannonic acid was being oxidized to *d*-mannuronic acid. Undoubtedly some keto-mannonic acid was also formed but the amount must have been small. That *d*-mannuronic acid (II) was further oxidized to *d*-mannosaccharic acid (V) was shown by the isolation of the monohydrate of calcium *d*-mannosaccharate.

Nelson and Cretcher[4] have reported that *d*-mannuronic acid lactone reacts to some extent with alkaline iodine solutions to produce iodoform. The odor of iodoform was detected in some of the iodometric titrations carried out but no precipitation of iodoform occurred in the dilute solutions titrated. The consumption of iodine in iodoform formation would result in high values for the calculated amounts of aldose present and thus would nullify to some extent the argument presented for *d*-mannuronic acid formation. The authors, however, believe the amount of iodine consumed in iodoform formation in the dilute solutions titrated to have been so small as not to affect the reasoning to any appreciable extent. That iodoform was formed was proved by treatment of the undiluted dehydrogenated mannitol solutions with alkaline iodine solution; iodoform precipitated and was identified by melting point.

Hexoses, at elevated temperatures and in acid solution, give levulinic acid which is known to react with alkaline iodine solution to give iodoform. *d*-Glucose, *d*-mannose, *d*-galactose, and *d*-fructose were heated for twenty-four hours in a *d*-galactonic acid–lactone solution under conditions which prevailed in the hexitol oxidations. Benedict and iodometric titrations were made on the solutions before and after such treatment. No marked difference in results was observed. Levulinic acid apparently was not generated and could not, therefore, have been the source of the iodoform in the iodometric analyses.

Dehydrogenation of *d*-Fructose.—The possible six-carbon atom aldehydes that could be formed from *d*-fructose (VI) are indicated below (VII and VIII). The aldehydes as well as the corresponding acids produced by their oxidation are reducing substances. Even after seventy-two hours of oxidation the *d*-fructose solution retained 88.3% of its original reducing power. Analysis of this solution showed a 34.7% aldehyde and a 30.0% acid content. Thus 35.3% of the *d*-fructose was left unoxidized. When this solution was treated with phenylhydrazine in the cold an abundant yellow precipitate, identified as *d*-glucosazone, formed in a few minutes. The speed with which the precipitate formed indicated its source was *d*-glucosone (VII) and not *d*-fructose (VI). A 2% solution of *d*-fructose and phenylhydrazine did not produce a precipitate for twenty-five minutes while a 5% solution required ten to fifteen minutes.



Dehydrogenation of Mannitol.—The facts and conclusions recorded above aid in arriving at an interpretation of the data for the dehydrogenation of mannitol presented in Tables II and III. These data and some additional facts presented below indicate a course of reaction represented by the following scheme chart.

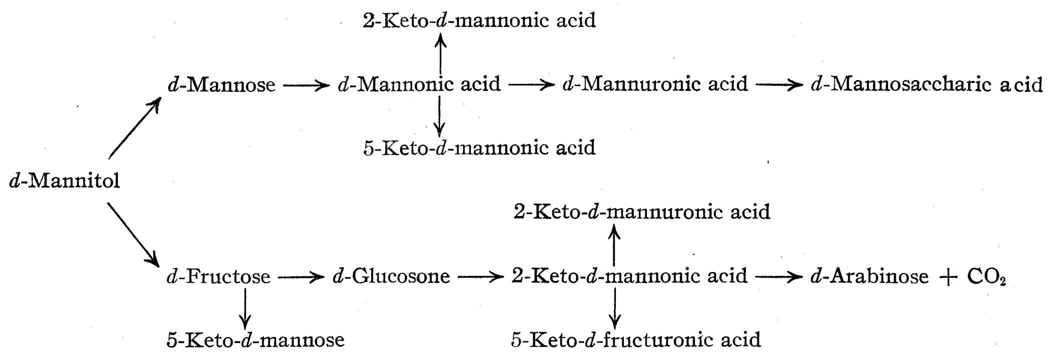
The first point to be noted is that the passage of air through a mannitol solution at 80–90° for thirty-five hours had practically no effect on the mannitol (Table II, 1). When platinic oxide monohydrate was added to a mannitol solution at 80–90° the mannitol was oxidized and the platinic oxide reduced to platinum (2, 3). The reaction between the oxide and mannitol was stoichiometric (4) (see Experimental Part). The passage of air through a mannitol solution which contained catalyst resulted in a dehydrogenation of the mannitol beyond the stoichiometric point. This indicates a catalytic effect of the platinum formed (5–8, etc.). Spent catalyst alone, *i. e.*, the platinum formed from the oxide in previous experiments, was without effect on mannitol (9). In the presence of air, however, the spent catalyst was a catalytic agent (10).

Experiments intended to compare oxygen with air as the oxidizing agent indicated the latter to be more efficient (11, 12). This was due to the fact that the oxide was reduced to platinum much more slowly in the presence of oxygen than in air

---

[4] W. F. Nelson and L. H. Cretcher, THIS JOURNAL, **52**, 2130 (1930).

SOME POSSIBLE OXIDATION PRODUCTS OF *d*-MANNITOL



which of course delayed the catalytic effect of the platinum. When time was allowed for the complete reduction of the oxide before the use of oxygen or air the former was more efficient. In such cases the time of reaction with oxygen was only 40–45% of that when air was used. Fifty grams of mannitol in 350 cc. of solution required the use of air for ninety-six hours in order to obtain maximum yields of mannose, whereas only fifty-five to sixty hours was required with oxygen. Twenty-five grams of mannitol in 200 cc. of solution required fifty-five hours with air but only thirty-two hours with oxygen.

The addition of the oxide in portions had no advantage. The addition of the entire amount of oxide at the start produced slightly better results because of longer contact between all of the catalyst and the solution (13b, 14). The amount of catalyst for best results depends somewhat on the amount of mannitol to be oxidized and the volume of solution (6, 7). Fifteen to 50 grams of mannitol in a 200–400 cc. volume can be dehydrogenated

[a] Thermometer in the oil-bath for all cases except when pressure was used; in pressure work the temperature of the solution is recorded. [b] In all experiments in which air was used the air was started immediately after the catalyst was added. [c] Active bubbling of air through the solution to maintain an excess at all times. [d] Catalyst added in 1-g. portions every two hours. [e] Intermittent heating, eight hours per day.

satisfactorily with 2 g. of platinic oxide monohydrate.

The length of time required to reduce the oxide to platinum, as determined by change of color from brown to black, was dependent on the temperature and concentration of material being oxidized; the higher the temperature and the more concentrated the solution, the faster the reduction. Two grams of platinic oxide monohydrate was not reduced by 5 g. of mannitol in 200 cc. of solution after twenty-four hours of stirring at 30° whereas only forty-five minutes was required at 75°. Twenty-five grams of mannitol in 200 cc. of solution reduced 2 g. of oxide in twenty to twenty-five minutes at 80° while 15 g. required thirty to thirty-five minutes.

The optimum temperature for the catalytic dehydrogenation was 80–85° (thermometer in bath). Higher temperatures caused excessive caramelization and decomposition whereas lower temperatures necessitated longer reaction periods.

The effectiveness of the catalyst was not altered by varying its temperature of preparation. Platinic oxide monohydrate samples prepared at 400, 485, 535, and 600° all proved equally effective.

The use of oxygen or air at increased pressures, without first allowing time for the reduction of the oxide to platinum black, was less effective than oxidation at atmospheric pressure (15–19). In most cases the oxide was not reduced after twenty-four hours of agitation at the increased pressure. If sufficient time was allowed for the reduction of the oxide and pressure then applied, dehydrogenation proceeded much faster at the increased pressures than by simply bubbling oxygen or air through the solution (see Experimental Part and Table IV).

After the preliminary work discussed above, an extended study of dehydrogenation with platinum oxide and air at atmospheric pressure was made. From the data of Table III it is seen that during the first twenty-four hours mannitol was oxidized to about equal amounts of *d*-mannose and other reducing material. During the first thirty-six hours the percentage mannitol oxidized to reducing material exceeded the percentage mannitol oxidized to acid. As the concentration of the sugars increased the rate of acid formation increased, and the iodometric aldose titrations indicated increasing amounts of aldehyde. A faint iodoform odor was perceptible in the iodometric titrations of the sixty and seventy-two hour samples. Iodoform crystals were deposited when the undiluted seventy-two hour sample was treated with sodium carbonate and iodine. All oxidized mannitol solutions gave positive ketose tests and the twenty-four hour sample as well as the subsequent samples gave positive naphthoresorcin tests indicative of uronic acids.

The maximum value obtained for percentage mannitol oxidized to reducing substances, calculated as *d*-mannose, was 64.7% [Table III, (1)]. In pressure dehydrogenations the maximum value obtained was 67.7% [Table IV, (7)]. These values are higher than any previously reported value and demonstrate the possibilities of the catalytic dehydrogenation of sugar alcohols when properly controlled.

Isolation Study

Mannitol.—It is apparent from the data of Table III (1) that the percentage mannitol oxidized to reducing material is in itself not a sufficient criterion of best condition for aldose isolation. A thirty-six hour sample showed 57.3% oxidation whereas a sixty-hour sample showed 58.8% oxidation to reducing material, yet the latter was contaminated with over twice as much acid as the former. Analysis of a solution might indicate 30–40% oxidation to reducing material and yet the solution might contain very little *d*-mannose, the reduction being due mainly to uronic acids. Such a solution would not be suitable for *d*-mannose isolation. The best criterion for isolation of *d*-mannose was found to be that point at which the solution showed 55–60% oxidation to reducing material and about 50% oxidation to acid.

The best yield of mannose from mannitol oxidation found recorded in the literature was that of Fenton and Jackson[5] who used hydrogen peroxide with ferrous catalyst and obtained a 42% yield of mannose as crude orange-colored phenylhydrazone. In the catalytic dehydrogenation of mannitol reported in this paper a 35.3% yield of mannose was obtained as white phenylhydrazone, which when decomposed according to the method of Herzfeld,[6] yielded a sirup which contained *d*-mannose equivalent to a 92% yield, from which in turn crystalline *d*-mannose in 50% yield was obtained calculated from the phenylhydrazone. Calculated from the mannitol the yield of *d*-mannose sirup was 32.5%, and of crystalline *d*-mannose 17.6%. The mannose was also isolated as α-methyl-*d*-mannoside, from the oxidized mannitol solutions from which the acids had been removed, in 19.9% yield and from solutions from which the acids had not been removed in 10.5% yield. The mannoside can be converted to crystalline *d*-mannose in 70% yield.[7]

After removal of the acids and of the *d*-mannose, phenylglucosazone was isolated. This was indicative of the presence of *d*-fructose. The Seliwanoff[8] ketose tests and the results of the iodometric analyses were also evidence for the presence of ketose. Calcium salts were isolated at various times from the reducing solutions. Analysis of one salt indicated it to be the monohydrate of calcium *d*-mannonate and that of another the monohydrate of calcium *d*-mannosaccharate (see below).

Dulcitol.—The analytical results obtained in the catalytic dehydrogenation of dulcitol are presented in Table III (2). The products of the reaction are of the same type as found with mannitol. Thus *dl*-galactose, *dl*-tagatose, *dl*-galactonic acid, *dl*-galactosone, 2-keto-*dl*-galactonic acid, *dl*-galacturonic acid, and mucic acid are present in the reaction solution.

The best yield of *dl*-galactose reported in the literature is that of Neuberg and Wohlegemuth[9] who used 3% hydrogen peroxide in the presence of ferrous sulfate to oxidize the dulcitol and obtained a solution which contained 40% reducing sugars. From this these authors obtained *dl*-galactose in 10% yield by direct isolation and in about 30% yield when they used phenylhydrazine. In the catalytic dehydrogenation of dulcitol herewith reported a 30% yield of *dl*-galactose, isolated as the phenylhydrazone, was obtained. Crystalline *dl*-galactose was isolated from the phenylhydrazone in 52% yield. The yield of crystalline *dl*-galactose obtained was 15.5% based on the dulcitol.

E. Votocek and co-workers[10] have reported the quantitative precipitation of *d*-galactose as 2,4-dibromophenylhydrazone monohydrate from aqueous acetic acid solution. With this fact in mind, a dulcitol solution was subjected to catalytic dehydrogenation until it showed about 50% oxidation to reducing material. *dl*-Galactose was isolated in 23.5% yield as a pink anhydrous 2,4-dibromophenylhydrazone.

dl-2,4-Dibromophenylgalactosazone and *dl*-phenylgalactosazone were isolated from the filtrates obtained after removal of the corresponding hydrazones. Mucic acid also was isolated.* Two barium salts were isolated and analyzed for barium. One contained 26.42% barium, the other 34.93% barium. Barium *dl*-galactonate contains 26.03% and the dihydrate of barium mucate contains 35.80% barium.

The salts isolated from the various reducing solutions cannot be considered pure substances even with satisfactory analyses. Barium *dl*-

galactonate contains 26.03% barium whereas barium *dl*-galacturonate contains 26.24%. The isolated barium salt which contained 26.42% barium did contain some of the barium *dl*-galacturonate. Its solution reduced Benedict's solution and gave a faint naphthoresorcin test.

Experimental Part

Reagents and Procedures.—(1) The platinic oxide monohydrate was prepared by the method of Adams, Voorhees, and Shriner[11] as modified by Schimpff[12] for larger amounts of catalyst. (2) The mannitol, dulcitol, and *d*-galactose were products of the Kahlbaum Chemical Company. (3) The *d*-glucose, *d*-fructose, and *d*-mannose were products of Pfanstiehl Chemical Company. (4) 2,4-Dibromophenylhydrazine was prepared from *β*-acetylphenylhydrazine by the method of Humphries and Evans.[13] The *β*-acetylphenylhydrazine was prepared by the method of A. Kaufmann.[14] (5) The naphthoresorcin was manufactured by the Eastman Kodak Company.

All iodometric analyses were made by the method developed by Cajori.[15] In all cases in which alcoholic solutions were to be analyzed, the alcohol was first removed by evaporation of the sample to a thick sirup *in vacuo* at 60–70°. Water was then added and the evaporation repeated. Iodoform formation due to the presence of the alcohol thus was avoided.

The acidimetric analyses were performed as follows. An excess of 0.1 *N* sodium hydroxide solution was added to the sample to be analyzed (phenolphthalein indicator). The solution was heated on a steam-bath for three minutes, after which time the solution still retained the pink color. An excess of 0.1 *N* hydrochloric acid was then added and the three-minute heating was repeated. The solution was then cooled and the excess acid determined by titration with standard alkali.

Tollens' naphthoresorcin[16] test for glycuronic acids was performed according to the modification of Neuberg and Kobel.[17]

1. Dehydrogenation of Mannitol

Preliminary Dehydrogenation Work.—All of the preliminary work was performed with mannitol. In all but the pressure work the solution of mannitol was made in a 500-cc. three-necked flask fitted with a mercury-seal stirrer, an efficient condenser, and an air inlet tube. The flask was immersed in a paraffin oil-bath which was heated on an electric hot plate. The temperature of the oil-bath was regulated by means of a rheostat. The conditions desired (recorded in Table II) were maintained by suitable adjustment of the rheostat, air flow, or other variables. In all cases in which the volume of air used is recorded a gasometer was used. In all cases, the air or oxygen was passed through concentrated sulfuric acid and then through a long calcium chloride tube before entrance into the reaction flask. The reaction solutions were filtered to remove platinum and then analyzed.

In the case of the test runs for which the data are presented in Table III the solutions were analyzed every twelve hours. All samples showed positive ketose tests. All samples beyond the twelve-hour sample showed positive naphthoresorcin tests.

All work performed under pressures greater than atmospheric was carried out in the hydrogenation apparatus manufactured by the Burgess–Parr Company of Moline, Illinois. The tank was filled with oxygen or air at the pressure desired. The pressure bottle was wired to maintain the reaction mixture at desired temperatures.

Stoichiometric Relationship between Catalyst and Hexitol.—Five grams of mannitol was dissolved in 200 cc. of boiled water at 75° in a three-necked flask fitted with a mercury-seal stirrer and condenser. The platinic oxide monohydrate (1.011 g.) was added with stirring. The oxide was reduced but did not settle readily after eight hours of stirring at 75°. The stirring at 75° was continued overnight, after which time the platinum settled readily and left a colorless solution. The platinum was removed by filtration and the filtrate was analyzed for total reducing material, aldose, and acid. The amount of mannitol oxidized to reducing material (calculated as *d*-mannose) was 0.953 g. (62.3% of the reducing material was aldose). This would require 0.642 g. of the platinic oxide monohydrate. The amount of mannitol oxidized to acid (calculated as monobasic acid) was 0.335 g. which would require 0.451 g. of the oxide. A total of 1.093 g. of oxide is thus theoretically necessary. This value is 0.082 g. in excess of the amount of oxide actually used and is slightly in excess of the amount accountable for by experimental error. The simplifications made in the calculation of the per cent. mannitol oxidized, however, would tend to make such small differences. There can be no doubt that the reaction is stoichiometric.

Preparation of the Phenylhydrazone of *d*-Mannose.—Fifty grams of mannitol was dissolved in 350 cc. of hot distilled water in a three-necked flask fitted with a mercury-seal stirrer, an efficient condenser, and an air-inlet tube. The flask was immersed in an oil-bath maintained at 80–85° throughout the dehydrogenation. Two grams of platinic oxide monohydrate was added. Stirring was begun and allowed to continue for thirty minutes. Oxygen was then passed through the solution rapidly enough to keep the catalyst uniformly suspended. The stirring and passage of oxygen was maintained for sixty hours (when air was used, ninety-six to one hundred hours was necessary). The platinum was allowed to settle (about ten minutes) and the solution was filtered. The filtrate and washings were concentrated to about 200 cc. at 55–60° under reduced pressure. A filtered solution of 40 g. of phenylhydrazine hydrochloride and 60 g. of sodium acetate trihydrate in 300 cc. of water (made by the application of gentle heat) was then added slowly and with stirring to the concentrated solution. A precipitate began to form in about one minute. The mixture was allowed to stand for one and one-half hours with occasional stirring. The yellow precipitate was separated by filtration and washed

with water. After it had been drained free of excess water on a Büchner funnel the precipitate was heated in about 700 cc. of acetone until the acetone boiled. The mixture was then cooled, subjected to filtration, and the solid washed with cold acetone. The phenylhydrazone of *d*-mannose was left as a fine white powder which weighed twenty-six grams. This corresponded to a 35.3% yield. The product melted with decomposition at 195–196° (corr.) and was found to be suitable for *d*-mannose isolation.

A portion of the phenylhydrazone was recrystallized twice from 95% alcohol, dried in a vacuum desiccator, and analyzed for carbon, hydrogen, and nitrogen with the results recorded below.

Anal. Calcd. for $C_{12}H_{18}O_5N_2$: C, 53.30; H, 6.71; N, 10.37. Found: C, 53.37; H, 6.53; N, 10.17.

Isolation of *d*-Mannose from Phenylhydrazone.—Twenty-five grams of the phenylhydrazone of *d*-mannose was added in small portions to a mixture of 20 g. of benzaldehyde, 25 cc. of alcohol, and 25 cc. of water which was kept hot on a steam-bath. The mixture was then refluxed for thirty minutes during which time 35 cc. of water was added. The mixture was cooled and subjected to filtration. The precipitate was triturated with small amounts of water and again separated by filtration. It was identified, after recrystallization from dilute alcohol, as the phenylhydrazone of benzaldehyde (m. p. 154.5°). The combined filtrates from the benzaldehyde phenylhydrazone were extracted with ether; the separated aqueous layer was heated with charcoal and filtered. The solution thus obtained had a volume of 225 cc. and a rotation of +2.00°. This indicates the presence of 15.2 g. of *d*-mannose (theoretical yield, 16.6 g.). The solution was evaporated to a sirup at reduced pressure and at 50°. The sirup weighed 16.5 g. and contained 91.7% mannose (Benedict titration). An optical rotation analysis showed the sirup to be 93.0% mannose.

A mixture of the sirup and 35 cc. of glacial acetic acid was warmed to 60° and maintained at 60° for one hour in order to effect complete solution of the sirup in the acid. The solution was allowed to cool slowly to room temperature and stored for one day, during which time crystals appeared. The mixture was then stored in the refrigerator for four days. The crystalline *d*-mannose was removed by filtration and washed with two 5-cc. portions of glacial acetic acid, followed by small volumes of alcohol and ether. The crystals were dried to constant weight in a vacuum desiccator which contained sodium hydroxide. The crystals then melted at 130–131° (corr) and weighed 7.0 g. This corresponded to a 50% yield of *d*-mannose. The specific rotation of the *d*-mannose was +14.9°. From the acetic acid filtrates 3.5 g. of a white sirupy mannose was precipitated by the addition of ether.

Isolation of α-Methyl-*d*-mannoside.—Fifty grams of mannitol dissolved in 350 cc. of water was oxidized with oxygen at 80–85° for fifty-five hours in the presence of 2 g. of platinic oxide monohydrate. The solution was filtered to remove platinum; the acids were removed from the filtrate with barium carbonate as described under the head "Isolation of Calcium and Barium Salts" below.

The combined alcohol filtrates obtained after the removal of the acids as barium salts were evaporated to a thick sirup *in vacuo* at 55°. The residue was kept at reduced pressure and 55° for one hour and then *in vacuo* overnight. It was then treated with 150 cc. of a 2% solution of hydrogen chloride in anhydrous methyl alcohol (acetone free). The mixture was gently refluxed for two hours on a steam-bath. Agitation was necessary during the first ten minutes to assist in the solution of the sirup. The solution was cooled somewhat, treated with 3–4 g. of charcoal, and then refluxed for thirty minutes. The solution was filtered hot. Small portions (a total of 20 cc.) of hot anhydrous methyl alcohol were used to complete the transfer. The filtrate was placed in the refrigerator for fifty hours. The crystalline mannoside was then removed by filtration and washed with a little cold absolute methyl alcohol followed by a little dry acetone. The air-dried α-methyl-*d*-mannoside melted at 189–191° (corr.), did not reduce Benedict's solution, and had a specific rotation of +79.0° at 20°. A 16.5% yield (8.8 g.) was obtained by this procedure. The filtrate was concentrated to 40 cc. at 35° *in vacuo* and placed in the refrigerator for four days. One and eight-tenths grams of crystals (m. p. 185–187°, corr.) was obtained, making a total yield of 19.9% (10.6 g.).

Isolation of Calcium and Barium Salts.—The following general procedure was used for the isolation of the calcium or barium salts from the solutions obtained by the oxidation of 25 g. of each of the oxidized hexitols. The platinum was first removed by filtration. The filtrate was treated with excess calcium or barium carbonate and the mixture maintained at 80° (thermometer in oil-bath) for one to two hours. Frequent or continuous stirring was employed throughout this heating. The excess carbonate was removed by filtration and the filtrate was concentrated at 55–60° *in vacuo* to a volume of about 50 cc. Three hundred cc. of hot alcohol was then added slowly and the mixture thoroughly shaken. The mixture was cooled and the supernatant liquid filtered. The residual gummy barium or calcium salts were treated with 25 cc. of hot water and the mixture again treated with 150 cc. of hot alcohol. After one hour the solution was again decanted through the filter. The barium or calcium salts were left behind in the form of a gum. The combined alcoholic solutions were used for aldose and osazone isolations (see below). The calcium or barium salt gums were dissolved in hot water, treated with charcoal, and the solutions filtered. Hot alcohol was added in small amounts to the hot filtrates until a permanent turbidity occurred. The solutions were then cooled and allowed to stand overnight. The salts which had crystallized out were separated from the solution by filtration, washed with 60–80% alcohol, and dried in a desiccator. The dried salts were then recrystallized by solution in hot water followed by reprecipitation with alcohol as described above. The salts thus obtained were dried in a vacuum desiccator.

Two calcium salts were thus isolated from twenty-five grams of mannitol which had been subjected to oxidation for forty-eight hours. During the recrystallization process the major portion of the calcium salt precipitated from the aqueous alcohol solution as an amorphous white solid. The filtrate from this solid deposited more salt on standing. The first salt contained 9.06% while the second contained 14.80% calcium. Calcium *d*-mannonate monohydrate contains 8.94% calcium, while calcium *d*-mannosaccharate

TABLE IV

PRESSURE DEHYDROGENATION

In all cases 25 g. of mannitol was dissolved in 200 cc. of water except in experiment 6 where 15 g. was dissolved in 100 cc. of water; the shaker was regulated at 300 rev. per min. In all cases thirty minutes of shaking at atmospheric pressure was used after each addition of catalyst. The temperature was 83°.

[a] The hours listed are in addition to those listed in the same experiment. [b] The hours listed in this case are only approximate; the wire connected to the bottle snapped off twice while shaking, thus allowing the bottle to cool.

monohydrate contains 15.05% calcium. Fischer and Hirschberger[18] prepared a hydrated calcium *d*-mannonate which contained 8.78% calcium.

Isolation of Phenylglucosazone from an Oxidized Mannitol Solution.—The aqueous alcohol solution from which the calcium salts had been removed was treated with a filtered solution of 20 g. of phenylhydrazine hydrochloride and 30 g. of sodium acetate trihydrate in 150 cc. of water. The mixture was allowed to stand for one and one-half hours and then subjected to filtration. The filtrate was reserved for the isolation of glucosazone. The precipitate was washed with water, heated with 200 cc. of acetone until the latter boiled, the mixture cooled, subjected to filtration, the precipitate washed with acetone, and dried. This yield of phenylhydrazone of *d*-mannose was 20%.

The filtrate saved for glucosazone isolation was treated with 10 g. of phenylhydrazine in 10 cc. of 50% acetic acid and the solution heated on a steam-bath for two hours. The mixture was cooled and subjected to filtration. The precipitate was washed with water followed by alcohol, and dried. A yield of 9.5% glucosazone was obtained. The melting point was 206–207° (corr.). The product was recrystallized from 65% alcohol, dried, and analyzed for nitrogen.

Anal. Calcd. for $C_{18}H_{22}O_4N_4$: N, 15.64. Found: N, 15.53.

Pressure Dehydrogenations.—Twenty-five grams of mannitol was dissolved in 200 cc. of hot water in a pressure bottle. The bottle was wired and by regulation of the current a temperature of 83° was maintained. Two grams of platinic oxide monohydrate was added and the bottle shaken at 300 revolutions per minute and at atmospheric pressure for thirty minutes, when the catalyst was black. The bottle was carefully evacuated until the solution began to boil and then filled with oxygen at 42 lb. (3 atm.) pressure. The evacuation and filling were repeated three times. After the third filling, shaking was started and maintained for one hour. The pressure decreased 4.8 lb. (0.3 atm.). After one hour of agitation at the increased pressure, the catalyst activity ceased and the use of oxygen by the mannitol stopped. One gram of platinic oxide was added after the pressure had been released, the mixture was shaken at atmospheric pressure for thirty minutes followed by evacuation and filling with oxygen at 42 lb. (3 atm.) pressure as described. This time there was a decrease of 2.2 lb. (0.15 atm.) in one hour. (It is to be noted that the catalyst was added in several portions during the pressure dehydrogenations rather than in one portion as was more desirable in atmospheric pressure dehydrogenations. The cessation of catalyst activity at the increased pressures makes such a procedure necessary.) The solution was cooled for about thirty minutes and then the pressure was released and the solution filtered. The small amount of colloidal platinum was removed from the filtrate by the use of charcoal. Analysis of the filtrate from the charcoal showed that 49.4% of the mannitol had been oxidized to reducing material, calculated as *d*-mannose, and that 56.2% had been oxidized to acids, calculated as hexonic acid. The *d*-mannose was isolated as the phenylhydrazone in 20.7% yield from this solution. Table IV lists the data for other experiments with different conditions.

The main disadvantage of pressure dehydrogenations is the tendency for the oxidation to proceed beyond the aldose in the later stages of the oxidation, thus building up high concentrations of acid at the expense of aldose. As a re-

---

sult, the yields obtained by pressure dehydrogenation were lower than those obtained at atmospheric pressure.

2. Dehydrogenation of Dulcitol

Isolation of Mucic Acid.—The data for the results obtained in a test run in which 15 g. of dulcitol in 200 cc. of water at 80° and 2.0 g. of platinic oxide monohydrate were used, are presented in Table III (2). The solution which remained after the seventy-two hour sample had been removed deposited a crystalline substance that was identified as mucic acid by its melting point (213°, corr.) and that of its diphenylhydrazide[19] (241°, corr.).

Isolation of *dl*-Galactose with 2,4-Dibromophenylhydrazine.—Fifteen grams of dulcitol in 200 cc. of water at 80° was treated with 2.0 g. of platinic oxide monohydrate and the procedure described in the case of mannitol carried out. After thirty minutes, air was passed through the solution for forty-four hours. This solution gave positive ketose and naphthoresorcin tests and showed that 47.2% of the dulcitol had been oxidized to reducing material (calculated as *dl*-galactose) and that 48.8% had been oxidized to acid (calculated as *dl*-galactonic acid). Iodometric analysis showed that 90% of the reducing material was aldose. The solution was filtered to remove platinum and the filtrate concentrated *in vacuo* at 50° to about 35 cc. A filtered solution of 20 g. of 2,4-dibromophenylhydrazine in 140 cc. of 50% acetic acid (prepared by gentle warming) was added slowly to this concentrate. The mixture was filtered rapidly to remove a small amount of red oil which formed and the filtrate allowed to stand for three hours at room temperature. The mixture was stirred several times during this period. The precipitate was removed by filtration, washed with 100 cc. of 5% acetic acid, 25 cc. of diluted alcohol, and finally with ether. The filtrate was saved for osazone isolation. The 2,4-dibromophenylhydrazone of *dl*-galactose thus obtained was faintly pink and melted at 151–152° (corr.). The yield was 23.5%. Three recrystallizations from dilute alcohol raised the melting point to 171–172° (corr.). Charcoal was used in each recrystallization. The pure 2,4-dibromophenylhydrazone was white. It was dried at room temperature over magnesium perchlorate for two days at 20 mm. pressure and was then analyzed for nitrogen.

Anal. Calcd. for $C_{12}H_{16}O_5N_2Br_2$: N, 6.55. Found: N, 6.64.

The 2,4-dibromophenylhydrazone of *dl*-galactose was decomposed with benzaldehyde by the method of Herzfeld and yielded the 2,4-dibromophenylhydrazone of benzaldehyde and *dl*-galactose. The former melted at 103° (corr.) after several recrystallizations from dilute alcohol while the latter melted at 142–144° (corr.).

Isolation of the 2,4-Dibromophenylosazone of *dl*-Galactose.—The filtrate saved for osazone isolation was heated for two hours on a steam-bath. A black oil settled out. The mixture was cooled and about 4 g. of solid crystallized out. This was separated from the oil which remained on the bottom of the flask and was recrystallized from dilute alcohol. It was identified as the 2,4-dibromophenylhydrazide of acetic acid by its melting point, 147° (corr.).

The oil was dissolved in boiling 60% alcohol and the solution treated with charcoal, filtered, and cooled. It deposited 4 g. of a yellow precipitate which decomposed at 145–149° (corr.). This was recrystallized from dilute alcohol to which charcoal had been added and thoroughly dried over phosphorus pentoxide. The compound decomposed at 152–153° (corr.).

Anal. Calcd. for $C_{18}H_{18}O_4N_4Br_4$: N, 8.32. Found: N, 8.37.

Isolation of *dl*-Galactose with Phenylhydrazine.—Twenty-five grams of dulcitol was dissolved in 350 cc. of hot water in a three-necked flask fitted as described for mannitol. Two grams of platinic oxide monohydrate was added when the solution had reached 80°. The mixture was stirred for one hour after which air was bubbled through the solution for seventy hours. The solution then showed 60.3% of the dulcitol to have been oxidized to reducing material (calculated as *dl*-galactose) and 56.0% to acid. The solution gave positive ketose and naphthoresorcin tests. The platinum was removed by filtration and the acids were removed as barium salts by the general method described.

The alcoholic filtrate from the precipitated barium salts was concentrated at 40–50° at reduced pressure to a thin sirup which was treated with 9 g. of distilled phenylhydrazine in an equal volume of 50% acetic acid. The mixture was warmed gently a few minutes on a steam-bath, stoppered, and set aside in a dark place at room temperature for twenty-four hours. The yellow precipitate was separated by filtration and washed with a small amount of 50% alcohol. The filtrate was saved for the isolation of the *dl*-osazone. The precipitate was washed further with absolute alcohol and ether and dried. It decomposed at 144–148° (corr.). The yield of this impure phenylhydrazone was 30%. Recrystallization of the phenylhydrazone resulted in considerable loss because of solubility and because of the formation of osazone. It was therefore used without purification for the isolation of *dl*-galactose.

The crude phenylhydrazone was treated with 300 cc. of water and 12 g. of benzaldehyde. The mixture was kept on a steam-bath for thirty minutes, cooled, and subjected to filtration. The filtrate was extracted with ether several times and the separated aqueous solution was decolorized with charcoal. The solution was optically inactive. It was concentrated at 50–55° at reduced pressure to a thick sirup which weighed 5.3 g. The sirup was dissolved in hot alcohol and the solution deposited 3.8 g. of *dl*-galactose crystals, a 15.5% yield calculated from dulcitol used. The crystals were dried in vacuum over calcium chloride at 15 mm. pressure for two days. The melting point was 145° (corr.). Oxidation with nitric acid yielded mucic acid. Analysis by Benedict titration showed the material to be 98.6% *dl*-galactose. Iodometric analysis showed it to be 99.2% *dl*-galactose.

Isolation of *dl*-Phenylgalactosazone.—The filtrate set aside for osazone isolation was treated with a filtered solution of 20 g. of phenylhydrazine hydrochloride and 30 g. of sodium acetate trihydrate in 100 cc. of water. The mixture was heated on the steam-bath for one and one-half hours, cooled, and subjected to filtration. The precipitate was washed with absolute alcohol and then with ether. The dry *dl*-osazone weighed 3.5 g. indicating a 7.3% yield. It decomposed at 207° (corr.). It was recrystallized from

alcohol and dried *in vacuo* over calcium chloride. The compound decomposed at 208–209° (corr.).

Anal. Calcd. for $C_{18}H_{22}O_4N_4$: N, 15.64. Found: N, 15.71.

Isolation of Barium Salts.—The gummy barium salt obtained in a sixty-hour oxidation of 25 g. of dulcitol was heated with charcoal and hot water which dissolved all but 0.5 g. of material. The solution was filtered and concentrated at reduced pressure and 55° to a thin sirup. Alcohol was added very slowly to precipitate the barium salt and the mixture then warmed on a steam-bath for one hour. The mixture was cooled and subjected to filtration. The precipitate was washed with alcohol and with ether. It was dried in a vacuum desiccator for one hour, followed by two hours in an oven at 100°.

Anal. Calcd. for barium *dl*-galactonate: Ba, 26.03; for barium *dl*-galacturonate, 26.24. Found: Ba, 26.43, 26.40.

The barium salt obtained by an identical procedure in a seventy-two hour oxidation contained 34.93% barium; calculated for barium mucate dihydrate, 35.80%. Neither salt decomposed at 250° and both gave naphthoresorcin tests.

Summary

A convenient method for the catalytic dehydrogenation of sugar alcohols was developed. Mannitol and dulcitol were the hexitols studied. The advantage of the method lies in the ease of controlling the amount of hexitol dehydrogenated. The results obtained indicate that the method is most satisfactory for aldose isolation in the case of alcohols which yield but one aldose or a *dl*-aldose when dehydrogenated.

Platinic oxide monohydrate was used as the source of the platinum catalyst. The oxide acts first as an oxidizing agent.

The effect of change in the possible variants was studied.

The course of the reaction was determined by a combination of isolation of products and analytical procedures. Mannitol was oxidized to *d*-mannose and *d*-fructose. *d*-Mannose was oxidized, in the main, to *d*-mannonic acid, *d*-mannuronic acid, and finally to *d*-mannosaccharic acid. The *d*-fructose was oxidized, in the main, to *d*-glucosone and 2-keto-*d*-mannonic acid. Other products were also formed in small amounts. The products with dulcitol were similar in nature.

d-Mannose was conveniently prepared by the catalytic dehydrogenation of mannitol. The *d*-mannose was isolated from the reaction mixtures as the phenylhydrazone and as the α-methyl-*d*-mannoside.

dl-Galactose was prepared similarly from dulcitol.

The catalytic dehydrogenation method gives promise of being satisfactory for the preparation of sugars like *dl*-erythrose from the alcohol, erythritol.

The Reductive Alkylation of Aniline

BY WILLIAM S. EMERSON AND PHILIP M. WALTERS

Although the reductive alkylation of amines is a well-known reaction,[1] it has found little application with primary aromatic amines. Clarke, Gillespie and Weisshaus,[1a] using formic acid as their reducing agent, methylated tribromoaniline with formaldehyde to give 77% of N,N-dimethyltribromoaniline. However, they obtained only polymers when aniline was used. While Skita and Keil[2] were able to prepare cyclohexylaniline from aniline and cyclohexanone in the presence of platinum and hydrogen, they did not mention their yield. Wallach[3] obtained di-*n*-amylaniline by heating valeraldehyde with phenylammonium formate, but he also gave no yield. The patent literature[4] contains references to the reductive alkylation of primary aromatic amines. In view of the importance of the reaction as a synthetic method, we felt that its possibilities with primary aromatic amines should be investigated.

The mechanism of the reaction is probably the following

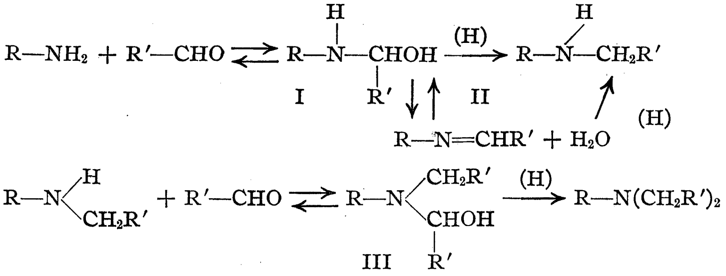
---

[1] (a) Clarke, Gillespie and Weisshaus, THIS JOURNAL, **55**, 4571 (1933); (b) Skita, Keil and Havemann, *Ber.*, **66**, 1400 (1933); (c) Forsee and Pollard, THIS JOURNAL, **57**, 1788 (1935).

[2] Skita and Keil, *Ber.*, **61**, 1682 (1928).

[3] Wallach, *Ann.*, **343**, 54 (1935).

[4] German Patents 376,013, 491,856, 503,113.



It cannot be said definitely that the amino alcohol (I) is reduced directly as suggested by Wallach[3] or that it is dehydrated to the Schiff base (II) before reduction. In either case the product would be the same, and it is quite possible the reaction follows both courses. Schiff bases have been reduced catalytically to secondary amines.[5]

In his study of the reaction between secondary aromatic amines and formaldehyde in the presence of hydrochloric acid, Wagner[6] found that the condensation product on immediate reduction gave the tertiary amine, while on reduction after a few hours of standing it gave the alkyltoluidine. Apparently the amino alcohol (III) which was first produced was dehydrated, forming the hydrochloride of the anhydro-benzyl alcohol as the intermediate in the rearrangement. Clarke, Gillespie and Weisshaus' results with aniline[1a] suggest that this intermediate or some rearrangement product of it polymerizes in the case of primary aromatic amines.

From a consideration of this mechanism, it was felt that in order for the reaction to be of value with primary aromatic amines, it would be necessary to employ a reducing agent powerful enough to reduce the amino alcohol (I) and a condensing agent mild enough to avoid dehydration and polymerization. For this purpose hydrogen and a catalyst seemed ideal. From a series of preliminary studies (Table I), it was found that Raney nickel as the reduction catalyst and sodium acetate as the condensing agent gave the best results.

Using this general procedure, the reaction was extended to other alkylanilines. The method as developed gave N-alkylanilines from aniline and aldehydes in 47 to 65% yields. The results are summarized in Table II.

Experimental

General Procedure.—All of the experiments were carried out in an Adams machine[7] for catalytic reduction. The catalyst was either platinum oxide[8] or Raney nickel.[9] In each case 9.3 g. (0.1 mole) of aniline was dissolved in 150 cc. of ethyl alcohol and from 0.2 to 0.5 mole of aldehyde added. This mixture, along with the catalyst, was then placed in the machine and shaken at an initial hydrogen pressure of about 50 lb. (3 atm.). When no more gas was absorbed (usually from 0.3 to 0.4 mole was taken up), the catalyst was removed by filtration and the alcohol distilled on the steam-bath. After the remaining oil had been steam-distilled, the distillate or the residue (depending on the amine) was fractionated to obtain the product.

[15] Brand, *Ber.*, **42**, 3460 (1909).

Preliminary Experiments.—These were carried out using aniline and acetaldehyde with a variety of reduction and condensation catalysts. The results are summarized in Table I.

The products were identified by their physical properties and picrates.

Alkylanilines.—Six alkylanilines were prepared using the procedure developed in preliminary experiment 6. In Table II are summarized the compounds prepared, the yields, and the method of identification. In the case of the first four alkylanilines up to 10% of the tertiary amines were produced, but no tertiary amines were found in the case of N,*n*-heptylaniline and N-benzylaniline. The reduction mixture always contained some aniline indicating the equation given above is reversible. This probably accounts for the fact that the yields range from 47 to 65%.

Summary

A procedure has been developed for the reductive alkylation of primary aromatic amines, using aldehydes in the presence of Raney nickel, hydrogen, and sodium acetate. By this method six alkylanilines have been synthesized in 47 to 65% yields.

The Reaction of Acid Anhydrides with Anils

BY H. R. SNYDER, R. H. LEVIN AND P. F. WILEY

Conjugated systems of the type —CH=N—N=CH— have not been shown to undergo the Diels–Alder condensation, but observations have been reported[1,2] which suggest that this type of reaction might be brought about under proper conditions. A study of the reaction between benzalazine and maleic anhydride was undertaken to test this idea. Heterocyclic compounds were not isolated, but the study has revealed certain facts which are of interest in connection with the general question of the reaction between acid anhydrides and anils.

When a solution of benzalazine and maleic anhydride in ordinary ether was refluxed, benzalmaleinhydrazine (I) and benzaldehyde were slowly formed. The use of ether containing dissolved water resulted in more rapid formation of the same products. With anhydrous ether solutions only a trace of benzalmaleinhydrazine was produced. The reaction therefore appears due to hydrolysis of benzalazine followed by reaction with maleic anhydride.

$$\begin{gathered}\text{(A)}\ C_6H_5CH{=}N{-}N{=}CH{-}C_6H_5 + H_2O \rightleftharpoons \\ C_6H_5CH{=}N{-}NH{-}CH(OH)C_6H_5 \rightleftharpoons \\ C_6H_5CHO + C_6H_5CH{=}N{-}NH_2 \xrightarrow{C_4H_2O_3} \\ C_6H_5CH{=}N{-}NHCOCH{=}CH{-}CO_2H \\ \text{(I)}\end{gathered}$$

Ekeley and Lefforge[3] recently reported the displacement of one or both of the benzal groups of benzalazine by treatment with acetic anhydride. By analogy with the previous interpretation of the reaction of acetic anhydride with anils,[4] they assumed the initial reaction to be the addition of acetic anhydride yielding C_6H_5-$CH{=}NN(COCH_3)CH(C_6H_5)OCOCH_3$ (II). La Parola[5] used this mechanism to account for the reaction of maleic anhydride with anils in the presence of water. In the present investigation it has been found that the rate of formation of the supposed addition product from benzalaniline and acetic anhydride is considerably increased when small amounts of acetic acid are added. The primary reaction, contrary to the assumption of Ekeley and Lefforge, is therefore addition of acetic acid. In the second step a molecule of acetic acid is liberated and may renew the cycle (B).

$$\begin{gathered}\text{(B)}\ C_6H_5CH{=}N{-}C_6H_5 + CH_3COOH \rightleftharpoons \\ C_6H_5CH(OCOCH_3)NHC_6H_5\ \text{(III)} \xrightarrow{(CH_3CO)_2O} \\ C_6H_5CH(OCOCH_3)N(COCH_3)C_6H_5\ \text{(IV)} + \\ CH_3COOH\end{gathered}$$

Compounds formed by addition of acetic acid and thioacetic acid to anils have been reported.[6–8] These substances have been formulated as containing the groupings —N(COCH₃)CH(OH)— and —N(COCH₃)CH(SH)—. The cyclization of benzalanthranilic acid, discussed later in this report, indicates the alternate mode of addition (B).

---

[1] Wagner-Jauregg obtained small amounts of a crystalline substance thought to be a *bis*-pyrazolidine by refluxing a benzene solution of maleic anhydride and benzalazine [*Ber.*, **63**, 3219 (1930)].

[2] W. W. Moyer observed the formation of an apparently neutral solid by heating a mixture of benzalazine and maleic anhydride to the boiling point (private communication).

[5] La Parola, *ibid.*, **64**, 919 (1934).

[6] Von Auwers, *Ber.*, **50**, 1599 (1917).

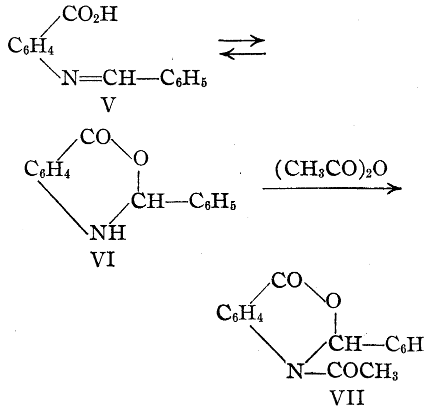
[7] Eibner, *ibid.*, **34**, 659 (1901).

[8] Galatis, *ibid.*, **66**, 1774 (1933).

Preliminary experiments indicate that a similar addition of acetic acid to the double bond in benzalazine does not occur to the same extent as in the case of benzalaniline. Thus we have so far been unable to obtain the compound (II) from benzalazine and acetic anhydride even when acetic acid was added to the mixture. However, addition of water to such a mixture brought about rapid reaction, with the production of *sym*-diacetylhydrazine and benzalacetylhydrazine in good yields. It is indicated, therefore, that the reaction observed by Ekeley and Lefforge was due to atmospheric moisture.

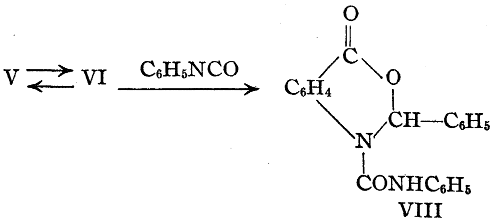
The behavior of benzalanthranilic acid is of particular interest. When this compound is heated with acetic anhydride the metoxazine derivative (VII) is formed.[4] The production of this substance might be accounted for on the basis of initial addition of acetic anhydride[4] or of acetic acid as discussed above. However, *intra*molecular addition of carboxyl group to the double bond might occcur yielding the oxazine VI which would be converted to VII by acetic anhydride.

(C)



That the metoxazine derivative (VI) may be formed from benzalanthranilic acid was proved by the reaction with phenyl isocyanate. When an equimolecular mixture of these substances was warmed a rapid reaction ensued and the expected phenylurea derivative (VIII) crystallized. Heating with dilute hydrochloric acid converted VIII into benzaldehyde and N-phenylcarbamylanthranilic acid.

(D)



Confirmation of the existence of the cyclic form of benzalanthranilic acid has been obtained by Rodebush, Buswell and Roy[9] in this Laboratory from measurement of the infrared absorption. The absorption curve of a solution of the substance in carbon tetrachloride indicated the presence of both —COOH and >N—H groups.

The reaction of benzalanthranilic acid with acetic anhydride therefore involves ring closure followed by acetylation (C). On the basis of this mechanism it might be expected that maleic anhydride, succinic anhydride or phthalic anhydride would react with benzalanthranilic acid under anhydrous conditions. However, attempts to induce such reactions under conditions similar to those employed with acetic anhydride have been unsuccessful, both in this work and that of La Parola.[5]

The production of the oxazoline observed by Galatis[8] in the reaction between *o*-benzalaminophenol and acetic anhydride may be explained on the basis of a similar cyclization.[10] The infrared absorption curve of *o*-benzalaminophenol in carbon tetrachloride solution at room temperature shows that under these conditions the compound exists entirely as the cyclic form.[9]

Experimental

Benzalmaleinhydrazine.—To 75 cc. of ether saturated with water in a glass-stoppered flask were added 5.2 g. of benzalazine and 2.5 g. of maleic anhydride. After four days the benzalmaleinhydrazine, 4.2 g. or 78% of the theoretical, was collected and washed with ether. This substance is almost insoluble in the common solvents. After purification from acetonitrile it melted at 183°.

Anal. Calcd. for $C_{11}H_{10}O_3N_2$: C, 60.55; H, 4.58; N, 12.84; neut. equiv., 218. Found: C, 60.11; H, 4.88; N, 13.06; neut. equiv., 221.

Extraction of the ethereal mother liquor with sodium bisulfite solution, followed by regeneration of benzaldehyde and treatment with phenylhydrazine gave 2.7 g. or 55% of benzalphenylhydrazine; m. p. 156–157°. Similar treatment of an ether solution of benzalazine gave no benzalphenylhydrazine.

In a parallel experiment in which no water was added to the ether employed as the solvent a very small amount, estimated as less than 0.05 g., of benzalmaleinhydrazine, was formed.

Degradation of Benzalmaleinhydrazine.—A mixture of 0.805 g. of benzalmaleinhydrazine and 150 cc. of water was heated to reflux for two hours. On cooling benzalazine

---

[9] Rodebush, Buswell and Roy, unpublished work.

[10] Cyclization of a corresponding thiophenol derivative has been demonstrated by Lankelma, THIS JOURNAL, **53**, 2654 (1931).

separated and was collected. The filtrate was diluted to 250 cc. in a volumetric flask. A 50-cc. portion required 16.2 cc. of 0.0502 *N* sodium hydroxide for neutralization to phenolphthalein. The neutralized solution was shaken with 2 cc. of benzaldehyde, causing the formation of more benzalazine. The solution became acid and required an additional 16.2 cc. of the alkali for neutralization. These values are in accordance with the equations below.

$$2C_6H_5CH{=}N{-}NHCOCH{=}CHCO_2H + H_2O \longrightarrow C_4H_4O_4(\text{maleic acid}) + C_6H_5CH{=}N{-}N{=}CHC_6H_5 + NH_2NH_2{\cdot}C_4H_4O_4 \quad (1)$$

$$NH_2NH_2{\cdot}C_4H_4O_4 + 2C_6H_5CHO \longrightarrow C_6H_5CH{=}N{-}N{=}CHC_6H_5 + C_4H_4O_4 \quad (2)$$

Catalysis of the Reaction between Benzalaniline and Acetic Anhydride by Acetic Acid.—In each of two 25-cc. flasks were placed 4.5 g. of benzalaniline and 2.5 cc. of pure acetic anhydride. To one mixture was added 0.5 cc. of glacial acetic acid. The flasks were closed with corks and allowed to stand at 55–65° for eighteen hours. They were then stored at +5° in a refrigerator overnight. The reaction mixture containing acetic acid was allowed to come to room temperature and was filtered. The solid was washed with two 5-cc. portions of cold ether. The weight of the supposed addition compound (IV) was 5.0 g.; m. p. 131–132°. An attempt to recover unchanged benzalaniline from the filtrate failed. Similar treatment of the reaction mixture to which acetic acid was not added gave 1.8 g. of IV. From the mother liquor there was recovered 1.6 g. of impure benzalaniline.

The Reaction of Benzalazine with Acetic Anhydride and Water.—Attempts to prepare the addition compound (II) from benzalazine and acetic anhydride by the method used with benzalaniline failed even when the reaction period was seven days.

A mixture of 10.4 g. of benzalazine and 15.3 g. of acetic anhydride was stirred over the steam-bath and 2.5 cc. of water was added in one portion. Heating and stirring were continued for thirty minutes. From the mixture, by a modification of the procedure of Ekeley and Lefforge,[3] there was obtained 2.0 g., 34% of the theoretical, of *sym*-diacetylhydrazine and 3.0 g., 37% of the theoretical, of benzalacetylhydrazine.

Benzalanthranilic Acid and Phenyl Isocyanate.—A mixture of 5.6 g. of benzalanthranilic acid and 3.0 g. of phenyl isocyanate, protected by a calcium chloride tube, was warmed. A reaction occurred and most of the material separated as transparent crystals. The mixture was cooled and washed with about 50 cc. of benzene. The yield of crude material (VIII) was quantitative. After purification from toluene or chloroform it melted at 171°.

Anal. Calcd. for $C_{21}H_{16}O_3N_2$: N, 8.14. Found: N, 8.12.

A mixture of 0.2 g. of the oxazine (VIII), 1 cc. of concentrated hydrochloric acid and 5 cc. of water was heated to the boiling point for about five minutes. The odor of benzaldehyde was clearly evident. The insoluble solid material was separated and shaken with 5 cc. of 5% sodium hydroxide solution. Acidification of the filtered extract gave N-phenylcarbamylanthranilic acid, m. p. 180–181°.

Benzalanthranilic Acid and Maleic, Succinic and Phthalic Anhydrides.—Anhydrous equimolecular mixtures of benzalanthranilic acid and one of these anhydrides heated on the steam-bath alone or in dioxane solution, or refluxed in benzene solution, did not react. When access of moisture was not prevented, for instance, when a benzene solution of benzalanthranilic acid, with maleic anhydride or succinic anhydride, was allowed to stand in an open beaker, an almost quantitative yield of *o*-carboxymaleanilic acid or of *o*-carboxysuccinanilic acid, respectively, was obtained as demonstrated by mixed melting points made with authentic samples. The mother liquor in each case smelt strongly of benzaldehyde.

Summary

In anhydrous ether solutions benzalazine and maleic anhydride do not react. If water is present the benzalazine undergoes hydrolysis, followed by reaction with maleic anhydride to form benzaldehyde and benzalmaleinhydrazine.

The reaction between benzalaniline and acetic anhydride is catalyzed by acetic acid.

Benzalanthranilic acid undergoes cyclization by addition of the carboxyl group to the nitrogen–carbon double bond. The cyclic form reacts with phenyl isocyanate.

Certain reactions previously formulated as *direct* addition of acetic anhydride to the nitrogen–carbon double bond are better interpreted as involving (1) addition of water or carboxylic acid to the double bond followed by (2) acetylation by acetic anhydride.

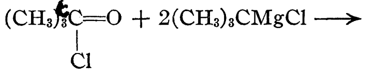
The Reducing Action of *t*-Butyl Grignard Reagent on Acyl Chlorides

BY FRED L. GREENWOOD, FRANK C. WHITMORE AND HARRY M. CROOKS

In an attempt to prepare di-*t*-butyl ketone or di-*t*-butylcarbinol by the action of *t*-butylmagnesium chloride on pivalyl (trimethylacetyl) chloride it was found that the chief products are neopentyl alcohol and neopentyl pivalate resulting from the reduction of the acid chloride by the Grignard reagent.



$$(CH_3)_3C\underset{\displaystyle Cl}{\overset{}{C}}{=}O + 2(CH_3)_3CMgCl \longrightarrow$$

$$(CH_3)_3CCH_2OMgCl + 2(CH_3)_2C{=}CH_2 + MgCl_2$$

The action of *t*-butyl Grignard reagent with pivalyl chloride has been studied by the addition of the Grignard reagent to a large excess of acid chloride at a low temperature, and by the addition of the acid chloride to a large excess of the Grignard reagent at the reflux temperature of ethyl ether. Moreover, we have added isobutyryl and *n*-butyryl chlorides to a large excess of Grignard reagent at ethyl ether reflux temperature. The results are summarized in Table I.

TABLE I

Acid chloride	Ratio of $(CH_3)_3CMgCl$ to acid chloride	Products % addition	% reduction
Pivalyl[a]	1/5	32.4	8
Pivalyl[b]	4/1	1.5	94.0
Isobutyryl	5/1	63.0	20.0
n-Butyryl	4/1	71.0	9.0

[a] Grignard reagent added to acid chloride at −10°: addition product hexamethylacetone, reduction product neopentyl pivalate. [b] Acid chloride added to Grignard reagent at about 40°. Addition product was di-*t*-butylcarbinol resulting from addition of 1 mole of Grignard reagent followed by reduction; reduction product was neopentyl alcohol.

In all reactions the isobutylene formed corresponded to two moles of Grignard reagent per mole of acid chloride reduced to primary alcohol plus one mole of Grignard reagent per mole of ketone reduced to secondary alcohol. The alcohols were identified by preparation of derivatives and mixed melting points with known materials. Exception was made in the case of *n*-propyl-*t*-butylcarbinol and isopropyl-*t*-butylcarbinol which were identified by comparison of the physical constants of the substances and of their derivatives with those reported for these compounds by Haller and Bauer,[1] and by Conant, Webb and Mendum.[2] Neopentyl pivalate was identified by hydrolysis and the preparation of known derivatives of the hydrolysis products.

In all cases the Grignard reagent used was filtered and free from particles of magnesium. All attempts to find the aldehyde corresponding to the primary alcohol obtained failed.

Experimental

Preparation of the *t*-Butylmagnesium Chloride Solution.—A calibrated three-liter flask was equipped, by means of a trident, with reflux condenser, separatory funnel and mercury-sealed stirrer. To 121.5 g. of magnesium turnings (5 moles) in the flask was added 5 cc. of tertiary butyl chloride in 30 cc. of dry ether. A few drops of ethyl bromide started the reaction. When vigorous reaction had started, 300 cc. of dry ether was added and followed by the remainder of 460 g. (5 moles) of tertiary butyl chloride (b. p. 50° at 738 mm.; $n^{20}D$ 1.3859) dissolved in 1400 cc. of dry ether. The halide solution was added at such a rate that refluxing was continuous. This required about eighteen hours. Sitrring was continued for an hour after end of addition. The solution was allowed to stand overnight and then titrated by the method of Gilman.[3] The yield of reagent was 75–85%. The clear solution was filtered through two layers of cloth under pressure of dry nitrogen. The filtrate contained no particles of magnesium.

Preparation of Acid Chlorides.—Pivalic acid was prepared by carbonation of *t*-butylmagnesium chloride in 60% yield.[4] Treatment of the acid with thionyl chloride gave an 80% yield of pivalyl chloride, b. p. 70.5–71° at 250 mm., $n^{20}D$ 1.4118.

Isobutyric acid (b. p. 151° at 732 mm., $n^{20}D$ 1.3920) was prepared by alkaline permanganate oxidation of isobutyl alcohol. Isobutyryl chloride was obtained in 75% yield by the use of thionyl chloride, b. p. 90–91°, $n^{20}D$ 1.4070.

n-Butyryl chloride was obtained in 80% yield by treatment of the acid (Eastman Kodak Co.) with thionyl chloride: b. p. 101–101.5° (730 mm.); $n^{20}D$ 1.4117.

Apparatus.—The reactions were carried out in the apparatus used in the preparation of the Grignard reagent except that the system was closed and the exit gases led through the condenser to a gas-collecting carboy.

Three fractionating columns were used, all of the adiabatic, total reflux, variable take off type packed with single-turn glass helices: column 1, 1.5 × 66 cm., 12 theoretical plates; column 2, 1 × 45 cm., 9 plates; column 3, 0.9 × 53 cm., 13 plates.

Addition of *t*-Butylmagnesium Chloride to Pivalyl Chloride.—A solution of 966.5 g. of pivalyl chloride (8.0 moles) in 1 liter of dry ether was placed in the reaction flask and cooled to −10° (thermometer in the solution). To

[4] "Organic Syntheses," Vol. VIII, 104 (1928).

this was added, over a period of seventeen hours, a solution of 1.5 moles of *t*-butylmagnesium chloride in 1 liter of dry ether. During the addition the temperature was kept at −10° or below. After addition was complete the ice-bath was exchanged for a water-bath and the reaction mixture heated to 50° to drive off dissolved gases. The Grignard complex was decomposed by pouring over crushed ice, the layers were separated and the aqueous layer extracted well with ether. The combined ether layers were extracted with an excess of saturated sodium bicarbonate solution which was saved for recovery of the excess pivalic acid. The ether solution was concentrated and fractionated through Column 1. Refractionation through Column 2 yielded the following fractions:

	B. p. (740 mm.)	n^{20}_{D}	Wt., g.	Product
1	151–153	1.4175–83	67.4	Hexamethylacetone
2	153–164	1.4161–40	50.3	Mixture (?)
3	164–165	1.4033–5	14.1	Neopentyl pivalate
4	124(93 mm.)	1.4093	15.3	Pivalic anhydride

Fraction 1 was identified as hexamethylacetone by comparison of the physical constants with a known sample and then by conversion to the carbinol by sodium reduction. The resulting di-*t*-butylcarbinol was identified by means of the phenylurethan, m. p. 120.5–121°, mixed with a known sample (118.5–120°) it melted at 120–121°. Haller and Bauer reported the m. p. as 118–119°.

Fraction 3 was hydrolyzed with 25% KOH, to give an solid alcohol, which was converted to the phenylurethan, m. p. 111.5–112°. Mixed with the known derivative of neopentyl alcohol (112–112.5°) it melted at 112°. Acidification of the alkaline layer yielded an acid which gave an amide of m. p. 153–154°. Mixed with the known amide of pivalic acid (153–153.5°) it melted at 153–154°.

Fraction 4 was hydrolyzed in aqueous potassium hydroxide solution to give a solid acid which gave pivalamide. No non-acidic hydrolysis products were formed.

During the reaction 6.5 l. of isobutylene were collected in the gas carboy, 0.25 mole, a 17% yield based on the Grignard reagent used which is in accordance with the 8% yield of neopentyl trimethylacetate as reduction product.

Addition of Pivalyl Chloride to *t*-Butylmagnesium Chloride.—To a solution of 3.9 moles of *t*-butylmagnesium chloride in 2 liters of ether was added 1.1 moles of pivalyl chloride, undiluted, over a period of four and one-half hours. During this time 90 liters of gas came off consisting of about 40% ether and 55% isobutylene (slightly over two moles of isobutylene measured at 29° and 733 mm.).

After standing overnight the Grignard complex was decomposed by pouring slowly over 2 kg. of crushed ice, the layers separated and the aqueous layer steam distilled until there was no further odor of alcohol in the fresh distillate. The aqueous distillate was saturated with sodium carbonate and thoroughly extracted with ether. All ether solutions were then combined and dried. The ether was removed through Column 3 and the products fractionated through the same column.

	B. p. (737 mm.) °C.	Wt., g.	Product
1	75–100	6.0	Impure hexamethylethane
2	106–112	88.0	M. p. 50°, neopentyl alcohol
3	163–166	1.8	Semisolid, di-*t*-butylcarbinol

The phenylurethan of 2 melted at 112.5–113.5°; mixed with the known derivative of neopentyl alcohol (112–112.5°), it melted 112–113°. The α-naphthylurethan of 2 melted 98.5–99°, mixed with the known (98.5–100.5°) it melted at 98.5–99.5°.

The phenylurethan of 3 melted 120.5–121°; mixed with the known derivative of di-*t*-butylcarbinol (119–121°) it melted at 120–121°.

The yield of neopentyl alcohol was 94% while that of di-*t*-butylcarbinol was 1.5%.

Addition of Isobutyryl Chloride to *t*-Butylmagnesium Chloride.—The addition of 0.84 mole of isobutyryl chloride (89 g.) to 4.2 moles of *t*-butylmagnesium chloride in 2 liters of ether required four hours. During the reaction 1.34 moles of gas was given off which contained 93.5% isobutylene, 1.49 moles, per mole of acid chloride.

The liquid products gave the following

	B. p. (738 mm.) °C.	n^{20}_{D}	Wt., g.	Product
1	79–81	1.3910	7.5	
2	90–103		2.2	Solid, hexamethylethane
3	103–106	1.3950	12.5	Isobutyl alcohol
4	145	1.4281	82.0	*t*-Butylisopropylcarbinol

The phenylurethan of 3 melted at 83–83.5°, mixed with the known derivative of isobutyl alcohol (84–84.5°) it melted at 83–84°. The α-naphthylurethan of 3 melted at 97–97.5°, mixed with the known derivative (98–98.5°) it melted at 97–98°.

The phenylurethan of 4 melted at 86.5–87° and the α-naphthylurethan at 103–104°. Conant gives the melting point of the phenylurethan as 89° and assumes Haller and Bauer's reported value of 79° to be a misprint.

The isobutyl alcohol isolated amounted to a 20% yield based on original acid halide while the secondary alcohol accounted for 63% of the original acid chloride.

Addition of *n*-Butyryl Chloride to *t*-Butylmagnesium Chloride.—The addition of 0.98 mole of *n*-butyryl chloride to 4.0 moles of Grignard reagent dissolved in two liters of ether required five and one-half hours. During the reaction 1.1 moles of gas was given off which contained 84% isobutylene, a yield of 94% isobutylene based on the acid chloride.

The liquid products were worked up as before.

	B. p. (744 mm.) °C.	n^{20}_{D}	Wt., g.	Product
1	79–82	1.3908	7.5	
2	100–106		2	Solid, hexamethylethane
3	115–116.5	1.3993	6.5	1-Butanol
4	152–153	1.4275	90.8	*t*-Butyl-*n*-propylcarbinol

The phenylurethan of 3 melted at 62–62.5°, mixed with the known derivative of 1-butanol (62–62.5°) it melted at 62–62.5°. The α-naphthylurethan melted at 70–71°, mixed with the known derivative (71–72°) it melted at 70–71°.

The phenylurethan of 4 melted at 70.5–71.5° and the α-naphthylurethan at 113–114°. Haller and Bauer report a boiling point of 155–157° for this carbinol and a melting point of 70–71° for the phenylurethan.

The 1-butanol isolated amounted to 9% based on the acid chloride used while the secondary carbinol isolated accounted for 71% of the acid chloride.

All melting points are uncorrected.

Summary

1. The reaction of *t*-butylmagnesium chloride with a large excess of pivalyl chloride at −10° gives a 32% yield of hexamethylacetone and an 8% yield of neopentyl alcohol as its pivalic ester.

2. The reaction of a large excess of *t*-butylmagnesium chloride at about 40° with pivalyl, isobutyryl and *n*-butyryl chlorides results, respectively, in a 1.5, 63 and 71% yield of addition and in a 94, 20 and 9% yield of reduction of the acid chloride to primary alcohol.

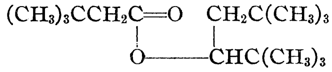
The Action of *t*-Butylmagnesium Chloride on *t*-Butylacetyl Chloride

BY FRANK C. WHITMORE AND J. W. HEYD

The preparation of *t*-butylneopentylcarbinol in quantity for use in a dehydration study involved the reaction of *t*-butylmagnesium chloride with *t*-butylacetyl chloride. An investigation of the reduction products has proved interesting when compared with the action of the same Grignard compound on trimethylacetyl chloride.[1] The addition of the acid chloride to *t*-butylmagnesium chloride produced *t*-butylneopentylcarbinol in 71% yield together with a 1% yield of neopentylcarbinol. Investigation of the products of this reaction boiling above the secondary carbinol indicates a 5% yield of *t*-butylneopentylcarbinyl *t*-butylacetate as the product of the esterification of the secondary alcohol complex with unreacted acid chloride. However, addition of *t*-butylacetyl chloride to a suitable excess of *t*-butylmagnesium chloride permitted all of the secondary carbinol to be recovered without esterification, thus raising the yield to 76%.

Addition of a slight excess of a filtered solution of *t*-butylmagnesium chloride to an ethereal solution of *t*-butylacetyl chloride, produced *t*-butylneopentyl ketone in 51% yield. In this case all of the secondary carbinol formed as reduction product underwent esterification in the presence of excess acid chloride to yield 17% of pure *t*-butylneopentylcarbinyl *t*-butylacetate. Attempts to saponify this ester by refluxing with alcoholic potassium hydroxide for seventy-one hours or by heating for fifty-six hours in a sealed tube at 90–100° were not successful. However, an authentic sample of the ester obtained from the reaction of *t*-butylneopentylcarbinol and *t*-butylacetyl chloride checked in physical constants with the reduction product and proved equally stable toward saponification under similar conditions.[2]

No reduction was obtained when *t*-butyl neopentyl ketone was treated with a solution of aluminum isopropylate in isopropyl alcohol. This inertness and the inability to form a semicarbazone or an oxime[3] are related to the steric arrangement about the carbonyl group of this ketone. The inertness of the ester is dependent on similar steric conditions.



$$\begin{array}{ll}(CH_3)_3CCH_2\underset{\displaystyle |}{C}{=}O & \underset{\displaystyle |}{CH_2}C(CH_3)_3 \\ \qquad\qquad\quad O\text{———} & CHC(CH_3)_3\end{array}$$

Experimental

Addition of *t*-Butylacetyl Chloride to *t*-Butylmagnesium Chloride.—A solution of 5.4 moles of *t*-butylmagnesium chloride in 2400 cc. of dry ether was prepared by the action of *t*-butyl chloride, b. p. 50° (732 mm.), $n^{20}D$ 1.3850, on magnesium. *t*-Butylacetyl chloride, b. p. 79° (150 mm.), $n^{20}D$ 1.4212, was prepared in 86% yield from *t*-butylacetic acid and thionyl chloride.[4] Addition of 336 g. (2.5 moles) of the acid chloride in a liter of ether to the Grignard solution (5.4 moles) was completed in three days and then the thick reaction mixture was refluxed for four days. The complex was decomposed with ice, the products extracted with ether and the solvent removed with an efficient column.[5] Fractionation of the products yielded: Fractions 1–3, 72.9 g., b. p. 34–81° (735 mm.), $n^{20}D$ 1.3520–1.3880; 4–5, 34.0 g., 81–167°, 1.4081–1.4220; 6–9, 282.3 g., 167–173°, solid; 10–11, 47.9 g., 122–208° (50–45 mm.), 1.4363–1.4450; solid residue, 15.4 g. Fractions 6–9 represent a 71% yield of *t*-butylneopentylcarbinol. A portion of the solid, by a series of fractional crystallizations, gave a pure sample of carbinol, m. p. 49.4° (corr.).

[1] Greenwood, Whitmore and Crooks, THIS JOURNAL, **60**, 2028 (1938).

[2] Since the completion of this paper, J. S. Whitaker of this Laboratory has succeeded in partially saponifying this ester and identifying *t*-butylacetic acid as the acid fragment.

[3] Bouveault and Locquin, *Bull. soc. chim.*, [3] **35**, 642 (1906).

[4] Homeyer, Whitmore and Wallingford, THIS JOURNAL, **55**, 4209 (1933).

[5] Whitmore and Lux, *ibid.*, **54**, 3451 (1932).

A similar run using 2.25 moles of acid chloride was also completed and the material from both reactions boiling above the secondary carbinol was refractionated to give 8 fractions, 61.1 g., b. p. 90° (5 mm.), $n^{20}\mathrm{D}$ 1.4392–1.4359. Refractionation of these gave 8 fractions, 39.7 g., b. p. 90° (5 mm.), $n^{20}\mathrm{D}$ 1.4367–1.4339, which represented a 5% yield of *t*-butylneopentylcarbinyl *t*-butylacetate. The refractive index gradually approached the correct index for the synthetic ester, $n^{20}\mathrm{D}$ 1.4320. The boiling point was correct for the ester. The mol. wt. found from the depression of the f. p. of benzene is 250; calcd. 256.

The fractions of the two preparations boiling in the range of 79–168° (732 mm.), were combined and refractionated to give 2 fractions, wt. 6.9 g., b. p. 139–143°, $n^{20}\mathrm{D}$ 1.4150–1.4179. These were identified as neopentylcarbinol by means of the α-naphthylurethan, m. p. 82–83°, which gave no depression with α-naphthylurethan of known neopentylcarbinol. The yield of this reduction product was thus 1%.

An addition of 0.65 mole of *t*-butylacetyl chloride to 1.5 moles of *t*-butylmagnesium chloride produced the secondary carbinol in 76% yield with no evidence for the formation of *t*-butylneopentylcarbinyl *t*-butylacetate.

Addition of *t*-Butylmagnesium Chloride to *t*-Butylacetyl Chloride.—To a solution of 128 g. (0.95 mole) of *t*-butylacetyl chloride in 1300 cc. of ether was added one mole of *t*-butylmagnesium chloride in a liter of ether over a period of thirty-six hours. The addition complex was decomposed with ice, extracted with ether, and the product fractionated, after removal of solvent, to give: 1, 2, 54.8 g., b. p. 33–110° (728 mm.), $n^{20}\mathrm{D}$ 1.3520–1.3640; 3–6, 7.8 g., 110–158°, 1.4042–1.4125; 7–9, 18.9 g., 158–161°, 1.4135–1.4150; 10–12, 75.4 g., 161°, 1.4158–1.4160; 13–14, 15.9 g., 161–164°, 1.4167–1.4175; residue, 39.2 g. Fractions 10–12 represent a 51% yield of *t*-butyl neopentyl ketone, which did not form a semicarbazone or oxime and yielded a 2,4-dinitrophenylhydrazone with great difficulty, m. p. 123.5–124.5°.

The residue of this fractionation was combined with that of a 0.5 mole run to give 6 fractions of pure *t*-butylneopentylcarbinyl *t*-butylacetate, wt. 33 g. (17% yield), b. p. 90° (5 mm.), $n^{20}\mathrm{D}$ 1.4320, d^{20}_4 0.8553. Molecular refraction; calcd. 77.74, found 77.73. *Anal.* Calcd. for $C_{16}H_{32}O_2$: C, 75.0; H, 12.5. Found: C, 75.6; H, 12.6.

Treatment of 19.8 g. of the pure ester with 12 g. of potassium hydroxide in 60 cc. of absolute methyl alcohol at reflux temperature for seventy-one hours gave no evidence of saponification. Treatment of 16.7 g. of the ester with 20 g. of potassium hydroxide in 125 cc. of 95% ethyl alcohol in a sealed tube at 90–100° for fifty-six hours likewise gave no evidence of saponification.

Preparation of *t*-Butylneopentylcarbinyl *t*-Butylacetate.—The addition of 53 g. (0.39 mole) of *t*-butylacetyl chloride to 55.3 g. (0.35 mole) of *t*-butylneopentylcarbinol, m. p. 50–51°, gave a slight evolution of heat. The reaction mixture was refluxed for two hours, cooled, washed with 10% sodium carbonate solution, dried with anhydrous potassium carbonate and fractionated to give: 1–5, 22.2 g., b. p. 30–94° (5–7 mm.), $n^{20}\mathrm{D}$ 1.4188–1.4260; 6–8, 16.5 g., 93° (7 mm.), 1.4312–1.4316; 9–12, 36.0 g., 93° (7 mm.), 1.4318–1.4320; 13, 5.7 g., 93° (7 mm.), 1.4311; residue, 1.6 g. Fractions 6–13 represent 65% yield of the ester. A density determination on fraction 10, $n^{20}\mathrm{D}$ 1.4320, indicated d^{20}_4 0.8549. Treatment of 10 g. of the synthetic ester with 20 g. of potassium hydroxide in 120 cc. of 95% ethyl alcohol gave no indication of saponification after refluxing the mixture for seventy-two hours.

Summary

1. A study has been made of the normal addition and reduction products formed by the addition of *t*-butylacetyl chloride to *t*-butylmagnesium chloride and of those formed by the reverse addition.

2. The synthesis and physical constants of *t*-butylneopentylcarbinyl *t*-butylacetate have been described.

Photochemical Studies. XXVIII. The Photochemical Decomposition of Ethyl Methyl Ketone by Wave Lengths from 1850–2000 Å.

BY VICTOR R. ELLS AND W. ALBERT NOYES, JR.

Ethyl methyl ketone, in common with other ketones, absorbs in the near ultraviolet, the approximate limits being 2400 and 3200 Å. No discrete structure could be found in this region,[1] although fluorescence may be excited, at least by the 3130 Å. line of mercury. However, recent work[2] on the fluorescence of acetone has raised the question as to whether the ketones or some of their decomposition products are mainly responsible for the emission of fluorescent radiation.

The photochemical decomposition of ethyl methyl ketone in the near ultraviolet has been investigated by Norrish and Appleyard.[3] The products of the reaction were found to be carbon monoxide and approximately equal amounts of ethane, propane and butane, together with small amounts of ethylene and acetaldehyde. In the

analogous decomposition of acetone at room temperature, biacetyl has been shown to be one of the main products.[4]

The second region of absorption in ketones occurs just below 2000 Å. and may be investigated also with the aid of quartz apparatus. At these wave lengths acetone gave approximately equal amounts of hydrocarbon (ethane) and carbon monoxide,[5] indicating thereby that little or no biacetyl is formed. However, the quantum yield for the decomposition did not approach unity, apparently, as the pressure was lowered, thus leading to some difficulties in the theoretical interpretation of the results.

The present work was undertaken with the object of ascertaining whether ethyl methyl ketone behaves in a manner analogous to acetone in the region of 1850 to 2000 Å. or whether the quantum yield is higher. The entire question of the adiabatic transfer of polyatomic molecules between energy states rests on a very insecure theoretical foundation and the introduction of such an idea[6] was made only because of the apparent difficulty in accounting by more rational means for the fate of all of the absorbed energy.

As will be seen it is not necessary, for ethyl methyl ketone, to use unorthodox ideas for the explanation of the experimental facts, at least in the wave length region studied.

Experimental Procedure and Results

(a) The Determination of Diketones among the Reaction Products in the Near Ultraviolet.—Since it is quite important to know all of the reaction products in order to arrive at a proper estimate of the quantum yield, it was decided first to ascertain whether diketones are produced upon irradiation of ethyl methyl ketone in the near ultraviolet region.

Reactions were carried out in a Pyrex cell with plane window using as a light source a capillary mercury arc.[7] The wave lengths were greater than 3000 Å. and the absorption was due almost entirely to the group of lines near 3130 Å.

The ethyl methyl ketone was synthesized by the acetoacetic ester synthesis. Ethyl acetoacetate was added to the proper amount of sodium metal dissolved in ethyl alcohol to form the sodium compound of the enol form. Methyl iodide was added and the mixture refluxed for several hours until it no longer gave an alkaline reaction. The alcohol was distilled off, water added and the ethyl methylacetoacetate extracted with diethyl ether. After purification by fractional distillation, the ethyl methylacetoacetate was hydrolyzed with 10% sodium hydroxide and the ethyl methyl ketone distilled off. In addition to fractional distillation, the ethyl methyl ketone was purified by formation of the bisulfite compound which was decomposed by potassium carbonate to reform the ketone. Fused potassium carbonate was used as the final drying agent. The boiling point of the final material was 79.4 ± 0.2°.

The ethyl methyl ketone was kept flowing through the reaction cell by immersing traps in water at different temperatures. After irradiation for a period of sixty to one hundred hours, liquid air was placed on one of the traps and the non-condensable gases collected by means of a Toepler pump, after which they were analyzed for carbon monoxide by the method of Blacet and Leighton.[8]

The condensed liquids were removed from the system and treated with hydroxylamine hydrochloride, nickel chloride and ammonium hydroxide solutions to quantitatively precipitate the diketones as nickel glyoxime salts. The precipitates were filtered through Gooch crucibles and weighed. Although a method has been developed by Johlin[9] for separating some of the possible salts, the small amount of precipitate (1–3 mg.) rendered this impracticable, so that an average molecular weight of 316.9 was taken.

Four runs were made showing that the following percentages of carbon monoxide appeared as diketones among the reaction products: 11.7, 9.9, 11.3, 10.6; average 10.9. It is apparent, therefore, that diketones are formed upon irradiation of ethyl methyl ketone in the near ultraviolet and this fact must be taken into account in obtaining a final theory of the mechanism of the reaction.

(b) The Determination of the Quantum Yield at 1850–2000 Å.—The light source has been described[5] and consisted of a spark between rotating aluminum disks. The group of lines from 1855 to 1990 Å. was separated by focal isolation. In this region ethyl methyl ketone shows several bands[1] and a weak continuous absorption.

The method of gas analysis used for the products was essentially that described by Manning[10] and used in the work on acetone.[5] After irradiation, the ethyl methyl ketone and products were, as far as possible, condensed with liquid air and the residual gases (carbon monoxide, ethane and methane, if present) were pumped off with a Toepler pump and measured with a McLeod gage. Prolonged pumping and several evaporations and recondensations were necessary to effect removal of the ethane. The analysis of this fraction was carried out exactly as described.[10] No ethylene was found in these gases, indicating that the Type II decomposition of ethyl methyl ketone described by Norrish and Appleyard[3] does not seem to be very important in this wave length region.

A second fraction of reaction products was next removed by replacing the liquid air by a solid–liquid pentane mixture at about −155°. This fraction would contain propane and butane as well as any acetaldehyde and carbon dioxide which might have been formed. This fraction was burned with oxygen using the hot platinum wire as previously described.[10]

[10] Manning, *ibid.*, **56**, 2589 (1934).

In all cases an excess of carbon monoxide was found, indicating superficially, as with acetone,[5] that diketones were not formed. However, it has been emphasized by Norrish and his co-workers[6] that the hydrocarbons are quite soluble in the condensed ketones and that some difficulty is encountered in effecting their removal.

To further test the possibility of diketone formation, the spectrum of biacetyl was photographed in the far ultraviolet.[11] An intense band at 57,295 cm.$^{-1}$, which is well removed from any bands of ethyl methyl ketone,[1] could be used for the identification of biacetyl. Other bands also furnished confirmatory evidence for the formation of this compound. A series of photographs was made with known pressures of biacetyl and a comparison of the spectra of the reaction products, from which carbon monoxide and ethane had been removed, with these standards permitted a very rough estimate to be made of the amount of biacetyl produced. No estimate of the amounts of the other possible diketones could be made, so that the three were assumed to be present in equal amounts. Moreover, some diketones would be formed during the photographing of the spectrum so that no great accuracy is claimed for the amount of diketones formed. One band at 58,086 cm.$^{-1}$ which appeared on some of the spectra may have been due to one of the other diketones.

The hydrogen bromide actinometer was used, as previously,[5] for the determination of the number of quanta absorbed. Runs made with the purpose of obtaining proof for the existence of biacetyl were made in an all quartz cell and the results agreed with those obtained in the cell with windows attached by wax.

Table I shows the analysis of the gases formed during reaction.

TABLE I

COMPOSITION OF REACTION PRODUCTS

Ketone pressure, mm.	Carbon monoxide (mm. in anal. app.)	Hydrocarbons, mm.	% Carbon monoxide	Ethane, mm.	Propane, mm.	Butane, mm.
70	0.0222	0.0197	53.0	0.0062	0.0066	0.0069
62	.0140	.0089	61.1	.0026	.0034	.0029
58	.0129	.0099	56.6	.0036	.0035	.0028
25	.0182	.0157	54.0	.0056	.0054	.0047
14	.0224	.0227	49.7	.0079	.0071	.0077
4	.0114	.0099	53.5	.0032	.0035	.0032
11	.0176	.0135	56.6	.0049	.0045	.0041

From the data in Table I it is seen that the average ratio ethane:propane:butane is 1:1.03:0.95, so that the relative amounts of these hydrocarbons agree very closely with those reported by Norrish and Appleyard[3] in the near ultraviolet.

Table II presents data on the number of molecules of carbon monoxide produced per quantum absorbed by ethyl methyl ketone.

In order to estimate how much biacetyl was formed, the spectrum of this substance was photographed in a 15-cm. tube at pressures which were estimated on a McLeod gage. As little as 0.0001 to 0.0002 mm. was sufficient to cause the 57295 cm.$^{-1}$ band to be recognizable.

After irradiation of ethyl methyl ketone, the liquids were condensed with liquid air and the carbon monoxide and ethane were pumped off. The trap, which was fitted with a small bulb which could be broken by a magnetic hammer, was sealed off and attached to the cell in front of the spectrograph. The trap was immersed in dry ice–ether mixtures during the photographing of the spectrum. The vapor pressure of biacetyl is about 0.01 mm. at −70° and about 0.004 mm. at −77°.

The volume of the cell used for photographing the spectrum was about 0.13 of the volume in which the gases were measured in the quantum yield determinations. If the three diketones are formed in equal amounts, multiplying the number of molecules of biacetyl by six will give the number of molecules of ethyl methyl ketone which have disappeared during irradiation due to diketone formation. Multiplication of the approximate pressure of biacetyl in the absorption cell by 0.77 gives the pressure of ethyl methyl ketone which would have disappeared in the larger volume.

Table III gives rough estimates of the extent of the diketone reaction in four runs.

The order of magnitude of the fraction of the reaction which leads to diketone formation seems to be the same as in the near ultraviolet, but the data are too inaccurate to permit a definite statement on this point to have much meaning.

It should be mentioned in passing that similar experiments were performed on acetone after the conclusion of this work to ascertain whether biacetyl was formed in sufficient quantity to make a correction necessary on the previous work.[5] No biacetyl could be detected in this case, but this matter is worthy of a more thorough investigation.

Since biacetyl is formed to a considerably less extent from acetone in the near ultraviolet as the temperature is increased it was decided to make quantum yield determinations at higher temperatures. Moreover, Winkler[12] studied the photochemical decomposition of acetone from 60 to 400°, at wave lengths 2200 to 3200 Å. and found methane and ketene among the products, the ketene being detected by effects observed by Ross and Kistiakowsky.[13] The quantum yield which was 0.3 at 60° increased to 1 at 160°.

36[c]	18	1.685	22.2	3.14	.71	....	0.75

[a] The absorption coefficient is calculated from the equation—kp (mm.) = $\ln_e$ (*fraction transmitted*). It is quite evident that Beer's law is not obeyed for the radiation used, thus indicating that more than one wave length is being absorbed. [b] The quantum yield in these runs is calculated using the same k (0.60) as found in Run 34. Since the fraction absorbed is thus probably too low, the quantum yields are probably too high. [c] This run was made in the all quartz cell referred to above.

TABLE III

EXTENT OF THE DIKETONE REACTION

Run	Ketone pressure, mm.	Estimated pressure biacetyl (abs. cell)	Press., CO, mm.	Equiv. press. of ethyl methyl ketone (in anal. app.)	Approx. quantum yield of diketone reaction
46	0.018	0.0001	0.0012	0.0001	0.06
45	13	.0020	.0250	.0016	.05
44	14	.0085	.0890	.0070	.06
47	43	.0012	.0080	.0009	.08

In the present work on ethyl methyl ketone runs were made from 100 to 200°. No thermal decomposition was found, but methane was formed photochemically. No method of testing for ketenes was practicable. Table IV presents the data.

TABLE IV

QUANTUM YIELD AT ELEVATED TEMPERATURE

Run	Ketone press., mm.	Temp., °C.	Quantum yield of CO formation	Fraction absorbed	Ratio CO/CH_4	Quantum yield of CH_4 formation
47	43	105–110	0.79	0.60	4.2	0.19
41	4.75	160–165	.79	.36	4.0	.20
42	45	160–165	.85	.74	2.2	.38
48	43	195–200	.71	.59	1.5	.47

The amount of methane seems to increase both with increasing temperature and with increasing pressure. In run 47 a spectroscopic test was made for biacetyl and only a trace was found. This might have been produced during the photographing of the spectrum.

Discussion

It is quite evident from the data in Tables II and III together that as the pressure is lowered the over-all quantum yield for the disappearance of ethyl methyl ketone in the wave length region 1850–2000 Å. approaches unity. The highest value observed experimentally is about 0.95 and this is well within the experimental error of 1.00.

At higher pressures the yield decreases, so that the average of runs conducted at pressures over 20 mm. is 0.83 (allowing 0.08 for the biacetyl reaction).

Since Beer's law is not obeyed, it is necessary to allow for at least two and probably more different types of absorption. Thus we may write down the following primary processes

$$I_1 \quad K + h\nu = K_1 \quad (1)$$

$$I_2 \quad K + h\nu = CH_3CO + C_2H_5 \quad (2)$$

$$I_3 \quad K + h\nu = C_2H_5CO + CH_3 \quad (3)$$

where K represents a molecule of ethyl methyl ketone and K_1 an excited molecule. The active molecules may fluoresce, may dissociate or may be deactivated by collision. No fluorescence could be detected in the visible, in contradistinction to the behavior in the near ultraviolet.[1] With acetone, also,[5] no fluorescence excited by these wave lengths could be detected. Therefore we may write the following reactions for K_1:

$$k_1 \quad K_1 + K = K + K \qquad (4)$$
$$k_2 \quad K_1 = CH_3CO + C_2H_5 \qquad (5)$$
$$k_3 \quad K_1 = C_2H_5CO + CH_3 \qquad (6)$$

If, now, none of the free radicals recombine to give ethyl methyl ketone, we arrive at the following expression for the quantum yield of ketone decomposition

$$\Phi = \frac{1}{I_1 + I_2 + I_3}\left[I_2 + I_3 + \frac{I_1}{\frac{k_1(K)}{k_2 + k_3} + 1}\right] \qquad (7)$$

Since the relative values of I_1, I_2 and I_3 change with pressure, the quantitative application of equation (7) would have little meaning. It is evident, however, that it may be made to fit the data on quantum yields. According to this equation the yield should become one at zero pressure and this seems to be true. At higher pressures the variation of quantum yield will depend upon the relative magnitudes of the absorption coefficients for the three primary processes as well as on the magnitudes of k_1, k_2 and k_3. Little more can be said concerning the variation of over-all quantum yield from the data at room temperature.

There may be a slight tendency for the amount of biacetyl to increase with the pressure, the tendency of this substance to dissolve in the ethyl methyl ketone being a factor which might prevent the increase from becoming more noticeable. This could be explained easily on the basis of the higher optical absorption and consequently greater chance of reaction between free radicals.

If (1), (2) and (3) are the only primary processes (the simultaneous splitting off of both alkyl groups would not be impossible), the following equations must be considered

$$CH_3CO = CH_3 + CO \qquad (8)$$
$$C_2H_5CO = C_2H_5 + CO \qquad (9)$$
$$CH_3CO + CH_3CO = (CH_3CO)_2 \qquad (10)$$
$$CH_3CO + C_2H_5CO = CH_3COCOC_2H_5 \qquad (11)$$
$$C_2H_5CO + C_2H_5CO = (C_2H_5CO)_2 \qquad (12)$$
$$CH_3 + CH_3 = C_2H_6 \qquad (13)$$
$$CH_3 + C_2H_5 = CH_3CH_2CH_3 \qquad (14)$$
$$C_2H_5 + C_2H_5 = C_4H_{10} \qquad (15)$$

As the temperature is increased, methane could be formed by

$$CH_3 + CH_3COC_2H_5 = CH_4 + C_4H_7O \text{ (free radical)} \qquad (16)$$

Rice and Herzfeld[14] ascribe a heat of activation of 15,000 cal. to the analog of (16) in acetone. The free radical could split off an ethyl or a methyl group to give ketene or methyl ketene. For this reaction Rice and Herzfeld give an activation energy of 48,000 cal., so that it would become important only at high temperatures.

The fact that equal quantities of the hydrocarbons ethane, propane and butane have been found in this work as well as by Norrish and Appleyard[3] is quite interesting. Presumably these reactions occur through the formation of quasi-molecules which must be stabilized by collision with a third body. That a statistical equilibrium is not established is evident since there is not twice as much propane as of either of the others. The number of binary collisions for (13), (14) and (15) will be in the ratio 1.00:0.87:0.83. With equal concentrations of the free radicals, the same steric factors, molecular diameters and activation energies, the rates of formation and hence the quantities produced should be in this same ratio. Assuming the same activation energies, the steric factors (or molecular diameters) must increase in the reverse order. This might imply that the more complex the quasi-molecule the greater the chance of a suitable *three-body collision*, a not unexpected result.

Reactions (8) and (9) involve small heats of reaction and for (8) Rice and Herzfeld give a heat of activation of 10,000 cal. This accounts for the fact that little diketone is formed at the higher temperature.

Summary

1. Photochemical decomposition of ethyl methyl ketone in the near ultraviolet (largely with the 3130 Å. line of mercury) leads to the production of diketones, approximately 11% of the reaction going in this way at room temperature.

2. The quantum yield of carbon monoxide formation from ethyl methyl ketone at room temperature with wave lengths from 1850 to 2000 Å. increases from about 0.70 to about 0.88 as the pressure decreases from 90 mm. to 0.1 mm.

3. Diketones are formed in this region of the spectrum. The formation of biacetyl has been shown spectroscopically.

---

[14] Rice and Herzfeld, THIS JOURNAL, **56**, 284 (1934).

4. The total quantum yield of ethyl methyl ketone decomposition with wave lengths below 2000 Å. is nearly one at low pressures when allowance is made for diketone formation.

5. At higher temperatures some methane is formed, but at room temperature the principal hydrocarbons are ethane, propane and butane in approximately equal amounts.

6. Possible secondary reactions have been discussed.

Studies on Aging and Properties of Precipitates. XXIII. The Postprecipitation of Ferrous Sulfide with Cupric Sulfide

By I. M. Kolthoff and Frank S. Griffith[1]

Böttger and Druschke[2] found that iron is found in a precipitate of copper sulfide when the latter is formed under such conditions that no precipitation of iron sulfide alone occurs. Even when the copper sulfide was precipitated from solutions which were 2 *N* in nitric, hydrochloric or sulfuric acid, iron was found in the precipitate. In the present paper it is shown that iron sulfide is not *co*-precipitated but *post*-precipitated with cupric sulfide.

Experimental

The materials used were c. p. products. The stock ferrous sulfate solution was kept in 0.1 *N* sulfuric acid, the latter inhibiting the air oxidation. A fresh solution was prepared frequently. Concerning the method of treatment of the solutions with hydrogen sulfide reference is made to previous papers.[3]

After shaking in an atmosphere of hydrogen sulfide for a given period of time the solutions were filtered and the precipitate washed with 0.1 *N* hydrochloric acid which had been saturated with hydrogen sulfide. The filtrate and washings were evaporated to a volume of 25–50 ml., thus removing the hydrogen sulfide, 5 ml. of 5 *N* hydrochloric acid was added and any ferric iron formed reduced with a slight excess of stannous chloride. After the further classical treatment the ferrous iron was titrated with 0.05 *N* potassium dichromate using sodium diphenylamine sulfonate as indicator. In those cases in which the amount of iron removed from solution was very small the iron was determined in the washed precipitate. The latter was dissolved, the iron oxidized and precipitated with ammonia. The precipitate was dissolved, the iron reduced to the ferrous state and titrated with 0.005 *N* potassium dichromate.

Experimental Results

In order to get an impression of the order of magnitude of the precipitation of iron, various preliminary experiments were carried out. One hundred ml. of solution containing 5 mmol. of cupric sulfate and 1.25 mmol. of ferrous sulfate and being 1.55 *N* in sulfuric acid (after precipitation of copper 1.65 *N*) was treated with hydrogen sulfide for fifteen minutes, filtered, and the iron determined in the precipitate. Only 0.05 mg. of iron or 0.07% of the original amount was found in the precipitate. The experiment was repeated with the solution heated to 95° before saturating with hydrogen sulfide; 0.19 mg. of iron (0.27%) was found in the precipitate. A similar set of experiments was run with the solution being 0.53 *N* in sulfuric acid (after precipitation of copper sulfide 0.63 *N*): precipitation at room temperature, 0.42 mg. of iron in precipitate (0.60%); precipitation started at 95°, 0.75 mg. of iron in precipitate (1.07%). The amounts of iron found in the precipitates (room temperature) are about one-fifth of those expected from the results of Böttger and Druschke. However, these authors do not state the time of precipitation; it is shown later that the amount of iron entering the precipitate increases with the length of time of contact with the copper sulfide.

Evidence of Postprecipitation: Effect of Time before Filtration, Concentration of Acid and of Temperature.—In the following experiments a mixture was used containing 5 mmol. of copper sulfate and 1.25 mmol. of ferrous sulfate in 100 ml. In some of the experiments the iron was present during the precipitation of the copper sulfide, in others it was added one or two minutes after precipitation of the copper. Hydrogen sulfide was bubbled through continuously during the course of the experiments; in the one-month experiments the gas outlet, after a few hours, had a fine capillary. The flasks were shaken continuously except in the one-month experiments. After the period of shaking given in Table I the filtrates were analyzed for iron.

From the fact that the extent of precipitation of the iron is about the same, regardless of whether the copper sulfide is precipitated in the presence of iron or the iron is added after precipitation of copper, it follows conclusively that we are dealing with a phenomenon of postprecipitation. The amount of postprecipitation decreases rapidly with

[a] Temperature is given at beginning of experiment after precipitation of copper sulfide. No further heat was applied.
[b] The suspension was reheated to 95° four times during the course of an experiment.

increasing sulfuric acid concentration. The rate of postprecipitation and probably also the amount of postprecipitation increases with the temperature. It is doubtful whether distribution equilibrium of iron between solution and solid has been attained in any of the experiments. The copper sulfide ages with time and, as will be shown later, its effect upon the postprecipitation of iron decreases with increasing age.

Precipitation at Higher Temperatures.—When higher temperatures were *maintained* the rate of postprecipitation was found to be much greater. Experiments were carried out with solutions of the same composition as those in Table I, the acid concentration being 0.125 *N*. The following are a few typical figures: temperature 50°; precipitated after one hour 7.0%, after four hours 8.0%, after thirty hours 9.6% of iron. Temperature 90°, precipitated after forty-five minutes 13 to 14% of iron, after twelve hours 15 to 16%. Apparently, most of the postprecipitation occurs during the first fifteen to thirty minutes.

Effect of Varying the Iron and Acid Concentrations.—In the following experiments 100 ml. of solution was taken containing 5 mmol. of copper sulfate and varying amounts of ferrous sulfate and sulfuric acid. The solutions were heated to the boiling point, put on the shaker in the air-bath at 95° and hydrogen sulfide was passed through for one hour. At the time these experiments were performed it was believed that the iron sulfide was present in the solid phase in the form of a solid solution. The experiments were made with the intention of determining the distribution coefficient of the iron sulfide between the liquid and solid phases. From the results given in Table II it is seen that the amount of iron postprecipitated increases with increasing iron concentration of the solution and decreases markedly with increasing acid concentrations, but the value of the distribution coefficient of the iron sulfide calculated from the results was not found to be constant. From the analytical view-point it is of interest to mention that no postprecipitation of iron is found at room temperature from solutions being at least 0.5 *N* in hydrochloric or 1 *N* in sulfuric acid, when filtration is made soon after the precipitation of copper.

TABLE II

EFFECT OF CONCENTRATION OF IRON AND OF ACID

Concn. of H_2SO_4 after pptn. of CuS, *N*	Concentration of $FeSO_4$ Original	Concentration of $FeSO_4$ Final *M*	Fe in ppt., %	Fe in ppt., mmol.

[a] Ten millimoles of copper sulfide instead of five.

Postprecipitation of Iron Sulfide with Aged Copper Sulfide.—At room temperature it was found to make little difference whether the iron was present during the precipitation of copper sulfide or added a few minutes afterward. At higher temperatures, however, the amount of iron found postprecipitated was always less (3 to 4%) when the iron was added after precipitation of the copper sulfide, indicating a rapid aging of copper sulfide at elevated temperatures. In order to study the effect of aging more systematically experiments were carried out in the following way. The acidified copper solution was introduced in an Erlenmeyer flask closed by a rubber stopper with two holes. Through one hole passed the inlet tube of the hydrogen sulfide; through the other a tube sealed to an ampoule containing 10 ml. of acid iron solution. The bottom of the ampoule had been blown thin in order to facilitate breaking. It was provided with a small hole in the neck which served as an exit for the gas. The copper solution was heated to the boiling point, and kept there for at least five minutes to bring the iron solution in the ampoule to the same temperature. After this time the flask was placed in a box maintained at 90°, and hydrogen sulfide passed through the copper solution. The mixture was shaken for the time specified in Table III as the "age of CuS" after which time the iron solution was added by punching a hole in the bottom of the ampoule with a glass rod. After shaking for fifteen minutes more the mixture was filtered and the filtrate analyzed for iron. The mixture contained 5 mmol. of copper sulfide, and 1.25 mmol. of ferrous sulfate in 100 ml.; the sulfuric acid concentration after adding the iron solution was 0.125 *N*.

Table III

Effect of Aging of Copper Sulfide at 95°

Age of CuS	0	2 min.	7 min.	20 min.	4 hours	17 hours	36 hours
Fe in ppt., %	12.5	9	6.0	5.5	2.0	0–1	0

The copper sulfide ages rapidly at 95° and becomes much less effective in its promotion of the precipitation of iron sulfide. Kolthoff and Pearson[4] showed that aged copper sulfide is more effective than the fresh product in causing the postprecipitation of zinc sulfide. The mechanism of the zinc postprecipitation is quite different from that of iron sulfide. The zinc sulfide separates from supersaturated solution as a separate phase; the iron, on the other hand, is removed from a solution undersaturated with respect to ferrous sulfide.

The rapid aging of cupric sulfide at 95° explains why it is not possible to attain distribution equilibrium of the iron in the long period experiments. Thus, working at 95° it was not possible to obtain more than 16 to 18% of the iron in the precipitate under conditions specified in Table I (final acidity 0.125 *N*). When, on the other hand, the copper solution was added slowly to the acid ferrous sulfate solution which was kept at 95° and saturated with hydrogen sulfide it was possible to obtain a precipitate containing 23 to 25% of the iron (final conditions as above).

All results reported so far indicate that the iron sulfide in the solid phase is present either as a solid solution or in the form of a chemical compound. X-ray investigations, kindly carried out by Mr. M. L. Fuller[5] of the New Jersey Zinc Co., Palmerton, Penna., by the power method with a mixed precipitate revealed the lines of copper sulfide and of chalcopyrite, $CuFeS_2$. Apparently, then, the speed of formation of copper sulfide is greater than that of chalcopyrite. The former, however, is not stable in the presence of ferrous iron and hydrogen sulfide in the solution, and at not too high acidities, it is slowly transformed into chalcopyrite.

Solubility of Ferrous Sulfide.—It has been stated before in this paper that the iron sulfide is postprecipitated with copper sulfide from solutions in which the solubility product of iron sulfide is not exceeded. Since the solubility of most slightly soluble sulfides depends much upon the degree of perfection and crystal modification it was decided to determine the solubility of iron sulfide aged under various conditions. Bruner and Zawadski[6] determined the solubility of ferrous sulfide by passing hydrogen sulfide through solutions of ferrous sulfate until equilibrium was reached and by dissolving ferrous sulfide in dilute acid. As an average they obtained in solutions saturated with hydrogen and ferrous sulfides a value of $[Fe^{++}]/[H^+]^2$ of 3.4×10^4. Moser and Behr[7] dissolved in 0.01 *N* sulfuric acid a product which had been precipitated at room temperature and aged for eighteen hours. Using the value of Noyes and Sherrill[8] for the second dissociation constant of sulfuric acid a value of $[Fe^{++}]/[H^+]^2$ of 5.5×10^4 is calculated from their data.[9]

The determination of the solubility of both fresh and well-aged iron sulfide was attempted. The following products were used:

Product 1: Fresh.—A solution of 30 g. of ferrous sulfate and 100 g. of ammonium acetate in 100 ml. of water was kept saturated with hydrogen sulfide at room temperature for one hour. A portion of the precipitate was washed four times with 0.012 *N* hydrochloric acid using the centrifuge for separating liquid and solid.

Product 2.—A solution of 28 g. of ferrous sulfate and 15 g. of sodium acetate in 100 ml. of water was kept saturated with hydrogen sulfide for eighteen hours at room temperature and the precipitate collected.

Product 3.—A molar solution of ferrous sulfate was saturated with hydrogen sulfide at 0°, the bottle containing the suspension was closed by a rubber stopper held by a wire and placed on the sand-bath at 80° for ten days (final *p*H was 2.30). The product was composed of black crystals sufficiently large to be seen by the naked eye.

An excess of the iron sulfide was shaken with acid, which previously had been saturated with hydrogen sulfide, for eight hours or longer. The sulfide was then allowed to settle or was centrifuged and the clear solution siphoned out of the flask by means of hydrogen sulfide under pressure from the Kipp generator. The hydrogen ion activity of the solution was determined colorimetrically or by means of the glass electrode and the iron content after filtration was determined by the dichromate method. The results are given in Table IV.

Table IV

Solubility of Iron Sulfide of Various Age in Acid at 25° (Direct Method)

Product used	Age	HCl, *N*	*p*H	Ml. 0.05 *N* $K_2Cr_2O_7$ for titrn. 50 ml. of soln.	$[Fe^{++}]/[H^+]^2$
1	Fresh	0.012	3.50 3.60[a]	5.75–5.46	8.3×10^4
1	Fresh	.012	3.60[b]	6.05	9.7×10^4
2	18 hrs., r. t.	.012	3.45[a]	6.33	5.0×10^4
3	10 days 80°	.025	3.19[b]	13.46	3.2×10^4
3	10 days 80°	.025	3.23[b]	12.20	3.5×10^4
3	10 days 80°	.025	3.18[b]	12.85	2.9×10^4
3	10 days 80°	.025	3.13[b]	11.95	2.2×10^4
3	10 days 80°	.025	3.20[b]	11.80	2.0×10^4

[a] Measured colorimetrically with tetrabrom phenol blue.

[b] Measured with the glass electrode.

It should be mentioned that an error of 0.05 in *p*H causes an error of 20% in the value of the quotient $[Fe^{++}]/[H^+]^2$. The value obtained with product 2 (5.0×10^4) which was prepared according to the directions of Moser and Behr[7] is in good agreement with that calculated from these authors' figures (5.5×10^4). From the results in Table IV it is seen that the solubility of iron sulfide depends little upon the age of the product, the value of $[Fe^{++}]/[H^+]^2$ being about 9×10^4 for a fresh product and about 3×10^4 for drastically aged products.

[8] M. S. Sherrill and A. A. Noyes, This Journal, **48**, 1861 (1926).

[9] Kolthoff, *J. Phys. Chem.*, **35**, 2711 (1931), in calculating this ratio from Moser and Behr's data made a mistake in that he failed to take into account the decrease of the concentration of the strong acid by the dissolved iron sulfide.

It was also attempted to reach solution equilibrium from the other side. One hundred milliliters of 0.125 *M* ferrous sulfate was placed in a flask which was shaken continuously while a slow stream of hydrogen sulfide was passed through. If the time of precipitation was longer than seven days, the flask was stoppered after that time and allowed to stand without further shaking.

TABLE V

SOLUBILITY OF IRON SULFIDE AFTER PRECIPITATION

Time of pptn.	Temp., °C.	*p*H	Ml. of 0.05 *N* $K_2Cr_2O_7$ for titrn. of 10 ml. of soln.	$[Fe^{++}]/[H^+]^2$
20 hours	25	3.01	23.68	1.2×10^5
70 hours	25	2.94	23.64	9.0×10^4
7 days	25	2.64	23.33	2.2×10^4
1 month	25	2.00	20.90	1.0×10^3
20 hours	90	2.60	23.28	1.9×10^4
70 hours	90	2.31	27.65	5×10^3

The solubility of iron sulfide at 90° in solutions saturated with hydrogen sulfide seems to be slightly less than that at room temperature. The figures indicate that the postprecipitation of iron sulfide with copper sulfide even at higher temperature (Tables I, II and III) cannot be a separation of the former in the pure form.

In order to substantiate this conclusion in an unequivocal way the following experiment was carried out. One hundred ml. of 0.0125 *M* ferrous sulfate in 0.125 *N* sulfuric acid was saturated with hydrogen sulfide and heated to the boiling point, whereupon some of the well-aged, crystalline product No. 3 of iron sulfide was added. The mixture was shaken for one hour at 90° while hydrogen sulfide was passed through the flask. The filtrate and washings required 41.9 ml. of 0.05 *M* potassium dichromate, whereas the original iron solution required only 26.00 ml. Thus, some of the iron sulfide had gone into solution. If cupric sulfide instead of the well-aged iron sulfide had been added (Tables I, II) some of the iron would have been removed from solution. This conclusion is in agreement with the results of the X-ray analysis, which showed that the iron is present in the precipitate in the form of chalcopyrite.

That the postprecipitated iron sulfide is incorporated in the copper sulfide precipitate was also shown by experiments in which mixed precipitates were extracted with 0.2 *N* hydrochloric acid. Hardly any of the postprecipitated iron was extracted. Even upon washing at room temperature with 1 and 3 *N* hydrochloric acid (saturated with hydrogen sulfide) it was impossible to extract all of the iron. A hot extraction with 3 *N* acid removed all of the iron.

Finally, experiments were made in which zinc and mercuric sulfides instead of cupric sulfides were used as promoting agents of the precipitation of iron in acid solution. In agreement with Böttger and Druschke[2] it was found that these sulfides did not cause the precipitation of any iron at room temperature and at 80° at an acidity of 0.125 *N* sulfuric acid, even after seventeen hours of shaking.

Summary

1. Iron sulfide is postprecipitated with cupric sulfide from acid solutions which are undersaturated with regard to pure ferrous sulfide. The postprecipitated iron sulfide is difficultly extracted with 3 *N* hydrochloric acid. The presence of $CuFeS_2$ in the mixed precipitate was shown by X-ray analysis.

2. The rate of postprecipitation is small at room temperature but large at 70–95°. Due to aging of the cupric sulfide it is difficult to attain the true state of equilibrium.

3. The amount of postprecipitated iron increases with increasing ferrous iron concentration and decreasing hydrogen ion concentration and increasing amounts of cupric sulfide.

4. The promoting effect of cupric sulfide upon the precipitation of iron sulfide decreases rapidly upon aging at 90°.

5. The solubility of fresh iron sulfide expressed by the ratio of $[Fe^{++}]/[H^+]^2$ in solution saturated with hydrogen sulfide was found to be 9×10^4 at room temperature, that of mildly or drastically aged products 5 to 3×10^4.

The Ternary Systems Sodium Iodate–Sodium Chlorate–Water and Potassium Iodate–Potassium Chlorate–Water at 25 and 50°

BY JOHN E. RICCI

Introduction.—The results of studies of ternary systems involving either sodium iodate or sodium chlorate indicated that it would be interesting to investigate the system sodium iodate–sodium chlorate–water. Sodium iodate, for example, is known to exhibit a rather marked tendency to form double compounds with other sodium salts, such as sodium chloride, bromide, iodide, nitrate and sulfate.[1] Sodium chlorate, on the other hand, has been found so far to form only one double salt, namely, $NaClO_3 \cdot 3Na_2SO_4$.[2] The present solubility measurements on the system sodium iodate–sodium chlorate–water were made for the purpose of extending the information on the two series of salts, alkali iodates and alkali chlorates, and to investigate any possible compound formation or solid solution taking place between the two specific salts at these temperatures. The system potassium iodate–potassium chlorate–water was studied simultaneously, both to extend the measurements to the corresponding potassium salt system and, by taking advantage of the more certain attainment of equilibrium in the latter system, to use it as a check on the analytical method needed for the investigation of the more troublesome sodium salt system. The results of the phase rule study of these systems, at 25 and 50°, indicate no compound formation in either combination, and no solid solution for any of the solid phases, within the limits of experimental accuracy.

Materials and Methods.—The sodium and potassium iodates were recrystallized C. P. material, dried at 100–110°. Analysis by titration with standard sodium thiosulfate (standardized against very pure potassium iodate), showed them both to be 100.0% pure. The chlorates were high grade C. P. material, powdered and dried at 150–200°.

The procedure for the solubility determinations was in general that usually described for similar phase rule investigations. Densities of saturated solutions, reported for the 25° isotherms, were determined by means of pipets calibrated for delivery. Temperatures were controlled to ±0.01°.

For the analysis of the saturated solutions, the iodate was determined by treatment with excess of potassium iodide and a limited amount of acetic acid, and titration of the liberated iodine by means of standard thiosulfate solution. Tests showed this method for the determination of iodate in the presence of large amounts of chlorate to be very exact. The procedure was to treat the iodate–chlorate solution, diluted to 50–60 ml., with 5–6 g. of potassium iodide and 2 ml. of glacial acetic acid, and to titrate at once with thiosulfate. In such low acidity the interference due to oxidation of iodide by even large amounts of chlorate, proves to be altogether negligible, while the reaction of the iodate is complete and rapid. Employing this acidity throughout, very small amounts (0.1 to 0.3 g.) of sodium iodate were titrated in the presence of up to 20 g. of sodium chlorate, the determination proving exact in every case (the average error being one part in three thousand).

A similar procedure was described by Barneby,[3] who, however, tried it in the presence of much smaller amounts of chlorate only.

The total dissolved solid was determined by evaporation to dryness, and the chlorate salt then calculated by difference.

No difficulty was encountered in the solubility determinations for the potassium salt system. The usual procedure—preparation of complexes of exact composition, analysis of the filtered saturated solution and identification of solid phases by algebraic extrapolation of the tie-lines connecting these two compositions—proved satisfactory and very accurate. To ensure attainment of equilibrium, the mixtures were stirred for periods of five to nine days, and the equilibrium checked by repeated analysis of the solution. The mean error of the extrapolation of tie-lines to the compositions of the pure phases was only 0.09%, verifying the applicability of the titration method employed and the dependability of the experimental procedure in general.

The attainment of solubility equilibrium in the sodium iodate–sodium chlorate system is much slower. Complexes of exact composition can be prepared only from anhydrous sodium iodate, while the stable phase for this salt, for the whole of the 25° and part of the 50° isotherm, is the monohydrate, $NaIO_3 \cdot H_2O$. The hydration of sodium iodate, however, particularly in the presence of high concentrations of other salts, is extremely slow in reaching completion. In every case in which the original sodium iodate was seeded with monohydrate crystals in the presence of dissolved sodium chlorate, even though the solid phase formed was always quite obviously the correct hydrate from its very distinctive appearance, nevertheless the mathematical extrapolation of tie-lines through the points representing saturated solution and total complex was always such as to indicate that the remaining solid contained about 1% either of sodium chlorate (in solid solution) or of unchanged anhydrous sodium iodate. This was observed repeatedly even for mixtures stirred for as long as sixty days (at 25°). Many experiments were

[3] Barneby, *ibid.*, **38**, 330 (1916).

made with this procedure, the results of which, however, are not included in the tables here presented, inasmuch as it was proved subsequently that the apparent deviation of the composition of the solid phase from that of pure $NaIO_3 \cdot H_2O$ was due simply to lack of equilibrium or incomplete hydration, and that there is in reality no formation of mixed crystals at all at the temperatures studied.

The procedure finally employed to obtain equilibrium results for this system, wherever the solid phase is $NaIO_3 \cdot H_2O$, involved the addition of the component sodium chlorate to mixtures already containing the completely hydrated $NaIO_3 \cdot H_2O$ and water, obtained by stirring sodium iodate and water, seeded with the monohydrate, for several days. As the composition of the total complex could not be known with any accuracy in such a procedure, the wet residue was analyzed in every case, and the solid phase then identified by algebraic extrapolation through saturated solution and wet residue. A check on the attainment of equilibrium was again made and the minimum time allowed (six days at 25°) was found to be sufficient; the analysis of one solution, stirred for six days, gave 1.52% $NaIO_3$ and 43.00% $NaClO_3$; after nineteen more days, 1.52% $NaIO_3$ and 42.98% $NaClO_3$.

For all other solid phases in both systems, at the temperatures studied, equilibrium was readily attained from the original complexes of exact composition, and the phases were regularly identified by ordinary algebraic extrapolation through solution and total complex. At 50° in the sodium salt system, metastability for either anhydrous or hydrated sodium iodate can be maintained easily, in the first case by starting with anhydrous sodium iodate and not seeding, and in the second case by following the procedure described above, hydrating the sodium iodate completely before addition of sodium chlorate.

TABLE I

exist in the pure state, without the formation of mixed crystals, within the limits of the accuracy of the algebraic extrapolation of tie-lines. For the case of the phases anhydrous sodium chlorate and anhydrous sodium iodate, this accuracy is quite high, since the extrapolation is performed through the accurately analyzed solution and the composition of a total complex of exact preparation. The mean absolute deviation from purity for these solid phases, as indicated by the extrapolations for both temperatures, was 0.026%, the algebraic mean being less than 0.004%. For the monohydrate of sodium iodate as solid phase, the extrapolation was by means of the saturated solution and the composition of the wet residue. At 25°, at which temperature the wet residue can be analyzed quite accurately, the mean absolute deviation of the extrapolated tie-lines from the point representing $NaIO_3 \cdot H_2O$ was 0.14%, the mean algebraic error being only −0.03%. At 50°, however, a wet residue cannot be analyzed so accurately, due to evaporation during sampling; as a consequence the absolute average error of extrapolation at this temperature was 0.38%, the algebraic average, however, being only −0.08%.

It can be said, therefore, that for all phases and at both temperatures the salts exist in the pure state, without formation of mixed crystals.

Anhydrous sodium iodate exists as a stable solid phase for the system $NaIO_3$–$NaClO_3$–H_2O at 50°, at high concentrations of sodium chlorate, even though the transition temperature between anhydrous and monohydrated sodium iodate in the binary system with water is 23.4° above this temperature. At the same time the solubility curve of the monohydrate can be followed continuously to a metastable isothermally invariant point, at which the solid phases are $NaClO_3$ and $NaIO_3 \cdot H_2O$. The two solubility curves, however—that for anhydrous and that for hydrated sodium iodate—are so nearly parallel and close together that it would be very difficult to determine their point of crossing directly. It can be estimated, nevertheless, from the concentration of sodium iodate along the two curves, that the isothermally invariant point representing equilibrium between the two forms of the iodate must have the approximate composition 2.2% $NaIO_3$ and 45% $NaClO_3$. At higher concentrations of sodium chlorate the anhydrous sodium iodate has the lower solubility and is therefore the stable phase. These relationships are indicated in the table of results for this isotherm, but cannot be shown with any clearness in the figure.

Summary

Solubility measurements are given for the two ternary systems KIO_3–$KClO_3$–H_2O and $NaIO_3$–$NaClO_3$–H_2O at 25 and 50°. Neither compound formation nor solid solution is observed for either system at these temperatures. In the 50° isotherm of the system $NaIO_3$–$NaClO_3$–H_2O, anhydrous sodium iodate is found to exist as a stable phase over a limited range of the solubility curve at high concentrations of sodium chlorate.

The Solubility of Halides in Anhydrous Acetic Acid

BY ARTHUR W. DAVIDSON AND WILBERT CHAPPELL

It was reported by Benrath,[1] as early as 1905, that a large number of chlorides are appreciably soluble in glacial acetic acid and may be crystallized unchanged from such solutions. Quantitative data on the solubility of halides in this solvent are limited, however, to the still earlier work of Étard[2] on mercuric chloride, the studies of Menschutkin on systems of acetic acid with calcium chloride, magnesium bromide and iodide,[3] and antimony chloride and bromide,[4] and the recent determination by Scholl, Hutchison and Chandlee[5] of the solubility of barium chloride in pure acetic acid and in the presence of various concentrations of sodium bromide.

The present paper includes solubility data, over a wide range of temperature, for sodium, potassium, ammonium, barium, strontium, cupric and mercuric chlorides, as well as for mercuric bromide and iodide. Of these salts, strontium chloride proved to be by far the most soluble at room temperature, and mercuric chloride to have the greatest solubility at the boiling point of the solvent. Experiments with cadmium chloride showed the solubility of this salt to be too small to be measured.

Method

Preparation of Materials.—Pure anhydrous acetic acid was prepared as described in previous papers of this series. All the salts used, except mercuric bromide and iodide, were purified by recrystallization and dried to constant weight under suitable conditions. Mercuric bromide and iodide were prepared by precipitation, and were dried for several days at 110 to 115°.

Determination of Solubility.—In every case except for the chlorides of barium and strontium, the synthetic method, as described in previous papers, was used. Duplicate determinations, with the usual precautions, were made of the equilibrium temperatures. The values given are believed to be correct to within 1° in the case of ammonium chloride and the mercuric halides, and to within 3° elsewhere, even in the case of cupric chloride, which gives a very steep temperature–concentration curve.

For barium and strontium chlorides the analytical method was used for determining solubilities. About 100 cc. of the solvent was placed in contact with an excess of the solid solute in a tightly stoppered bottle, which was then maintained at the desired temperature in a suitably adjusted thermostat. After equilibrium had been reached, filtered samples were withdrawn by means of a pipet with a bit of cotton fitted over its tip, and the chlorine content of each sample was determined by the usual gravimetric method.

Analysis of Solid Phases.—The solids to be analyzed were separated from their saturated solutions by filtration with gentle suction, rapidly pressed between dried pieces of porous tile, and allowed to remain over pellets of sodium hydroxide in a desiccator, for a few minutes only. Samples were then weighed as quickly as possible, and their chlorine content was determined in the usual way.

Results

Cupric, Sodium, Potassium and Ammonium Chlorides.—In the tables given below, S denotes the mole percentage of solute, and T the corresponding equilibrium temperature. These data are presented graphically in Fig. 1.

In the case of the alkali chlorides, the solid phases that separated from the saturated solution were shown, by analysis, to be the unsolvated salts. In the case of the copper salt it was impossible to obtain sufficient solid for an accurate analysis, but the brownish-yellow color of the crystals indicated that they probably consisted of unsolvated cupric chloride.

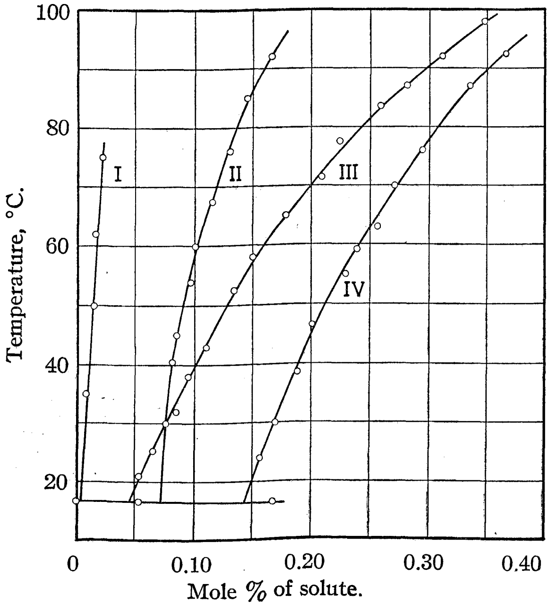

Fig. 1.—Solubility curves for $CuCl_2$ (I), NaCl (II), NH_4Cl (III) and KCl (IV) in anhydrous acetic acid.

Because of the extremely slow rate at which the alkali chlorides dissolve in acetic acid at low temperatures, there was room for some doubt as to whether or not the temperatures at which disappearance of crystals was observed, corresponded to true equilibrium. In order to check this point, analyses were made on solutions which had been maintained at 30°, with continuous agitation, for ten days, after having been heated to 100° for an hour in contact with excess solute. The solubility values so obtained, in mole %, are compared below with those obtained by interpolation from the preceding tables. It will be noted that the agreement, even at this low temperature, is fairly good. Incidentally, the value given by Eichelberger[6] for the solubility of ammonium chloride (temperature not specified) corresponds to 0.078 mole %.

	NaCl	NH_4Cl	KCl
Solubility, synth.	0.076	0.076	0.170
Solubility, anal.	.073	.080	.175

Barium and Strontium Chlorides.—The solubility of barium chloride is too low to be determined accurately by the synthetic method. Analysis of solutions saturated by contact with excess solid for a week at 30 and at 45° gave, respectively, 0.0077 and 0.0100 mole % of solute. The figure given by Scholl, Hutchison and Chandlee[5] (p. 3084) for the solubility at 25° is equivalent to 0.0059 mole %.

Preliminary experiments with strontium chloride immediately revealed that its solubility in acetic acid rapidly diminishes with increasing temperature. An attempt was made to determine the solubility by noting the temperature at which the last of the solid phase just disappeared, on *cooling* the solution; the crystals dissolved too slowly, however, for concordant results to be obtained by this method. Accordingly, a saturated solution was prepared at about 15°, and transferred to a thermostat at the desired temperature. An abundant crop of crystals was formed, and equilibrium was attained after agitation of the mixture for twelve hours. That portion of the freezing point curve in which acetic acid was the solid phase, however, was obtained by the determination of equilibrium temperature in the usual manner.

[6] Eichelberger, THIS JOURNAL, **56**, 799 (1934).

The data are tabulated below, and plotted in Fig. 2.

STRONTIUM CHLORIDE–ACETIC ACID

S	*T*	*S*	*T*
(a) Solid phase $HC_2H_3O_2$		(b) Solid phase $SrCl_2$	
0	16.60	1.67	98.9
0.55	16.32	2.22	83.0
1.09	16.05	3.28	60.0
1.81	15.68	4.04	45.0
3.07	15.05	5.12	30.0
3.93	14.50	6.11	19.0
5.11	13.65		

Analysis of solid phase (b) showed it to be unsolvated. It will be noted that the solubility of the salt at 20° is almost four times as great as at 100°; up to the present, this is the only case of retrograde solubility to have been observed in an acetic acid system.[7]

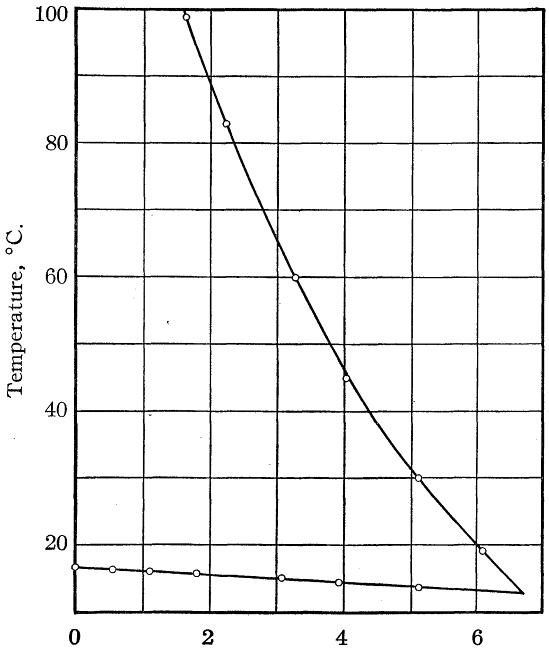

Fig. 2.—System $SrCl_2$–$HC_2H_3O_2$.

Mercuric Halides.—Unlike the alkali chlorides, the mercuric halides were found to dissolve rather rapidly in acetic acid, so that saturation equilibria were readily attained in these systems. It is noteworthy that when a solution of mercuric iodide, saturated at 100°, was suddenly chilled to about 60°, the crystals deposited consisted of the metastable yellow variety of the salt; when the mixture was stirred, this gradually changed to the stable scarlet form. The intense color of the latter greatly facilitated the accurate determination of equilibrium temperatures.

The data are tabulated below, *S* and *T* having

(7) The solubility of strontium chloride in water shows no such trend. In aqueous solution, however, the solid phases in equilibrium with the saturated solution, at least up to 200°, are hydrates, not the unsolvated salt. See Menzies, THIS JOURNAL, **58**, 934 (1936).

the same significance as before, and are presented graphically in Fig. 3.

In series I, the solid phase was shown to be unsolvated by the fact that a 1-g. sample did not impart any appreciable acidity to the water in which it was suspended. In II, analysis for bromine gave a result in accord with the composition of the unsolvated salt.

Benrath[1] (p. 237) reported that mercuric chloride may be recrystallized unchanged from glacial acetic acid. The course of the solubility curve here obtained, however, clearly indicated the existence of two distinct solid phases of the solute, with a transition point at 33°. The mean of two analyses[8] of the solid phase III (b) gave Cl, 17.68% (calcd. for $HgCl_2 \cdot 2HC_2H_3O_2$, 18.11%); while the mean of three analyses of solid phase III (c) gave Cl, 25.61% (calcd. for $HgCl_2$, 26.12%). Phase (b), then, is evidently a disolvate, which has not been reported previously. The solubility values presented in series III (b) and III (c) are, for the most part, considerably lower than those of Étard,[2] who represented the solubility curve throughout this region as a straight line, and overlooked the presence of a solvate.

Discussion

For purposes of comparison, the solubilities at 30° of the nine halides here studied have been brought together in Table I.

TABLE I

SOLUBILITY OF HALIDES IN ANHYDROUS ACETIC ACID AT 30°

Salt	Mole %	Moles per 1000 g. solvent	Salt	Mole %	Moles per 1000 g. solvent
$CuCl_2$	0.0070	0.0012	$SrCl_2$	5.12	0.899
NaCl	.075	.0125	$HgCl_2$ (disolvate)	0.936	.157
NH_4Cl	.080	.0133			
KCl	.175	.0292	$HgBr_2$	.284	.047
$BaCl_2$	.0077	.0013	HgI_2	.011	.0018

As might have been expected from their high melting points and small tendency toward solvation in this relatively slightly polar solvent, the first five of these salts are but slightly soluble in acetic acid. No explanation can be offered at present for the highly anomalous behavior of strontium chloride, whose differential heat of solution, at saturation, must be negative. The greater solubility of mercuric chloride, as compared to the alkali chlorides, is probably due to the lower melting point of the former and its greater tendency toward solvation. This salt is almost as soluble in acetic acid as in water, while mercuric bromide and iodide, especially the latter, are distinctly *more* soluble in acetic acid than in water.

Freezing point depression data, which were available over a wide concentration range in the case of strontium chloride, were used to calculate values of the freezing point divergence function, j, for these solutions. The value of j was found to remain practically constant, for molalities between 0.1 and 0.7, at 0.72. Such constancy in the value of j is in accord with previous observations for this solvent,[9] and its magnitude for this salt is almost identical with that found for the same concentration range in the case of strontium acetate.[10]

Summary

1. Solubility data over a wide range of temperature have been obtained for cupric, sodium, potassium, ammonium, strontium and mercuric chlorides, and mercuric bromide and iodide, and at 30 and 45° for barium chloride, in anhydrous acetic acid.

2. Strontium chloride has been found to exhibit retrograde solubility in this solvent.

3. The new solvate $HgCl_2 \cdot 2HC_2H_3O_2$ has been isolated and analyzed.

The Calculation of the Ionization Constants of Inorganic Oxygen Acids from their Structures

BY ALEXANDER KOSSIAKOFF[1] AND DAVID HARKER

Introduction

In a given solvent, the free energy of ionization of an acid is directly related to its atomic configuration. The object of this paper is the formulation of a theoretical approach to the evaluation of this relationship. Due to the importance which is generally attached to theoretical calculations correlating physical properties with the structures of molecular systems, it is hoped that the treatment presented here will prove of general interest.

The complicated nature of most acid molecules and of highly polar solvents renders a rigorous calculation of the free energy of ionization impracticable, if not entirely impossible. However, if the treatment is limited to non-resonating oxygen acids a number of reasonable assumptions may be made which facilitate a direct calculation of this quantity. The method of evaluation given here depends on the resolution of the free energy of ionization into one part which is essentially constant for all acids in a given solvent, and another part which depends strongly on the structure of the acid. The constant part constitutes a parameter in the equation; the variable part can be explicitly calculated from structural data. Having determined the parameter from the experimental ionization constant of a single acid, the constants of other acids are uniquely determined. The procedure is simple and direct, enabling a calculation of the ionization constant of an inorganic oxygen acid to be made in a short time with an average accuracy of ±0.8 in log K.

Previous Work.—The wide variation found in the ionization constants of acids has aroused the interest of many investigators. The majority of these have contented themselves with making purely qualitative observations. G. Oddo[2] noted that the ratio of oxygen to hydrogen atoms in an oxygen acid was related to its strength. Hantzsch and Langbein[3] observed that the strength of an acid increased with the number of oxygen atoms per replaceable hydrogen and with the negativity of the central atom. Similar qualitative correlations have been made by a number of other authors.[4]

The problem has been treated quantitatively by Smallwood[5] and by van Arkel and Carriere.[6] Smallwood calculated the relative strengths of some organic acids on the basis of dipole interaction. Since carboxylic acids are resonating systems, it is impracticable to check Smallwood's calculations by the method of this paper. Van Arkel and Carriere attempted to calculate the strengths of acids from the assumption that the charge distribution in the acid molecule is determined by the ions formed by the separate atoms. This assumption is not in agreement with the known structures for most of these molecules, and it is consequently not surprising that the treatment does not lead to results in agreement with experiment. It may be noted that neither Smallwood nor van Arkel and Carriere have considered the properties of the solvent.

Mechanism of Ionization.—There is good evidence that the ionization of an acid takes place through the transfer of the proton from the anion to a water molecule followed by the subsequent exchange of protons between water molecules.[7] The absence of free protons in solution, together with the abnormally large mobility of hydronium ion, provide ample justification for this picture. As will appear later, the mechanism involving proton exchanges is extremely valuable in simplifying the calculation of acid strength. The process may be symbolized thus

and so forth. This process removes the proton from the anion and reorients the water molecules in the immediate vicinity of that oxygen on the anion from which the proton has been removed. Thus, there is no extensive displacement of water, but there is a certain amount of reorientation. It will be seen from the subsequent discussion that a calculation of the free energy change involved in this process is a good approximation to the total free energy of ionization of an acid.

By confining our attention to non-resonating oxygen acids of the non-metallic elements, we are enabled to make approximations which permit the calculation of their free energies of ionization. Oxygen acids—those in which the removable proton is attached to an oxygen atom—comprise a large majority of the inorganic acids, and consequently the limitation of the treatment to this class causes no great loss in scope. The lack of knowledge concerning the energetics of resonating systems requires the elimination of the acids of boron, carbon, and nitrogen from the present treatment. A careful consideration of the ionization process for the non-resonating oxygen acids makes the following assumptions reasonable:

1. The forces between a proton and an acid ion are due to an electron-pair bond with the nearest oxygen atom and to the electrostatic field of the ion.
2. The hydroxyl electron-pair bond is the same for all acids. Variations in strength from one acid to another are due solely to changes in the electrostatic field and symmetry of the ion.
3. Acid and anion molecules form hydrogen bridges to adjacent water molecules, and orient the more distant water molecules by their electrostatic fields. These effects constitute the hydration of the molecules.

The first assumption is based on the fact that exchange forces diminish rapidly with distance and, therefore, will be extremely small between non-bonded atoms. The second assumption is reasonable due to the similarity of the binding of the central atom to the oxygens in the various acids. The third assumption is an expression of the geometry of hydration of anions and acid molecules. Hydroxyl groups rigidly orient the water molecules surrounding them thus:  $\mathrm{M{-}O{-}H{-}{-}{-}O}\langle^{\mathrm{H}}_{\mathrm{H}}$, non-hydroxyl oxygen thus:  $\mathrm{M{-}O{-}{-}{-}H{-}O}\backslash_{\mathrm{H}}$.

Analysis of the Free Energy of Ionization.—Consider an elementary ionization process, in which a particular proton is transferred from a given acid molecule to a particular water molecule. The reversible work done on the system is the sum of the work done in each of the following processes.

1. Rupture of the O–H bond in the acid molecule.
2. Formation of the O–H bond in hydronium ion, H_3O^+.
3. Removal of the proton from the electrostatic field of the anion.
4. Reorientation of the water molecules.
5. Compression of the water molecules.
6. Change in volume of the system against atmospheric pressure.

Let A_1 to A_6 represent the reversible work done on the system in the processes 1 to 6, respectively. The work done on the system, ΔA, is given by the expression

$$\Delta A = \Delta F - \Delta(PV)$$

At constant pressure $\Delta(PV) = -A_6$, the work done against atmospheric pressure. Therefore, the free energy change, $\Delta F'$, for the elementary ionization process, defined above, may be written

$$\Delta F' = A_1 + A_2 + A_3 + A_4 + A_5 \qquad (1)$$

Assumption 2 implies that A_1 is constant for all the acids considered, and A_2 does not depend upon the acid involved.

A_5 is the change in the compression work during ionization. T. J. Webb,[8] in his calculation of the free energy of hydration of ions, has evaluated the compression work, W_c, in terms of the radii and charges of monatomic ions. For a univalent ion of radius 1.5 Å., W_c is calculated to be 1 kcal. It increases as the square of the charge for a monatomic ion. However, for a polyatomic ion containing widely separated centers of charge, W_c will increase approximately with the first power of the total charge. The polyatomic anions of the oxygen acids are cases intermediate between these two extremes. The increase of W_c with the charge of the acid anion will be, therefore, considerably less than second power. The deviations from constancy in A_5 for the large complex anions under consideration should not exceed 0.5 kcal. The error involved in assuming A_5 to be constant is, consequently, small enough to obviate the necessity of its calculation for each acid.

Since A_1, A_2, and A_5 are essentially constant for

---

[8] T. J. Webb, This Journal, **48**, 2589 (1926).

the acids under consideration, we make the approximation that

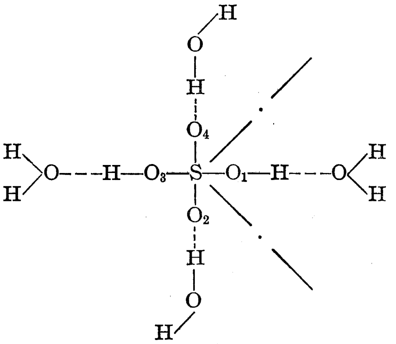
$$A_1 + A_2 + A_5 = C \qquad (2)$$

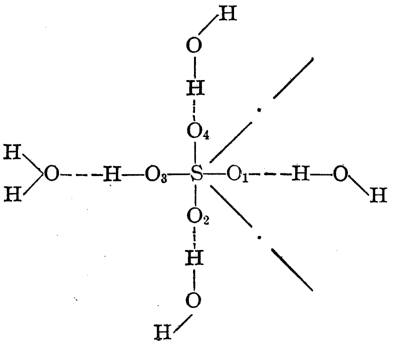
where C depends only on the temperature. Consequently

$$\Delta F' = A_3 + A_4 + C \qquad (3)$$

The Calculation of $A_3 + A_4$.—It is now necessary to show that $A_3 + A_4$ may be calculated by computing the work done in removing a proton from the anion by successive transfers between water molecules. It has been noted that this process reorients the water molecules in the immediate vicinity of that oxygen in the anion from which the proton has been removed. It remains to be shown that this work constitutes practically the entire work of reorientation resulting from the ionization process and, therefore, that A_4 is indeed included in the calculation.

The molecules of oxygen acids are, in general, complex structures, the peripheries of which consist of strongly orienting groups. The assumption has been made that these groups (oxygen and hydroxyl groups) rigidly orient the water molecules surrounding them in a definite way. The consequence is that upon ionization, which changes one hydroxyl group in the molecule into a free oxygen, only the water molecules surrounding this hydroxyl are reoriented. As an example consider H_2SO_4, which changes upon ionization into HSO_4^-. The molecules in the immediate neighborhood will be arranged thus





The main reorientation takes place in the solid angle including O_1, the waters surrounding O_2, O_3, and O_4 maintaining their original orientations. Obviously, the first two proton transfers produce the total change in orientation of the nearest neighboring waters. While subsequent transfers will not reorient all the more distant water molecules, the energy of reorientation of those water molecules which are neglected in the process is small, due to the much greater dielectric constant at large distances and to thermal agitation. Since a rigorous calculation of the total orientation effect would result in only a small correction, and would be extremely involved, the approximation is justified that the proton transfer mechanism calculation includes practically all of the reorientation energy which depends on the structure of the acid.

We write, therefore, the work required to remove the proton from the electrostatic field of the anion, A_3, plus that required to reorient the water molecules, A_4, to a sufficient approximation, as the sum

$$A_3 + A_4 = W_1 + W_2 + W_3 + W_4 + \ldots = \Sigma W_i \qquad (4)$$

where W_i is the change in potential energy accompanying the ith proton transfer. Webb[8] has shown that a calculation of the electrical work involved in a process of this type leads to a term in the free energy change (ΔF) rather than to a term in the internal energy change (ΔE).

The calculation will consist in the evaluation of the W_i's using the familiar formula for the change in mutual potential energy of two particles with charges q_1 and q_2 as the distance between them changes from r_1 to r_2

$$\Delta V = \int_{r_1}^{r_2} \frac{q_1 q_2}{\epsilon r^2}\, dr \qquad (5)$$

where ϵ is the dielectric constant.

In order to apply the formula, we must investigate the charge distribution in the anion and the dielectric properties of the medium.

Distribution of Charge.—There is considerable evidence that in an electron-pair bond between non-metallic atoms the two electrons are shared approximately equally.[9] Since the molecules of the acids under consideration are held together by single electron-pair bonds, we assign to each atom all its non-bonding and half its bonding electrons for the purpose of calculating its effective charge.[10]

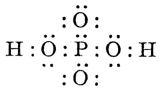
---

(9) L. O. Brockway and H. O. Jenkins, THIS JOURNAL, **58**, 2036 (1936).

(10) L. Pauling, *ibid.*, **53**, 1367 (1931).

The numerical value of this charge will be equal to the atomic number of the atom minus the number of electrons assigned to it. This number has been called the "formal charge."

Let us take $H_2PO_4^-$ as an example. The Lewis structure of this ion is



$$\begin{array}{c} :\ddot{O}: \\ H:\underset{..}{\ddot{O}}:\ddot{P}:\underset{..}{\ddot{O}}:H \\ :\underset{..}{\ddot{O}}: \end{array}$$

The phosphorus atom has a formal charge of 15 − 14 = +1, the two "free" oxygens each have a charge of 8 − 9 = −1, all other atoms have zero formal charge.

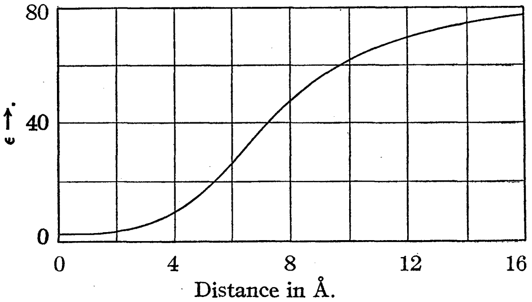


Fig. 1.

In general, the actual charge distribution in a molecule is only approximately represented by the formal charges assigned to its atoms. In addition to the single ionic structure $M^+—O^-$, the doubly covalent structures $M=O$ and completely ionic structures $M^{++}O^=$ must be taken into account in any exact calculation of the energy of the M–O bond. The effects of these two additional bond types on the charge distribution will be in opposite directions, and, therefore, will partially cancel. Moreover, since we shall make calculations only for oxygen acids of the elements in the last three columns of the periodic table (not including the first row), we feel that due to the similarity in the central atoms the small differences between the actual charge distributions and those given by the formal charge method should all be approximately equal. Since there is already a parameter C in the calculated free energy, this uniform difference can be appropriately included in the parameter.

The excellent agreement between the experimental and the calculated free energies of ionization leads us to believe that the actual charge distribution for the acids considered can deviate only slightly from that given by the "formal charge" method.

Dielectric Constant.—The dielectric constant of a solvent in the immediate neighborhood of a charged particle, such as an ion, has an abnormally low value due to the electrical saturation effect produced by the orientation of the solvent dipoles by the field. By the application of the Langevin theory to this problem, Debye[11] has calculated the effective dielectric constant of water as a function of the distance from a univalent ion. The result is shown in the graph, Fig. 1.

It is significant that the dielectric constant remains at a value of 3.0 up to a distance of about 2 Å. from the charged particle. Since the first proton transfer occurs within a distance of 1.8 Å. from the nearest free oxygen atom (which determines the value of ϵ in this region), the change in potential energy, W_1, of the proton during this transfer should be calculated using a constant value of 3.0 for ϵ. For W_1, equation (5) now reduces to the simple form

$$W_1 = \Sigma_j \frac{q_j e}{3.0}\left(\frac{1}{r_{j1}} - \frac{1}{r_{j2}}\right) \qquad (6)$$

where j refers to the jth atom in the anion.

Since the subsequent proton transfers occur at larger distances from the ion, where ϵ is much greater, their contribution to ΣW_i is small compared to W_1. Consequently, deviations of the dielectric constant at distances of over 2 Å. from the ion from the values predicted by Debye will not seriously affect the result.

The Calculation of the Free Energy of Ionization, ΔF, from $\Delta F'$.—It is now necessary to consider the relation between the free energy change $\Delta F'$ and ΔF which is defined in terms of the measured ionization constant

$$\Delta F = -RT \ln K$$

where, for an acid HA

$$K = \frac{(A^-)(H_3O^+)}{(HA)}$$

It will be shown that the difference between $\Delta F'$ and ΔF consists of two terms: one independent of the nature of the acid, the other depending only upon the symmetry of the acid and anion molecules.

In the process to which $\Delta F'$ refers, it is implied that a particular proton is transferred from an acid molecule to a particular position on a certain water molecule; in the reverse process it is im-

---

(11) M. P. Langevin, *Ann. chim. phys.*, [8] **5**, 70 (1905); P. Debye, "Marx' Handbuch der Radiologie," Akademische Verlagsgesellschaft, Leipzig, 1925, Vol. VI, pp. 618–680; "Polar Molecules," Chemical Catalog Co., New York, N. Y., 1929.

plied that a particular proton is transferred from a hydronium ion to a certain free oxygen on an anion. ΔF, however, refers to a process in which this differentiation between equivalent positions is not made.

That term in the difference between the two quantities which arises from the equivalence of positions on water molecules, and of protons in hydronium ions, is dependent on the concentration of the solution, but not on the nature of the acid. Inasmuch as ionization constants are generally extrapolated to infinite dilution, this term is constant and can be absorbed in the parameter.

The term in the difference between $\Delta F'$ and ΔF which varies with the nature of the acid can be calculated as follows: Let n_H be the number of equivalent hydrogens on the acid molecule and n_O the number of equivalent oxygens in the anion. Accordingly, in K'—calculated from the relation, $\Delta F' = -RT \ln K'$—the acid concentration to be used is $n_H(\mathrm{HA})$ and the anion concentration is $n_O(\mathrm{A}^-)$. Therefore, disregarding factors independent of the nature of the acid

$$K' = \frac{n_O(\mathrm{A}^-)(\mathrm{H_3O}^+)}{n_H(\mathrm{HA})} = \frac{n_O}{n_H} K$$

Consequently

$$\begin{aligned} \Delta F &= -RT \ln K' + RT \ln \frac{n_O}{n_H} \\ &= \Delta F' + RT \ln \frac{n_O}{n_H} \\ &= \Sigma W_i + RT \ln \frac{n_O}{n_H} + C \qquad (7) \end{aligned}$$

The Numerical Computation of ΔF.—The first step in the calculation of the work involved in the various proton transfers is the construction (on paper) of a scale model of the hydrated acid molecule. The correct distances between atoms and the bond angles are obtained from published results of X-ray and electron diffraction investigations.[12] The electrostatic energy of the proton in the acid molecule is calculated, and from this is subtracted its energy in a position adjacent to the oxygen in the nearest water molecule. This is the work W_1. The work involved in the subsequent proton transfers is calculated in an analogous manner.

We have taken the O–H–O hydrogen bridge distance to be 2.70 Å. and the O–H bond distance to be 0.95 Å. Each proton transfer, therefore, moves the proton a distance 0.80 Å. along the hydrogen bridge.

To evaluate C we take the experimentally determined free energy of ionization of a single acid for which both the structure and the ionization constant are well known. We have chosen H_3PO_4 for this purpose. From this one experimental free energy we are enabled to calculate uniquely the ionization constant of any non-resonating oxygen acid for which the structure is known. Conversely, if a number of structures can be written for a given acid, the experimental value of the ionization constant allows us to choose the true one.

The crystal structures of BPO_4 and KH_2PO_4 have shown the system PO_4 to be tetrahedral. The average P–O distance from these and other measurements is 1.53 Å. Taking the P–O–H angle as 110° we can construct a scale model for the molecule H_3PO_4.

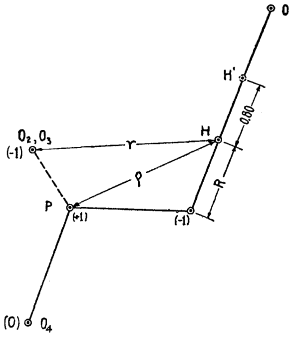

Fig. 2.—O_2 and O_3 out of plane of fig. Formal charges given in parentheses. O_3 and O_4 are hydroxyl oxygens.

By the use of equation (6) we find for the first proton transfer

$$W_1 = \frac{1.44 \times 10^{13} e^2}{3.0} \left[\left(\frac{1}{R_1} - \frac{1}{R_2}\right) - \left(\frac{1}{\rho_1} - \frac{1}{\rho_2}\right) + \left(\frac{1}{r_1} - \frac{1}{r_2}\right)\right]$$

$$= 52.4 - 12.4 + 4.9 = 44.9 \text{ kcal.}$$

Subsequent proton transfers contribute 1.2 kcal. more (calculated by the use of equation (5)), so that $\Sigma W_i = 46.1$ kcal. Since there are three equivalent protons in H_3PO_4 and two equivalent free oxygens on $H_2PO_4^-$, $RT \ln \frac{n_O}{n_H} = RT \ln \frac{2}{3} = -0.2$ kcal. Experimentally $-RT \log K$ for H_3PO_4 in water at 298.1°K. is 2.9 kcal. From these data we can evaluate the parameter C in equation (7).

$$2.9 = 46.1 - 0.2 + C \qquad C = -43.0 \text{ kcal.}$$

Since W_1, which is very easy to compute, turns

[a] d = central atom-oxygen distance. [b] The parameter, C, is determined by this value. [c] The P–P distance in $H_4P_2O_7$ = 3.12 Å. [d] Since the Te covalent radius is 0.04 Å. greater than that for I,[13] this distance has been added to the experimentally determined I–O distances to obtain the Te–O distances in corresponding compounds.

out to be a good approximation to ΣW_i, we have thought it worth while to evaluate a parameter C_1 for the simpler calculation by means of the relation

$$\Delta F_1 = W_1 + RT \ln \frac{n_O}{n_H} + C_1 \qquad (8)$$

and to list values of $-\log K_1$ calculated from ΔF_1 to show the relatively good results obtainable in this way.

$$2.9 = 44.9 - 0.2 + C_1 \qquad C_1 = -41.9 \text{ kcal.}$$

Having fixed the parameter in our equation, it can be used for the prediction of the free energy of ionization of other acids. For instance, for the second ionization step of H_3PO_4 (the ionization of $H_2PO_4^-$) ΣW_i is found to be 51.7 kcal., and $RT \ln \frac{n_O}{n_H} = RT \ln \frac{3}{2} = +0.2$ kcal. Adding C, $\Delta F = 8.9$ leading to a value of $-\log K = 6.5$ as compared to be experimentally determined value of 7.2.

Numerous other acids have been treated in the same way as $H_2PO_4^-$ and the results are set forth in Table I. In Fig. 3 $-\log K$ (observed) is plotted against $-\log K$ (calculated). A line of unit slope appears in the plot on which all points would fall if the agreement were perfect. The horizontal distance from a point to the line is numerically equal to the deviation of the calculated from the experimental result.

The agreement of the calculated with the observed values is quite striking in view of the simplicity of the calculation. While the acids included are all oxygen acids of the elements in the last four columns of the periodic table, the elements considered range from chlorine, whose properties are typically non-metallic, to tellurium, which is a metalloid. Moreover, the ion acids, such as HSO_4^-, fit nicely into the scheme. The quantities calculated represent differences between large numbers, making the resulting agreement all the more encouraging.

The values of $-\log K$ (calculated) for the first

ionization step, for which the assumptions should be most nearly valid, show a mean absolute deviation of about 0.8 from $-\log K$ (observed). This means an average agreement of the calculated with the experimental ionization constants within a factor of 6. When the ion acids are included, the total mean absolute deviation in $-\log K$ is 0.9, or an average agreement of the ionization constants within a factor of 8. There seems to be no trend in the deviations, notwithstanding the fact that there is only one parameter to be determined from experimental data.

Prediction of Structures.—In case several reasonable atomic configurations can be postulated for a given acid, the true one usually can be chosen by comparing the strength calculated for each of these structures with the experimental value, since the calculated strength is very sensitive to change in the structure of the acid. In general, the strength corresponding to one structure agrees closely with the observed value, while the strengths corresponding to the other structures differ from that observed by far more than the error of the method. Calculations of this type have been made for a number of such acids and the results appear in Table II.

It is seen that the structures $Ge(OH)_4$, $HPO(OH)_2$, $As(OH)_3$, $Te(OH)_6$, and $IO(OH)_5$ give calculated ionization constants in good agreement with those observed. The alternate structures, on the other hand, lead to completely unreasonable values. The correct structures of phosphorous, arsenious,[12] telluric,[19] and periodic[20] acids have been determined previously by other methods; this calculation merely confirms these results. We believe that our result provides the first evidence concerning the structure of germanic acid.

Strong Acids.—There are a number of oxygen acids which are completely ionized in aqueous solution. The calculated values of $-\log K$ for these acids are all negative, in general agreement with experiment (see Table III). The theory predicts that in any hydroxylated solvent, such as alcohol, the free energies of ionization of non-resonating oxygen acids will differ from those in aqueous solution only by a change in the parameter C. The relative strengths of the acids would be the same as in water, the change being an additive constant in the expression for $-\log K$.

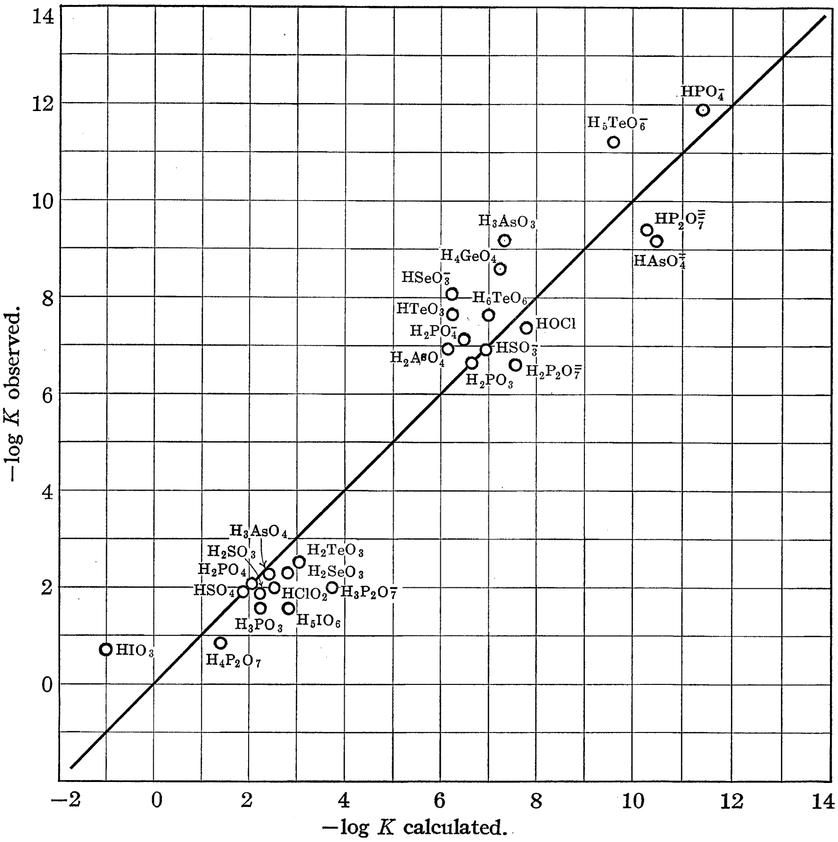

Fig. 3.—$HPO_4^=$, $HTeO_3^-$, $H_2AsO_4^-$, $H_2PO_3^-$, H_3PO_4, etc.

At present there are insufficient data on the strengths of these acids in non-aqueous solvents to permit a reliable evaluation of C. However, we have tabulated the results of the calculations for some of these acids so that, when the data become available, we may compare our results with experiment. The results of these calculations appear in Table III.

Oxygen Acids of First Row Elements.—Boric, carbonic, nitric, nitrous, and the carboxylic acids have atomic configurations which permit more than one electron structure to be written either

[a] The calculation does not exclude the possibility of a carbonic acid structure for germanic acid:  $\mathrm{HO}\overset{\overset{\mathrm{O}}{\|}}{\mathrm{Ge}}\mathrm{OH}$. However, double bonds to elements in the second row of the periodic table are rare, and have never been found for third row elements. Together with crystal structure data for GeO_2, this fact makes the existence of the double bonded structure for germanic acid extremely improbable.

for the acid molecule, or for the anion, or for both. This fact makes it impossible to assign a unique formal charge to each atom and, consequently, the calculation of the ionization constants of these acids cannot be made by the method of this paper. However, we can calculate the ionization constant corresponding to any one electron structure and compare it with the experimental result. If the true charge distribution is close to that used in the calculation, the calculated and observed ionization constants should be in good agreement.

The ionization constants of these acids, calculated on the basis of their classical structures, all turn out to be smaller than the observed values, except for the case of H_3BO_3. While the deviations may be considered to be within the error of the calculation for carbonic acid and bicarbonate ion, the deviations for nitric, nitrous, and the carboxylic acids are far outside the error of the calculation. Measurements of absorption spectra[21] and bond distances[12] for these latter substances indicate the absence of localized double bonds, and therefore the classical structures should not be expected to lead to true ionization constants.

The resonance phenomenon accounts not only for the absence of localized double bonds but also for the decrease in the work of ionization. Resonance in the acid molecule decreases the negative charge on the hydroxyl oxygen. The removal of the proton increases the resonance of the system, thereby producing a further decrease in the work of ionization. Thus, the presence of this effect may well account for the magnitude and direction of the differences between the calculated and observed ionization constants of these acids.

The case of boric acid deserves special mention in view of the interest attached to the type of bonding present in boron compounds. The structures of a large number of boron compounds have been determined recently.[22–26] It has been assumed generally that the boron halides (except perhaps BF_3) possess double bond resonance of the graphite type. On the other hand, boron trimethyl has been shown by Lévy and Brockway[25] to have a structure containing three coplanar single bonds (sp^2). Evidence as to the type of bonding present in boric acid can be obtained from its ionization constant. The ionization constant calculated from the planar, single bond structure,  $\begin{matrix}H{-}O\\ H{-}O\end{matrix}\!\!>\!B{-}O{-}H$ agrees with experiment within the error of the calculation, showing that the sp^2 structure is a good approximation to the true one. The deviation between the calculated and observed values is in the opposite direction from the deviations observed for acids exhibiting double bond resonance and, therefore, indicates that such resonance is absent or very small in the structure of boric acid. The calculation points to the presence of ionic structures such as $(OH)_2B^+(OH)^-$, although the deviation is not great enough compared to the error of the experiment to justify an estimate of the importance of these structures.

Acknowledgment.—We are deeply indebted to Dr. Joseph E. Mayer, of this department, and to Dr. Linus Pauling and Mr. Henri Lévy, of the California Institute of Technology, for many constructive suggestions and criticisms which were extremely valuable in the preparation of this paper.

Summary

The calculation of the ionization constants of inorganic oxygen acids has been carried out on the basis of reasonable assumptions concerning the structures of the acid molecules and the mechanism of ionization. Most of the calculated ionization constants agree with the experimental ones to within a factor of 8.

1. The free energy of ionization has been shown to consist of a term depending only on the structure of the acid and a term depending only on the solvent and the temperature. The constant term has been evaluated from the ionization constant of a single acid of known structure.
2. The ionization constants of a large number of acids have been evaluated, and have been found to agree well with experimental values.
3. On the basis of the calculation the structures of a number of acids have been determined from their known strengths.
4. The effect of resonance on the strength of acids has been discussed.

Glycofuranosides and Thioglycofuranosides. III. New Crystalline Furanosides of *d*-Galactose and *l*-Arabinose

BY JOHN W. GREEN[1] AND EUGENE PACSU

In Part I of this series[2] the synthesis of β-ethylgalactofuranoside by the reaction of the ethylmercaptal of the sugar with mercuric chloride in alcohol solution under neutral conditions was described. The isolation of the α-isomer[3] in crystalline form was also presented. This method has now been extended with success to other alcohols and also to the pentose *l*-arabinose. Three new β-alkylgalactofuranosides and two α-alkylarabinofuranosides have been prepared in crystalline form, and they are listed with their physical properties in Table I.

These substances, with the exception of β-benzylgalactofuranoside, are very hygroscopic. The yields are mostly low, as the presence of even a small amount of the other isomer seems to hinder crystallization very strongly. The β-propylgalactofuranoside crystallizes spontaneously, with a good yield. The α-methyl *l*-arabinofuranoside sirup was crystallized by seeding with its mirror image, crystalline α-methyl-*d*-arabinofuranoside.[4]

Galactose ethylmercaptal reacts quite slowly with benzyl alcohol and the resulting sirup has a smaller negative rotation than those of the other reaction sirups.

Attempts to prepare an intermediate thioarabinofuranoside, analogous to the thioglucosides,[2,5] failed, so the formation of the arabinofuranosides must be similar to that of the galactofuranosides.

As shown in Table I, the rotations of all these furanosides agree satisfactorily with the rotations calculated on the basis of Hudson's isorotation rules.

The $B_{(1-4)}$ value for the galactofuranosides was calculated from the molecular rotations for α- and β-ethylgalactofuranosides; the respective A_x values for the galactofuranosides were calculated from the molecular rotations of the galactopyranosides. The $B_{(1-4)}$ value for the *l*-arabinofuranosides was calculated from the molecular rotation of α-methyl-*d*-arabinofuranoside; the respective A_x^0 values for the *l*-arabinofuranosides were calculated from the molecular rotations of the *l*-arabinopyranosides.

Experimental

Preparation of β-Methylgalactofuranoside.—A mixture of 5.7 g. of galactose ethylmercaptal, 10.9 g. of mercuric chloride (2 moles), 5 g. of yellow mercuric oxide, and 3 g. of drierite was shaken with 60 cc. of absolute methyl alcohol for four hours at room temperature. The mixture was filtered, the filtrate treated with 5 cc. of pyridine and kept at 0° for two hours. The pyridine-mercuric chloride was filtered off and the filtrate evaporated *in vacuo* at 40° to a sirup. The sirup was dissolved in cold water, the solution filtered and neutralized with a few drops of sodium hydroxide solution to phenolphthalein, then evaporated *in vacuo* at 40° to a sirup. After several evaporations from absolute ethyl alcohol, the sirup was extracted with dry ether on a shaking machine. About four liters of solvent was used and the resulting solution was distilled off from a bath at 40–50°. The sirup left was dissolved in a small amount of absolute methyl alcohol and the solution filtered and concentrated to a hard sirup in a vacuum desiccator over calcium chloride. The sirup, rotating −83° in water solution, was then kept in an icebox and after one month changed to a solid crystalline mass.

The latter was dissolved in 100 cc. of warm ethyl acetate and the solution seeded at 0°. Crystals were slowly deposited in the form of hard buttons. On further recrystallization from ethyl acetate pure crystals were obtained: yield 20%; m. p. 63–65°, $[\alpha]^{20}\text{D}$ −108° (0.0500 g. substance, 3 cc. of water solution, 2-dm. semi-micro tube, rotation 3.60° to the left). The crystals did not reduce Fehling's solution and were quite hygroscopic. The mother liquor slowly deposited more crystalline material.

Anal. Calcd. for $C_7H_{14}O_6$: C, 43.3; H, 7.2. Found: C, 43.1; H, 7.1.

Preparation of β-Propylgalactofuranoside.—A mixture of 5.7 g. of galactose ethylmercaptal, 10.9 g. of mercuric chloride (2 moles), 5 g. of yellow mercuric oxide, and 3 g. of drierite was shaken with 60 cc. of absolute *n*-propyl alcohol for five hours at room temperature. The mixture was filtered and worked up as in the preparation of the methylgalactofuranoside. The ether extraction solution was distilled on a water-bath at 40–50° and the residue crystallized spontaneously.

The crystalline material was recrystallized from 30 cc. of dry ethyl acetate, when a crop of 2.8 g., with specific rotation −96° in water solution, was obtained. On further crystallization from 30 cc. of ethyl acetate, a crop of 1.00 g. of needle-like crystals was obtained, whose rotation did

TABLE I

Substance	Mol. wt.	M. p., °C.	$[\alpha]^{20}_D$ in H_2O	Mol. rot. in H_2O	A_x	$B_{(1-4)}$	$[\alpha]^{20}_D$ calcd.
β-Methylgalactofuranoside	194	63–65	−108	−20,950	19,110	−1150	−104.4
β-Propylgalactofuranoside	222	89–90	−100	−22,200	20,710	−1150	− 98.5
β-Benzylgalactofuranoside	270	80–81	− 96	−25,920	25,800	−1150	− 99.0
α-Methylarabinofuranoside	164	. . .	−125	−20,500	−18,810	−1360	−123.0
α-Ethylarabinofuranoside	178	48–49	−116	−20,650	−19,830	−1360	−119.0

not change on further recrystallization: yield of pure material 23%; m. p. 89–90°; $[\alpha]^{20}_D$ −100° (0.0500 g. substance, 3 cc. of water solution, 2-dm. semi-micro tube, rotation 3.32° to the left). The crystals did not reduce Fehling's solution and were fairly hygroscopic.

Anal. Calcd. for $C_9H_{18}O_6$: C, 48.7; H, 8.1. Found: C, 48.9; H, 7.9.

Preparation of β-Benzylgalactofuranoside.—A mixture of 5.7 g. of galactose ethylmercaptal, 10.9 g. of mercuric chloride (2 moles), 5 g. of yellow mercuric oxide, and 3 g. of drierite was shaken with 60 cc. of benzyl alcohol for ten hours at room temperature. The mixture was filtered and the filtrate diluted with 480 cc. of petroleum ether (b. p. 30–60°) and 120 cc. of benzene, then extracted[6] with four 60-cc. portions of water. The bulk of the mercuric chloride precipitated at this stage in the separatory funnel and was filtered off. The water solutions were combined, filtered, extracted with a little ether to remove any benzyl alcohol, and finally treated with 1 cc. of pyridine. A small amount of pyridine–mercuric chloride was filtered off, the solution neutralized with a few drops of sodium hydroxide solution to phenolphthalein, and evaporated *in vacuo* at 40° to a sirup. The latter was evaporated several times with absolute ethyl alcohol.

The sirup, rotating −40° in water solution, crystallized after five to six weeks in a desiccator at room temperature, and from a solution in 25 cc. of dry ethyl acetate 1.25 g. of crystals was obtained, rotating −70° in water solution. After three recrystallizations from ethyl acetate 0.65 g. of pure crystals was obtained: yield 12%; m. p. 80–81°; $[\alpha]^{20}_D$ −96° (0.0500 g. substance, 3 cc. of water solution, 2-dm. semi-micro tube, rotation 3.20° to the left). The crystals were very fine needles, were only faintly hygroscopic and did not reduce Fehling's solution.

Anal. Calcd. for $C_{13}H_{18}O_6$: C, 57.7; H, 6.8. Found: C, 57.7; H, 6.7.

Preparation of α-Methyl-*l*-arabinofuranoside.—A mixture of 5.1 g. of *l*-arabinose ethylmercaptal, 10.9 g. of mercuric chloride (2 moles), 5 g. of yellow mercuric oxide, and 3 g. of drierite was shaken with 60 cc. of absolute methyl alcohol for two hours at 25°. The reaction proceeded very fast and liberated some heat. The mixture was filtered and worked up as above for methylgalactofuranoside, and the sirup extracted with ether.

The sirup obtained rotated −96° in water solution and, upon seeding with a trace of crystalline α-methyl-*d*-arabinofuranoside, solidified in two days. From 25 cc. of dry ethyl acetate solution, 0.45 g. of pure crystals was deposited slowly at 0°. The rotation did not change on further recrystallization from 100 cc. of dry ether: yield 14%; m. p. not taken due to extreme hygroscopic nature of crystals; $[\alpha]^{20}_D$ −125° (0.0400 g. substance, 3 cc. of water solution, 2-dm. semi-micro tube, rotation 4.16° to the left). The crystals are extremely hygroscopic and devoid of action toward Fehling's solution.

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.8; H, 7.3. Found: C, 43.7; H, 7.3.

Preparation of α-Ethyl-*l*-arabinofuranoside.—A mixture of 5.1 g. of *l*-arabinose ethylmercaptal, etc., as immediately above, was shaken for two hours with 60 cc. of absolute ethyl alcohol at 25°. The mixture was filtered, etc., and extracted with ether in the usual way. The sirup, which rotated −79° in water solution, changed into a crystalline mass after four months over phosphorus pentoxide.

The product was dissolved in 10 cc. of dry ethyl acetate and 0.9 g. of crystals was deposited at 0°. These crystals rotated −116° in water solution and further recrystallizations did not change this value; yield 24%; m. p. 48–49°; $[\alpha]^{20}_D$ −116° (0.2055 g. substance, 10 cc. of water solution, 2-dm. semi-micro tube, rotation 4.77° to the left). The crystals were very hygroscopic and did not reduce Fehling's solution.

Anal. Calcd. for $C_7H_{14}O_5$: C, 46.96; H, 7.86. Found: C, 46.9; H, 7.7.

Summary

β-Methyl-, β-propyl-, and β-benzylgalactofuranoside, and α-methyl- and α-ethyl-*l*-arabinofuranoside have been obtained in the crystalline state, by reaction of the ethyl mercaptal of the two sugars with mercuric chloride in a neutral solution of the respective alcohol. The rotations of the new compounds agree well with the values calculated from Hudson's rules of isorotation.

Sulfophenylarsonic Acids and Certain of their Derivatives. I. *p*-Sulfophenylarsonic Acid

BY J. F. ONETO

In a recent paper Barber[1] suggests that the Bart reaction appears not to be applicable to aminophenylsulfonic acids due to the strongly negative group present.

This investigation was undertaken with the object of preparing derivatives of a number of sulfo- and sulfonamidophenylarsonic acids and of studying the application of the Bart reaction in the preparation of the parent compounds.

p-Sulfophenylarsonic acid was first prepared by Hewitt, King and Murch[2] through application of the Leuckardt xanthate method[3] to arsanilic acid. The product thus obtained was purified by recrystallization from water. This is a very unsatisfactory method because of the extreme solubility of the acid. Voegtlin[4] refers to *p*-sulfophenylarsonic acid as being so freely soluble in water at any *p*H that it is very difficult to obtain the acid in pure form.

Sodium *p*-sulfophenylarsonic acid was prepared in this Laboratory in 28% yields by application of the Bart reaction to sulfanilic acid. The free acid, obtained from the sodium salt through the barium salt stage, was purified readily by dissolving in the least amount of boiling 80% acetic acid and precipitating the acid in glistening, colorless needles by the addition of boiling glacial acetic acid. The work of Hewitt and coworkers was repeated and the acid thus obtained purified in the same manner with satisfactory results.

With the piperidine salt of N-pentamethylenedithiocarbamic acid,[5] sodium *p*-sulfophenyldiiodoarsine forms a well-defined, crystalline, piperidine salt of *p*-sulfophenylarsylene N-pentamethylenedithiocarbamate.

Sodium *p*-sulfophenylarsine oxide, containing three molecules of water, was obtained by hydrolysis of the corresponding bromo-arsine with sodium hydroxide. This product forms a crystalline silver salt when its hot aqueous solution is treated with a solution of silver nitrate.

Experimental Part

Sodium *p*-Sulfophenylarsonic Acid.—A mixture consisting of 76 g. of sulfanilic acid, 28 g. of anhydrous sodium carbonate and 400 cc. of water was diazotized at 0° with 100 cc. of 37% hydrochloric acid and a solution of 32 g. of sodium nitrite in 160 cc. of water in the usual manner. The diazo solution was coupled at 10–15° with an alkaline arsenite solution prepared by dissolving 80 g. of sodium hydroxide, 98 g. of arsenic trioxide and 1.2 g. of copper sulfate in 1000 cc. of water. After standing for two days, the reaction mixture was concentrated to 350 cc., thoroughly cooled and the precipitate of inorganic salts removed by filtration. The filtrate was heated to boiling, made acid to congo red paper with 37% hydrochloric acid and then allowed to stand at room temperature for twenty-four hours. The heavy, granular precipitate which consisted chiefly of sodium *p*-sulfophenylarsonic acid was partially purified by repeatedly boiling with decolorizing carbon in aqueous solution, concentrating the solution to a small volume and precipitating the sodium salt by the addition of 95% alcohol; yield 60 g. Thirty grams of the material thus obtained was dissolved in 125 cc. of boiling water and 30 g. of sodium chloride was added to the boiling solution. Colorless, crystalline sodium *p*-sulfophenylarsonic acid started to precipitate almost immediately. The mixture was cooled in ice, filtered and the product washed with cold, saturated sodium chloride solution, then with small portions of cold 80% alcohol and finally with acetone. Eighteen grams of product was obtained sufficiently pure for analysis.[6] It is insoluble in alcohol and acetic acid, exceedingly soluble in water.

Anal. Calcd. for $C_6H_6O_6AsSNa$: As, 24.64. Found: As, 24.36.

Barium *p*-Sulfophenylarsonic Acid.—Ten grams of sodium *p*-sulfophenylarsonic acid was dissolved in 30 cc. of boiling 0.7% hydrochloric acid. To the hot solution was added 20 cc. of a saturated solution of barium chloride. The barium salt started precipitating at once from the hot solution in the form of colorless needles. After cooling, the product was filtered, washed first with cold 0.7% hydrochloric acid, then with water and finally with acetone. The material thus obtained, which was sufficiently pure for analysis, is relatively soluble in water; yield 9.5 g.

Anal. Calcd. for $C_{12}H_{12}O_{12}As_2S_2Ba$: As, 21.42; Ba, 19.64. Found: As, 21.09; Ba, 19.64.

***p*-Sulfophenylarsonic Acid.**—Five grams of barium *p*-sulfophenylarsonic acid was dissolved in 100 cc. of boiling water and the barium was precipitated from the hot solution by adding the calculated amount of 0.1 *N* sulfuric acid. After removal of the barium sulfate, the filtrate was allowed to evaporate at room temperature. The residue was purified by dissolving in the least amount of boiling

(6) A halogen analysis indicated the presence of 0.7% sodium chloride.

80% acetic acid and then treating the hot solution with boiling glacial acetic acid. The *p*-sulfophenylarsonic acid crystallized in the form of colorless, glistening needles; yield 2.5 g. When heated, the product gradually darkens but remains solid up to 300°. It is insoluble in ether, acetone and benzene; soluble in alcohol.

Anal. Calcd. for $C_6H_7O_6AsS$: As, 26.56. Found: As, 26.51.

Sodium *p*-Sulfophenyldiiodoarsine.—Ten cc. of 50% hydriodic acid was added to a hot solution of 2 g. of sodium *p*-sulfophenylarsonic acid in 5 cc. of water. The crystalline iodoarsine began precipitating immediately. The mixture was filtered after cooling thoroughly and the product washed first with glacial acetic acid and then with acetone. The yield was 2 g. after recrystallizing from 80% acetic acid. It is insoluble in cold glacial acetic acid and alcohol but readily soluble in water. When heated the compound liberates vapors of iodine.

Anal. Calcd. for $C_6H_4O_3AsI_2SNa$: As, 14.75; I, 49.98. Found: As, 14.65; I, 49.76.

Sodium *p*-Sulfophenyldibromoarsine.—A solution prepared from 10 g. of sodium *p*-sulfophenylarsonic acid, 30 cc. of water, 20 cc. of 48% hydrobromic acid and a trace of hydriodic acid was saturated with sulfur dioxide at room temperature. The mixture was then concentrated on the steam-bath to about 20 cc., chilled in ice and the product removed by filtration; 8.5 g. of sodium *p*-sulfophenyldibromoarsine was obtained after recrystallizing from glacial acetic acid–ethyl acetate mixture. The product is readily soluble in alcohol and water.

Anal. Calcd. for $C_6H_4O_3AsBr_2SNa$: As, 18.10; Br, 38.62. Found: As, 18.07; Br, 38.36.

The Piperidine Salt of *p*-Sulfophenylarsylene N-Pentamethylenedithiocarbamate.—To a hot soluiton of 0.5 g. of sodium *p*-sulfophenyldiiodoarsine in 13 cc. of 50% alcohol there was added a hot solution of 0.5 g. of the piperidine salt of N-pentamethylenedithiocarbamic acid in 25 cc. of alcohol. The colorless needles which formed were removed by filtration and washed repeatedly with cold 95% alcohol. The product weighed 0.3 g. and when heated decomposed at 230–232°. The compound is insoluble in ether, acetone and benzene.

Anal. Calcd. for $C_{23}H_{36}O_3N_3AsS_5$: As, 11.75. Found: As, 12.01.

Sodium *p*-Sulfophenylarsine Oxide.—Five grams of sodium hydroxide was added to as olution of 15 g. of sodium *p*-sulfophenyldibromoarsine in 100 cc. of water and the solution boiled under a reflux condenser for fifteen minutes. The solution was then cooled, made acid to congo red paper with 37% hydrochloric acid and allowed to evaporate at room temperature. After several days a heavy mass of large colorless crystals was obtained which weighed 8 g. The product, containing three molecules of water, was purified by dissolving in water, concentrating the solution in a desiccator over sulfuric acid to a small volume and recovering the crystalline residue.

Anal. Calcd. for $C_6H_4O_4AsSNa\cdot 3H_2O$: As, 23.11. Found: As, 23.00.

The product effloresced at room temperature and was completely dehydrated by heating to 200° for four hours in an oil-bath under reduced pressure.

Anal. Calcd. for $C_6H_4O_4AsSNa$: As, 27.74. Found: As, 27.81.

On adding 10 cc. of 0.25 *N* silver nitrate solution to a hot solution of 0.52 g. of sodium *p*-sulfophenylarsine oxide in 10 cc. of water, a silver salt of *p*-sulfophenylarsine oxide crystallized on slight cooling; yield 0.5 g.

Summary

The preparation of sodium *p*-sulfophenylarsonic acid by the Bart reaction and a method for the purification of the free acid have been described. The following derivatives and salts have been prepared: barium *p*-sulfophenylarsonic acid, the piperidine salt of *p*-sulfophenylarsylene N-pentamethylenedithiocarbamate, sodium *p*-sulfophenyldiiodo and -dibromoarsine and sodium *p*-sulfophenylarsine oxide.

The Cleavage of the Carbon Chain of α-Methyl-*d*-lyxopyranoside by Oxidation with Periodic Acid[1]

BY W. DAYTON MACLAY AND C. S. HUDSON

The known α-methyl-*d*-lyxoside (m. p. 108–109°, $[\alpha]^{20}D$ + 59.4° in water)[2] has been shown by Hirst and Smith[3] through methylation methods to be a pyranoside and it is regarded as the alpha form because it is more dextrorotatory than *d*-lyxose ($[\alpha]^{20}D$ −14°, final); under this classification its structure is (I). It is to be expected that the oxidation of this substance by periodic acid will proceed in the manner that has been demonstrated in the case of the alpha forms of the methyl pyranosides of *d*-xylose and *d*-arabinose[4] to produce the dialdehyde (II); the latter substance, on oxidation by bromine water in the presence of strontium carbonate, should be oxi-

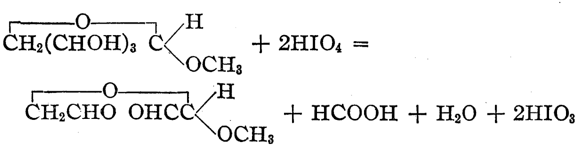
dized to the strontium salt (III), which has been obtained from the xylose and arabinose pyranosides. The experiments have borne out these expectations fully and the crystalline strontium salt, which has been obtained in a yield of 76%, proves to be identical with that which results from the xylose and arabinose *α*-methyl pyranosides. The result therefore confirms the conclusion from methylation data that the lyxoside is a pyranoside and also proves that it is of the alpha classification, as was previously inferred from the comparison of its rotation with that of lyxose.[5]

TABLE I

COMPARISON OF OXIDATION PRODUCTS OF *α*-METHYL-*d*-LYXOSIDE WITH THOSE OF *α*-METHYL-*d*-ARABINOSIDE AND *α*-METHYL-*d*-XYLOSIDE

Substance	Methyl glycoside $[\alpha]^{20}_D$	Dialdehyde $[\alpha]^{20}_D$	Dibasic acid $[\alpha]^{20}_D$	Strontium salt $[\alpha]^{20}_D$
α-Methyl-*d*-lyxoside	+59.4	+124.1	−12.8	−54.7
α-Methyl-*d*-arabinoside[4]	−17	+124.2	−12.7	−55.5
α-Methyl-*d*-xyloside[4]	+154	+125.2	−12.1	−55.5

The oxidation of the methyl-lyxopyranoside by periodic acid follows the reaction equation that has been found to hold for the xylose and arabinose methyl-pyranosides,[4] namely



$$\overbrace{\mathrm{CH_2(CHOH)_3\,C}}^{\mathrm{O}}\genfrac{}{}{0pt}{}{\diagup \mathrm{H}}{\diagdown \mathrm{OCH_3}} + 2\mathrm{HIO_4} =$$

$$\overbrace{\mathrm{CH_2CHO\ \ OHCC}}^{\mathrm{O}}\genfrac{}{}{0pt}{}{\diagup \mathrm{H}}{\diagdown \mathrm{OCH_3}} + \mathrm{HCOOH} + \mathrm{H_2O} + 2\mathrm{HIO_3}$$

Experimental

Oxidation of *α*-Methyl-*d*-lyxopyranoside with Periodic Acid.—To a solution of 1.3583 g. of pure *α*-methyl-*d*-lyxoside in 60 cc. of water was added 28.27 cc. of 0.615 *M* periodic acid solution (2.1 molecular equivalents). The solution was quickly diluted to 100 cc. and the rotatory changes observed at about 20°. From an initial specific rotation of +59.4° the rotation rapidly increased during the first ten minutes and became practically constant at the end of twenty-five minutes. After standing at 20° for twenty-one hours the solution had a specific rotation of +124.1° (referring to the dialdehyde). Five cubic centimeters of the solution was analyzed for periodic acid and the result showed that one mol of the lyxoside had consumed 1.988 mols of periodic acid, which conforms with the equation previously stated.

The free methoxy-diglycolic aldehyde (II) was obtained in a sirupy form by following the procedure used by Jackson and Hudson in the isolation of the dialdehyde resulting from the periodic acid oxidation of other methyl pentopyranosides. To the sirupy dialdehyde, dissolved in 330 cc. of water, 25 g. of strontium carbonate and 2 cc. of bromine were added and the mixture was shaken for five hours. After standing at room temperature for an additional eighteen hours the excess bromine was removed by aeration and the strontium carbonate by filtration. The bromide ions were removed by shaking with 17 g. of silver carbonate, the silver ions precipitated by hydrogen sulfide and the excess hydrogen sulfide removed by aeration. The solution was concentrated *in vacuo* in a bath at 60° to a volume of 10 cc., when crystallization of the strontium methoxy-diglycolate trihydrate commenced: yield, 1.8 g. (76%). Recrystallized three times from 8 parts of water the substance was obtained in the form of needle-like crystals exhibiting a rotation of −43.7° (*c*, 0.8; *l*, 4).

Anal. Calcd. for $C_5H_6O_6Sr \cdot 3H_2O$: C, 19.75; H, 3.98; OCH_3, 10.21; Sr, 28.85; H_2O, 17.79. Found: C, 19.86; H, 4.11; OCH_3, 10.14; Sr, 28.62; H_2O, 17.73.

Anhydrous strontium methoxy-diglycolate was obtained by heating the trihydrate at 100° *in vacuo* for four hours. Its solution in water gave a specific rotation of −54.7° (*c*, 1.2; *l*, 4).

Anal. Calcd. for $C_5H_6O_6Sr$: C, 24.03; H, 2.42. Found: C, 24.01; H, 2.61.

Summary

The oxidation of *α*-methyl-*d*-lyxoside by periodic acid yields a dialdehyde which, on oxidation by bromine water in the presence of excess strontium carbonate, forms the same crystalline strontium D′-methoxy diglycolate trihydrate (76% yield) that has previously been obtained from the *α*-methyl-pyranosides of *d*-arabinose and *d*-xylose. The result confirms the conclusion of Hirst and Smith from methylation data that the lyxoside is a pyranoside, and proves that it is an *α*-form.

WASHINGTON, D. C. RECEIVED JUNE 24, 1938

---

[5] I have expressed some years ago the view that the lyxoside is a furanoside because of a certain anomaly in its optical rotation [*ibid.*, **52**, 1689 (1930)] but the methylation data of Hirst and Smith[3] show that it is a pyranoside and their conclusion is now confirmed by the results of the periodic acid oxidation.—C. S. HUDSON.

Cleavage of the Carbon Chain of Glycosides by Oxidation with Lead Tetraacetate[1]

BY W. S. McCLENAHAN[2] WITH R. C. HOCKETT

The glycol-splitting power of lead tetraacetate has been used in several instances to prepare carbohydrate derivatives.[3] In these cases it has been the practice to mask certain hydroxyl groups of a polyhydric alcohol so that no pair of free hydroxyl groups would remain on adjacent carbon atoms except at the position where the carbon chain is to be broken and aldehyde groups produced. Difficulties in preparing such derivatives have seriously limited the extension of this type of synthesis.

Since *cis* glycols are reported to be oxidized much more rapidly than *trans*[4,5] it was thought that a compound containing both types of diol structure might, when treated with an equimolar quantity of lead tetraacetate, be split preferentially at the *cis* position to such an extent that the masking of groups would be unessential. In this respect α-methyl-*d*-mannopyranoside (I)[6] seemed of particular interest since its oxidation with lead tetraacetate might be expected to produce a mixture of (II) and (III) containing a high percentage of the former; hydrolysis of the product would then give a considerable quantity of the difficultly accessible tetrose, *d*-erythrose.

However, Criegee[7] has found that lead tetraacetate produces *two* moles of formaldehyde from glycerol, which can occur only by the further oxidation of the glycolaldehyde first formed; since both (II) and (III) contain an alpha-hydroxyaldehyde grouping, they would probably be capable of further oxidation to a common product (IV). No information exists regarding the rates of such reactions. Karrer and Pfaehler[8] have oxidized α-methyl-*d*-glucoside (V) with lead tetraacetate, but although this would also be expected to produce (II) and (III), the glycoside contains no *cis* glycol structure and its oxidation therefore provides no evidence regarding possible preferential attack at such a position. The products isolated by these workers fail, moreover, to show unequivocally the ultimate fate of the dialdehydes.

Our experiments with the oxidation of α-methyl-*d*-mannoside by somewhat less than an equimolar quantity of lead tetraacetate have provided strong evidence, however, that the product formed is largely (IV), since nearly half the mannoside was recovered unchanged after all the tetraacetate had been consumed, and hydrolyzed portions of the product yielded large quantities of glyceraldehyde osazone. These observations indicate that wherever the initial fission may have occurred, the secondary oxidation of hydroxyaldehyde (II) or (III) is even more rapid and consumes additional oxidizing agent faster than does the unattacked methylmannoside remaining in the mixture. Finally, oxidation of the product with bromine water in the presence of strontium carbonate gave a strontium salt (VI) which was identical in all measured properties with that obtained by Jackson and Hudson[9] when they oxidized α-methyl-*d*-mannopyranoside with periodic acid followed by strontium hypobromite.

The investigation was extended to other glycosides, and in each case the final product corresponded to that obtained by Jackson and Hudson[9] or Maclay and Hudson[10] from the same compound (Table I).

The results show that the method for determining ring structures and alpha and beta configurations of glycosides as developed by Jackson and Hudson may be carried out with lead tetraacetate as well as with periodic acid. The former may be preferable for compounds more soluble in water; the latter, for derivatives more soluble in organic solvents.

[6] The configuration of the groups about an asymmetric carbon atom is not conceived, in itself, to restrict the possibility of free rotation about the carbon–carbon bonds; *e. g.*, it is not appropriate to look upon the hydroxyls of active tartaric acids as fixed either in *cis* or *trans* position despite the fact that conventional projectional formulas make them appear so. On the other hand, where a ring structure exists as in a glycoside or in cyclohexanediol, conventional considerations indicate that the rotation around carbon–carbon bonds is prevented and hydroxyl groups bear a fixed relation to one another in space which moreover is determined by the configurations of the asymmetric carbons.

[a] Calcd. from rotation of aqueous solution after oxidation, on the basis of 100% yield of dialdehyde (IV).

[b] Determined by liberating the acid (c = *ca.* 1%) from its anhydrous salt with an equivalent quantity of hydrochloric acid.

[c] Recrystallized to constant rotation (c = 1.2108). The values for other salts were determined after one or two recrystallizations.

The reaction of lead tetraacetate with glycosides is slow in acetic acid and by-products resembling acetates frequently formed. This could be prevented by substituting chloroform for acetic acid as the solvent, which greatly accelerates the reaction.

Preliminary studies have also been made concerning the rates of oxidation of the various glycosides. These have proved very useful in determining the quantities of lead tetraacetate to be used and the time required for the different reactions. These experiments will be reported in a separate communication.

Experimental

Lead Tetraacetate.—A mixture of 530 cc. of glacial acetic acid and 115 cc. of acetic anhydride was heated to 75° in a 1-liter, 3-necked Pyrex flask provided with an electric stirrer and a thermometer. To this was added 150 g. of dry red lead in six portions. The solution was allowed to become colorless between successive additions, and the temperature was kept below 90°. When the reaction was complete the slightly turbid solution was decanted from a small amount of undissolved red lead and allowed to cool in a closed vessel. The white, crystalline lead tetraacetate was filtered off on a Büchner funnel, washed with a little glacial acetic acid, and was stored in a desiccator over phosphorus pentoxide. These operations could be carried out in the open air if performed rapidly. The product weighed about 60–70 g. and was not recrystallized for use in these experiments.

Oxidation of α-Methyl-*d*-lyxopyranoside.—Three grams (0.0183 mole) of dry lyxoside (of rotation +59.4°) was added to 150 cc. of dried chloroform ($CaCl_2$) in a 500-cc. 3-necked flask, and during the course of an hour 17.5 g. (0.0395 mole) of dry lead tetraacetate was added in small portions with continuous mechanical stirring. The temperature remained below 35° at all times. Stirring was continued for two hours after the last addition. The chloroform solution was then decanted from the nearly insoluble lead diacetate and the chloroform was removed under reduced pressure. The residue was taken up in water, which formed a precipitate of brown lead dioxide, and an excess of hydrogen sulfide was passed into the mixture. The lead diacetate was also dissolved in water and treated with hydrogen sulfide separately. After filtration and aeration the first solution gave a strong Fehling's test, the second only a slight one. The two were combined, concentrated under reduced pressure to a sirup, and reconcentrated several times after addition of sulfur-free toluene to remove all acetic acid. The resulting sirup was diluted to 500 cc., and 20 g. of strontium carbonate and 3 cc. of bromine were added. The flask was shaken until the bromine dissolved, then placed in the dark at room temperature and occasionally shaken during the first hour. After eighteen hours nearly all reducing power had disappeared. The bromine was removed by aeration, and

---

(11) All rotations reported in this paper represent specific rotations of the D line of sodium by aqueous solutions at 20°; c is concentration in grams per 100 cc. of solution, and l is the tube length in decimeters.

the excess strontium carbonate was filtered off and washed with cold water. The filtrate and washings were shaken with silver carbonate until free from bromide ion; the solids were then filtered off and washed. Silver was removed from the filtrate as the sulfide. After filtration and aeration, a slight acidity was neutralized to phenolphthalein with strontium hydroxide solution. The solution was then filtered through carbon and concentrated under reduced pressure to 50 cc., filtered, and the concentration continued to 10 cc. The addition of a few drops of alcohol caused a turbidity which increased slightly after a few hours at room temperature. After filtering, the addition of a little more alcohol caused crystallization to begin. Several crops of fine needles were obtained by alternately adding alcohol and chilling; yield of trihydrate of the salt, 3 g. or 54%. After four recrystallizations of the salt[12] from 8 parts of water the rotation of the anhydrous substance became constant at −56.6° (*c*, 1.2108; *l*, 2).[11] The corresponding free acid rotated −11.5° (*c*, 0.9648; *l*, 4).[11]

Anal. Calcd. for $C_5H_6O_6Sr{\cdot}3H_2O$: H_2O, 17.8. Found (loss in wt. at 105° *in vacuo*); 17.6. Calcd. for $C_5H_6O_6Sr$: Sr, 35.01. Found: Sr, 34.94.

Oxidation of β-Methyl-*d*-arabinopyranoside.—The procedure was the same as reported for α-methyl-*d*-lyxoside. The yield of strontium salt was 65%. The anhydrous substance rotated +55.0° (*c*, 1.0080; *l*, 2).[11] The corresponding free acid rotated +11.9° (*c*, 0.8390; *l*, 1).[11]

Anal. Calcd. for $C_5H_6O_6Sr{\cdot}3H_2O$: H_2O, 17.8. Found (loss in wt. at 105° *in vacuo*): 17.6. Calcd. for $C_5H_6O_6Sr$: Sr, 35.01. Found: Sr, 34.32.

Oxidation of α-Methyl-*d*-mannopyranoside.—This oxidation proceeds more rapidly than in the previous cases so the total reaction time was reduced to one and a half hours. The yield of strontium salt (IV) was 55% after correcting for a small amount of mannoside which was recovered unchanged. The anhydrous form rotated −52.2° (*c*, 0.6280; *l*, 4).[11] The corresponding free acid rotated +25.2° (*c*, 1.044; *l*, 1).[11]

Anal. Calcd. for $C_6H_8O_7Sr{\cdot}2H_2O$: H_2O, 11.41. Found: (loss in wt. at 105° *in vacuo*), 12.18. Calcd. for $C_6H_8O_7Sr$: Sr, 31.25. Found: Sr, 31.08.

Oxidation of α-Methyl-*d*-glucopyranoside.—The total reaction time was three and a half hours, and the yield of strontium salt (VI) was 59% after correcting for a small amount of unchanged glucoside. The anhydrous salt rotated −50.7° (*c*, 0.6492; *l*, 2).[11] The corresponding free acid rotated +24.7° (*c*, 1.1440; *l*, 4).[11]

Anal. Calcd. for $C_6H_8O_7Sr{\cdot}2H_2O$: H_2O, 11.41. Found: (loss in wt. at 105° *in vacuo*), 11.8. Calcd. for $C_6H_8O_7Sr$: Sr, 31.25. Found: Sr, 31.13.

Summary

1. Several methyl-pyranosides have been oxidized with lead tetraacetate in glacial acetic acid and in chloroform solutions.

2. There has been observed in each case cleavage of the carbon chain with elimination of one carbon and formation of a dialdehyde through the consumption of two moles of oxidizing agent per mole of glycoside.

3. Further oxidation of these dialdehydes with strontium hypobromite has led to isolation of strontium salts of dibasic acids identical with those produced by Jackson and Hudson and Maclay and Hudson through the action of periodic acid and strontium hypobromite on the same methyl-glycosides.

4. In the case of α-methyl-*d*-mannoside it has been shown that in acetic acid at room temperature the removal of carbon three from the first fission product proceeds at a more rapid rate than does the initial cleavage.

CAMBRIDGE, MASS. RECEIVED JUNE 24, 1938

The Coupling Action of the Grignard Reagent. VI. A New Synthesis of Hexaalkylbenzils

BY REYNOLD C. FUSON AND JOSEPH CORSE

The coupling action of the Grignard reagent on halogen compounds has been shown to take place according to the general equation $2RMgX + 2R'X \longrightarrow R{-}R + R'{-}R' + 2MgX_2$.[1] The reaction seems to be conditioned largely by the activity of the halogen atom in the R′X molecule. In fact, similar results are obtained when the alkyl halide is replaced by other types of halogen compounds, notably certain metal halides such as cupric chloride[2] and silver bromide.[3] The metals suffer reduction—a change which is analogous to coupling. It would appear that any halogen compound in which the halogen atom is loosely bound might serve to bring about such effects.

It occurred to us that the halogen atoms of

[2] Krizewsky and Turner, *J. Chem. Soc.*, **115**, 559 (1919).

[3] Gardner and Borgstrom, THIS JOURNAL, **51**, 3375 (1929); Gardner, Joseph and Gollub, *ibid.*, **59**, 2583 (1937).

acyl halides should possess sufficient activity for this purpose. However, experience has shown that these react with Grignard reagents to give ketones or carbinols, and it is reasonable to suppose that addition to the carbonyl group takes precedence over other possible types of reactions. By the introduction of steric hindrance, however, it is possible to reduce the rate of the addition reaction and so favor any tendency there may be to undergo coupling.

To test this suggestion, we have made 2,4,6-trimethylbenzoyl chloride and 2,4,6-triethylbenzoyl chloride and treated them with solutions of methylmagnesium iodide. The results verified our prediction; both alkylation and coupling occurred. By analogy with similar types of reactions the equations for the alkylation and the coupling would be as follows

$$\text{Coupling: } 2R_3C_6H_2COCl + 2CH_3MgI \longrightarrow R_3C_6H_2COCOC_6H_2R_3 + C_2H_6 + 2MgICl$$

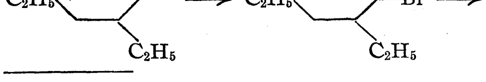
$$\text{Alkylation: } R_3C_6H_2COCl + CH_3MgI \longrightarrow R_3C_6H_2COCH_3 + MgICl$$

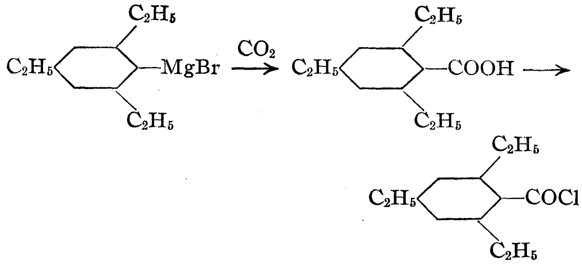
Alkylation alone occurred when the acid chloride was added to the solution of the Grignard reagent. In order to bring about coupling it was necessary to add the reagent to a dilute ether solution of the acid chloride. Under these conditions the yields of hexamethylbenzil and hexaethylbenzil were 39 and 32%, respectively. The alkylation products, acetomesitylene and 2,4,6-triethylacetophenone, were obtained in yields of 35 and 38.5%, respectively.

As a synthetic method for the preparation of hexamethylbenzil this is far superior to those of Kohler and Baltzly,[4] Gray and Fuson[5] and Fuson, Matuszesky and Gray.[6] It is somewhat more convenient than the method of Arnold and Fuson.[7] The hexaethylbenzil had not been made previously.

The work with triethylbenzene derivatives was greatly facilitated by the fact that this hydrocarbon has recently been made readily available by the excellent method of Norris and Rubinstein.[8]

The 2,4,6-triethylbenzoyl chloride was made by the following series of transformations





2,4,6-Triethylacetophenone, the product which accompanied the hexaethylbenzil, had been reported previously by Kunckell[9] but was not characterized. In the present work this ketone and its dinitro and benzal derivatives were synthesized and characterized.

Experimental Part

2,4,6-Triethylacetophenone.—A mixture of 162 g. of 1,3,5-triethylbenzene, 500 cc. of carbon disulfide and 300 g. of anhydrous aluminum chloride was placed in a 2-liter three-necked flask equipped with dropping funnel, stirrer and reflux condenser leading to a gas absorption trap. The mixture was heated to reflux and 101 g. of acetic anhydride was added over a period of one and one-half hours, the rate of addition being adjusted to keep the mixture boiling slightly. The mixture was stirred for an additional hour and allowed to stand for three hours. It was decomposed by pouring into 2 kg. of cracked ice to which 100 cc. of concentrated hydrochloric acid had been added. The layers were separated and the aqueous portion was extracted twice with 100-cc. portions of carbon disulfide. The extracts were added to the separated layer and the combined liquid was dried with calcium chloride. The solution was then filtered and the solvent removed on the steam-bath. The ketone distilled at 115–118° (5 mm.). The yield was 163 g. or 80% of the theoretical amount; n^{20}_D 1.5097; d^{20}_4 0.9475.

Anal. Calcd. for $C_{14}H_{20}O$: C, 82.26; H, 9.86. Found: C, 82.20; H, 9.79.

3,5-Dinitro-2,4,6-triethylacetophenone.—To 15 cc. of fuming nitric acid cooled to 0° was added 1 g. of 2,4,6-triethylacetophenone. The mixture was allowed to stand for ten minutes and then was poured into 50 g. of chipped ice. The precipitate was collected on a filter and recrystallized from aqueous alcohol. The yield of dry product was 1.3 g. or 90% of the theoretical amount. The compound crystallizes from alcohol in needles which melt at 112–113°.

Anal. Calcd. for $C_{14}H_{18}O_5N_2$: C, 57.13; H, 6.16. Found: C, 57.05; H, 6.06.

Benzal-2,4,6-triethylacetophenone.—A solution of 2.8 g. of sodium hydroxide in 22 cc. of water was made in a 50-cc. flask. To this was added 10 g. of 2,4,6-triethylacetophenone, 30 cc. of 95% ethyl alcohol and 5.8 g. of freshly distilled benzaldehyde. The flask was placed on the shaking machine for eighteen hours. The mixture was then diluted with 10 cc. of water and cooled. The crystalline product was separated and washed with 15 cc. of cold 80% alcohol. The yield of crude product was 14.2 g. or 90% of

the theoretical amount. The compound crystallizes in slightly tinted prisms which melt at 66°.

Anal. Calcd. for $C_{21}H_{24}O$: C, 86.24; H, 8.28. Found: C, 86.14; H, 8.25.

2,4,6-Triethylbromobenzene.—Three hundred and twenty-four grams of 1,3,5-triethylbenzene was added to 200 cc. of carbon tetrachloride in a 2-liter three-necked flask equipped with a stirrer, dropping funnel and reflux condenser which was attached to a gas absorption trap. Ten grams of powdered iron was added and the mixture cooled to 0°. The flask was protected from light as much as possible and 320 g. of bromine dissolved in 200 cc. of carbon tetrachloride was added with vigorous stirring over a period of five hours. The reddish-brown solution was allowed to stand overnight. It was then washed twice with 500-cc. portions of water, once with 500 cc. of 10% sodium hydroxide and with water until the aqueous layer was neutral to litmus. The carbon tetrachloride solution was dried with calcium chloride, filtered and the carbon tetrachloride removed by distillation. The residue was then refluxed one-half hour with an alcoholic solution of sodium hydroxide prepared from 400 cc. of 95% ethyl alcohol and 20 g. of sodium. The solution turned dark red and some sodium bromide precipitated. After standing overnight the solution was diluted with 1 liter of water and the bromide layer separated. The aqueous portion was extracted with three 200-cc. portions of carbon tetrachloride which were added to the halide layer The carbon tetrachloride layer was dried with calcium chloride, filtered and solvent removed on the water pump. The remaining solution was fractionated with the oil pump. Three hundred and forty grams of product boiling at 96–99° (2–3 mm.) was obtained. The yield amounted to 70% of the theoretical; $n^{20}{}_{D}$ 1.5366; $d^{20}{}_{4}$ 1.2076.

Anal. Calcd. for $C_{12}H_{17}Br$: C, 59.76; H, 7.11. Found: C, 59.89; H, 7.06.

2,4,6-Triethyl-3,5-dinitrobromobenzene.—Five grams of 2,4,6-triethylbromobenzene was added to 50 cc. of fuming nitric acid cooled to 0°. The mixture was allowed to stand at room temperature for twenty minutes and then poured into 250 cc. of water. The precipitate was collected and recrystallized from alcohol, giving needles which melt at 78.5–79°. The yield amounted to 4.6 g. or 67% of the theoretical.

Anal. Calcd. for $C_{12}H_{15}O_4N_2Br$: N, 8.46; Br, 24.13. Found: N, 8.66; Br, 23.72.

2,4,6-Triethylbenzoic Acid.[10]—Twelve and one-half grams of magnesium turnings was placed in a 1-liter three-necked flask equipped with stirrer, reflux condenser and dropping funnel. A solution of 120.5 g. of 2,4,6-triethylbromobenzene in 200 cc. of dry ether was then added at such a rate that, after the reaction started, gentle refluxing ensued. The addition of reagent takes about two and one-half hours. Stirring was continued for an additional hour, with heating the last twenty minutes. The mixture was then cooled in an ice–salt bath to −5°, and small pieces of dry ice were added cautiously. Care was taken not to add very large pieces because considerable heat is produced in spite of the coldness of the dry ice. After the reaction had spent its force and no appreciable heating took place on addition of dry ice, 50 to 75 g. of dry ice was added and the ice–salt bath removed. The mixture was allowed to come up to room temperature unaided and was then poured into 300 cc. of ice water containing 40 g. of ammonium chloride and 20 cc. of concentrated hydrochloric acid. The ether layer was separated and the aqueous layer washed twice with 100-cc. portions of 0.25 normal hydrochloric acid. The ether was then extracted with one 200-cc. and two 100-cc. portions of 10% sodium hydroxide solution. These were combined, made acid and the precipitate collected. The precipitate was dissolved in a 10% potassium bicarbonate solution. This solution was then extracted with 200 cc. of ether, the aqueous layer separated and boiled a little to remove dissolved ether. The aqueous solution was then cooled and made acid with dilute hydrochloric acid. The yield amounts to 68 g. or 66% of the theoretical. After recrystallization the acid melted at 113–113.5°.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80. Found: C, 75.71; H, 8.86.

3,5-Dinitro-2,4,6-triethylbenzoic Acid.—One gram of 2,4,6-triethylbenzoic acid was mixed with 20 cc. of fuming nitric acid and warmed on the steam-bath for thirty minutes. The yellow solution was then poured into 100 cc. of ice water and allowed to stand. The crystals were collected and after recrystallization from ligroin the melting point was 128.5–129°, as compared with 128–129° in the literature.[10]

2,4,6-Triethylbenzoyl Chloride.—To 51.5 g. of 2,4,6-triethylbenzoic acid in a 200-cc. modified Claisen flask, 51 g. of phosphorus pentachloride was added in small portions. When all the phosphorus pentachloride had been added and the reaction subsided, the mixture was warmed slightly for five minutes. The phosphorus oxychloride was removed by the water pump and the acid chloride was then distilled. The acid chloride boiled at 112–113° (4–5 mm.); the yield was 47 g. or 83% of the theoretical amount; $n^{20}{}_{D}$ 1.5182; $d^{20}{}_{4}$ 1.0424.

Anal. Calcd. for $C_{13}H_{17}OCl$: Cl, 15.78. Found: Cl, 15.54.

2,4,6-Triethylbenzamide.—To 40 cc. of concentrated aqueous ammonia was added 3.4 g. of 2,4,6-triethylbenzoyl chloride. The mixture was shaken for one hour. The precipitate was then collected and recrystallized from aqueous alcohol. The yield was 2.6 g. or 83% of the theoretical amount. The melting point was 148–150°, and after recrystallization rose to 154.5–155.5°. The literature[10] gives 155–156°.

2,4,6,2′,4′,6′-Hexaethylbenzil.—To a solution of 28.3 g. of 2,4,6-triethylbenzoyl chloride in 200 cc. of absolute ether placed in a 1-liter three-necked flask equipped with stirrer, reflux condenser and dropping funnel, was added 200 cc. of 1.35 molar methylmagnesium iodide solution. The Grignard reagent was added at a regular rate over a two-hour period, and the solution was stirred vigorously. The reaction mixture was then decomposed with an ice–ammonium chloride solution. The ether layer was separated and washed with water twice. The aqueous portion was extracted with two 100-cc. portions of ether, which were added to the ether layer. This ether solution was dried with anhydrous sodium sulfate, then filtered, the ether removed on the steam cone and the residue distilled

---

[10] Gattermann, Fritz and Beck, *Ber.*, **32**, 1123 (1899).

with the oil pump. Nine and eight-tenths grams of 2,4,6-triethylacetophenone came over at 112–114° (4–5 mm.). The distillation slowed up and was discontinued at this point. After standing overnight at room temperature, the flask contained yellow crystals. These were removed, filtered and washed with a little 85% alcohol. On recrystallization from petroleum ether, 7.75 g. of product was obtained. The yields of diketone and monoketone were 32.5 and 38.4%, respectively.

The monoketone was identified by means of a mixed melting point of its benzal derivative with an authentic specimen. The diketone crystallized in golden-yellow prisms melting at 75–75.5°.

Anal. Calcd. for $C_{26}H_{34}O_2$: C, 82.49; H, 9.06. Found: C, 82.53; H, 9.01.

2,4,6,2′,4′,6′-Hexamethylbenzil.—The Grignard reagent prepared from 23.7 g. of methyl iodide and 4.06 g. of magnesium diluted to 200 cc. with absolute ether was added with vigorous stirring over a period of seventy minutes to 10.95 g. of 2,4,6-trimethylbenzoyl chloride dissolved in 200 cc. of absolute ether. The reaction mixture was then decomposed and treated in a manner similar to that described for the triethyl compound. The yield of acetomesitylene was 3.44 g. and that of the benzil was 3.45 g., or 35 and 39%, respectively. The acetomesitylene was converted to the benzal derivative which was identified by means of a mixed melting point with an authentic specimen. The dimesityl diketone was likewise identified by comparison with an authentic specimen.

When the acid chloride was added to the solution of the Grignard reagent, it was not possible to isolate any benzil from the reaction products. Instead, acetomesitylene was formed in 88% yields.

Summary

2,4,6-Trimethylbenzoyl chloride and 2,4,6-triethylbenzoyl chloride are coupled by the action of methylmagnesium iodide to give, respectively, 2,4,6,2′,4′,6′-hexamethylbenzil and 2,4,6,2′,4′,6′-hexaethylbenzil.

A Phase Study of the System Sodium Palmitate–Sodium Chloride–Water at 90°

BY ROBERT D. VOLD[1] AND R. H. FERGUSON

It is the aim of this paper to present a complete equilibrium diagram of the system sodium palmitate–sodium chloride–water at 90° with greater precision than that which has characterized any previous published account of a similar system of soap, inorganic electrolyte and water. Especial emphasis is directed to the support of the interpretation of those parts of the diagram where the curd phase[2] is shown.

The practical soap maker has long been familiar with curd soap as an intermediate, distinctive form, differing markedly in its properties from neat soap, the usual finished product of the soap boiling process. However, the first clear concept of curd as a separate and discontinuous phase from neat soap, and of the relations of both these forms of soap to the other coexisting phases is of recent origin. This concept has been developed in a remarkable group of papers by McBain,[3] dealing with the properties and behavior of soap. In these papers both the experimental results and the imagination exhibited in the interpretation are of the first importance in the whole field of soap chemistry.

Inevitably, however, the evidence is not equally convincing with respect to all parts of the diagram constructed by McBain and his co-workers. For example, it is possible to derive conflicting views[4] relating to the presence of definite hydrates in the system at high temperatures, and the early dew-point results[5] do not support the existence of the three-phase invariant equilibrium, neat soap–curd phase–lye. In fact no definite constancy of phase composition has been clearly established hitherto for this equilibrium.

In general, the results of the present work, involving careful, systematic vapor pressure measurements of the system at 90°, are in agreement with McBain's conception of the equilibrium diagram. There are some quantitative divergencies, as may be noted by comparing the McBain diagrams with Fig. 6 below. In particular we have obtained definite proof that crystalline curd phase of sodium palmitate exists at 90° as a distinct phase different from neat soap, and that the neat–

---

[1] Present address: Department of Chemistry, Stanford University, California.

[2] The term *curd phase* will be used herein to refer to a homogeneous solid phase. In the literature, in addition to this meaning, the word curd has been used to describe variously a heterogeneous mixture of solid soap and other phases, any cooled and solidified soap system, and the upper curdy layer of soap in the soap kettle.

[5] McBain and Salmon, *J. Chem. Soc.*, **119**, 1374 (1921).

curd phase–lye equilibrium at this temperature is invariant. Contrary to the hypothesis of McBain, Lazarus and Pitter we find no evidence for the existence of stoichiometric hydrates of sodium palmitate at 90°.

Experimental

(a) **Methods Used.**—The solid nature of the systems encountered in highly concentrated soaps makes it virtually impossible to employ the method of phase separations developed by Ferguson and Richardson[6] for delimiting middle soap equilibria. Middle soap, while exceedingly gummy, is not as difficult to push to a condition of separation from other phases as is curd phase in the upper concentrated region of the diagram. Accordingly the phase separation method was used only to determine the boundaries of the middle soap and nigre fields.

For the various equilibria relating to curd phase and to check phase boundaries in the neat and middle soap fields an isopiestic vapor pressure method was devised. Essentially the method was adapted from that described by Collins and Menzies,[7] and has the advantage that it is independent of subjective visual observation of the appearance of the system, and is unaffected by whether or not the different phases present separate nicely or remain in intimate admixture.

A dew-point vapor pressure method was also employed in certain instances as discussed below.

(b) **Vapor Pressure Relations.**—The use of vapor pressure data to determine phase equilibrium diagrams is based directly on the requirements of the phase rule. A condition of invariance results whenever two condensed phases are simultaneously present in a binary system at constant temperature. Under such conditions the vapor pressure must remain constant despite changes in total composition, and thus give rise to flat portions in the vapor pressure–composition curve. The compositions at the ends of such "flats" give points on the phase boundaries of the two soap phases in equilibrium with each other.

In the ternary system soap–salt–water, at constant temperature, three condensed phases must be present before the pressure is independent of the total composition. In this case, however, the compositions at the ends of the flat in the vapor pressure curve give points on boundary lines connecting the compositions of the three phases present instead of giving the phase compositions themselves as in the binary system. This is equivalent to saying that "flats" in the vapor pressure curves in a ternary system are indicative of and specify the positions of triangles in the equilibrium diagram.

The composition at which transition from a one-phase to a two-phase region occurs in the ternary system at constant temperature may be determined from the vapor pressure–composition curve, since it is marked by a definite change in slope. This arises from the fact that in the one-phase region the rate of change of vapor pressure is directly dependent on the total composition, whereas in the two-phase region it is determined by the change of the compositions of the individual phases themselves.

Where lye (the technical name for any solution of electrolyte containing but little soap) is present, tie-line directions can be deduced from vapor pressure data. At equilibrium the partial pressure of water must be the same over all phases in the system. Consequently, the composition of a lye phase can be determined from the observed pressure in conjunction with standard recorded values for the vapor pressure of salt solutions, provided the solubility of sodium palmitate in the lye is not sufficient to change its vapor pressure appreciably. Lines drawn between the known composition of the total system and the composition of the equilibrium lye determined in this manner give the tie line upon which the composition of the equilibrium soap phase must lie.

That this procedure is valid in the present system was demonstrated by direct analyses of several lye layers which showed that sodium palmitate is practically insoluble in fairly concentrated salt solutions at 90°. Furthermore, it was found that the vapor pressure of systems consisting of curd phase, saturated lye and solid salt agreed exactly with that in the literature for the vapor pressure of a saturated salt solution at 90° and with our own values for the dew-point of saturated salt solution.

(c) **Procedure.**—In the more dilute systems phase boundaries were determined by methods of phase separation and analysis similar to those used with commercial soap systems.[8] In a few cases analyses were made of the partially separated phases, thus obtaining tie line directions. In all cases the visual appearance of the equilibrium systems was noted carefully in order to identify the phases present and facilitate interpretation of the vapor pressure curves.

[8] Ferguson, *Oil & Soap*, **14**, 115 (1937).

Studies by this (separation) technique were actually carried out at 100° instead of at 90°. The results were calculated to 90° for incorporation with the results of vapor pressure studies by use of temperature coefficients of phase boundary concentrations deduced from McBain's equilibrium diagrams at 90 and 100°. That no appreciable error is introduced by this procedure is evident since (a) the phase boundary concentrations for these phases—nigre, middle soap and neat soap—change but slowly with temperature, thus making the total correction small, and (b) for these phases the results obtained by McBain at 100° agree within 2% with those obtained in our study.

Phase equilibria in the more concentrated systems were deduced from vapor pressure curves as described above. After considerable preliminary work it was found that satisfactory results were obtained when 10-cc. portions of sulfuric acid solution were equilibrated with 1-g. soap samples in a closed system. During the experiment the acid concentration remains essentially constant while the soap system gains or loses water as required to make its vapor pressure the same as that of the acid.

In this work soap systems and sulfuric acid solutions were measured into the respective legs of an inverted Y-shaped Pyrex tube of about one inch (2.5 cm.) diameter. The tubes were then chilled in a salt–ice mixture and sealed off under vacuum from a water pump. After immersion in an oil-bath held at 90 ± 0.2° for a sufficient period to establish equilibrium (usually about five days) the two legs of the tube were simultaneously plunged into ice water thus preserving the compositions present at 90°. In this operation care was taken to make the level of the ice water the same as the level of the soap and acid in the respective legs in order to minimize distillation of water either into or out of the soap sample during the quenching process. The tube was then broken open and the contents of the two legs analyzed. The water content of the soap system was determined from the loss of weight on heating the *whole* sample to constant weight at 105°. The concentration of the sulfuric acid solution was determined by titration of a known weight of solution with standard alkali. Vapor pressures were obtained from the sulfuric acid concentrations of a plot of Collins'[9] vapor pressure results for such solutions at 90°.

A very large number of experiments was carried out with both binary and ternary systems over the whole composition range to test the validity of this method of vapor pressure determination as applied to soap systems and to establish the accuracy of the results. That the isopiestic method is satisfactory for use with soap systems is evident from the following experimental generalizations based on this work.

(1) Any two soap–water systems, one of higher and the other of lower water content, reach the same final concentration when sealed up in separate tubes with an acid of aqueous vapor pressure between the vapor pressures of the original soap systems.

(2) Duplicate soap samples sealed up in different tubes with the same acid reach the same equilibrium concentration at 90° even though one is brought to 90° by heating up from room temperature and the other by cooling down from 103°.

(3) Although the relative amounts of soap system and sulfuric acid were varied fivefold in some cases, the same vapor pressure and soap concentration were reached at equilibrium in all instances.

(4) Vapor pressures of salt solutions at 90° determined by the isopiestic method are in satisfactory agreement with the literature values, and with our dew-point determinations.

(5) Soap systems of widely differing initial concentration came to the same final concentration within a maximum deviation of ± 0.6% when equilibrated with the same acid. Some of the data on which this conclusion is based appear in Table I.

The reliability of the methods of analysis used was verified by analyzing samples of known composition and also by comparison of results with those obtained by analyses of samples for real soap content by standard methods.

To prove the absence of any systematic errors in the isopiestic vapor pressure method which conceivably could have led to erroneous vapor pressure–composition curves with resultant misconception of the nature of the phase equilibria involved, the vapor pressures of sodium palmitate–water systems at 90° were redetermined using an entirely independent method. For this purpose a dew-point method was used patterned after that described by McBain and collaborators.[10]

Use of the dew-point method for the determination of vapor pressures in the present work rests on the fact that the partial pressure of water vapor from a soap system at 90° is the same as that of pure water at some lower temperature. The temperature of pure water having the same vapor pressure as the soap system at 90° is given by the temperature at which dew just begins to form on a polished metal tube suspended in a closed space above the soap system. The vapor pressure of the soap system of known composition is then found simply from standard tables giving the vapor pressure of water at the dew-point temperature.

The technique of our determinations was essentially the same as that described by McBain, and modified by Ferguson and Vold.[11] The apparatus consisted of a glass tube closed at top and bottom with monel metal plates. These were equipped with circular grooves in which rubber washers were placed, and were held tightly against the glass by means of four "tie bolts." The top plate had a threaded hole through which the dew-point tube proper could be screwed down tightly against a rubber washer. The dew-point tube itself was a chromium-plated copper tube whose temperature could be varied by forced circulation of water from an auxiliary bath.

Extraordinary precautions were required to obtain accurate rather than merely reproducible results by this method. Soap samples (about 15-g. systems) were homogenized by heating to 295° in sealed tubes in a rotating autoclave prior to studying them in the dew-point apparatus. It was shown experimentally that the composition of the sample in the dew-point apparatus did not change during the time of the experiment. This is important since a small change in total composition may give rise to a

surface layer of sufficiently different composition from the bulk of the sample to cause a serious error in the dew-point. At least fifteen hours was allowed for attainment of equilibrium since preliminary experiments showed that in many cases shorter periods of time were inadequate.

The validity of the technique finally evolved was confirmed by several tests. The vapor pressure of salt solutions at 90° determined by this dew-point method agreed within 1 mm. with the values listed in the "International Critical Tables."[12] In several experiments the equilibrium temperature was approached from higher and lower temperatures without causing any change in the observed dew-point of the soap sample at 90°. Finally, it was shown with several samples that the dew-point remained unchanged for periods of time running up to a week in the apparatus at 90°.

As appears from the results shown in Fig. 1, vapor pressures determined by the dew-point technique agree within the experimental error of that method with those obtained by the isopiestic method. Both series of experiments for systems containing NaP and H_2O alone, *i. e.*, along the left axis of the ternary phase diagram, show a step in the vapor pressure–composition curve, thus furnishing proof of the simultaneous presence of curd phase and neat soap as distinct phases.

It is of interest that the same result is obtained despite the fact that homogenized samples were used in the dew-point experiments whereas soap systems used in the isopiestic experiments had never been heated much above 105° and were used directly without preliminary equilibration. This fact would seem to show that we are dealing with the same equilibrium solid phase in both cases despite the difference in initial treatment.

(d) **Materials.**—The sodium palmitate used in these experiments was prepared by neutralizing (to phenolphthalein) a hot alcoholic solution of palmitic acid with a nearly saturated carbon dioxide-free aqueous solution of sodium hydroxide. The resulting soap was dried at 130–140°.[13] The palmitic acid was Eastman best product. The two lots used to prepare the sodium palmitate at different times during the course of the experimental work had the following characteristics.

Iodine value	0.09	0.05
Incipient fusion	61.5	61.9
Complete fusion	62.6	63.0
Molecular weight (by titration)	260	261

Sodium palmitate–water samples of the same composition made up from the two different preparations of sodium palmitate had the same vapor pressure.

Coleman and Bell C. P. sodium chloride was used throughout.

(e) **Results.**—The vapor pressure data obtained for the sodium palmitate–water system at

(12) "International Critical Tables," Vol. III, 1928, p. 370.

(13) A dilatometric investigation of sodium palmitate has indicated the existence of more than one form of anhydrous solid soap, and additional liquid crystalline phases. Transitions from one phase to another may be slow (or incomplete) with the result that the modification obtained may depend on the experimental conditions of the preparation. The curd phase under discussion in this paper always contained some water; it formed spontaneously in the system and so must be the stable equilibrium solid phase at this temperature. Furthermore, equilibria involving curd phase at 90° were shown experimentally to be perfectly reversible. Hence, it is difficult to imagine that the results obtained with aqueous systems at this temperature are subject to any uncertainty arising from possible differences in the initial crystalline modification of the anhydrous sodium palmitate.

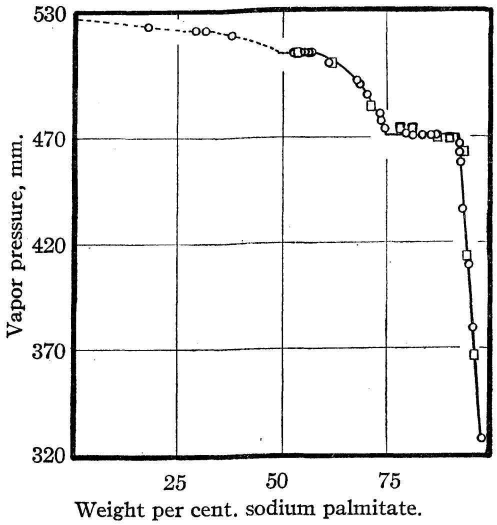

Fig. 1.—The vapor pressure of sodium palmitate–water systems at 90°: ○, points by the isopiestic method; □, points by the dew-point method.

90° are assembled in Table I. To conserve space the data for ternary systems are shown graphically in Figs. 2, 3, 4 and 5. The compositions at which phase changes occur, deduced from the vapor pressure curves and from the phase analysis and delimiting experiments, are given in Table II.

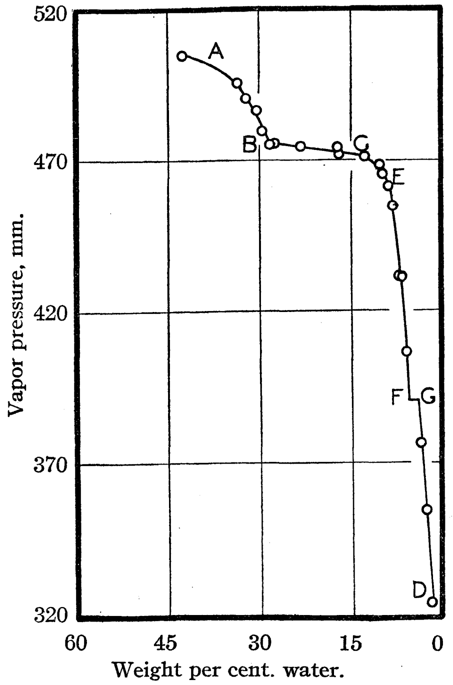

Fig. 2.—The vapor pressure of sodium palmitate–sodium chloride–water systems at 90°: sodium chloride concentration equals 0.80% sodium palmitate concentration.

In Fig. 1 the partial pressure of water vapor is plotted as a function of composition for the sodium palmitate–water system at 90°. The three flats in the curve correspond respectively to the coexistence of middle soap–nigre, middle soap–neat soap and neat soap–curd phase. The compositions of the phases in equilibrium, determined from the ends of the flats in the vapor pressure curve in the case of middle soap–nigre and middle soap–neat equilibria, are in good agreement with the values found directly by the delimiting method. The flat for the neat soap–curd phase equilibrium constitutes conclusive experimental proof of the existence of these two forms of soap as independent phases.

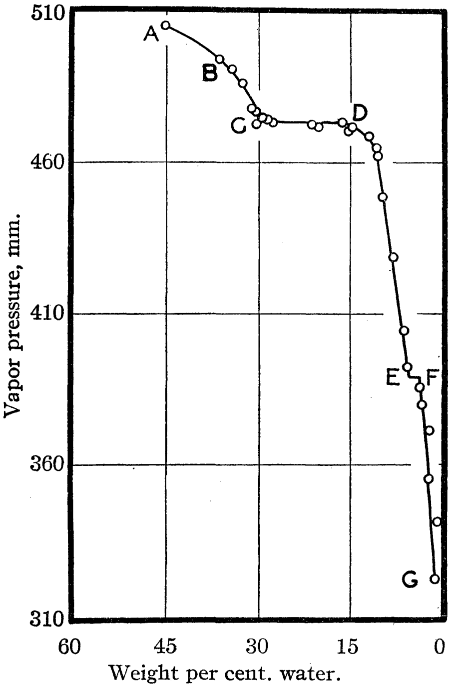

Fig. 3.—The vapor pressure of sodium palmitate–sodium chloride–water systems at 90°: sodium chloride concentration equals 1.22% sodium palmitate concentration.

Figure 2 shows the change in partial pressure with change in water content for systems in which the ratio of salt concentration to soap concentration is held constant at 0.0080. The application of phase rule principles to this curve, coupled with visual observation of the phases present, leads to the following interpretation. Above 28.5% water (point B) neat soap is present. Between 28.5% and 12.5% water (B to C) neat soap and curd phase are present. Since three condensed phases are required for a condition of invariance in a ternary system at set temperature, the pressure is not constant but changes slowly with the total composition. After all the neat soap has disappeared (point C) curd phase alone remains and the pressure falls more rapidly with further decrease in water content. At 9.0% water (point E) a two-phase region, curd phase–lye, is again entered with a resultant slight change in slope of the vapor pressure curve. Between 5.1 and 3.9% water (points F and G) the vapor pressure remains constant, thus showing three condensed phases are present in the system. These are curd phase, saturated lye and solid salt. Below 3.9% water only the two solids, curd phase and crystalline salt, remain and the vapor pressure decreases rapidly and continuously with further decrease in water content.

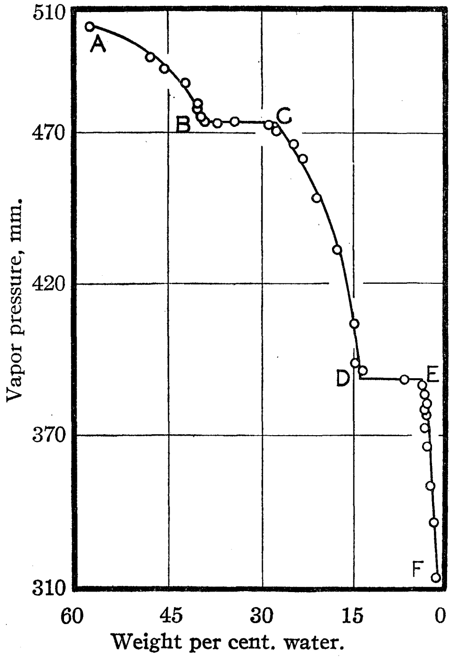

Fig. 4.—The vapor pressure of sodium palmitate–sodium chloride–water systems at 90°: sodium chloride concentration equals 5.27% sodium palmitate concentration.

The change from curd phase to curd phase–lye, evidenced by the inflection in the curve at E, is so slight that it was identified as such only after subsequent work determining the equilibrium diagram had shown the necessity for its existence. The compositions at the ends of flats, indicative of the presence of three condensed phases, are much more accurately determined than are the compositions of inflections representing transitions from one-phase to two-phase regions.

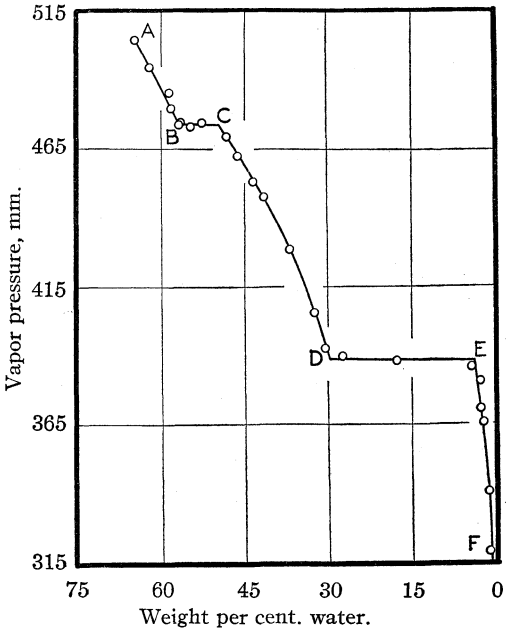

Fig. 5.—The vapor pressure of sodium palmitate–sodium chloride–water systems at 90°: sodium chloride concentration equals 17.70% sodium palmitate concentration.

Figures 3, 4 and 5 show the results at higher relative salt concentrations where progressive decrease in water content results in the formation of two different three-phase equilibria. The compositions at the ends of the higher flat in each curve represent the range within which neat soap, curd phase and lye exist in equilibrium with each other. The lower flat determines the composition range of coexistence of curd phase, saturated lye and solid salt.

The phase equilibrium diagram at 90° is shown in Fig. 6. This diagram is simply a modification of the customary Gibbs triangle for representation of the equilibria in ternary systems and is especially convenient in representing soap systems. Ordinates show the weight per cent. of sodium palmitate and abscissas the weight per cent. of sodium chloride, the per cent. water being obtained by difference. A straight line, passing through the origin and any given composition, represents the compositions of all systems which can be obtained by altering the water content of the original system.

The experimental data on which the equilibrium diagram is based are assembled in Table II. The compositions of the curd phase and neat soap corners of the curd phase–neat soap–lye triangle were determined within about 2% by comparison of the vapor pressure curves for systems with salt to soap concentration ratios of 0.008 and 0.012. On the first curve (Fig. 2) the compositions of curd phase and neat soap at the inflection points (C and B) lie just outside the triangular area; on the second curve (Fig. 3) corresponding points (D and C) lie just inside this area. The composition limits of the neat soap–middle soap–nigre and neat soap–nigre–lye triangles at 90° were obtained indirectly from values for these points at 100°. These compositions at 100° were corrected for the 10° decrease in temperature by the same relative amounts deduced for corresponding points in phase rule diagrams of the system: tallow soap–sodium chloride–water at 100 and 80°.[14] Use also was made of McBain's data showing the change in the isotropic solution boundary in the sodium palmitate–sodium chloride–water system from 100 to 90°.

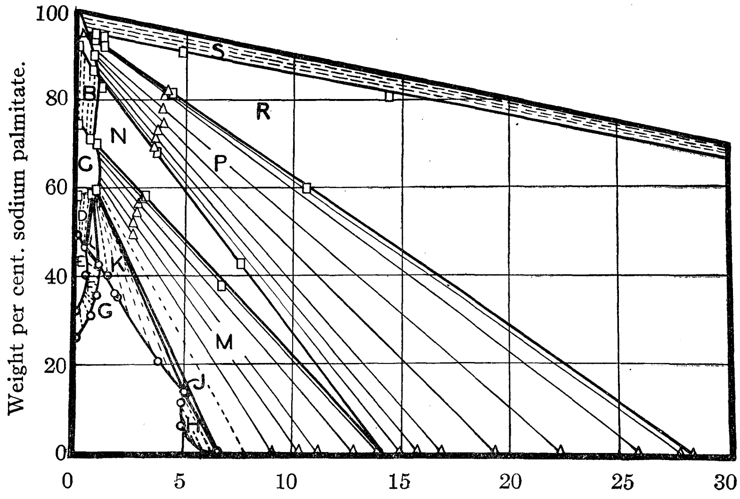

Fig. 6.—The system sodium palmitate–sodium chloride–water at 90°: ○, points from delimiting experiments; □, points from vapor pressure data; △, points from tie line determinations. A, curd phase; B, curd phase–neat; C, neat; D, neat–middle; E, middle; F, middle–nigre; G, nigre; H, nigre–lye; J, neat–nigre–lye; K, neat–nigre; L, middle–neat–nigre; M, neat–lye; N, neat–curd phase–lye; P, curd phase–lye; R, curd phase–lye–salt; S, curd phase–salt.

The following considerations establish the validity of the present experimental results. Theoretically two of the lines forming the boundaries of the neat soap–curd phase–lye triangle should converge to a point on the lye axis corresponding to a lye composition above which curd phase is in equilibrium with lye and below which neat soap is in equilibrium with lye. It is clear from Fig. 6 that the experimental points do fall nicely on straight lines which intersect exactly at a point on the water–salt axis. In all cases the same vapor pressure (473–474 mm.) was found experimentally for all systems having compositions within the triangle.

In the curd phase–saturated lye–solid salt equilibrium theoretically one of the lines forming the sides of the triangle should run to the point representing pure salt and another to the composition of a saturated lye solution (28.4%). As appears in Fig. 6 the experimental points do define two straight lines which satisfy these requirements. Here again the same vapor pressure was found experimentally for all systems within the triangle regardless of wide variations in total composition. Furthermore, the value found for this vapor pressure, 389 mm., is in good agreement with the literature value for the vapor pressure of a saturated salt solution at 90°.[12]

The accuracy of the results by the analytical and phase-delimiting method for equilibria involving fluid soap phases is attested by their self-consistency. Furthermore, the boundaries obtained by this method are in relatively good quantitative agreement with those obtained by McBain[3] by an entirely different method.

Discussion

(a) Description of Phases.—Descriptions of the physical nature of equilibria involving liquid and liquid crystalline soap phases have already been given in considerable detail for several systems, notably tallow soap–sodium chloride–water,[6,15] potassium oleate–potassium chloride–water[16] and potassium laurate–lauric acid–water.[17] Since the corresponding phases in the sodium palmitate–sodium chloride–water system at 90° closely resemble those referred to above, it will be unnecessary to describe them here in detail.

More attention will be devoted to equilibria involving curd phase since these have not been so adequately described.

As appears in Fig. 6 sixteen different equilibrium conditions are possible at 90°, the particular state of any given system being determined by the relative amounts of soap, salt and water present. Inspection of the phase diagram shows the concentration limits for the existence of these various equilibria.

1. Nigre, or isotropic solution of soap and salt (Field G), is a single homogeneous phase, despite its colloidal nature and capacity for existing as mobile liquid, thick viscous liquid or even elastic transparent jelly.

2. Middle soap (Field E) is also a single phase of variable composition, a liquid crystalline solution. It combines the mechanical properties of a stiff fluid having a pronounced yield value[18] with certain of the optical properties of a crystal. Generally it occurs as clear gummy lumps of very great viscosity.

3. Neat soap (Field C), a single phase of variable composition, is another liquid crystalline solution. It is more turbid and at 90° in this system is less viscous than middle soap.

4. Curd phase (Field A) is another single phase of continuously variable composition. It is a crystalline form of solid soap. When formed in the presence of neat soap it is characterized by

10.2	57.9	406	26.1
10.5	59.3	393	27.8

[a] In these systems salt concentration was only 15% of soap concentration.

the presence of long, lustrous fibers and tufts of shorter, finer fibers. We have obtained these fibers in lengths up to two or three centimeters.

Analysis of fibers in the binary system shows that they consist of neutral soap and water, thus proving that their development is not due to the formation of acid soap. Expulsion of water by drying to constant weight at 105° results in no change in the appearance of the fibers nor are they affected by cooling from 90° to room temperature. Fibers developed in binary systems of sodium palmitate–water were no different in appearance from those formed in the ternary system.

Plates 1, 2 and 3 are typical of the appearance of these fibers. Plate 1 shows a mixture of macroscopic curd phase fibers and neat soap. Plates 2 and 3 are photomicrographs of curd phase fibers at successively higher magnifications. They illustrate the similarity in form between the large fibers visible to the unaided eye and the finer ones visible with the microscope. This same structural form also has been observed in the ultramicroscope.[19]

Curd phase formed without contact with neat soap, as by diffusion of water vapor into anhydrous sodium palmitate, does not develop visible fibers. Under these circumstances the appearance is that of a white solid of granular formation.

5. Two-phase equilibrium between nigre and middle soap (Field F). It is of interest here that addition of salt to the soap solution actually results in an increase in the solubility of the soap.

6. Two-phase equilibrium between nigre and neat soap (Field K). Here increased salt concentration in the soap solution results in a rapid decrease in the solubility of the soap, the saturation phase being liquid crystalline neat soap.

7. Two-phase equilibrium between nigre and lye (Field H). At low soap concentrations sufficient increase in salt concentration results in separation into two isotropic liquid phases.

8. Two-phase equilibrium between neat soap and lye (Field M). Reasonably good separations of molten liquid crystalline neat soap over isotropic lye occur throughout this range of concentrations.

9. Two-phase equilibrium between neat soap and middle soap (Field D). This is a very difficult field in which to obtain separation of phases.

10. Two-phase equilibrium between neat soap and curd phase (Field B). Complete separation of phases was never attained in this range, although a fairly good degree of segregation was obtained in a centrifuge. Even systems of total composition such that they were mostly neat soap appeared to the naked eye to consist primarily of fibrous solid material.

11. Two-phase equilibrium between curd phase and lye (Field P). As the total soap concentration is increased, the appearance of the curd phase changes from a feathery white solid, covered with a fuzz of fine whiskers, to a damp granular solid of no pronounced structure. Sometimes a clear lye layer separated below the soap

(19) McBain, Darke and Salmon, *Proc. Roy. Soc.* (London), **A98**, 395 (1921).

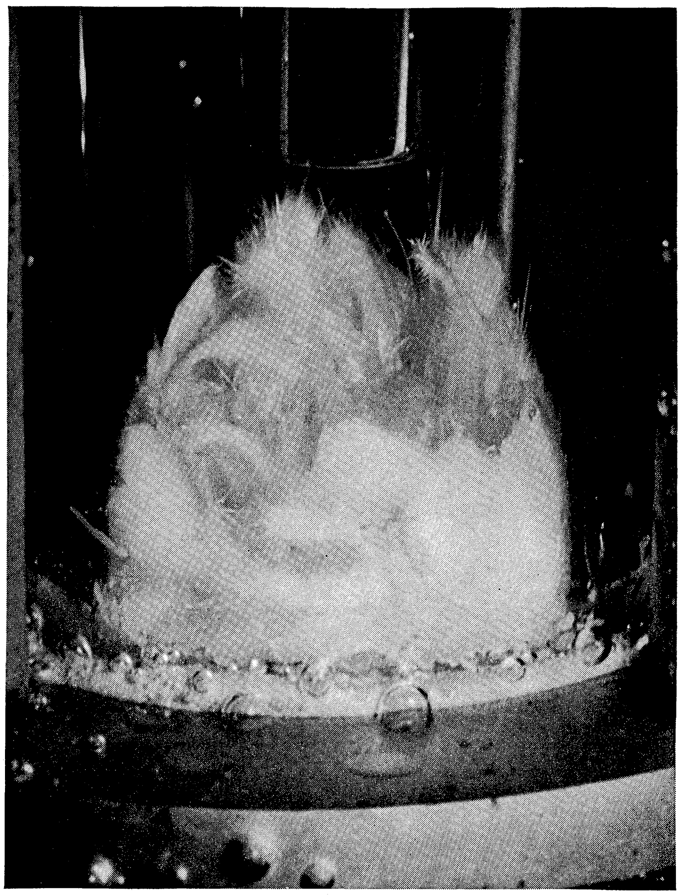

Plate 1.—Macroscopic fibers at 90°: NaP–H_2O system, 76.9% NaP after a few days at 90°.

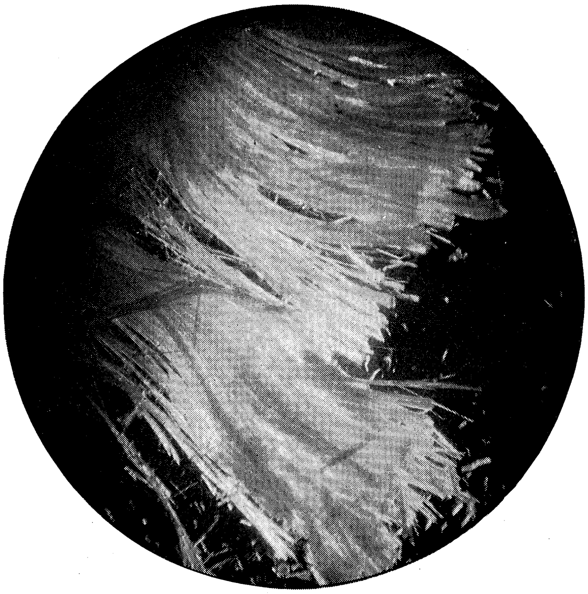

Plate 2.—Photomicrograph of macroscopic curd fibers: NaP–H_2O system, about 76% NaP, polarized light ×13, crossed Nicols.

Plate 3.—Photomicrograph of macroscopic curd fibers: reflected light ×42.

layer; at other times all the lye was mechanically enmeshed in the curd phase forming a macroscopically homogeneous mass.

12. Two-phase equilibrium between curd phase and solid salt (Field S). The appearance of these systems is very similar to the soap layers found in the region of curd phase–lye equilibria. As the water content is decreased the soap gradually becomes drier and changes from a loosely caked solid to a granular dry free-flowing solid. In most cases crystals of salt can be seen mixed with the soap.

13. Three-phase equilibrium between neat soap, middle soap and nigre (Field L). (Separations have been obtained in certain commercial soap systems.[6])

14. Three-phase equilibrium between neat soap, nigre and lye (Field J). The relatively low soap content of the neat soap separating in the sodium palmitate system compared to that separating in this region in systems of ordinary commercial soaps is of technical interest.

15. Three-phase equilibrium between neat soap, curd phase and lye (Field N). As in the case of curd phase–neat soap equilibria, systems in this composition range usually developed pronounced macroscopic soap fibers. Occasionally a small amount of lye settled out beneath the soap layer but in general these systems appeared macroscopically homogeneous despite the actual presence of three phases.

16. Three-phase equilibrium between curd phase, saturated lye and solid salt (Field R). Here again most of the salt and lye are enmeshed in the curd phase forming a damp mass of white solid. Sometimes crystals of free salt were observed.

(b) **Comparison with Previous Work.**—The present results are in agreement with McBain's general concept of curd phase existing in true reversible equilibrium with neat soap and lye. In the fields of nigres, middle soap, neat soap, middle soap–nigre, middle soap–neat soap–nigre, neat soap–nigre, neat soap–nigre–lye and neat soap–lye our results by phase analysis and delimiting methods are in satisfactory quantitative agreement with McBain's results obtained by extrapolation from observations of temperatures at which phase changes occurred in systems of varying composition.

In the equilibria involving solid soap phases there are considerable discrepancies between the present results obtained by the vapor pressure method and the older work. For instance, our results show that the presence of small amounts of salt in curd phase actually increases the amount of water it can contain before "melting" to neat soap, whereas McBain tentatively drew the phase boundary as though the water content of curd phase decreased on addition of salt. However, this is not a difference in kind but only of degree. It is not surprising inasmuch as previous diagrams of the equilibria involving curd phase were derived from a few scattered incidental observations by a process of reasonable deduction rather than from systematic experimental data. The upper apex of our curd–lye–salt triangle is considerably different from McBain's. This may be due to a difference in the soap used, in the method of preparation of the soap before determining the vapor pressure, or to a systematic error in the older vapor pressure work.

(c) **Nature of Curd Phase.**—The present work, in agreement with the first work of McBain and collaborators, shows that curd phase in this system consists of sodium palmitate associated with varying amounts of salt and water. On the basis of the fact that at room temperature quite different amounts of water can be contained in the curd phase, McBain[3,10] tentatively assumed the existence of definite sodium palmitate hydrates. Contrary to this hypothesis all the present work favors the view that the curd phase of sodium palmitate at 90° is a single phase of continuously variable composition.

Let us consider the vapor pressure—composition curve for the binary system, sodium palmitate–water, at 90°. If there is a stoichiometric hydrate, application of the phase rule in its usual form necessitates a flat in the vapor pressure curve corresponding to the equilibrium between anhydrous sodium palmitate and the hydrate. Actually the vapor pressure of curd phase at 90° was found to decrease continuously with decrease in water content.

Points on the curd phase boundary could not be obtained directly by phase analysis or delimiting experiments because of incomplete separation of phases. However, in many cases tie-line directions could be ascertained by analysis even though the composition of the uncontaminated soap phase at the end of the tie-line remained unknown. All tie lines involving curd phase extrapolated to points of continuously variable composition on the curd phase boundary. If curd phase consisted of one or more definite hydrates these tie-lines would have had to converge to the points representing the compositions of the hydrates. In this connection it might also be mentioned that in an earlier paper McBain[5] himself has commented on the fact that the water content of soap curd appears to vary continuously with the concentration of the electrolyte used to salt it out.

Summary

An isopiestic vapor pressure method has been developed which is suitable for studying soap systems at high temperatures and high soap concentrations where the usual methods based on observation of phase changes or analysis of phases are inapplicable due to non-separation of phases. By means of vapor pressure measurements in a pure single soap system at 90°, it has been demonstrated (a) that curd phase can exist in true reversible equilibrium with neat soap, and that the two are separate phases; (b) that no stoichiometric hydrates occur in the system at 90°, the curd phase varying continuously in water content.

The complete equilibrium diagram has been drawn for the system sodium palmitate–sodium chloride–water at 90°.

The formation and appearance of curd fibers have been described.

The Preparation of Some Higher Alkylglucosides

BY C. R. NOLLER AND W. C. ROCKWELL

The following records the preparation and some properties of *n*-hexyl-, *n*-octyl-, *n*-nonyl-, *n*-decyl- and *n*-dodecylglucoside. These compounds were synthesized in order to make available for physical-chemical investigations pure surface-active compounds of known constitution that have suitable solubility characteristics and do not ionize in aqueous solutions.

The method of synthesis was essentially that of Fischer and his co-workers,[1] namely, the condensation of acetobromoglucose with the appropriate alcohol and hydrolysis of the tetraacetyl derivative to the alkyl glucoside. One important change was made in the method of deacetylating the tetraacetates, namely, the replacement of hydrolysis using barium hydroxide or ammonium hydroxide by catalytic transesterification[2] with methyl alcohol and sodium methoxide. In this way the time of hydrolysis is greatly reduced and the isolation of the pure glucoside is simplified.

It will be noted from the tables that while the melting points of the tetraacetyl derivatives are fairly sharp, those of the alkyl glucosides especially from octyl up are over a very wide range. This was noted by Fischer and Helferich,[1] who stated that they were unable to explain the phenomenon. We have noted that during a melting point determination the solid changed to a semi-transparent state at the lower temperature noted. On further raising the temperature little change took place until the higher temperature was reached when sharp melting to a clear liquid occurred. It appears to us that the lower temperature marks the transition from the solid to the liquid–crystal state and the higher temperature the transition from the liquid–crystal to the liquid state.

n-Hexylglucoside is very soluble in water and its aqueous solutions show little tendency to foam on shaking. As the length of the alkyl group increases the foam-producing ability is greatly increased, the nonyl-, decyl- and dodecylglucosides giving very stable foams. The solubility in water decreases, the dodecylglucoside being only sparingly soluble in cold water but readily in hot water. Cetylglucoside was reported by Fischer and Helferich[1] as being insoluble in water.

It was not determined whether these glucosides are hydrolyzed by emulsion but the work of Fischer and Helferich and the observed negative rotations would indicate that they are β-glucosides.

Experimental

Pentaacetylglucose and Acetobromoglucose.—When pentaacetylglucose was prepared according to the proced-

ure of Fischer,[3] using 100-g. quantities of glucose, charring took place due to the heat of the reaction. This was obviated by adding the glucose in portions of about 10 g. at such a rate that the temperature did not rise above 110°. Glucose hydrate may be used instead of the anhydrous glucose recommended by Fischer without changing the yield or quality of the product.

Considerable trouble was encountered in the preparation and storage of acetobromoglucose. Of the various procedures reported in the literature and modifications which were tried, the method of Freudenberg, Noe and Knopf[4] gave the best results.

Tetraacetylalkylglucosides.—A mixture of 0.15 mole of the pure alcohol, 0.02 mole of acetobromoglucose, 200 cc. of absolute ether and 0.025 mole of freshly prepared, dry silver oxide[5] in a tightly stoppered flask was shaken mechanically for two hours. At the end of this time a small sample gave no precipitate when tested with silver nitrate solution. The ether solution was filtered through a thin layer of diatomaceous earth on a Büchner funnel, the ether evaporated and the excess alcohol removed by steam distillation. Upon cooling the residue in the flask, the crude tetraacetylglucoside congealed and was filtered and crystallized from dilute aqueous methyl alcohol. The products frequently came down as a milky emulsion which crystallized on cooling in an ice-bath. The yields varied from 40 to 60% of the calculated amount. The properties and analyses of the individual compounds are given in Table I. The specific rotations were determined in methyl alcohol solution.

TABLE I

TETRAACETYLALKYLGLUCOSIDES

Alkyl radical	M. p., °C.	$[\alpha]^{25}D$	Saponification equivalent Calcd.	Found
n-Hexyl	51–52.5	−22.4	108.1	106.7
n-Octyl	53–54	−21.7	115.1	116.5
n-Nonyl	39.5–40.5	−20.9	118.6	118.4
n-Decyl	47.5–48.5	−21.5	122.1	123.0
n-Dodecyl	58.5–59.5	−18.8	129.1	131.0

Alkylglucosides.—To a solution of 0.01 mole of tetraacetylalkylglucoside in 100 cc. of absolute methyl alcohol was added 2 cc. of a 0.1 *N* solution of sodium methylate in methyl alcohol. The solution was boiled for one-half hour under a reflux condenser protected by a calcium chloride tube and the methyl alcohol then removed under reduced pressure. The sirupy residue was taken up in hot ethyl acetate and on cooling in a freezing mixture the glucoside crystallized and was filtered and washed with petroleum ether. Considerable difficulty was encountered in crystallizing the crude glucosides since there was a tendency to separate as a gel. The dodecylglucoside crystallized best from water. The properties and analyses of the glucosides are given in Table II, the rotations being determined in methyl alcohol solution. The analyses for glucose were made by hydrolyzing the sample with dilute sulfuric acid and determining iodimetrically the amount of glucose formed. We are indebted to Mr. S. Kinsman for the rotations and analyses of the alkylglucosides.

TABLE II

ALKYLGLUCOSIDES

Alkyl radical	M. p., °C.	$[\alpha]^{25}D$	% glucose after hydrolysis Calcd.	Found
n-Hexyl	88–91	−33.7	68.1	68.9
n-Octyl	65–99	−30.3	61.6	62.2
n-Nonyl	65–118	−28.8	58.8	58.3
n-Decyl	75–130	−27.8	56.2	56.3
n-Dodecyl	77–137	−24.7	51.7	51.2

Summary

n-Hexyl-, *n*-octyl-, *n*-nonyl-, *n*-decyl- and *n*-dodecylglucosides and their tetraacetates have been prepared in a pure state. Aqueous solutions of the glucosides from octyl through dodecyl foam on shaking but dodecylglucoside is only slightly soluble in cold water. These glucosides should be of value in physical-chemical investigations where a non-ionizing surface-active substance is desired.

A Method of Distinguishing Primary, Secondary and Tertiary Aliphatic Acids

BY FRANK C. WHITMORE AND HARRY M. CROOKS, JR.

Whitmore and Laughlin[1] found that when certain aliphatic acids were treated with phosphorus pentoxide at temperatures in the neighborhood of 150° the relative yields of carbon monoxide and carbon dioxide were dependent upon the character of the alkyl group attached to the carboxyl carbon. Their results indicated this as a possible method of distinguishing between primary, secondary and tertiary acids RCH_2COOH, $RR'CHCOOH$ and $RR'R''CCOOH$. In the present study this has been confirmed and extended to cover fifteen aliphatic acids other than those reported by Whitmore and Laughlin. The studies have included six primary acids, eight secondary acids and five tertiary acids.

In the case of primary acids, the gaseous products totaled 5–13% of the theoretical amount required by complete loss of the carboxyl group, the ratio of carbon dioxide to carbon monoxide increasing, with increase in molecular weight of the acid, from 5:1 to a 13% yield of carbon dioxide with no carbon monoxide. With secondary acids, the yield of carbon monoxide increased from 9 to 30% and the yield of carbon dioxide decreased from 1.7 to 0.5% with increase in molecular weight of acid. With tertiary acids, the carbon monoxide yield increased from 55 to 90% with increase in molecular weight of acid, only traces of carbon dioxide being formed.

A method for distinguishing between secondary and tertiary acids is especially important in view of the confusion about the two acids, $C_{11}H_{23}CO_2H$, obtained by the oxidation of triisobutylene.[2] From their speeds of esterification they were thought to be tertiary although one later was proved to be secondary. The present method distinguishes them definitely, the dineopentylacetic acid forming 30% CO and 0.5% CO_2 while the isomeric methyl-*t*-butylneopentylacetic acid gives 90% CO and 0.2% CO_2.

All reactions were run at the same temperature (155–160°). The yield of gas is probably dependent on this factor. Thus, Kipping[3] obtained 30–60% yields of ketone and presumably a corresponding yield of carbon dioxide, by treating primary acids with phosphorus pentoxide at 200–220°.

In all cases, a heavy tar was formed in the reaction.

Experimental

The apparatus used consisted of a three-necked, 200-cc., round-bottomed flask fitted with a gas inlet tube, a dropping funnel and a reflux condenser. Gases from the reaction were led through the condenser to a calibrated gas collecting carboy. The system was so assembled that all parts could be flushed out with nitrogen. In the case of acids solid at room temperature a procedure was devised permitting introduction of the solid in small portions without opening the system.

Gas analyses were made with a standard Orsat apparatus using 10% sodium hydroxide solution for carbon dioxide and cuprous chloride in hydrochloric acid for carbon monoxide.

Procedure.—Approximately one-tenth mole runs of each acid were made. For this, 25 g. of phosphorus pentoxide was weighed into the reaction flask, the acid placed in the dropping funnel, the apparatus assembled and tested for leaks. The apparatus was then swept out with from three to five liters of dry nitrogen with the gas-collecting carboy disconnected. The carboy was connected and the bath surrounding the flask heated to 100–110°. The acid was then added slowly (about forty minutes for 0.1 mole) to the hot oxide. After all the acid was added the bath temperature was raised to 155–160° and held at that point

for an hour to ensure complete reaction. During this time the mass in the reaction flask became black and gummy.

The flask was allowed to cool to room temperature and then the excess of pentoxide was hydrolyzed by adding 30–60 cc. of water through the dropping funnel (air excluded). When hydrolysis was completed, the gaseous contents of the flask were swept into the carboy with 2 liters of dry nitrogen and the total gas analyzed for carbon dioxide and carbon monoxide.

The results are given in tabular form. The data for *n*-butyric, isobutyric, trimethylacetic and methyl-*t*-butylneopentylacetic acids, determined previously,[1,4] were included for purposes of comparison.

Summary

Fifteen aliphatic acids have been treated with phosphorus pentoxide at 150–160° and the yields of carbon monoxide and carbon dioxide recorded.

On the basis of the yield and composition of the gaseous products of this reaction a method of discriminating between acids having a primary, secondary or a tertiary alkyl group attached to the carboxyl carbon is proposed.

Studies on Phenothiazine. IV. Potentiometric Characterization of Thionol

BY FLOYD DEEDS AND C. W. EDDY

In a previous report[1] we have described a simple method for the conversion of phenothiazine to thionol (hydroxyleucophenthiazone). We have pointed out that thionol is a reversible oxidation–reduction system and reported the potential of the system under conditions when the ratio of the concentration of the oxidant to the concentration of the reductant was unity. This paper is concerned with details of the potentiometric studies of the system thionol–leuco thionol.

All oxidation–reduction potentials were measured with bare platinum electrodes, the saturated calomel half cell being used as the working standard of reference. Two platinum electrodes were used in each measurement and no potential reading was accepted as final until the two electrodes agreed within 0.1 mv. when the system was well poised. When the concentration of one component was low relative to that of the other, a discrepancy of not more than 0.5 mv. was considered indicative of equilibrium. Before using the electrodes they were cleaned in aqua regia, washed thoroughly, and their behavior checked in 0.001 *M* ferri–ferrocyanide solution in which the concentration of oxidant and reductant was equal. All potentials were measured with a Leeds and Northrup type K potentiometer placed in the grid circuit of a General Electric FP 54 tube as shown in the accompanying diagram.

Measurements were made in an air-bath at a temperature of 21–22°. Potentials were measured in an atmosphere of pure nitrogen which was passed over heated copper gauze to remove all traces of oxygen. The leuco base of thionol was prepared by reduction of thionol with platinized asbestos and a stream of hydrogen freed of oxygen by passage over heated platinized asbestos. When reduction was completed the solution of leuco base was freed of hydrogen with a stream of oxygen-free nitrogen. The stream of nitrogen also served to force the solution of leuco thionol through a sintered glass filter to remove the asbestos and to transfer the solution to an oxygen-free buret. Since the measured amount of solution of oxidant (10 cc.) placed in the titration vessel and the solution treated for reduction to the leuco base were aliquots of the same thionol solution, the ratio of oxidant to reductant after each addition of reductant from the buret was determined readily.

For the determination of the curve relating the potential to the ratio of reductant to oxidant a solution of thionol

It has been shown by Clark and Cohen[2] that at constant *p*H the relation of potential to the ratio of reductant to oxidant is given by the equation

$$E_h = E_0' - \frac{RT}{nF} \ln \frac{[Sr]}{[S_0]}$$

where E_h is the observed potential referred to the normal hydrogen electrode.

$$E' = E_h \text{ when } \frac{[Sr]\text{, the concentration of reductant}}{[S_0]\text{, the concentration of oxidant}} = 1$$

R is the gas constant.
T is the absolute temperature.
F is one faraday.
n is the number of electrons exchanged when one molecule of oxidant is changed to one molecule of reductant, or *vice versa*.

At a temperature of 21° this electrode equation may be given numerical form

$$E_h = E_0' - \frac{0.05833}{n} \log \frac{[Sr]}{[S_0]}$$

In the reports of Clark, including that on methylene blue, the value of n was found to be 2. Since thionol is very closely related to methylene blue, we have assumed $n = 2$ in our studies. Using this value we have solved the electrode equation for E_h for all values of the ratio $[Sr]/[S_0]$. Comparison of the calculated values with the observed is shown in Table I.

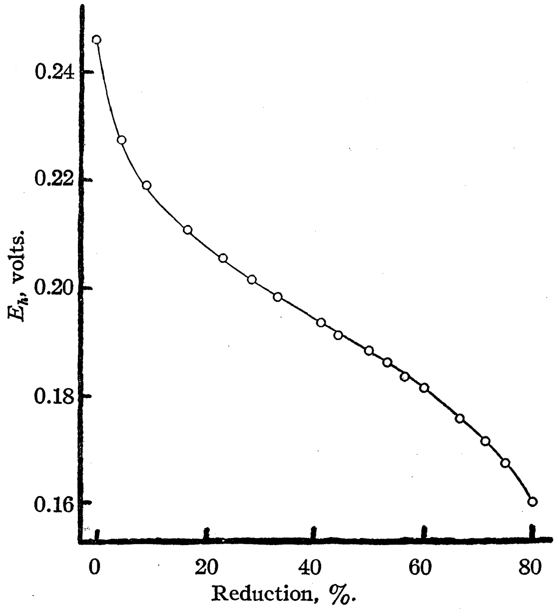

Fig. 2.—Relation between electrode potential and percentage reduction when *p*H is constant at 6.57: titration of thionol with leuco thionol at *p*H 6.57.

Comparison of the observed and calculated values for E_h shows that the difference is appreciable as the ratio $[Sr]/[S_0]$ becomes smaller or greater than unity. We do not believe that this error is due to the assumption that $n = 2$, but rather to the fact that leuco thionol is photosensitive. In other experiments to be reported in another paper, the agreement between observed and calculated E_h values was much closer, the maximum difference being 0.0011 v. in a single instance. The deviation reported does not invalidate the conclusion that thionol–leuco thionol is a reversible oxidation–reduction system nor does

---

[2] W. M. Clark and B. Cohen, *U. S. Pub. Health Repts.*, **38**, 666 (1923).

it detract from the significance of the potential when $[Sr]/[S_o] = 1$ and the system is well poised.

The photosensitivity of the leuco thionol was demonstrated by the following experiment. A solution of thionol was reduced to the leuco base with platinized asbestos and hydrogen. A portion of the colorless solution was transferred to each of two oxygen-free Pyrex vessels. One of these was kept in the dark as a control for six days, and the other subjected to irradiation under a sun lamp. A pronounced red color developed in the irradiated vessel. At the end of six days the solution in the control vessel was colorless, but after two hours of exposure under the skylight in the laboratory a definite red coloration was noticeable. The rapidity with which the leuco thionol was converted to the red thionol under the influence of irradiation with the appropriate wave length of light suggested the feasibility of following the photosensitive action potentiometrically. At the same time advantage was taken of the opportunity to observe the effect of conversion of leuco thionol to thionol upon hydrogen ion concentration under strict anaerobic conditions.

A solution of thionol in distilled water was prepared and reduced to leuco thionol as previously described. The reduction vessel was then swept free of hydrogen with a stream of oxygen-free nitrogen which also served to force the solution of leuco thionol through a sintered glass filter into an oxygen-free vessel provided with a glass electrode for detecting potential changes due to alteration in *p*H and a bare platinum electrode for measuring of oxidation–reduction potential changes. The vessel was wrapped with black paper provided with a flap which could be raised for purposes of irradiation. The source of light for irradiation was an argon-filled glow lamp, which emits a wave length of light fairly efficient in converting leuco thionol to thionol. Throughout the course of the potential measurements the solution was stirred by a stream of oxygen-free nitrogen.

The time–potential curves of two such experiments are presented in Fig. 3. Since small increments of thionol induced by irradiation of leuco thionol produce large changes in the oxidation–reduction ratio, the irradiation in the early part of the experiment was limited to five-minute periods. Later when the rate of change of the ratio was small continuous irradiation was resorted to.

The change in potential registered by the bare platinum electrode is in harmony with the observation that as irradiation was prolonged the intensity of red color, due to increasing concentration of thionol, increased. The potential changes are due chiefly to a change in oxidation–reduction potential but not entirely so, for the solution was intentionally unbuffered to permit detection of *p*H changes. In the experiment at a temperature of 26° where the data are designated by circles the glass electrode registered a change of 64 mv., or somewhat more than one *p*H unit in the direction of increased acidity. At the same time the platinum electrode registered a change of 288.2 mv. The quantitative aspects of the experiment cannot be emphasized in the absence of exact knowledge of the molar concentration of the leuco thionol solution. The important points are the demonstration of the photosensitivity of leuco thionol, and the fact that conversion to thionol is accompanied by an increase in hydrogen ion concentration in unbuffered solutions. Clark, Cohen and Gibbs[3] have called attention to the photosensitivity of methylene white. These authors state: "We are not sure that the absence of visible coloration can be regarded as proof that there did not take place changes too small for positive identification but large enough to have a significant part in cumulative errors. Indeed, our titration curves often have the form which would result from the presence of very small percentages of oxidant in a solution treated as if it were completely reduced." Similarly, in the present study of thionol–leuco thionol inspection of Table I shows that the difference between the observed and calculated values of E_h might well be accounted for by the presence of small amounts of oxidant in the solution of reductant as the result of photodynamic action.

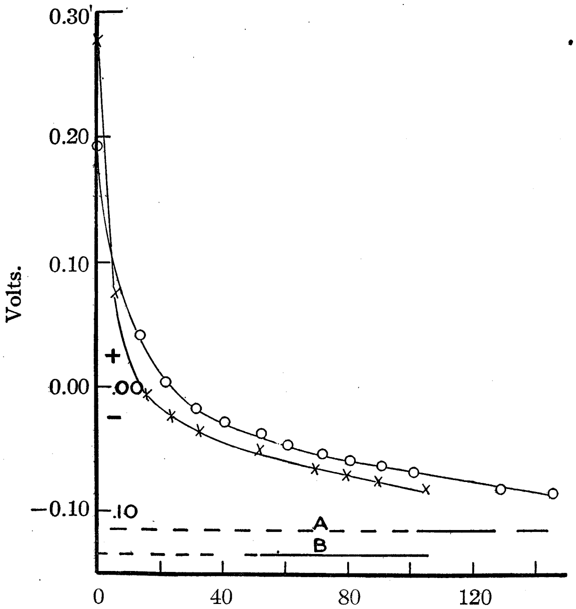

Fig. 3.—Time–potential curve showing change in oxidation–reduction potential due to photosensitivity of leuco thionol: A, length of dash indicates time of irradiation for experiment plotted with circles; B, length of dash indicates time of irradiation for experiment plotted with crosses.

---

(3) W. M. Clark, B. Cohen and H. D. Gibbs, *U. S. Pub. Health Repts.*, **40**, 1131 (1925).

Because of the presence in the system thionol-leuco thionol of OH and NH groups, which may be capable of ionization, the system may be characterized further by a determination of the curve relating pH to the potential when $[Sr]/[S_0] = 1$. The curve was determined in the following manner. An approximately 0.2 M solution of phosphoric acid was titrated with an approximately 0.2 M solution of sodium hydroxide, and the change in pH followed with glass electrode measurements. The resulting curve relating pH to cc. of sodium hydroxide added was plotted on a large scale. From this curve the amount of sodium hydroxide required to bring a given amount of phosphoric acid to a given pH was determined. On the basis of such information a series of buffers was prepared and their exact pH values then determined with the hydrogen electrode. A chloroform solution of thionol was prepared by dissolving 0.1 g. in 100 cc. Five cc. of this chloroform solution was added slowly to 75 cc. of each buffer heated and mechanically stirred until all the chloroform was volatilized. The buffer solution of thionol was cooled and made up to 100 cc. with additional buffer. This procedure did not modify the pH of the buffers except in the case of the two most alkaline buffers used. The exact pH of these two buffer solutions of thionol was determined by duplicating the procedure in the absence of thionol and measuring their values with the hydrogen electrode. These buffers originally had values of 8.89 and 10.69 which were shifted to 8.70 and 9.90, respectively. A portion of each thionol solution was reduced as previously stated, and, under anaerobic conditions, 10 cc. of the reductant added to 10 cc. of the oxidant. The potentials were measured as before using two bare platinum electrodes. Final readings were recorded when the two electrodes were in substantial agreement. The data are given in Table II and presented in the form of a curve in Fig. 4.

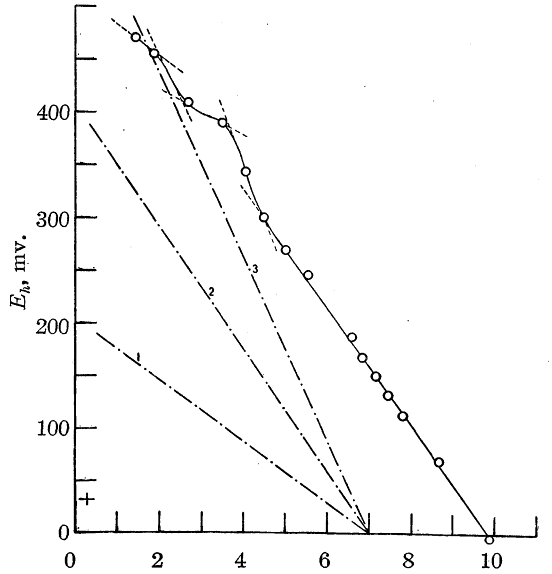

Fig. 4.—Relation between electrode potential and pH when total oxidant and total reductant are equimolecular: thionol, E_0' *vs.* pH.

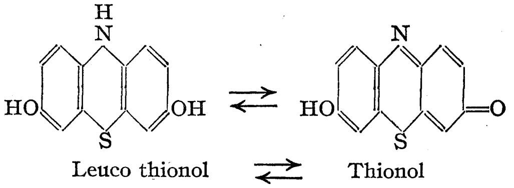
TABLE II

VARIATION OF E_0' WITH pH, $T = 21°$

pH	$E_h = E_0'$, v.	
	Electrode 1	Electrode 2
1.42	+0.4712	+0.4725
1.85	+ .4573	+ .4579
2.65	+ .4105	+ .4105
3.47	+ .3917	+ .3917
4.03	+ .3450	+ .3450
4.47	+ .3021	+ .3023
4.99	+ .2710	+ .2710
5.53	+ .2482	+ .2477
6.57	+ .1882	+ .1882
6.84	+ .1687	+ .1687
7.14	+ .1515	+ .1515
7.44	+ .1333	+ .1333
7.78	+ .1132	+ .1132
8.70	+ .0700	+ .0700
9.90	− .0041	− .0038

The deflections of the curve in Fig. 4, in terms of ionizable groups, may be interpreted as follows. Each point on the curve designated by a circle represents the potential of a mixture of oxidant and reductant in equal concentrations at a definite pH value. As will be seen from the formula for leuco thionol there are two hydroxyl groups and an NH (3) capable of ionization. The formula for the oxidant shows that there is one hydroxyl group capable of ionization and a double bonded oxygen which may ionize if hydration occurs. For convenience of interpretation the broken lines 1, 2 and 3 radiating from a pH value of 7 in Fig. 4 represent slopes or $-\mathrm{d}E/\mathrm{d}p\mathrm{H}$ values of 29.2, 58.3 and 87.5 mv. per unit of pH, respectively, at 21°. It will be seen that between pH



values of 4.47 and 9.90 the observed potentials fall on a line, the slope of which approximates that of line 2. Between *p*H values 4.47 and 3.47 the potentials fall on a line approximately parallel to line 3. The potentials at *p*H values of 3.47 and 2.65 fall on a line approximately parallel to line 1. From *p*H 2.65 to 1.85 the slope of the curve once more approximates that of line 3. The dotted line extensions of the straight line portions of the curve give intersections corresponding to *pK* values of 3.16×10^{-3}, 2.24×10^{-4}, and 3.39×10^{-5}.

As has been shown in the papers by Clark and co-workers, deflections in the E_0':*p*H curve denote the presence of detectable dissociations either in the oxidant or reductant, or in both. To determine whether a particular dissociation occurs in the oxidant or reductant these authors made use of a principle which Hall, Preisler and Cohen[4] stated as follows: "In the E_0':*p*H curve, the bend with a convexity in the direction of negative e. m. f. always corresponds to a dissociation in the reductant; and, vice versa, a deflection with a concavity toward negative e. m. f. denotes a dissociation in the oxidant. That is, when the change in slope (defining slope as $-\mathrm{d}E/\mathrm{d}p\mathrm{H}$) is negative, the dissociation causing the change is assignable to the reductant; when the change is positive, the corresponding dissociation belongs to the oxidant." Therefore at *p*H 4.47 the dissociation is assignable to the reductant and likely due to the NH group. At *p*H 3.65 the change in slope involves two ionizable groups in the oxidant. Since the change in slope occurs suddenly both groups have the same or very nearly the same dissociation constant. At *p*H 2.5 the change in slope involves the two ionizable groups in the reductant. Here again the change in slope occurs suddenly, suggesting that both groups have the same dissociation constant, as might be expected from the symmetrical placement of the hydroxyl groups in the molecule.

Development of an equation relating the potential of the fixed ratio of thionol to leuco thionol with change in hydrogen ion concentration failed to yield a set of calculated E_0' values showing satisfactory agreement with the observed values. This failure to correlate the physical chemical findings with the structural formulas for thionol and leuco thionol might be attributed to inaccurate *pK* values traceable to errors caused by the photosensitivity of the leuco thionol. However, the attempt to explain the deflections of the E_0':*p*H curve requires the assumption that both hydroxyl groups of the reductant have the same *pK* value, and that the double bonded oxygen of the oxidant undergoes hydration and subsequent ionization. Therefore an explanation for the deflections of the E_0':*p*H curve was sought on some basis other than ionizable groups.

The close relationship of thionol to α-phenazine and pyocyanine studied by Michaelis[5] and Friedheim and Michaelis[6] suggested the possibility that the system thionol–leuco thionol might be characterized by the existence of a semiquinone in the *p*H range from 0 to 4. Evidence for the existence of a semiquinone should be obtainable both colorimetrically and electrometrically.

Colorimetric tests for the presence of a semiquinone were made at *p*H values of 1.00, 1.21, 1.47, 1.85, 3.06, and higher. At *p*H values of 3.06 and higher reduction of thionol with stannous chloride, titanium trichloride, or platinized asbestos and hydrogen gas gave a change of color which proceeded directly from red to colorless, and was reversed directly to red by the addition of hydrogen peroxide. At the lower *p*H values of 1.00, 1.21, 1.47, and 1.85 reduction by the above methods gave a color change from red through purple to blue, light green and finally colorless. Reoxidation with hydrogen peroxide reversed the order of color change. The more acid the reaction the more pronounced the intermediate colors and the greater the ease with which partial reduction characterized by the intermediate colors could be maintained over a period of time. These observations are in conformity with the behavior to be expected in the presence of a semiquinone.

Attempts to confirm this colorimetric evidence with potential measurements have failed, a major difficulty being the instability of the potentials in the extreme acid range.

Nevertheless, the difficulties encountered in seeking an explanation of the deflections in the E_0':*p*H curve do not invalidate the curve, which was found to be reproducible, nor do they detract from the usefulness of the curve as discussed in a succeeding paper.[7]

It is of interest to compare the potential of this

thiazine, thionol, with the values given by Clark[3] for two other thiazines, Lauth's violet and methylene blue. At *p*H 7 the E_0' for thionol is 0.158, for methylene blue 0.011, and for Lauth's violet 0.062 at *p*H 6.967, and 0.045 at *p*H 7.517, which gives 0.061 at *p*H 7 by interpolation. These values place thionol appreciably closer to the oxygen electrode than the other two thiazines, being about midway between 1-naphthol-2-sulfonate-indophenol and 2,6-dichlorophenol-indo-*o*-cresol. This is in agreement with the observation that spontaneous oxidation of leuco thionol exposed to air occurs more slowly than is the case with methylene white at the same *p*H. Likewise, the reducing power of a given sample of urine is more readily demonstrated with thionol than with methylene blue.

Summary and Conclusions

1. The potentiometric characteristics of thionol have been determined.
2. Colorimetric evidence for the existence of a semiquinone has been submitted.
3. The three thiazines, methylene blue, Lauth's violet and thionol have been compared with regard to their position on the oxidation–reduction scale.

Oxidation Processes. XII.[1] The Autoxidation of Hydroquinone and of the Mono-, Di- and Trimethylhydroquinones

BY T. H. JAMES, J. M. SNELL AND A. WEISSBERGER

A study of the primary reaction in the autoxidation of hydroquinone is severely complicated by the presence of secondary reactions involving nuclear hydrogens. In order to avoid such complications, we investigated the autoxidation of durohydroquinone.[1] In this compound, the four nuclear hydrogens of hydroquinone are replaced by methyl groups. This prevents secondary reactions, which complicate the hydroquinone autoxidation. Hydrogen peroxide and duroquinone could be shown to be the reaction products, and it was further observed that duroquinone exerts a marked catalytic effect upon the reaction. In order to apply these results to the autoxidation of hydroquinone, we have investigated the autoxidation of the intermediate members of the homologous series, namely, toluhydroquinone, the three xylohydroquinones, and ψ-cumohydroquinone (trimethylhydroquinone) and we have extended previous observations on the oxidation of hydroquinone itself.

Materials[2]

***p*-Benzoquinone**, twice sublimed; m. p. 116°.

Hydroquinone, recrystallized from benzene, or three times from water slightly acidified with hydrochloric acid; m. p. 172°. No kinetical difference between these samples and the original material was detected.

Toluquinone, recrystallized from ligroin (b. p. 70–90°), and sublimed at 100°.

Toluhydroquinone, recrystallized from toluene; m. p. 127–128°.

Dimethylquinones were made from the corresponding xylidines, as follows.

The xylidine (61 g., 0.5 mole) was dissolved in 200 ml. of concentrated sulfuric acid and 1000 ml. of water, and a solution of 60 g. of sodium bichromate in 150 ml. of water was slowly run in, with stirring, at a temperature below 10°. The mixture was left standing in a cool place for twenty-four hours, and then 80 g. of bichromate in 240 ml. of water was added in the same manner. After another twenty-four hours, the precipitate was collected, washed with water, and the filtrate extracted with ether. The combined precipitate and ether solution was steam distilled. The distillate was half saturated with sodium chloride, cooled, the quinone collected, and the filtrate extracted with ether. The combined precipitate and ether extract residue was recrystallized from petroleum ether or ligroin and sublimed.

2,5-Dimethylquinone.—Yield 40%; m. p. 124–124.5°.

2,5-Dimethylhydroquinone was prepared according to Conant and Fieser[3]; recrystallized from ethanol, yield 46%; m. p. 210–212°.

2,6-Dimethylquinone.—Yield 10%; m. p. 72–73°.

2,6-Dimethylhydroquinone was prepared analogously to the 2,5-dimethylhydroquinone;[2] recrystallized from water (Norite), yield 60%; m. p. 153–154°.

2,3-Dimethylquinone.—From 3-amino-1,2-dimethylbenzene; yield 8%; m. p. 59–60°.

2,3-Dimethylhydroquinone.—The solution of the quinone (0.6 g.) in 25 ml. of 25% ethanol was reduced at 0° with sulfur dioxide for one hour; yield 17%; m. p. 224–225°.

[2] All materials the origin of which is not stated are Eastman grades.

[3] Conant and Fieser, THIS JOURNAL, **45**, 2199 (1923).

3-Amino-1,2-dimethylbenzene.[4]—Forty-eight grams of 3-nitro-1,2-dimethylbenzene was reduced with 56 g. of iron powder in 150 ml. of water containing 10 ml. of concentrated hydrochloric acid, followed by stirring and heating on the steam-bath for three hours, followed by steam distillation: yield 70%; b. p. 109–111° at 22 mm. The acetyl derivative was recrystallized from toluene; m. p. 133–134°.

3-Nitro-1,2-dimethylbenzene.—*o*-Xylene (100 g.) was run slowly into a mixture of 600 g. of fuming nitric acid (sp. gr. 1.52) and 200 g. of glacial acetic acid, with rapid stirring, at 20–25°. Stirring was continued at this temperature for one hour, the mixture poured into water, extracted with benzene and washed.

The isomers were separated by fractional distillation through a 17-cm. Widmer column at 12 mm. Fractions were collected at intervals of 3–4°, between 113 and 126°, cooled in an ice–salt bath and crystals collected. The filtrates were refractionated; yield of 3-nitro-1,2-dimethylbenzene, b. p. (12 mm.) 113–116°, 48 g., 37%; 4-nitro-1,2-dimethylbenzene, b. p. (12 mm.) 125–126°, 35 g., 27%.

2,3,5-Trimethylquinone (ψ-Cumoquinone).—The method of L. I. Smith[5] was not used because no pseudocumidine of satisfactory quality was available. Instead, isoduridine was oxidized with elimination of the methyl group[6] in the para position to the amino group. Isoduridine was prepared from isodurene through the monobromo derivative.[7]

Bromoisodurene was prepared closely following the procedure for the bromination of durene[4]; yield, 61 g., 77%; b. p. 148–149° at 30 mm.

Nitrobromoisodurene.—Sixty-one grams of bromoisodurene in 280 g. of chloroform was added to 226 g. of concentrated sulfuric acid, cooled to 0°, and, with rapid stirring, a mixture of 22 g. of fuming nitric acid (sp. gr. 1.52) and 55 g. of chloroform was run in from a dropping funnel, at about 5°. After stirring had been continued for five minutes, 500 ml. of chloroform was added to dissolve the solid reaction product. The chloroform layer was separated and washed with sodium carbonate and with water, and the chloroform distilled off until the residue (about 125 cc.) started to crystallize. An equal volume of methyl alcohol was added, the mixture was cooled in ice and the crystals were filtered off and washed with methyl alcohol; yield, 49 g., 66%; m. p. 168–173°. Calcd. for $C_{10}H_{12}NO_2Br$: N, 5.44; Br, 31.0. Found: N, 5.35; Br, 31.4.

2-Amino-1,3,4,5-tetramethylbenzene (Isoduridine).—The method employed by Willstätter and Kubli[4] for the preparation of duridine did not eliminate the halogen from the isodurene derivative. To crude nitrobromoisodurene (49 g.) in 600 ml. of boiling glacial acetic acid and 100 ml. of concentrated hydrochloric acid was added, with boiling and stirring, 50 g. of zinc dust in small portions. When the reaction slowed down, an additional 50 g. of zinc dust and 50 ml. of hydrochloric acid were added, and boiling and stirring continued for one hour. The solution was cooled, the crystals filtered off, the filtrate concentrated until crystals formed (about 150 ml.) diluted with water and hydrochloric acid and the resulting precipitate combined with the main product.

The crude bromoisodurene hydrochloride was debrominated with a solution of 160 g. of potassium hydroxide in 375 ml. of water and 600 ml. of 95% ethyl alcohol, with 125 g. of zinc dust and 1 g. of mercuric chloride with boiling and stirring overnight. This was usually sufficient for reduction, but in one case it was necessary to continue boiling for an additional twenty-four hours, adding more alkali (100 g.), water (250 ml.), and zinc (50 g.), with 1 g. of mercuric chloride.

The reaction mixture was steam distilled and the distillate, which contained insoluble oil, was collected. The amine was salted out and extracted with ether. The yield of isoduridine, b. p. (16 mm.) 134–136°, was 18.5 g., 66%, based on the nitrobromoisodurene. The acetyl derivative was recrystallized from alcohol, m. p. 219–220°.[8]

2,3,5-Trimethylquinone (ψ-Cumoquinone).—Isoduridine (18.5 g.) in 1500 ml. of water and 170 ml. of concentrated sulfuric acid was oxidized below 5° with 44 g. of sodium bichromate crystals in 150 ml. of water, added slowly from a dropping funnel with rapid stirring. After one hour, the mixture was kept in a cool place for twenty hours. Then an additional 34 g. of sodium bichromate in 80 ml. of water was added as before at 5° and the mixture stirred at room temperature for twenty-four hours. It was worked up as mentioned; yield of pure quinone 1.27 g., m. p. 28.5–29.5°.

2,3,5-Trimethylhydroquinone (ψ-Cumohydroquinone) was prepared analogously to the 2,5-dimethylhydroquinone,[3] using the residue of the petroleum ether filtrate from the quinone purification. About 3 g. was warmed on the steam-bath with a solution of 5 g. of stannous chloride in 45 ml. of 2 *N* hydrochloric acid. The colorless solution was cooled, filtered, and the product recrystallized from 30% ethanol and from toluene; colorless needles, m. p. 171–173°, 1.86 g.; combined yields of pure quinone and hydroquinone, 17%, based on the isoduridine.

Tetraethylquinone.—We are indebted to Professor L. I. Smith, of the University of Minnesota, for a sample of this material; m. p. 58–59°.

Tetraethylhydroquinone.—The quinone (1.14 g.) was reduced in alcohol (15 ml.) with stannous chloride (25 g.) in concentrated hydrochloric acid (6 ml.) on the steam-bath. Water (30 ml.) was added to the colorless solution, cooled, and the crystals washed with a little water; recrystallized from toluene; yield 0.8 g., 67%; m. p. 170.5–171.5°.

Durohydroquinone Monomethyl Ether.—Durohydroquinone (3.2 g.) was heated in a nitrogen-filled sealed tube with 4.6 g. of methyl iodide and 50 cc. of absolute ethanol, in which 0.46 g. of sodium had been dissolved, for two hours in a steam-bath. The contents were poured into 100 ml. of water, filtered, and the precipitate extracted with 75 ml. of boiling benzene. The insoluble material consisted of 0.8 g. of durohydroquinone. The residue of the solution was stirred under nitrogen with 50 cc. of warm (2 *N*) sodium hydroxide, and cooled and filtered. Hydrochloric acid precipitated colorless crystals which were recrystallized from ligroin: yield, 0.7 g., 19.5%; m. p. 115–116°. The alkali-insoluble material consisted of durohydroquinone dimethyl ether and a little duroquinone.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.3; H, 8.9. Found: C, 73.1; H, 8.8.

[a] Oxidation in presence of 0.2 g. of 2-methylbenzothiazole-metho-*p*-toluenesulfonate.

The other materials were identified with or prepared according to the same methods as those described in the preceding paper of this series.[1]

Reaction Products

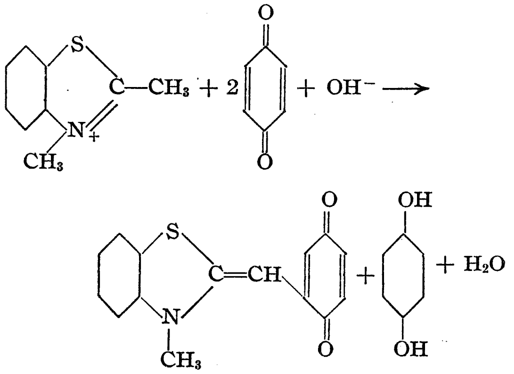
Tests for hydrogen peroxide in the autoxidized solutions were positive. With the xylohydroquinones and ψ-cumohydroquinone, the procedure described for durohydroquinone was used. This method failed in the case of hydroquinone itself, supposedly because the reaction between peroxide and quinone[9] was too rapid. The test was therefore carried out after hydroquinone (0.11 g.) had been oxidized in aqueous borate buffered solutions (50 ml.) containing 2-methylbenzothiazole-metho-*p*-toluenesulfonate (0.3 g.). The latter acted as a quinone acceptor (see formula (1)), forming a water-insoluble reaction product, and the filtered solution gave a positive peroxide test (perchromate reaction).

Peroxide was determined quantitatively by measuring the oxygen evolved when aqueous 0.1 *M* potassium permanganate solution was added in excess to the autoxidized solutions buffered at *p*H 7.6–8.0. Acidulated permanganate could not be used in many cases, since carbon dioxide was formed in the reaction between the acid permanganate and the quinone. Control experiments showed that neutral permanganate did not cause evolution of gas on addition to the buffered (*p*H 7.8–8.0) solutions of hydroquinone, quinone, or hydroxyquinone.

A representative example of the results of the peroxide tests is given in Table I.

ψ-Cumoquinone and the *xyloquinones* were extracted from the oxidized solutions of the corresponding methylhydroquinones with benzene and identified by melting point determinations.

Proof that *quinone* was formed in the autoxidation of *hydroquinone* itself was obtained by making use of the reaction of quinone with 2-methylbenzothiazole-metho-*p*-toluenesulfonate. According to our colleague Dr. L. G. S. Brooker,[10] these substances react in alkaline solution with formation of [(3-methyl-2(3)-benzothiazolylidene)-methyl]-*p*-benzoquinone



(1)

This is in agreement with our observation that the addition of 2-methylbenzothiazole-metho-*p*-toluenesulfonate to an alkaline solution of hydroquinone increases the oxygen absorption through the regeneration of hydroquinone. In the case of ψ-cumohydroquinone, the total oxygen absorption increased from 1 to 2 moles. The experiments were carried out in aqueous borate buffered solutions (50 cc.) at *p*H 8.2.

(1) Hydroquinone (0.25 mmol.), oxidized in the presence of an excess of 2-methylbenzothiazole-metho-*p*-toluenesulfonate (1.0 mmol.), yielded a blue-violet precipitate.

(2) Quinone, added to a buffered 2-methylbenzothiazole-metho-*p*-toluenesulfonate solution, yielded a blue-violet precipitate.

(3) Hydroquinone which had absorbed 1 mole of oxygen yielded, on addition of methylbenzothiazole-metho-*p*-toluenesulfonate, a green solution without a precipitate.

(4) Quinone, which had stood for some time in the alkaline solution in the presence of excess hydrogen peroxide, yielded, on addition of methylbenzothiazole-metho-*p*-toluenesulfonate, a green solution without a precipitate.

(5) Hydroxyquinone, added to the methylbenzothiazole-metho-*p*-toluenesulfonate solution, yielded a green solution of the same appearance.

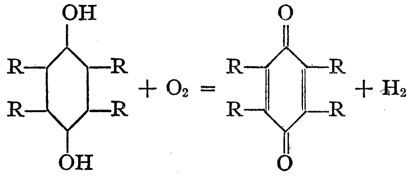
---

(9) Reinders and Dingemans, *Rec. trav. chim.*, **53**, 209 (1934).

(10) Private communication; see also F. Kröhnke and H. Schmeiss, *Ber.*, **70**, 1728 (1937).

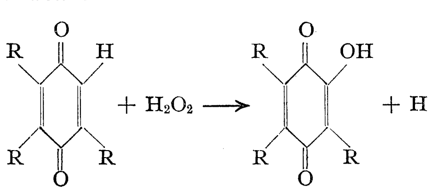
Precipitates (1) and (2) were filtered off, washed, dried, and dissolved in ethanol. The absorption spectra of the resulting solutions were measured.[11] They were identical, having a maximum absorption at 620 mμ and a minimum at 420–460 mμ. A solution prepared from hydroxyquinone and methylbenzothiazole-metho-*p*-toluenesulfonate gave an entirely different spectrum with a maximum absorption at 450–460 mμ, a small minimum at 540–550 mμ, and another slight maximum at 620–630 mμ.

The analogy between hydroquinone and its homologs makes it unlikely that the *formation* of quinone and hydrogen peroxide with the former is due to an interference of the methylbenzothiazole-*p*-toluenesulfonate. These experiments therefore generalize the results reported in the preceding paper and show that the *first products in the autoxidation of hydroquinone and its homologs are the corresponding quinones and hydrogen peroxide.* The general equation for the first step in the autoxidation of hydroquinone and its mono-, di, tri-, and tetramethyl homologs can thus be written



(2)

where R represents alkyl groups or hydrogen. The experiments (3–5) show further that quinone reacts with the hydrogen peroxide with formation of hydroxyquinone. It appears safe to generalize that if at least one of the R's is hydrogen, the further reaction



(3)

(3) takes place, and polymerization of the hydroxyquinone provides for the formation of "humic acids."[12]

Kinetics

The apparatus and general procedure employed in the study of the kinetics were those described in the preceding papers of this series. All experiments, unless otherwise specified, were carried out at 20.00 ± 0.03°, and with a total solution volume of 50.0 ml. The aqueous buffers were prepared from 25.0 ml. of 0.15 *M* borax plus 0.8 *M* boric acid, or 25.0 ml. of 0.5 *M* disodium phosphate and 0.2 *M* monosodium phosphate. Because of the slight solubility of some of the compounds in water, 20% ethanol solutions were used in some of the experiments. In these experiments the buffer was prepared from 10.0 ml. of 0.2 *M* disodium phosphate and sufficient 0.1 *M* hydrochloric acid to give the desired *p*H value. Measurements of *p*H were made on the completed solutions by means of a calibrated glass electrode.

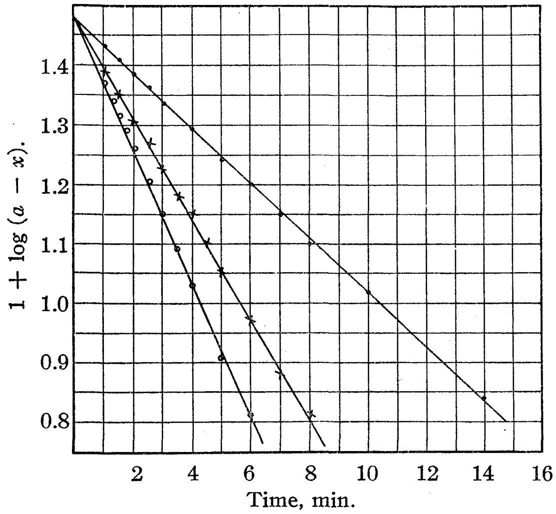


Fig. 1.—Oxidation of xylohydroquinone phosphate buffer, *p*H 7.75: —·—·— *o*-xylohydroquinone; —x—x— *p*-xylohydroquinone; —o—o— *m*-xylohydroquinone.

The data were analyzed as follows: log $(a - x)$ was plotted against t for each set of data (a is the theoretical oxygen uptake if 1 mole of oxygen is absorbed per mole of the hydroquinone; x, the volume absorbed at time t (minutes)). The slope of the resulting curve was then determined for various values of x. If the rate of oxygen uptake is governed by a first-order equation, the slope will be independent of x, and its value, k_{10}, multiplied by 2.3, will give the first-order reaction constant (k). In the case of the xylohydroquinones, k_{10} was constant throughout the greater part of the reaction (Fig. 1). The autoxidation of toluhydroquinone and of hydroquinone likewise follows the first-order equation for oxygen uptakes to 50–70% mole. Beyond this, compli-

---

[11] We are indebted to Mr. E. Richardson for the absorption measurements.

[12] Eller and Koch, *Ber.*, **53**, 1469 (1920).

cations arise which are due to further oxidation of the primary reaction products.

The use of the theoretical oxygen uptake a is suggested by the results with durohydroquinone in combination with the observations about the reaction products reported above. After 1 mole of oxygen has been absorbed, further uptake is much slower with ψ-cumohydroquinone and the dimethyl hydroquinones so that a break in the ml. O_2/t curve occurs. (For *m*-xylohydroquinone, the character of this subsequent reaction was substantiated by the fact that a mixture of equal molecular portions of the quinone and of hydrogen peroxide absorbed oxygen at the same rate as the oxidized solution of the hydroquinone at the same *p*H.) The oxygen values where the breaks in the ml. O_2/t curves occur check well with the theoretical values. This is shown in Table II.

Table II

Total Amounts of Oxygen Absorbed (N. T. P.)

Compound	O_2 Absorbed	Theoretical
ψ-Cumohydroquinone	5.45	5.6
p-Xylohydroquinone	2.75	2.8
m-Xylohydroquinone	2.7	2.8
o-Xylohydroquinone	2.7	2.8

The differences between observed and theoretical values obviously are caused by the action of hydrogen peroxide on the hydroquinones. With toluhydroquinone and with hydroquinone itself, the difference in the reaction rates between the initial and the subsequent reaction is less pronounced. It is sufficient, however, as mentioned above, to produce a straight line on our plots for about 70 and 50%, respectively, of an oxygen uptake of one mole.

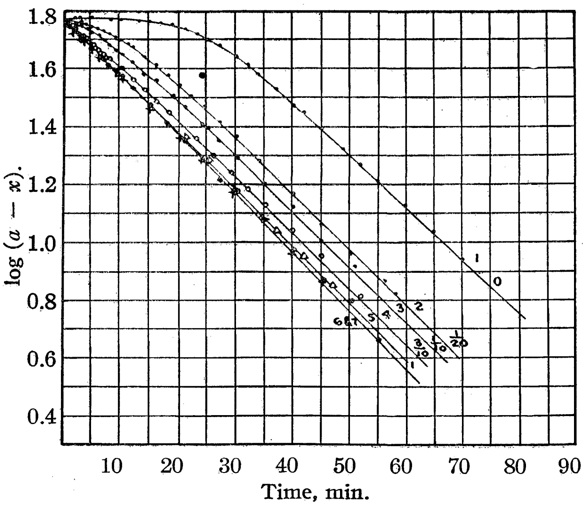

Fig. 2.—Oxidation of ψ-cumohydroquinone. Effect of added ψ-cumoquinone on $^1/_4\,M$ mol. of ψ-cumohydroquinone: Curve 1, no added ψ-cumoquinone; Curve 2, $^1/_{80}\,M$ mol.; Curve 3, $^1/_{40}\,M$ mol.; —○—○— 4, $^3/_{40}\,M$ mol.; —Δ—Δ— 5, $^3/_{20}\,M$ mol.; —·—·— 6, $^1/_4\,M$ mol.; —x—x— 7, $^1/_2\,M$ mol.

For **the autoxidation of cumohydroquinone,** which will be considered first, 20% ethanol was used as solvent because of the low solubility of the material. A phosphate buffer was employed for most of the work, although check runs were made in a buffered borate solution. The buffers used kept the *p*H of the solutions constant within 0.02 unit throughout the entire course of the oxidation.

The reaction exhibits a pronounced *induction period*, as shown in curve 1 of Fig. 2. The slope of the curve attains a maximum, and this constant value is maintained throughout the remainder of the oxidation, in conformity with the kinetics of a first-order reaction.

The induction period does not appear to be due to the presence of an inhibitor. Successive purifications of the ψ-cumohydroquinone gave no significant change, and identical oxidation curves were obtained when the ethanol normally used was replaced by a sample obtained from an entirely different source and purified according to the method of Danner and Hildebrand.[13] Moreover, the induction period persisted if the solutions were prepared, mixed, and stored for one hour in an atmosphere of pure nitrogen before oxidation was begun.

The induction period is shortened by the addition of ψ-cumoquinone to the reaction mixture at the start of the oxidation, and it is eliminated completely if about 0.15 mmol. of *ψ-cumoquinone* is added to the 0.25 mmol. of ψ-cumohydroquinone used in these experiments Thus, it appears that the ψ-cumoquinone formed during the autoxidation acts as a catalyst. Other quinones, phenosafranin and indophenol, also eliminate the induction period.

In Fig. 3, values of k_{10} obtained from curve 1 of Fig. 2 are plotted against the corresponding amounts of oxygen absorbed. In the same figure, the initial values of k_{10} obtained from curves 2–7 (Fig. 2) are plotted against the amounts of ψ-cumoquinone added. The close similarity of the curves confirms the fact that the governing factor in the acceleration is the ψ-cumoquinone. The slight difference between the two curves is

---

(13) Danner and Hildebrand, This Journal, **44**, 2827 (1922).

explained by the action of the hydrogen peroxide upon the ψ-cumoquinone in the experiments recorded by curve 2.

The dependence of k_{10} upon the initial amounts of ψ-cumohydroquinone present is given in Table III.

TABLE III

DEPENDENCE OF k_{10} UPON THE INITIAL CONCENTRATION OF ψ-CUMOHYDROQUINONE; PHOSPHATE BUFFER, *p*H 7.40

Total volume of solution	50.0	50.0	100.0	50.0
Mmol. ψ-cumohydroquinone	0.50	0.25	0.25	0.125
Mmol. O_2 absorbed	k_{10}	k_{10}	k_{10}	k_{10}
0.005	0.0014	0.0014	..	0.0012
.010	.0028	.0026	0.0012	.0025
.015	.0042	.0044	.0020	.0044
.020	.0057	.0058	.0026	.0052
.040	.0102	.0100	.0046	.0110
.060	.0135	.0133	.0065	.0145
.080	.0170	.0170	.0094	.0172
.100	.0175	.0176	.0110	.0175
.200	.0175	.0176	.0170	..

With a constant volume of solution, the induction period disappears in all cases after the *same amount* of oxygen has been absorbed. The elimination of the induction period does not depend upon the ratio of ψ-cumoquinone to ψ-cumohydroquinone, but it depends either on the absolute amount or on the concentration of the ψ-cumoquinone. The data obtained when a total volume of 100 ml. was employed instead of the customary 50 ml. showed that the *concentration* of the ψ-cumoquinone is the essential factor.

The observation that the quinone eliminates the induction period in the autoxidation of ψ-cumohydroquinone is analogous to our results with durohydroquinone.[1] At variance with the case of durohydroquinone, however, an initial velocity which might be interpreted as that of the uncatalyzed reaction, is not indicated by the curves in Fig. 3 which go through the origin. A more important difference consists in the dependence of the reaction velocity on the concentration of the quinone. With durohydroquinone, the reaction rate rises linearly with the concentration of the quinone; *with ψ-cumohydroquinone, however, the catalytic influence drops with increasing concentration of the quinone until a further addition becomes irrelevant* (see Fig. 3).

Duroquinone, upon standing in an alkaline solution, gradually loses its power of catalyzing the autoxidation of durohydroquinone. The rate of this loss, which is probably due to self condensation of the quinone, is too low to be of significance in the experiments recorded in the previous paper.[1] In order to determine whether a similar, but more rapid, loss occurring in the case of ψ-cumoquinone could account for the fact that its catalytic effect reaches a limiting value, experiments were carried out where the mixture of ψ-cumohydroquinone and ψ-cumoquinone was allowed to stand for varying times in an atmosphere of pure nitrogen before oxidation was started. Some of the results are recorded in Table IV.

TABLE IV

1/8 mmol. ψ-Cumohydroquinone, 1/8 mmol. ψ-Cumoquinone

Time elapsing before start of oxidation	Volume oxygen absorbed, 20°, 760 mm.				
Oxidation time, min.	15 sec.	30 min.	74 min.	75 min.[a]	0[b]
2	0.40	0.40	0.40	0.40	..
4	.80	.75	.70	.70	0.03
7	1.22	1.10	1.00	1.13	.10
12	1.80	1.52	1.45	1.70	.40
15	2.02	1.80	1.68	1.95	.68
20	2.35	2.10	2.00	2.30	1.13
75	2.95	2.95	2.95	..	2.90

[a] Quinone alone stood in alkaline solution. [b] No quinone added.

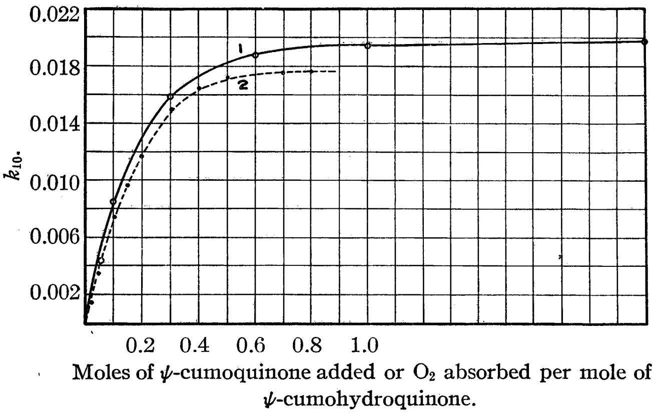

Fig. 3.—Quinone catalysis of the autoxidation of ψ-cumohydroquinone: —○—○— 1, ψ-cumoquinone added; — —•— —•— — 2, from oxidation curve.

Only very little loss occurred in the catalytic activity of ψ-cumoquinone which stood in alkaline solution for the length of time required for completion of the normal autoxidation of ψ-cumohydroquinone. The peculiar behavior of ψ-cumoquinone is therefore due to other causes.

The dependence of the maximum value of k_{10} upon the pH of the solution is shown in Table V. The maximum velocity of the reaction varies with the square of the hydroxyl-ion concentration, and plot of log k_{10} against *p*H gives a straight line of slope 2.0.

Table V

Dependence of k_{10} upon the Hydroxyl-Ion Concentration; 0.25 Mmol. ψ-Cumohydroquinone

*p*H	k_{10}	2+log k_{10}
7.84	0.140	1.15
7.64	.056	0.75
7.48	.0252	.40
7.40	.0180	.26

The *p*H values given in the first column were measured by means of a glass electrode placed in solutions of the buffer which contained all the ingredients of the solution used in oxidation measurements except the ψ-cumohydroquinone and alcohol. The latter was replaced by an amount of water sufficient to give the same total volume. The *p*H values may therefore be wrong in their absolute amounts, but their gradation is right, since no significant effect on the oxidation velocity is observed when successive amounts of water are replaced by alcohol in experiments with hydroquinone, using the same phosphate buffer as that employed in the present case (see page 2091).

Table VI shows the *variation of k_{10} with the partial pressure of oxygen* for three *p*H values.

Table VI

0.25 Mmol. ψ-Cumohydroquinone. Dependence of k_{10} upon Partial Pressure of Oxygen

O_2 abs./ψ-Cumohydroquinone	*p*H 7.84		*p*H 7.64		*p*H 7.40	
	O_2	Air	O_2	Air	O_2	Air
0.02	0.016	0.013	0.0030	0.0026	0.0014	0.0012
.05	.034	.022	.0090	.0075	.0035	.0024
.10	.060	.028	.0175	.0107	.0070	.0040
.15	.076	.032	.0250	.013	.0095	.0046
.20	.090	.034	.0325	.0144	.0118	.0052
.30	.110	.035	.0425	.0135	.0150	.0048
.40	.126	.035	.0480	.0135	.0163	.0046
.50	.130	.035	.0520	.0135	.0172	.0046

Although the accuracy with which k_{10} can be determined in the early stages of the oxidation is low, the data show that the dependence of the rate of autoxidation upon the oxygen pressure increases as the reaction progresses. It did not quite attain a direct proportionality, however, in these experiments.

The autoxidation of the xylohydroquinones, toluhydroquinone, and hydroquinone itself follows the first-order law with respect to the concentration of the dihydroxy compound. This is demonstrated both by the straight line obtained in a log $(a-x)$, t plot and by the independence of the reaction constant upon the initial concentration of the hydroquinone over tenfold variations in concentration. The autoxidation rate varies linearly with the concentration of the oxygen (Table VII).

Table VII

Dependence of k upon Partial Pressure of Oxygen

Borax buffer, 0.25 mmol. hydroquinone, 20% ethanol

	o-Xylohydroquinone	*m*-Xylohydroquinone	*p*-Xylohydroquinone
Pure oxygen	0.024	0.045	0.042
Air	.0051	.0095	.0089
Ratio	4.71	4.73	4.72

The dependence of the rate of autoxidation upon the hydroxyl-ion concentration of the solution has been a subject of some dispute. Euler and Brunius, and Reinders and Dingemans observed a dependence upon the square of the hydroxyl-ion concentration. La Mer and Rideal found a relationship between the first power of the reaction rate and the 1.5 power of the hydroxyl-ion concentration. St.-Maxen claimed a first-power relationship.[1] We have found a dependence upon the square of the hydroxyl-ion concentration for the following materials: durohydroquinone, ψ-cumohydroquinone, *o*-, *m*-, and *p*-xylohydroquinone, toluhydroquinone, and hydroquinone.

These data are summarized in Fig. 4, in which log k is plotted against *p*H. The slope of each line is very nearly 2.0. All data given are for aqueous solutions. Two series of buffers were used, phosphate and borate. The ionic strengths were kept as nearly as possible constant in each series. Measurements of *p*H were made on the complete solutions with a glass electrode. The fact that, in every case, the slope measured is slightly less than 2.0 can be understood on the assumption that the singly charged hydroquinonate ion is also oxidizing, but at a much lower rate than the doubly charged ion.

This assumption gains support from the fact that monomethyl ethers undergo autoxidation, albeit at a very low rate, as exemplified in Table VIII; this is parallel with the autoxidation of benzoin methyl ether.[14]

Table VIII

Autoxidation of Monomethyl Ethers

Monomethyl ethers of	Amount mmol.	1.0 *M* KOH ml.	Rate, ml./min.	Solution
Durohydroquinone	$^1/_8$	2.0	0.003	45 cc. 30% ethanol
Hydroquinone	½	0.4	.002	50 cc. water
Hydroquinone	½	4.0	.002	50 cc. water

The addition of hydrogen peroxide at the start of the oxidation has no measurable effect upon

---

(14) James and Weissberger, This Journal, **59**, 2040 (1937).

the initial rate of autoxidation. As the oxidation proceeds, however, the oxidation of the hydroquinone by the peroxide becomes appreciable and the total oxygen uptake decreases. This action of the hydrogen peroxide accounts for the fact that the observed "end" volumes of oxygen absorbed (see page 2089) are somewhat less than 1 mole in the cases of durohydroquinone, ψ-cumohydroquinone, and the xylohydroquinones. With toluhydroquinone and hydroquinone itself, the subsequent reactions prevent the determination of "end" volumes.

An apparent slight induction period was noted in several experiments in the autoxidation of the xylohydroquinones, but in no case was the existence of such an induction period established beyond doubt. *No catalysis was observed when the corresponding quinone was added to the oxidation mixture at the start of the experiments with these compounds.*

Benzoquinone itself autoxidizes at a rate which, at the maximum, is roughly 0.01 of that of hydroquinone under the conditions of our experiments. It therefore can be neglected here.

Effect of Alcohol upon the Rate of Oxidation.—Inasmuch as the low solubility of ψ-cumoquinone and the xylohydroquinones made it necessary to use alcohol–water mixtures as solvent, it was desirable to know to what extent the change of solvent influenced the rate of oxidation. A borate buffer could not be used for this purpose, since the rapid reaction between borate and alcohol affects the hydroxyl-ion concentration of the solution. A phosphate buffer of the following composition was therefore employed: 0.2 M Na_2HPO_4, 10 ml.; 0.067 M NaH_2PO_4, 1 ml.: total volume of solution, 50 ml. The results obtained are recorded in Table IX.

TABLE IX

EFFECT OF ETHANOL ON THE RATE OF OXIDATION OF HYDROQUINONE

Ethanol, %	k_{10}	$k_{10}/[O_2]$
0	0.0172	14.6
1	.0176	14.9
5	.0173	15.0
20	.0162	15.2

In the last column, a correction has been made for the change in solubility of oxygen in the ethanol solution. The variation in the oxidation rate observed scarcely exceeds the limits of experimental error.

Effect of Substitution.—From the data given in Fig. 4, the relative rates of oxidation of hydroquinone and its mono- and dimethyl homologs can be calculated. The figures obtained are given in Table X (aqueous solution, phosphate buffer). In addition, the maximum rate of oxidation of ψ-cumohydroquinone relative to hydroquinone in 20% ethanol solution is added. No corresponding value can be stated, of course, for durohydroquinone, for which the rate of the uncatalyzed reaction is given for comparison.

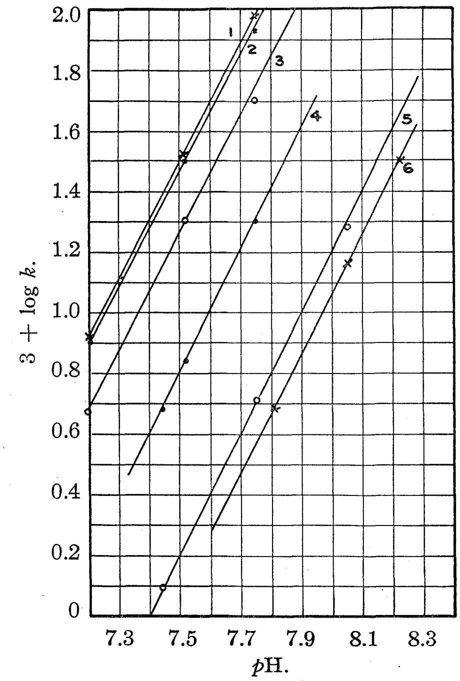

Fig. 4.—pH dependency: 1, m-xylohydroquinone, phosphate buffer, slope 1.95; 2, p-xylohydroquinone, phosphate buffer, slope 1.96; 3, o-xylohydroquinone, phosphate buffer, slope 1.96; 4, toluhydroquinone, phosphate buffer, slope 1.97; 5, hydroquinone, phosphate buffer, slope 1.98; 6, hydroquinone, borate buffer, slope 1.98.

TABLE X

Compound	Relative rate of oxidation
Hydroquinone	1.00
Toluhydroquinone	3.9
o-Xylohydroquinone	10.5
m-Xylohydroquinone	18.2
p-Xylohydroquinone	17.0
ψ-Cumohydroquinone (max. value 20% ethanol)	31.0
Durohydroquinone (uncatalyzed reaction)	1.00

It appears that substitution by methyl groups raises the rate of autoxidation. This can be due to an increase in the dissociation constants, or to other factors. The reaction rate of durohydroquinone may be low by reason of steric hindrance. It might be, however, that the correct value for comparison would be that of a quinone-catalyzed reaction of this compound. This raises the question of whether the values given for hydroquinone, toluhydroquinone, and the xylohydroquinones belong to the uncatalyzed reaction or are maximum values of quinone-catalyzed reactions to be compared with the value given for ψ-cumohydroquinone.

Discussion of Results

The qualitative and quantitative analyses of the *autoxidation products* of hydroquinone, toluhydroquinone, the xylohydroquinones and ψ-cumohydroquinone show that the reaction products are analogous to those of durohydroquinone, *i. e.*, the corresponding quinones and hydrogen peroxide. The *kinetics* of the oxidation are identical with regard to the dependency of the reaction rate on the hydroxyl-ion concentration. This is in the *p*H range 7.2–8.2 very nearly proportional to the square of the hydroxyl-ion concentration. This reveals that the reaction is controlled by the concentration of the doubly charged ion. A slight deviation from the second power may be due to some reactivity of the monovalent ion.

Durohydroquinone, on the one hand, however, and *hydroquinone, toluhydroquinone* and the *xylohydroquinones*, on the other, differ essentially with regard to the directly observed existence of an induction period, and with regard to the catalytic influence of quinones which may be added or formed during the reaction. The autoxidation of *durohydroquinone* is catalyzed by duroquinone, whereas the addition of quinones to *hydroquinone* and its lower homologs is without effect on their autoxidation velocities. The rate of the uncatalyzed oxidation of *durohydroquinone*—under the conditions of our experiments—is proportional to the oxygen concentration, whereas the quinone-catalyzed reaction is unaffected by the latter. The autoxidation rate of *hydroquinone, toluhydroquinone* and the *xylohydroquinones* is proportional to the oxygen concentration.

The autoxidation of *ψ-cumohydroquinone* furnishes the transition between the two types. It shows an induction period and a strong catalysis by small amounts of quinone. (The rate of the uncatalyzed reaction in the absence of quinone could not be determined.) The reaction rate, however, does not increase linearly with the concentration of the quinone, but increases at a slower and slower rate until a further addition of the quinone remains without effect. The oxygen dependency in the region of the strong quinone catalysis resembles that of the quinone-catalyzed autoxidation of *durohydroquinone*. The oxygen dependency in the region where further addition of quinone is without effect corresponds to the behavior of *hydroquinone* and its lower homologs. It may be suggested, therefore, that our observations with durohydroquinone correspond to that autoxidation of ψ-cumoquinone which is represented by the lower portion of the curve in Fig. 3, whereas the autoxidation which we observe with hydroquinone and its lower homologs corresponds to the type of reaction represented by the section of the curve with slope zero. In other words, we suggest that *the autoxidation of the lower members of the series is catalyzed by traces of the quinone too small to be ascertained.* This assumption fits in with the observations recorded in Table X. It offers further an interesting aspect of various photographic problems, of which only the following will be mentioned here.

The catalytic effect of the oxidation products may be significant for the photographic behavior of developers, since this catalysis enhances the differentiation between parts of the emulsion where reaction has started and those which are unattacked.

The quinone catalysis throws new light on the problem of the induction period of hydroquinone developers, since, as far as has been tested, those substances (quinone, phenosafranin, indophenol) which cut down the latter,[15] also remove the induction period in the autoxidation processes.

Sodium sulfite inhibits the autoxidation of hydroquinone and its methyl homologs with the exception of durohydroquinone, *i. e.*, it acts in those cases where it can form hydroquinone sulfonates with the quinone and not in the case where this action is impossible. It may be, therefore, that the inhibiting action of sodium sulfite is due to the removal of the catalyzing quinone.

The probable mechanism of the quinone catalysis of the autoxidation of durohydroquinone has been suggested in the preceding paper. A semiquinone is formed by the interaction of the divalent ion and the quinone, and this semiquinone is oxidized rapidly. If the formation of the semiquinone is the rate-controlling reaction and the subsequent interaction with oxygen proceeds smoothly at a comparatively high rate, the kinet-

---

[15] Frötschner, *Phot. Ind.*, **35**, 801 (1937).

ics observed with durohydroquinone are those to be expected.

The fact that, with ψ-cumohydroquinone, the quinone catalysis reaches a saturation value is open to various interpretations and further work must, therefore, be done on the investigation of this problem.

Summary

1. Hydroquinone, toluhydroquinone, the three xylohydroquinones, and ψ-cumohydroquinone are oxidized in alkaline solution by molecular oxygen with the formation of hydrogen peroxide and the corresponding quinones. This is followed by a reaction between the hydrogen peroxide and the quinones.

2. The high rate of the reaction between benzoquinone and hydrogen peroxide made it necessary to use an acceptor (2-methylbenzothiazole-metho-*p*-toluenesulfonate) for the quinone to protect the hydrogen peroxide and to make it available for analysis.

3. The quinones were, in general, identified after isolation. In the case of the autoxidation of hydroquinone, the condensation product with the acceptor was identified spectroscopically and through it the quinone.

4. The formation of hydroxyquinone by reaction of quinone and hydrogen peroxide in the autoxidation of hydroquinone was confirmed by spectroscopic analysis of the condensation products with 2-methylbenzothiazole-metho-*p*-toluenesulfonate.

5. Very close dependency of the autoxidation rate of hydroquinone and its homologs upon the square of the hydroxyl-ion concentration in the *p*H range 7.2 to 8.2 shows that the oxidation involves mainly the doubly charged hydroquinone anion.

6. A slight deviation from the second power may be due to a comparatively slow oxidation of the monovalent ion, suggested by the autoxidation of monomethyl ethers of hydroquinone and of durohydroquinone.

7. The oxidation of ψ-cumohydroquinone is strongly catalyzed by small amounts of quinones. This catalytic action approaches a maximum.

8. In the maximum, the autoxidation rate is proportional to the concentration of the ψ-cumohydroquinone.

9. The rate of reaction of ψ-cumohydroquinone is independent of the oxygen concentration with low amounts of quinone as a catalyst. As the quinone catalysis reaches its maximum, the reaction rate becomes almost proportional to the oxygen concentration.

10. In the presence of small amounts of the quinone, the kinetics of the autoxidation of ψ-cumohydroquinone resemble those of the quinone-catalyzed durohydroquinone reaction; as the quinone concentration increases, the kinetics pass over into those of the autoxidation of the lower members of the hydroquinone series.

11. The rates of oxidation of hydroquinone, toluhydroquinone, and the xylohydroquinones vary directly with the concentrations of oxygen and of the hydroquinones.

12. No quinone catalysis was detected in the autoxidation of hydroquinone, toluhydroquinone, and the xylohydroquinones. However, on the basis of the transition which ψ-cumohydroquinone affords between the kinetics of the oxidation of durohydroquinone and the lower members of the series, it is suggested that quinone catalysis exists for the latter, and that the maximum value is reached at quinone concentrations sufficiently low to escape detection.

13. Sodium sulfite inhibits the autoxidation of hydroquinone, toluhydroquinone, the xylohydroquinones, and ψ-cumohydroquinone.

14. Suggestions are made for the interpretation of the inhibition of the oxidation of hydroquinones by sulfite and of the action and the nature of the induction period of photographic developers.

The Rate and Mechanism of Hydrolysis of Benzhydryl Chloride in Acetone

BY WILLIAM TAYLOR

Three current mechanisms which have been adopted to interpret the first-order reaction between an alkyl halide and a relatively high concentration of water, alcohol, or acetic acid are those of (a) Hughes and Ingold[1] who assume partially for secondary and completely for tertiary, a slow *unimolecular* ionization of the halide as the rate-determining stage followed by a rapid reaction of the organic cation with a solvent molecule; (b) Taylor,[2] and Olson and Halford,[3] who assume for alkyl halides generally a one-stage *bimolecular* reaction involving the simultaneous addition and dissociation of the reactants, according to the ideas of London,[4] Polanyi,[5] and Olson,[6] and (c) Hammett,[7] who assumes a *polymolecular* reaction, which depends essentially upon the affinity of alcohol or water molecules for halide ion, reaction taking place within something of the nature of a solvation complex.

Taylor[2c] showed that the reaction of *t*-butyl bromide with water of low concentrations in acetone at 50° was kinetically of the second order and that therefore the mechanism of hydrolysis could not be unimolecular but is presumably bimolecular. Olson and Halford,[3] at about the same time, showed that the hydrolysis and alcoholysis of *t*-butyl chloride in aqueous methanol are both second-order reactions, if the fugacities of the reactants (as measured by their vapor pressures) and not their concentrations are employed in calculating the rate constants. These results appear to remove the possibility of mechanism (a). There remain (b) and (c).

Mechanism (c) was based partially on Hammett and co-workers[7] finding that at 25° when benzhydryl chloride (or α-phenylethyl chloride) and small concentrations of water (or of ethyl alcohol) are both dissolved in acetone, the rate of reaction is very low, whereas at the same temperature in dry or wet ethyl alcoholic solution the rate of reaction is high. The purpose of the present investigation was to find whether or not this state of affairs obtains with benzhydryl chloride at 50°. In brief it does not, since there is a measurable rate of hydrolysis of benzhydryl chloride in acetone containing 1, 2, 5 or 10 g. of water per 100 cc. of solution at this temperature. (These solutions are referred to as containing 1, 2%, etc., of water.) Thus, to this extent, the basis of the polymolecular mechanism (c) is weakened. Positive evidence in support of mechanism (b) was sought along the lines of the previous work with *t*-butyl bromide.[2c] Since, when either 2 or 10% aqueous acetone was used, no *s*-tetraphenyldimethyl ether could be detected in the reaction products (compare Ward[8]) but only benzhydrol, the sole reaction between benzhydryl chloride and water which occurs under these conditions can be represented

$$\mathrm{Ph_2CHCl} + \mathrm{H_2O} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{Ph_2CHOH} + \mathrm{HCl}$$

and is reversible. Figure 1 shows the dependence of the rate of hydrolysis upon the concentration of water even at the lowest water concentrations.

However, as with the hydrolysis of *t*-butyl bromide in acetone, a slow reaction persisted beyond the equilibrium position due again presumably to the formation of mesityl oxide and other acetone condensation products in the presence of hydrogen chloride. This caused the elimination of water and hence the continued hydrolysis of benzhydryl chloride. The slow increase in acidity thus produced was approximately directly proportional to time for a considerable time interval and thus the equilibrium position for any one system was determined by extrapolation of the straight-line portion of the curve back to the x-axis. From the equilibrium constants $K = k_1/k_2$ the equilibrium positions (n) were calculated,[2c] n being the equilibrium value of x. As in the case of *t*-butyl bromide there is close agreement between the calculated values of n and those observed for the forward reaction (Table I).

5.5556	.1170	.0636	.0186	3.42	.1140	.1157

The catalytic effect of water on the hydrolysis reaction, as shown by the increase in the values of the second-order coefficient k_1 with a rise in the water concentration, is ascribed[9] to the dissociating effect of water on itself in acetone solution *i. e.*

$$(H_2O)_n \underset{COMe_2}{\overset{H_2O}{\rightleftarrows}} nH_2O$$

the associated form being assumed to be relatively unreactive, compared with the simple form, toward the alkyl halide. Constant values of k_1, therefore, could not be expected since these were calculated using ordinary water concentrations, owing to lack of information regarding the active mass of the simple form.

From the evidence presented, then, the view is taken that the hydrolysis of benzhydryl chloride in acetone is a second-order reaction and that the mechanism is bimolecular.

Experimental

Materials.—"AnalaR" *acetone*, refluxed for ten hours over potassium permanganate and calcium oxide, boiled at 56–56.5°. *Benzhydryl chloride*, prepared by the method of Farinacci and Hammett, had b. p. 190–191° (47 mm.) (Calcd.: Cl, 17.53. Found: Cl, 17.54). *Benzhydrol* (commercial) recrystallized from alcohol melted at 68°.

Rate Measurements.—These were made at 50°. The procedure was identical with that used for *t*-butyl bromide.[2c] As with this compound a dark color developed in the reaction liquids of lower water concentrations. The values of k for the forward reaction were calculated for an irreversible second-order reaction from $k_1 = [2.303/t(a - b)] \log_{10} b(a - x)/a(b - x)$, t being the time in hours, and a and b the concentrations (in g. moles/liter) of water and benzhydryl chloride, respectively.

The value of k_1 employed in the calculation of the equilibrium constant $K = k_1/k_2$, where k_2 is the second-order rate constant for the reverse reaction, was that extrapolated at $t = 0$ from the plot of k_1 against t. Typical data for the forward reaction in 1 and 5% aqueous acetone are given in Table II.

TABLE II

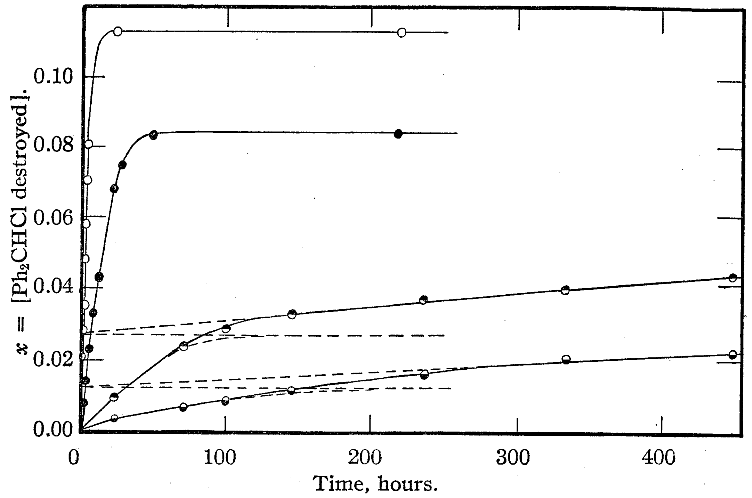

Fig. 1.—Effect of water on the rate of hydrolysis of benzhydryl chloride in acetone. Water "Percentages": ◒, 1; ◓, 2; ●, 5; ○, 10.

The determination of the second-order rate coefficients of the reverse reaction in acetone, containing initially the same concentrations of water as for the forward reaction, was complicated by the rapid removal of hydrogen chloride by the acetone. These constants were therefore calculated from the equation

$$[HCl \text{ removed by } Ph_2CHOH]/t = k_2[Ph_2CHOH][HCl]$$

t being the time in hours, and all concentrations being in g. moles/liter, the two latter being mean concentrations for any one time interval. The amount of water formed by the condensation of acetone under the influence of hydrogen chloride

---

(9) Taylor, *J. Chem. Soc.*, 840 (1938).

was so great as not only greatly to retard the formation of benzhydryl chloride in all except the initial stages, but ultimately even to cause the slow hydrolysis of that already formed, as shown by the rapid decrease in acidity giving place to a slow increase and this in spite of the continuous and simultaneous removal of hydrogen chloride by the acetone. Hence the equilibrium positions could not be observed for this reverse reaction. Typical data for the reverse reaction in 1 and 5% aqueous acetone are shown in Table III.

TABLE III

TYPICAL KINETIC DATA OF THE REVERSE REACTION IN ACETONE AT 50°

In column C is shown the rate of removal of hydrogen chloride by 1 and 5% aqueous acetone containing no benzhydrol.

Examination of Reaction Products.—These were examined in 2 and 10% aqueous acetone. Benzhydryl chloride (2.2 g.) in aqueous acetone (100 cc.) was kept at 50° for two hundred and forty and twenty-four hours, respectively; excess anhydrous sodium carbonate was added to remove water and acid. After filtering, and distilling the acetone, approximately 3 cc. of brown oil containing some crystalline solid was obtained; (1) the product had a faint odor of mesityl oxide but no 2,4-dinitrophenylhydrazone could be obtained from it; (2) that from 2% aqueous acetone contained considerable unchanged benzhydryl chloride (Found: Cl, 5.6) whereas that from 10% aqueous acetone contained negligible chlorine; (3) to 2 cc. of the product in each case was added ethyl alcohol (2 cc.) but there was no solid residue and hence no *s*-tetraphenyldimethyl ether had been formed.[8] Addition of water to the alcoholic solution gave benzhydrol only (m. p. and mixed m. p. with authentic specimen).

Summary

The hydrolysis of benzhydryl chloride and the action of hydrogen chloride on benzhydrol have been studied kinetically in acetone containing low concentrations of water. The hydrolysis reaction, under these conditions, yields benzhydrol and hydrogen chloride as the only reaction products. Assuming that both are second-order reactions, there is close agreement between the calculated equilibrium positions and those observed for the hydrolysis reaction, with different initial concentrations of water. This agreement indicates that the assumption is correct; and thus for both reactions a bimolecular mechanism is presumed.

Methyl Bromide. The Heat Capacity, Vapor Pressure, Heats of Transition, Fusion and Vaporization. Entropy and Density of the Gas

BY CLARK J. EGAN AND J. D. KEMP[1]

Entropies obtained from low temperature calorimetric data with the aid of the third law of thermodynamics recently have been employed to estimate the magnitudes of the potential barriers hindering the free rotation of methyl groups in hydrocarbon molecules.[2-4] In these calculations the height of the barrier has been determined as that necessary to bring the spectroscopic entropy value into agreement with the experimental entropy value. This procedure assumes that the entropies of these molecules containing methyl groups can be obtained correctly from low temperature experimental measurements.

Because the presence of similar barriers in the methyl halides is quite unlikely, the entropies of these compounds may be obtained readily from spectroscopic and molecular structure data. Calorimetric investigations of these halides offer then an opportunity to compare the experimental and spectroscopic entropies in order to confirm further the above assumption.

Purification of Methyl Bromide.—Methyl bromide from a cylinder was condensed in the calorimeter without purification. From the change of the melting point with percentage melted, the amount of impurity was estimated to be 0.1 mole per cent. Another portion of material from the cylinder was distilled twice in a vacuum-jacketed fractionating column, the middle one-third being collected each time. This procedure did not appreciably decrease the amount of impurity. The end portions of the first distillation were then bubbled through 36 N sulfuric acid and passed through a tube containing phosphorus pentoxide. This treatment removed practically all of the impurities and this portion was used for the heat capacity measurements. Additional material purified in the same manner was used in the measurements of the heats of vaporization. From the constancy of the melting point and the course of the premelting heat capacity curve, the amount of liquid-soluble solid-insoluble impurity was estimated to be 0.001 mole per cent.

Apparatus and Measurement of Amount. The Density of Methyl Bromide Gas at 1 Atmosphere and 298.10°K.—The calorimetric apparatus and procedure have been described previously.[5,6] Gold Calorimeter IV was used for the investigation.

After the heat capacity measurements the amount of material in the calorimeter, 2.0610 moles, was condensed and weighed in a previously evacuated bulb. The methyl bromide used for the heats of vaporization was measured volumetrically by means of the 5-liter measuring bulb described by Giauque and Johnston.[7] The gas was then condensed and weighed in order to determine its density under these conditions. At P near 1 atm. and T near 298°K. the molal volume V was found to be

$$V = 82.06T/P - (569 \pm 5) \text{ cc.} \qquad (1)$$

This, combined with the molecular weight of CH_3Br, 94.950,[8] gives 3.9739 ± 0.0009 grams/liter for the density of methyl bromide gas at $P = 1$ atm. and $T = 298.10$°K.

Vapor Pressure.—The procedure used in the measurements of vapor pressure has been described previously.[5] The observations have been represented by the equation

liquid methyl bromide, 203 to 278°K.

$$(0°\text{C.} = 273.10°\text{K.})\ \log_{10} P(\text{Int. cm. Hg}) = -(1541.437/T) + 8.49274 - 0.00424740T + 1.7599 \times 10^{-6}T^2 \qquad (2)$$

A summary of the measurements is presented in Table I. The calculated and observed values are compared in columns 3 and 4. The temperatures have been given to 0.001° because of the high relative accuracy. The absolute temperatures may be in error by several hundredths of a degree. Column 5 contains values of the rate of change of pressure with temperature calculated from equation (2).

The boiling point calculated from equation (2)

277.682	79.056	.000	.000	3.044

is 276.66 ± 0.05°K. (3.56 ± 0.05°C.). This is higher than the value 276.33°K. from the vapor pressure equation of Hsia.[9]

Melting Point.—The melting point was observed with various percentages of the methyl bromide melted. The results are summarized in Table II.

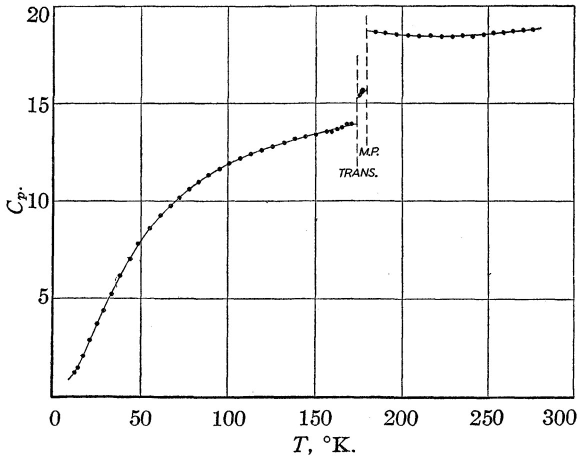

Fig. 1.—Heat capacity of methyl bromide in cal./deg. per mole.

Transition Point.—Methyl bromide undergoes a transition in the solid about 5.7° below the melting point. Determinations of the transition temperature are summarized in Table III. During these observations equilibrium was established very slowly. A region of indifference exists in which the methyl bromide may be superheated or supercooled 0.1–0.2° above or below 173.75°K.

Heat Capacity of Methyl Bromide.—No previous measurements of the heat capacity were found in the literature. The present observations are tabulated in Table IV. One calorie was taken equal to 4.1833 International joules. A graphical representation of the data is shown in Fig. 1. Table V contains values of the heat capacity taken from a smooth curve through the data.

was already present at the start of the heating period. For this reason these values were given no weight in obtaining the accepted value.

Heat of Fusion.—No measured values of the heat of fusion were found in the literature. The present measurements are summarized in Table VII.

TABLE VII

HEAT OF FUSION OF METHYL BROMIDE

Temp. interval, °K.	Corr. heat input per mole	$\int C_p dT$	ΔH cal./mole
177.826–182.511	1545	115	1430
178.006–181.879	1524	95	1429
175.556–181.742	1574	146	1428

Average value 1429 ± 2

Heat of Vaporization.—The methyl bromide was vaporized from the calorimeter into the 5-liter measuring bulb mentioned previously. A constant pressure regulating device described by Giauque and Johnston[7] was used. Table VIII contains a summary of the individual measurements. The value given by Hsia,[9] and that calculated from equation (2) and Berthelot's equation are also included.

TABLE VIII

HEAT OF VAPORIZATION OF METHYL BROMIDE

Boiling point, 276.66°K.; molecular weight, 94.950.

No. mole vaporized	Time of energy input, min.	ΔH at 760 mm. cal./mole
0.22073	47	5714
.22870	48	5719
.22616	48	5711
	Average value	5715 ± 6
From vapor pressure equation (2). (This includes a Berthelot correction of −189 cal.)		5716
Value of Hsia		5885

Entropy from Calorimetric Data.—The calculation of the entropy of methyl bromide at the boiling point, 276.66°K., from calorimetric data is summarized in Table IX.

TABLE IX

ENTROPY OF METHYL BROMIDE FROM CALORIMETRIC DATA

0–15°K., Debye extrapolation, ($h c \nu / k$ = 91)	0.61
Solid, 15–173.75°K., graphical	19.328
Transition, 113.4/173.75	0.653
Solid, 173.75–179.44°K., graphical	0.489
Fusion, 1429/179.44	7.964
Liquid, 179.44–276.66°K., graphical	8.034
Vaporization, 5715/276.66	20.657
Entropy of actual gas at the boiling point	57.74 ± 0.1
Correction for gas imperfection	0.12
Entropy of ideal gas at 1 atm. and 276.66° K.	57.86 cal./deg. per mole

The correction for gas imperfection was obtained from the expression

$$S_{\text{ideal}} - S_{\text{actual}} = 27RT_c^3P/32T^3P_c$$

Measured values of the critical temperature and critical pressure could not be found in the literature. T_c was estimated to be 475°K. and P_c to be 68 atm.

Entropy from Spectroscopic and Molecular Structure Data.—Stevenson and Beach[10] recently have calculated the entropy of methyl bromide at 298.10°K. The same frequencies and molecular constants were used in the present calculation at the boiling point

C–Br = 1.91 ± 0.06 Å.[11]
C–H = 1.09 Å.
H–C–H = 111°

The values used for the natural constants were those given in the "International Critical Tables." From the above data the moments of inertia times 10^{40} g. cm.^{2} were found to be $I_1 = 5.36$ and $I_2 = I_3 = 85.3$. The symmetry number σ was taken equal to 3.

The following vibration frequencies were used.[12–14]

cm.$^{-1}$	Weight
$\nu_1 = 2900$	1
$\nu_2 = 3061$	2
$\nu_3 = 1305$	1
$\nu_4 = 1450$	2
$\nu_5 = 610$	1
$\nu_6 = 957$	2

Table X contains a summary of the calculation. An uncertainty of ±0.06 Å. in the C–Br distance affects the entropy by ±0.12 cal./deg. per mole. The entropy effect due to the presence of isotopes and of nuclear spin has been neglected.

TABLE X

ENTROPY OF METHYL BROMIDE AT ONE ATMOSPHERE FROM SPECTROSCOPIC AND MOLECULAR STRUCTURE DATA

	T = 276.66°K.	T = 298.10°K.
$S_{\text{trans.}} = 3/2\,R \ln M + 5/2\,R \ln T - R \ln P - 2.300$	39.203	39.572
$S_{\text{rot.}} = R/2 \ln I_1I_2I_3 \times 10^{120} + 3/2\,R \ln T - R \ln 3 - 6.851$	18.226	18.448
$S_{\text{vib.}} = \Sigma_{\nu_1 \text{ to } \nu_6} S_{\text{Einstein}}$	0.563	0.720
Entropy in cal./deg. per mole	57.99	58.74

The good agreement between the experimental entropy at the boiling point, 57.86 ± 0.10 cal./deg. per mole and the spectroscopic value, 57.99, further establishes the validity of using the third law of thermodynamics in conjunction with low temperature calorimetric data to obtain the entropies of compounds containing methyl groups.

The experimental entropy (ideal gas) at 298.10°K. is 58.61 cal./deg. per mole, and the spectroscopic value (ideal gas) is 58.74 cal./deg. per mole.

Summary

The heat capacity of condensed methyl bromide has been measured from 15°K. to the boiling point.

[10] Stevenson and Beach, *J. Chem. Phys.*, **6**, 25 (1938); **6**, 108 (1938).

[11] Lévy and Brockway, THIS JOURNAL, **59**, 1662 (1937).

[12] Bennett and Myer, *Phys. Rev.*, **32**, 888 (1928).

[13] Barker and Plyler, *J. Chem. Phys.*, **3**, 367 (1935).

[14] Adel and Barker, *ibid.*, **2**, 627 (1934).

This substance has a transition in the solid about 5.7° below the melting point. Equilibrium in the transition was attained very slowly and the methyl bromide could be superheated or supercooled one or two-tenths of a degree above or below the transition point, 173.75 ± 0.15°K.

The melting point was found to be 179.44 ± 0.05°K., the boiling point 276.66 ± 0.05°K., the heat of transition 113.4 ± 1 cal./mole, the heat of fusion 1429 ± 2 cal./mole, and the heat of vaporization 5715 ± 6 cal./mole.

Vapor pressure measurements have been made on liquid methyl bromide and the results have been represented by the following equation

liquid methyl bromide, 203 to 278°K. (0°C. = 273.10°K.)

$$\log_{10}P(\text{Int. cm. Hg}) = -(1541.437/T) + 8.49274 - 0.00424740T + 1.7599 \times 10^{-6}T^2$$

The density of methyl bromide gas at 298.10°K. and one atmosphere was found to be 3.9739 ± 0.0009 grams/liter.

The entropy of methyl bromide (ideal gas) at one atmosphere and at the boiling point, 276.66°K., has been calculated from calorimetric data to be 57.86 ± 0.10 cal./deg. per mole and compared with the value 57.99 obtained from spectroscopic data.

The good agreement indicates that it is correct to use the third law value in thermodynamic calculations. It also gives more experimental substantiation to the assumption made in the calculation of potential barriers in compounds containing methyl groups, namely, that the entropies of these compounds may be obtained correctly from low temperature calorimetric data.

The experimental entropy (ideal gas) at 298.10°K. is 58.61 cal./deg. per mole, and the spectroscopic value (ideal gas) is 58.74 cal./deg. per mole.

2-Alkyl-1,2,3,4-tetrahydroisoquinoline Hydrochlorides[1]

BY JOHANNES S. BUCK AND WALTER S. IDE

With a view to carrying out a detailed pharmacological examination of the effects of various 2-alkyl groups on the action of tetrahydroisoquinolines, three series of 2-alkyl-1,2,3,4-tetrahydroisoquinolines were prepared. One series has no nuclear substituents, the second carries 6,7-dimethoxy groups and the third has 6,7-dihydroxy groups. Hydrochlorides were chosen for pharmacological reasons. In no case was a substituent present in the 1-position.

The preparation of the unsubstituted compounds was carried out substantially according to the method of Wedekind, *et al.*[2] and offered no particular difficulties. However, a general method was required for future work, and Wedekind's procedure could not be applied to the substituted derivatives, owing to the relative inaccessibility of substituted isoquinolines. Attempts were made to N-alkylate homoveratrylamine by the Decker[3] method with a view to cyclizing the alkylated amines,[4] but these did not succeed with alkyl groups larger than ethyl, the alkiodides of the Schiff bases being non-crystalline and the homogeneity of the secondary amine being therefore in doubt. However, some 2-ethyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline was made by this route, from ethylhomoveratrylamine.

Direct alkylation of 6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline[5] with ethyl iodide gave considerable amounts of quaternary compound and unchanged material, with some of the desired 2-ethyl derivative.[6] The method, however, was regarded as unsatisfactory. Similar objections apply to the use of toluene sulfonic esters.[7] Attempts to alkylate by means of α-bromo acids[8] gave only the hydrobromide of the starting material.

Finally, 6,7-dimethoxy-3,4-dihydroisoquinoline was investigated. This readily formed crystalline

alkiodides which could be reduced to the 2-alkyl-1,2,3,4-tetrahydro derivatives, which, in turn, could be demethylated to give the corresponding dihydroxy compounds. The series of reactions is convenient and the yields are good, and the possibility of the presence of secondary amine and quaternary compound has been eliminated. The substituted hydrochlorides described below were made by the foregoing route.

Experimental

2-Alkyl-1,2,3,4-tetrahydroisoquinoline Hydrochlorides.—This series of compounds was prepared by the reduction of the isoquinoline alkiodides, following the double reduction technique of Wedekind, *et al.*[2] The product was recovered from the steam distillate as hydrochloride and was recrystallized from alcohol–ether until pure. The hydrochlorides all form white crystalline compounds, readily soluble in alcohol (with which they are often solvated) and in water, and insoluble in ether and in ethyl acetate. The three isoalkyl hydrochlorides have a saline taste, the others quinine-like tastes. The *n*-butyl and *n*-amyl compounds have a numbing effect. The properties of the hydrochlorides are described in Table I. The 2-methyl-1,2,3,4-tetrahydroisoquinoline hydrochloride was checked against a specimen prepared by sodium–alcohol reduction.[4]

The majority of the isoquinoline alkiodides and reduced bases are described by Wedekind, *et al.*,[2] but hydrochlorides, although sometimes mentioned, are not described. The isobutyl compound, not obtained by the above authors, was prepared in small yield by reaction of equimolecular amounts of isoquinoline and isobutyl iodide, and, after steam distilling, reducing the residual oil in the usual way. The *n*-amyl compounds were not attempted by Wedekind, *et al.* The present authors are indebted to the Ciba Company for the isoquinoline used.

Isoquinoline *n*-amyl iodide, recrystallized from alcohol–ether, forms small, lemon-yellow prisms, soluble in alcohol, methanol and water, insoluble in ether and ethyl acetate, and melting at 139° (corr.).

Anal. Calcd. for $C_{14}H_{18}NI$: C, 51.39; H, 5.55. Found: C, 51.35; H, 5.64.

2 - Alkyl - 6,7 - dimethoxy - 1,2,3,4 - tetrahydroisoquinoline Hydrochlorides.—6,7 - Dimethoxy - 3,4 - dihydroisoquinoline was prepared from formylhomoveratrylamine (homoveratrylamine formate heated for one and one-half hours at 210°) by cyclization with phosphorus oxychloride, the experimental details being practically the same as those used by Haworth[9] for the 5,6-dimethoxy compound. The alkiodides were prepared by dissolving equimolecular amounts of the dihydroisoquinoline and alkyl iodide in twice the volume of benzene and allowing the solution to stand in a warm place until no further reaction was evident. The alkiodides were filtered off and recrystallized from alcohol–ether or alcohol–ethyl acetate. Their properties are described in Table II. The isobutiodide was not obtained, only the hydriodide of the starting material being isolable, and hence 2-isobutyl compounds are missing in Tables II, III and IV.

Reduction of the alkiodides was carried out by means of zinc powder and dilute sulfuric acid on the water-bath.[9] After filtration and cooling the sulfate of the product crystallized out and was filtered off and the base liberated by sodium hydroxide and extracted by ether. Alternatively, the reduction mixture was made strongly alkaline and extracted with ether. After drying the extract over solid potassium hydroxide, the hydrochloride was precipitated by hydrogen chloride, filtered off, dried *in vacuo*, and recrystallized from methanol with ether or ethyl acetate. The hydrochlorides form white, crystalline compounds, moderately to readily soluble in alcohol, more soluble in methanol, readily soluble in water, and insoluble in ether and ethyl acetate. The tastes are not intense or distinctive. The compounds are described in Table III. The 2-methyl compound, prepared by cyclization, has been previously described.[4] Pyman also has prepared this compound, together with the 2-ethyl and 2-*n*-propyl derivatives (the latter as picrate), from laudanosine or papaverine.[10]

2 - Methyl - 6, 7 - dihydroxy - 1, 2, 3, 4 - tetrahydroisoquinoline Hydrochlorides.—The dihydroxy compounds are prepared readily by demethylating the corresponding dimethoxy hydrochlorides with hydrochloric acid (two hours at 165° in a carbon dioxide-filled tube), evaporating the solution to dryness *in vacuo*, and recrystallizing the residue from methanol with ether or ethyl acetate. The solubilities, etc., of the hydrochlorides are practically the same as those of the dimethoxy compounds. The properties are given in Table IV. The corresponding 2-methyl compound has been described previously.[4,11] The hydrochlorides have no distinctive taste.

Note on Pharmacology.[12]—Complete results will be published elsewhere, but it can be stated that the nuclear-unsubstituted compounds show a slight depressor effect and that they are relatively strong sympatholytics. The M. E. D. (dogs) ranges from 1 to 10 mg./kg. and L 50 (mice) from 70 to 185 mg./kg.

The first of the series of dimethoxy compounds, 2-methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline hydrochloride, is a rather poor depressor, the M. E. D. (dogs) being 1 to 2 mg./kg. and L 50 (mice), 52 mg./kg.

The corresponding dihydroxy compound, 2-methyl-6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline hydrochloride, is a relatively powerful pressor, the M. E. D. (dogs) being 1 to 2 mg./kg. and L 50 (mice), 280 mg./kg.

Summary

A series of 2-alkyl-1,2,3,4-tetrahydroisoquinoline hydrochlorides is described, together with the corresponding 6,7-dimethoxy and 6,7-dihydroxy derivatives. Some 2-alkyl-6,7-dimethoxy-3,4-dihydroisoquinolinium iodides are included, and preliminary pharmacological data are given.

Syntheses in the Quinoline Series. I. 2-Hydroxy- and 2-Chloroquinolinearsonic Acids

BY JULIUS D. CAPPS[1] AND CLIFF S. HAMILTON

This investigation deals with the preparation of several quinoline amines and quinoline arsonic acids, most of the amines being produced by the catalytic reduction of certain nitroquinolines and most of the arsonic acids by diazotization of these amines and subsequent treatment with sodium arsenite. 2-Hydroxyquinolinearsonic and 2-chloroquinolinearsonic acids are given extensive consideration.

The 2-hydroxy-4-methyl-7-aminoquinoline used in this investigation was prepared according to the procedure of Besthorn and Byvanck[2] by condensing *m*-phenylenediamine with ethyl acetoacetate. The proof of structure of this product follows from its conversion to 2-chloro-4-methyl-7-methoxyquinoline, which was originally obtained by another method.[3] This structure was further confirmed in our experimental work by its conversion to 2-hydroxy-4-methyl-7-chloroquinoline.[4]

2-Chloroquinolines have been prepared by the replacement of hydroxyl through the use of phosphorus pentachloride and phosphorus oxychloride. Hydrochloric acid was found to hydrolyze 2-chloroquinoline-8-arsonic acid to give 2-hydroxyquinoline-8-arsonic acid.

2-(β-Ethoxyethoxy)-quinoline derivatives were made from 2-chloroquinolines by the use of ethylcellosolve to which had been added metallic sodium.

Experimental

2-Chloro-4-methyl-7-methoxyquinoline was prepared by treating 2-chloro-4-methyl-7-hydroxyquinoline, obtained from 2-hydroxy-4-methyl-7-aminoquinoline according to the method of Besthorn and Byvanck,[2] in 10% by weight sodium hydroxide solution with dimethyl sulfate as well as by refluxing 2-hydroxy-4-methyl-7-methoxyquinoline with phosphorus oxychloride.[3]

Nitroquinolines.—**5-Nitroquinoline** was obtained in a 32% yield by nitrating quinoline sulfate and in a much poorer yield by subjecting *m*-nitroaniline to the conditions of the Skraup reaction. A slight modification of the method of Meigen[5] proved satisfactory for the nitration of quinoline sulfate and for the separation of the isomers formed during the nitration. **6-Nitroquinoline** in a 45% yield and **7-nitroquinoline** in a 5% yield were produced by the method of Knueppel,[6] the procedure of Kochanska and Bobranski[7] being used for the isolation of the 7-nitroquinoline rather than that given by Knueppel.

2-Hydroxyquinolines.—Ten grams of 5-nitroquinoline, dissolved in 50 ml. of water by the addition of sulfuric acid, was poured into 2 liters of water at 60°. Sodium hydroxide solution was added until the *p*H was just sufficient to keep the nitroquinoline in solution. Upon introducing, with stirring, a 5.25% by weight solution of sodium hypochlorite, a solid began to appear. After standing overnight, filtering off the solid, digesting it with 10% by weight sodium hydroxide solution and making acid with sulfuric acid, an 85% yield of **2-hydroxy-5-nitroquinoline** precipitated.[8] When 6-nitroquinolinoline was treated in a similar manner and the resulting product recrystallized from glacial acetic acid, a 46% yield of **2-hydroxy-6-nitroquinoline** was obtained. An 85% yield of **2-hydroxy-7-nitroquinoline** likewise resulted from 7-nitroquinoline.

2-Hydroxyaminoquinolines.—**2-Hydroxy-4-methyl-7-aminoquinoline** in 45 to 60% yields was obtained by heating 30 g. of dry crystalline *m*-phenylenediamine and 37.8 ml. of ethyl acetoacetate in an autoclave at 130° for nineteen hours. Almost quantitative yields of **2-hydroxy-5-aminoquinoline** and **2-hydroxy-7-aminoquinoline** were obtained by the catalytic reduction of 2-hydroxy-5-nitroquinoline in 95% ethanol and 2-hydroxy-7-nitroquinoline in acetone, respectively, using Raney nickel catalyst.

2-Chloroaminoquinolines.—The catalytic reduction of an acetone solution of 2-chloro-5-nitroquinoline at 50° gave an almost quantitative yield of **2-chloro-5-aminoquinoline.** The amine was isolated by partial distillation of the acetone and the addition of water to the concentrated solution resulting. Recrystallization from dilute ethanol–water solution gave long, slender, light green colored needles belonging to the orthorhombic system; soluble in acetone, ethanol, benzene, diethyl ether and acids; m. p. 110–111° (corr.).

Anal. Calcd. for $C_9H_7ClN_2$: N, 15.67; Cl, 19.88. Found: N, 15.60; Cl, 19.72.

Dry 2-chloro-6-nitroquinoline was dissolved in a small quantity of cold hydrochloric acid (sp. gr. 1.19) and the amount of dry powdered stannous chloride calculated for complete reduction added slowly with stirring. The tin double salt, that formed upon standing, was filtered off on a dry filter, dried and dissolved in a small amount of water. After making acid, bringing to the boiling temperature and saturating with hydrogen sulfide, the tin sulfide was removed by filtration. The filtrate was neutralized with ammonium hydroxide, concentrated by evapora-

tion and cooled. **2-Chloro-6-aminoquinoline** precipitated as long, slender, light yellow colored needles belonging to the orthorhombic system; soluble in ethanol, acetone, hot water, warm petroleum ether, diethyl ether and benzene; m. p. 149° (corr.); yield, 67% of the theoretical.

Anal. Calcd. for $C_9H_7ClN_2$: N, 15.67; Cl, 19.88. Found: N, 15.70; Cl, 19.75.

Catalytic reduction of 2-chloro-8-nitroquinoline[9] in absolute ethanol under the same conditions used for reducing 2-chloro-5-nitroquinoline gave **2-chloro-8-aminoquinoline.** After concentrating the alcoholic solution of the amine by distillation and adding water to the resulting concentrated solution, an oil separated; this crystallized upon standing. Recrystallization from dilute ethanol–water solution gave light green colored (almost white) needle-like leaflets, soluble in ethanol, acetone, warm benzene and acids, m. p. 84° (corr.), yield, 98% of the theoretical.

Anal. Calcd. for $C_9H_7ClN_2$: N, 15.67; Cl, 19.88. Found: N, 15.70; Cl, 19.75.

2-Hydroxyquinolinearsonic Acids.—Crushed ice was added to a solution of 0.16 mole of the hydroxyquinoline amine in 2 moles of hydrochloric acid. When a temperature below 5° had been attained, the amine was diazotized with sodium nitrite solution. After making just basic to litmus paper by the careful addition, in the presence of ice with stirring, of 5 *N* sodium hydroxide solution, the diazotized solution was poured slowly with good mechanical mixing into a water solution of 26 g. of sodium metaarsenite to which previously had been added 5–6 ml. of a saturated water solution of copper sulfate. After being stirred for one hour and having stood overnight, the resulting mixture was brought slowly to the boiling temperature and boiled for five minutes. This hot mixture was filtered and the filtrate carefully neutralized with hydrochloric acid. Upon charcoaling this neutral solution, evaporating until a volume of 350 ml. remained, and making acid to Congo red paper with hydrochloric acid, the crude hydroxyquinolinearsonic acid precipitated. When this acid was dissolved in a small quantity of hot dilute sodium hydroxide solution, 3% hydrogen peroxide solution added, the solution boiled for five minutes and made acid to Congo red paper with hydrochloric acid, the pure acid precipitated.

Hydrolysis resulted when 2-chloroquinoline-8-arsonic acid was heated in an autoclave with 12 parts by weight of hydrochloric acid (sp. gr. 1.19) at 125° for one and one-half hours, and 2-hydroxyquinoline-8-arsonic acid was obtained.

When a solution of 2-hydroxy-4-methylquinoline-7-arsonic acid in one equivalent of hot sodium hydroxide solution was added dropwise to cold 95% ethanol in a container fitted with a mechanical stirrer, the monosodium salt of 2-hydroxy-4-methylquinoline-7-arsonic acid precipitated.

2-Chloroquinolinearsonic Acids.—The 2-chloroquinolinearsonic acids were prepared from the corresponding 2-chloroaminoquinolines by a slight modification of the method used for synthesizing the 2-hydroxyquinolinearsonic acids. Instead of neutralizing the diazotized solution of the amine before it was added to the arsenite solution, enough alkali was added to the arsenite solution to neutralize exactly the acid in which the amine was dissolved, and the diazotized amine was added directly.

2 - (β-Ethoxyethoxy) - 4 - methylquinoline - 7 - arsonic Acid.—Five-tenths gram of dry 2-chloro-4-methylquinoline-7-arsonic acid was refluxed with a solution of 0.60 g. of clean dry sodium in 50 ml. of ethylcellosolve for two and one-half hours. After cooling and filtering, the filtrate was made neutral to litmus paper by the careful addition of hydrochloric acid (sp. gr. 1.19). The sodium chloride

formed was filtered off and the filtrate diluted with 50 ml. of water. When this was evaporated on a hot-plate until 25 ml. remained and made acid to Congo red paper with hydrochloric acid, 2-(β-ethoxyethoxy)-4-methylquinoline-7-arsonic acid precipitated.

2-(β-Ethoxyethoxy)-quinoline-5-arsonic acid was obtained from 2-chloroquinoline-5-arsonic acid by the same method used in preparing 2-(β-ethoxyethoxy)-4-methylquinoline-7-arsonic acid.

Summary

1. It was proved that 2-hydroxy-4-methyl-7-aminoquinoline rather than 2-hydroxy-4-methyl-5-aminoquinoline resulted when equimolecular quantities of *m*-phenylenediamine and ethyl acetoacetate condensed in an autoclave at 130°.

2. A number of quinoline amines were produced by the reduction of nitroquinolines.

3. Several 2-hydroxyquinoline and 2-chloroquinolinearsonic acids were obtained from the corresponding quinoline amines by diazotization and coupling with sodium arsenite. The monosodium salt of 2-hydroxy-4-methylquinoline-7-arsonic acid was made.

4. The hydrolysis of 2-chloroquinoline-8-arsonic acid resulted in the formation of 2-hydroxyquinoline-8-arsonic acid.

5. 2-Chloro-4-methylquinoline-7-arsonic acid and 2-chloroquinoline-5-arsonic acid reacted with the monosodium salt of ethylcellosolve to give 2-(β-ethoxyethoxy)-4-methylquinoline-7-arsonic acid and 2-(β-ethoxyethoxy)-quinoline-5-arsonic acid, respectively.

The Viscosity Function

BY E. P. IRANY

Viscosity is well defined as a physical quantity and accurately measurable. Yet, so far, its relations to temperature, pressure, dilution, chemical constitution, and so forth, are somewhat obscure.

Numerous empirical rules have been proposed but none of them can claim general validity or real physical significance. It may even be questioned whether the task of formulating the exact viscosity laws is not far beyond our present knowledge of the liquid state as such.

It is the main purpose of this paper to offer evidence that such laws exist and can be expressed. Of course, without reliable mathematical assumptions, explicit formulas cannot be derived; the method adopted is one of graphical analysis. It will be shown that, if applied to the large number of measurements and data already available in the literature, this method reveals in them fundamental but so far undiscovered regularities.

Viscosity may be considered a form of friction if the latter is explained in terms of internal forces. Few molecules—probably none—are in so perfect equilibrium that no attractions would be active between them. These forces are chemical by nature though not in intensity, and it is obvious that they are the cause of the mutual interference with motions and mobility of the molecules which is observable as viscosity. The effect may vary between actual chemical union, association, and mere transitory attraction.

For considerations of viscosity the usual distinction between associated and non-associated liquids is only secondary. It is conceivable that a substance may be so perfectly associated that in its larger complexes all residual forces are well compensated; reversely, in a non-associated liquid the identity of the molecules as the structural units may be preserved, but not their independent mobility. Hence, the fundamental distinction should rather be drawn between "ideal" and "non-ideal" conditions, depending not only on existence and magnitude of the intermolecular forces but, primarily, on their constancy. What the mobile entities are—molecules or molecular complexes of some kind—is immaterial as long as problems of internal constitution are not dealt with; for the time being, these must be left outside the scope of this investigation.

The supposed general law of viscosity can only appear in substances of constant structure and force disposition. The question now arises as to where to find and how to recognize "ideal" liquids which may serve as objects of study. Experimental proof of "ideality" such as, *e. g.*, derived from other physical properties, is of doubtful value because it seems that viscosity is still very sensitively affected by intermolecular conditions which would not reveal themselves distinctly enough in calorimetric, gravimetric, or cryoscopic effects.

Recourse must therefore be taken to mere assumption that certain substances are ideal and may be accepted as standards. The best choice are the paraffin hydrocarbons because all that is known about them not only suggests that they are as nearly ideal as possible, but also that this condition is maintained through the whole series which covers the entire range of measurable viscosities.

I. The Viscosity Function of Dilution

Ideal Mixtures.—If two liquids are miscible in such a manner that no specific effects appear between them which depend on and vary with the composition of the mixture, the system can be considered ideal.

For example, the components may be a viscous paraffin oil and a light petroleum fraction with widely differing viscosities at the same temperature. The viscosities fall upon a sharply ascending curve (Fig. 1). This curve represents in graphical form a presumably simple case of the law according to which viscosities should be additive or computable. By selecting any other pair of standard hydrocarbons, a whole series of such curves could be drawn across the diagram.

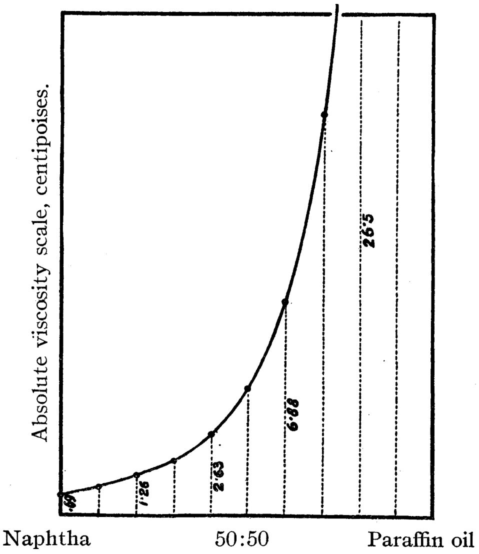

Fig. 1.

If a given system of other components were now to be examined for ideality, one would select two paraffins of the same respective viscosities and construct the ideal curve between them; the mixture under survey would then be recognizable as ideal if its curve coincided with that of the standard.

However, it would be much more convenient to compare in a diagram in which the ideal course would appear as a straight line. For any single standard curve this is easily realized by plotting viscosity not in absolute units, but in a scale which compensates for the curvature in such a manner that a straight line results. This scale would then embody the unknown law according to which viscosities are additive.

There have been numerous attempts to formulate such viscosity functions empirically. For example, the function log (viscosity) has been proposed by Arrhenius.[1] In this case the scale embodying the law of additivity is the logarithm of the natural value of the viscosities, *i. e.*, a semi-log diagram may be used. However, this rule is only a very imperfect approximation, neither accurate nor generally valid. The same applies to other such assumptions, *e. g.*, reciprocal viscosity ("fluidity") by Bingham,[2] or its cube root, by Kendall–Monroe.[3] The true mathematical form of the scale function is unknown, it can only be represented by graphical means.

How the scale function is determined from a number of points fixed by actual viscosity measurements is shown in Fig. 2.

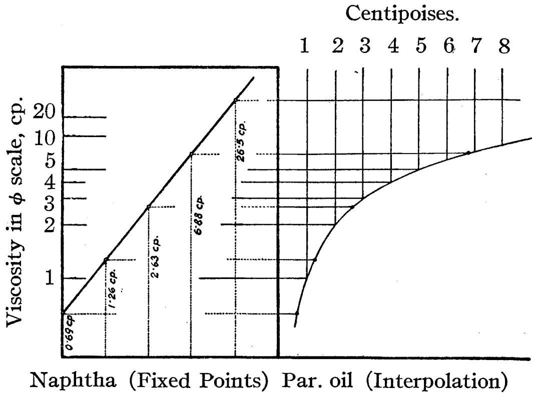

Fig. 2.

A straight line of any convenient position and gradient is assumed to represent the original curve; its intersections at the given mixtures yield the fixed points, and the scale is completed by means of an interpolation curve.

If this is done with other standard curves representing ideal mixtures, a very interesting regularity appears: the resulting scale is always the same, no matter from what particular pair of

(3) Kendall and Monroe, THIS JOURNAL, **39**, 1787, 1806 (1917).

components it has been derived. In other words, there is a general function of viscosity according to which it is additive in ideal mixtures. In terms of graphical analysis: *In a diagram in which the scale of viscosity is adjusted so as to make one given ideal mixture appear as a straight line, all other ideal mixtures appear also as straight lines.*

This rule holds with complete accuracy in all ideal mixtures; it is not restricted to those composed of paraffin hydrocarbons, but is independent of the nature of the components. The function expressed in the scale is neither logarithmic, nor otherwise readily representable in mathematical form. It will be referred to as the "Viscosity Function ϕ." This "ϕ-scale," completed over a considerable range of viscosities, appears in Fig. 3.

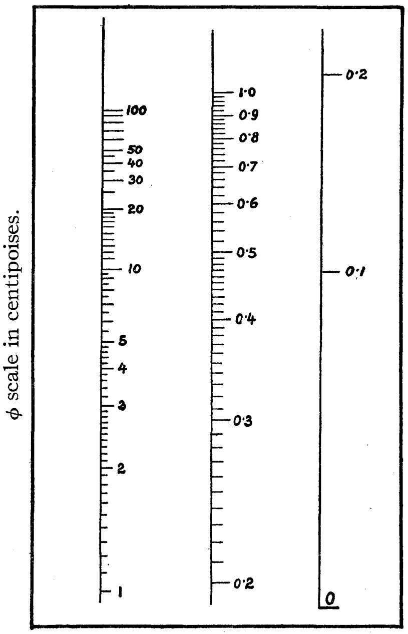

Fig. 3.

The question as to what units should be chosen for the concentrations of the components, *i. e.*, weight, volume, molarity, etc., has been controversial, and each one of the previously proposed empirical rules was based on different terms. It can be shown that the ϕ scale is generally valid if volume concentrations are used, and that all other units of quantity fail to reveal any regularity. Hence, *the unit of quantity with reference to viscosity is volume.*[4]

Various examples of ideal mixtures are shown in Fig. 4. Apart from systems consisting of paraffin hydrocarbons, others of entirely different nature have been described in the literature. Thus, Kendall and Monroe[3] concluded from exact calorimetric, cryoscopic, and density measurements that the following four systems should be ideal:

Benzene–Ethyl benzoate
Benzene–Benzyl benzoate
Toluene–Ethyl benzoate
Toluene–Benzyl benzoate

All these systems appear as straight lines in Fig. 4, including the last-mentioned which failed to satisfy the authors' empirical cube root formula—an exception which they were unable to explain. Actually, there is no exception.

Kendall and Wright[5] investigated other pairs, ethers and esters which should give ideal mixtures. One of these

Phenyl ether–Phenetole

is also shown in Fig. 4.

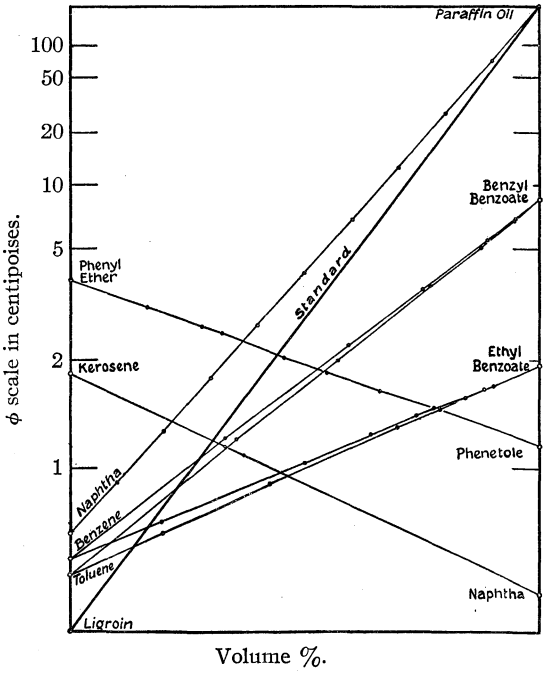

Fig. 4.

Ideal solutions of solid substances can be regarded as ideal mixtures, and they follow the same law. If the viscosities in ϕ scale are plotted against volume concentrations, straight lines result, Fig. 5. Even very complex substances, such as some resins, obey the ϕ function very accurately, also highly concentrated electrolytes, *e. g.*, zinc chloride in water.

---

(4) All data used in the diagrams have been recalculated in volume percentages.

(5) Kendall and Wright, This Journal, **42**, 1776 (1920).

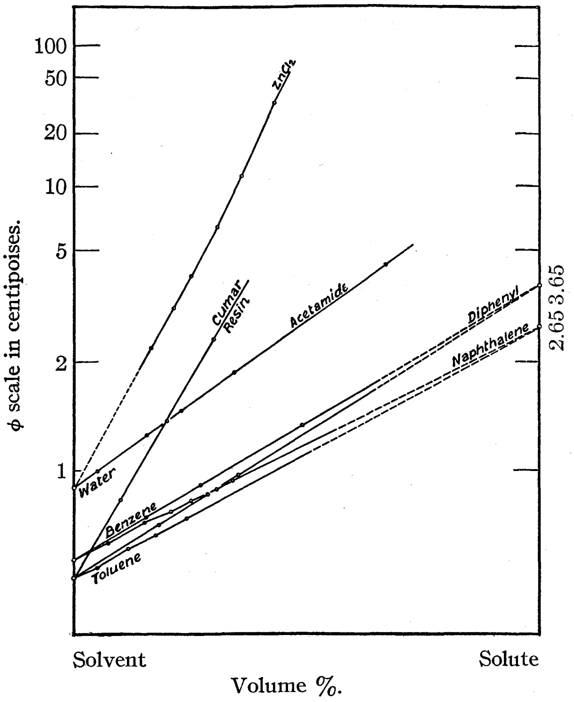

Fig. 5.

Solids in solution are, in fact, components of a liquid system. The straight lines may be extrapolated as far as 100% solute; the viscosity thus intercepted would be that of the solute itself if it could exist in liquid form under the given conditions. It will be seen later that such viscosities, though not readily realizable, have a physical significance; they are the same as those obtained by extrapolating the temperature function below the melting point.

Kendall and Monroe[3] offer evidence for the ideality of

Naphthalene in benzene
Naphthalene in toluene
Diphenyl in benzene
Diphenyl in toluene

In the scale of their assumed cube root formula the extrapolated viscosities of the solutes vary with the solvent: 2.25 and 1.83, respectively, for naphthalene, and 3.44 and 2.82 for diphenyl. In the ϕ scale, however, the lines of each solute converge exactly toward the same point on the 100% axis—2.65 cp. for naphthalene and 3.65 cp. for diphenyl. The temperature function of naphthalene, extrapolated to 25°, gives 2.75 cp., which is in very good agreement with the above value.

Ternary ideal mixtures can be computed in the same manner as binary ones. First, two of the components are combined according to their volume ratios, and the resulting ϕ ordinate is then proportioned against the third component. Examples of this kind are

Benzene–Ethyl ether–Acetone[6]
Allyl phenyl thiourea–Aniline–Toluene[7,8]

The graphical computation of the viscosities of these mixtures agrees perfectly with the measurements.

Some originally binary mixtures may become ternary if a chemical reaction occurs between the components. However, if the reaction is quantitative, and completely consumes one of them, leaving the other in binary mixture with the reaction product, the system may divide itself into two binary parts: A–(AB), and (AB)–B. Many such cases have been plotted and found ideal; *e. g.*

Chloral–(Chloral hydrate)–Water[9]
Stannic chloride–(Mol. compound)–Ethyl benzoate[10]
Allyl thiocyanate–(Subst. thiourea)–Aniline[8]
Allyl thiocyanate–(Subst. thiourea)–Methyl aniline[11]

All these systems give the same kind of diagram; the ascending branches appear as straight lines intersecting at molar ratios of exactly 1:1. Figure 6 shows the last-mentioned system in absolute viscosity and ϕ scale.

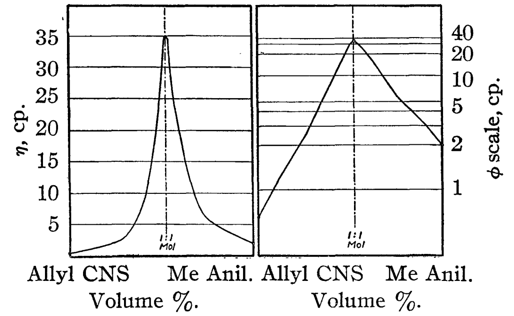

Fig. 6.

Non-ideal Mixtures.—Non-ideal effects occur if either the volume or the force field surrounding the molecules is subject to change. Association generally raises, and dissociation reduces, viscosity from the values it should normally assume. It must be emphasized, however, that these effects need not be real or permanent in order to cause deviations; mere attractions or tendencies in the

---

(7) Allyl thiocyanate and aniline yield quantitatively allyl phenyl thiourea; the latter forms an ideal binary mixture with excess aniline, and ideal ternary mixtures with toluene.

(11) Kurnakov and Zhemchuzhnui, *ibid.*, **18**, 125 (1913).

sense of, *e. g.*, association, would be evident in the viscosity record, without formation of any definite compound.

The difficulty is not in the sensitivity with which viscosity, as a measurable property, responds to these influences; it is mainly in the quantitative evaluation of the results obtained. Empirical formulas are entirely unreliable; they are neither generally valid, nor accurate even within limited ranges. The ϕ scale, however, indicates deviations from the ideal course, no matter how small, or over what range, in the right sense, magnitude and location.

In the following examples the existence of definite association compounds is supported by other evidence, *e. g.*, by maxima in the freezing point curves.

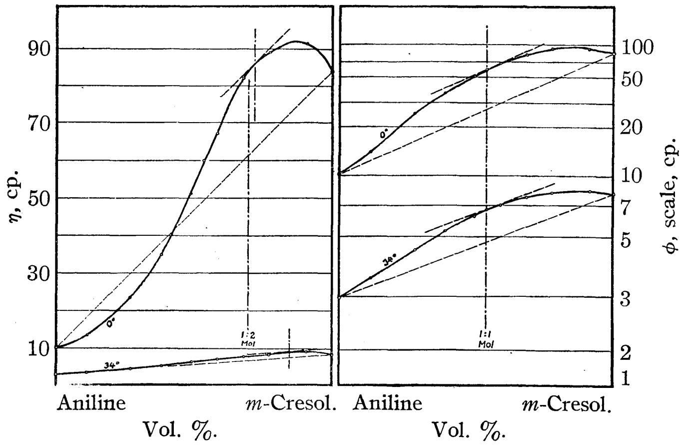

Fig. 7.

Tsakalatos[12] concluded from the absolute viscosities of the systems

m-Cresol–Aniline
m-Cresol–*o*-Toluidine

that compound formation occurred at a ratio of 2:1 moles in both cases. However, Kremann[13] found only 1:1 molar compounds in the freezing point curves. As shown in the diagrams of the first-mentioned system, Fig. 7, the absolute viscosity curves are distorted, and their maxima[14] appear displaced; the ϕ curves deviate steadily toward maxima at exactly equimolar ratios which are not shifted with varying temperature. The second case and many similar systems give analogous figures; among these are, using the data by Bramley[15]

Phenol–Aniline	1:1 mole
Phenol–Dimethylaniline	0.548:0.452 mole
Phenol–Diphenylaniline	No compound

In some cases different compounds seem to occur in the solid and liquid phase. Thus

Phenol–Quinoline[15]

indicate a definite association effect for sharply 1:1 mole. Freezing points show maxima at 2:3 and 2:1 moles, but no singularity at 1:1 mole. The ϕ curve of the system

o-Chlorophenol–Pyridine[15]

has a maximum at 1:1 mole coinciding with the freezing point record; between this mixture and the phenol the ϕ curve, but not the freezing points, shows another sharp maximum.

Where the ϕ curves sag below linearity, dissociation (des-association) either of one or both components must be assumed. Such cases are surprisingly rare; examples are

Phenol–Nitrobenzene[15]
Ethyl alcohol–Benzene[9]

This is interesting, for such "negative" curvatures appear very frequently, not only in absolute viscosity diagrams but also in all empirically assumed scales, particularly where the range of viscosities between the components is considerable. Actually, it seems that associated substances, as a rule, have quite stable constitutional units which do not vary or break down as readily as commonly assumed. This is also evident in their mostly normal response toward temperature changes, as explained in the following.

II. The Viscosity Function of Temperature

Here, again, ideal and non-ideal conditions must be anticipated, depending on the absence or presence of variable individual factors. As in the case of ideal mixtures, the paraffin hydrocarbons may be considered suitable standards.

If the absolute viscosities at different temperatures, *e. g.*, of *n*-octane, are plotted and the resulting curve is straightened into a line by the same method that was used in obtaining the viscosity function ϕ, a scale is obtained which, again, is generally valid. The viscosity–temperature functions of all substances, except those

---

(13) Kremann, *Wien. Ber.*, **113**, 878 (1904).

(14) These maxima or minima must be reckoned from the straight line connecting the two terminals and indicating the ideal course. In the points of greatest deviation from this line the tangent to the curve is parallel to it.

(15) Bramley, *J. Chem. Soc.*, **109**, 10, 434 (1916).

of variable nature, appear as straight lines.

There is, moreover, a very significant relation between these two functional scales—the one derived from ideal mixtures, and the other from temperature effects—they are actually identical over their whole extent. *The general law of viscosity relative to temperature is identical with that of viscosity relative to dilution.*

The validity of this postulate has stood the test of all data represented or mentioned in this paper. The complete ϕ scale used in the diagrams and shown in Fig. 3 was assembled from numerous over-lapping sections in which mixture and temperature standards were used indiscriminately. The continuity of the function was found real and precise in all ranges.

Figure 8 shows a selection of liquids, representing various chemical types. The following partial list contains substances which give absolutely straight lines between 0° and their boiling points, using the measurements by Thorpe and Rodger[16] which are recognized as the most accurate on record. Lack of space prevents the reproduction of the diagrams.

Hydrocarbons.—Isoprene, *n*-pentane, isopentane, *n*-hexane, isohexane, diallyl, *n*-heptane, isoheptane, *n*-octane, benzene (0–70°), toluene, *o*-, *m*-, *p*-xylene, ethyl benzene.

Ethers.—Diethyl, methyl propyl, ethyl propyl, dipropyl.

Esters.—Methyl formate, methyl, ethyl and propyl acetates, propionates, *n*- and isobutyrates, valerates.

Ketones.—Acetone, methyl ethyl, diethyl, methyl propyl, methyl butyl.

Halogen Compounds.—Propyl chloride, propyl bromide, propyl iodide, isopropyl chloride, methylene dichloride, chloroform, carbon tetrachloride, ethylene chloride, ethylidene chloride, perchloroethylene, bromine.

Sulfur Compounds.—Methyl sulfide, ethyl sulfide, carbon disulfide, thiophene.

Only very few liquids—the lowest alcohols and fatty acids, for example—show distinct and significant deviations from the straight course, due without doubt to variable association. Even water follows an absolutely straight line with the exception of the well-known anomalous region above its melting point. These examples show very clearly that association in itself does not interfere with normal behavior as long as it remains constant; associated substances may very well conform with ideality.

The almost universal prevalence of ideal conditions in pure substances is important in view of the fact that ideal mixtures are far less common. This suggests that pure substances are in most cases homogeneous, and contain molecular entities of uniform structure. Consequently, the various fractional association factors ascribed to nearly all of them by Ramsay and Shields,[17] Traube,[18] and McLeod,[19] do not seem to have a purely constitutional meaning, *i. e.*, do not correctly represent association.

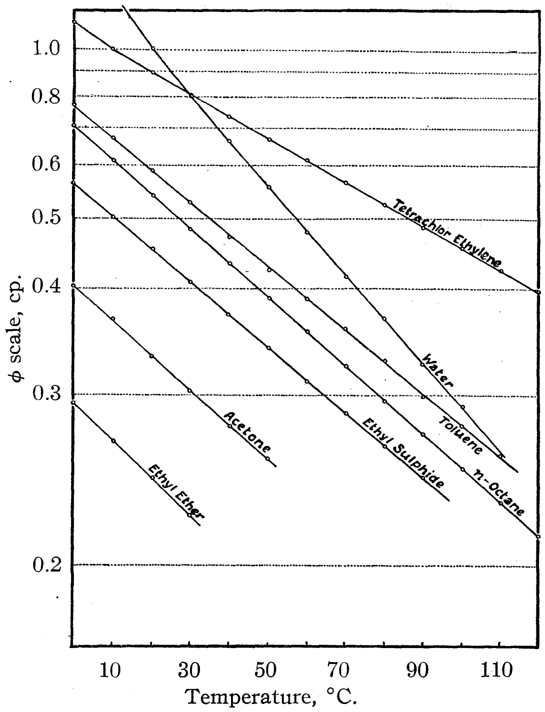

Fig. 8.

The Critical Region.—The present analysis deals with the viscosity of liquids; that of gases is an entirely different phenomenon, and of a negligible order, if expressed in the same measure. The viscosity typical for the liquid state must disappear at the critical temperature; the viscosity of gases is no functional extension of it. One may, therefore, speak of a "zero level of liquid viscosity" at the discontinuity between the gaseous and the liquid states. Since the linearity of the ϕ functions is perfect within the recorded ranges, an extrapolation as far as the critical point may be considered significant.[20]

---

(16) Thorpe and Rodger, *Phil. Trans.*, **185**, 397 (1894); *Proc. Roy. Soc.* (London), **60**, 152 (1896).

(17) Ramsay and Shields, *Trans. Chem. Soc.*, **63**, 1089 (1893).

(18) Traube, *Ber.*, **30**, 283 (1897).

(19) McLeod, *Trans. Faraday Soc.*, **19**, 17 (1923).

(20) Data on viscosities above the boiling points of, *e. g.*, benzene, toluene, ether, ethyl and isobutyl acetate, ethyl bromide, carbon tetrachloride, etc., by Heydweiller [*Wied. Ann.*, **59**, 193 (1896)], show that the general straight course continues. Phillips [*Proc. Roy. Soc.* (London), **87**, 48 (1912)] measured viscosities of liquid carbon dioxide within the critical region; these are on a curve which does not merge into that of the gas viscosities, but intersects it.

The linearity of the ϕ function is not affected if, instead of centigrade, reduced absolute temperatures $(1 - T/\Theta)$ are used as abscissas. In such a diagram all lines should converge toward one point, because at the critical temperature Θ, or for $T_r = 0$, all liquid viscosities become equal, *i. e.*, nil. As shown in Fig. 9, many lines are crowded together, and reach the critical temperature at a reasonably well defined level which, therefore, can be taken as that of zero liquid viscosity. However, there are also several whose intercepts indicate viscosities of considerable magnitude at their known critical temperatures.

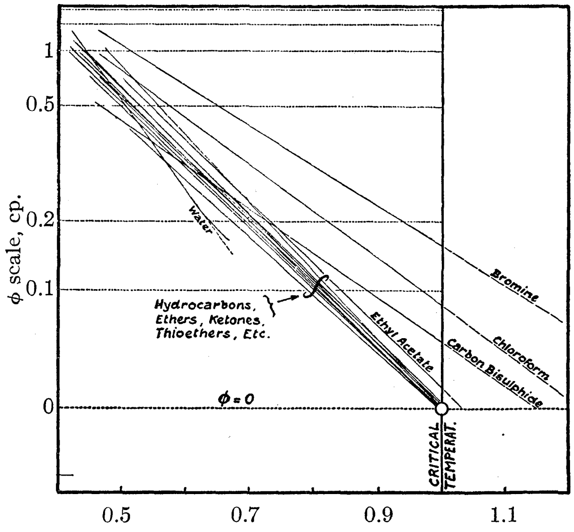

Fig. 9.

This probably means that in these cases the critical temperatures, as of record, are too low, that the observable disappearance of the surface does not mark the end of all liquid structure. That this survival should be most appreciable in substances with strong internal forces, is to be expected and is borne out in Fig. 9.

If then it be justifiable to consider the critical discontinuity expanded over an appreciable temperature interval, this would reach from the conventionally observed critical temperature upward as far as another "limiting" critical temperature which would be defined by the actual and complete disappearance of liquid viscosity.

This critical range can be estimated in Fig. 9; it is represented by the distance from $T_r = 0$ to the intersection of the ϕ line with the zero level.

A peculiar exception is that of water. Its line in Fig. 9 is unusually steep and passes through the zero level at much lower than the critical temperature—the only case of this kind. This is obviously impossible, and it must be assumed that a structural rearrangement occurs at some higher temperature which would cause the curve to reach the critical point. Three viscosity measurements between 100 and 153° seem to indicate this course which is probably due to increasing association.

Table I

Absolute Critical Temperature

	Observed	"Limiting"	Range
n-Pentane	470	464	...
n-Hexane	507	500	...
n-Heptane	540	541	...
n-Octane	569	572	...
Benzene	565	566	...
Toluene	594	597	...
Ethyl ether	466	474	8
Acetone	508	514	6
Ethyl acetate	525	541	16
Thiophene	590	615	25
Carbon disulfide	550	633	83
Methylene chloride	518	594	76
Chloroform	533	649	116
Carbon tetrachloride	557	676	119
Propyl chloride	494	520	26
Ethyl bromide	499	576	77
Ethyl iodide	554	680	126
Bromine	575	810	235

The expansion of the critical discontinuity into a range which, according to the above estimates, may assume the extent of hundreds of centigrade degrees, is of great fundamental importance. Of course, the correctness of the extrapolation of the ϕ lines depends on the absence of discontinuities in the large temperature ranges within which no viscosity data are available. Viscosity measurements over the entire course and up into the critical region, particularly on such substances as, *e. g.*, bromine, would yield very valuable information.

III. The Viscosity Function of Pressure

Moderate variations of pressure hardly affect the viscosity of liquids. It is necessary to employ thousands of atmospheres in order to study the quantitative relation between viscosity and pressure. Such measurements have been carried out by Bridgman[21] in a specially constructed viscometer.

Absolute viscosity, plotted against pressure in atmospheres, yields curves which, after a very

[21] Bridgman, *Proc. Nat. Acad. Am.*, **11**, 603 (1925).

gradual ascent, bend sharply upward. In ϕ scale, these curves are not represented as straight lines, but strongly concave toward the pressure axis, Fig. 10.[22]

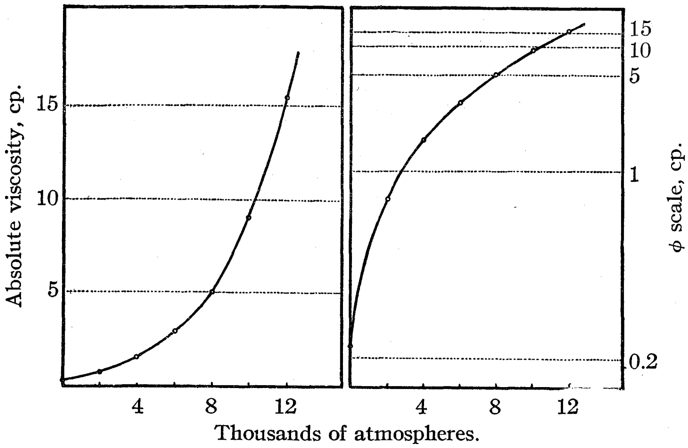

Fig. 10.—Viscosity of *n*-pentane at 30° under high pressures.

The effect of pressure on viscosity, therefore, is not additive in the same function as that of dilution and temperature, but follows a different law.

However, it is possible to rationalize this relation by the same method as was used in the construction of the ϕ scale in Fig. 2. Choosing, *e. g.*, the isotherm of *n*-pentane at 30° as a standard, a functional scale Π can be obtained. This Π scale, shown and applied in Fig. 11, represents the pressure functions of all hydrocarbons, at various temperatures, as well as those of all ideal substances, as straight lines. *All viscosity-pressure functions follow a general law. This law is different from that relating viscosity with dilution and temperature.*

Figure 11 shows Bridgman's data on paraffin hydrocarbons at two different temperatures, and it reveals a very interesting fact: all lines meet in one point.

In this point, viscosity assumes the same value at all temperatures, and for all paraffins. This is conceivable only if the intermolecular forces which control viscosity are counterbalanced by external pressure, so that their effect disappears. Hence, the negative abscissa of the intersection point is the "internal" or cohesional pressure of the liquid, and its level must be that of zero viscosity. That all paraffin hydrocarbons should have the same internal pressure is well in keeping with their known nature and relationship.

The intersections of different isotherms of the same liquid always fall on the zero level of the Π function, except in those cases where association is known to be variable, *e. g.*, water, alcohols, glycerol, etc. The negative pressure intercepts which indicate the internal pressures, are characteristic constants of the normally behaving substances. The values obtained from Π scale diagrams of Bridgman's data agree very well with those deduced by other methods, *e. g.*, from van der Waals' equation or the latent heat of vaporization. It is impossible to reproduce all the diagrams but the resulting internal pressures appear in Table II.

The Π functions of substances of variable association are not linear but they approach the straight course at high pressures, and the negative pressure intercept assumes a definite value.

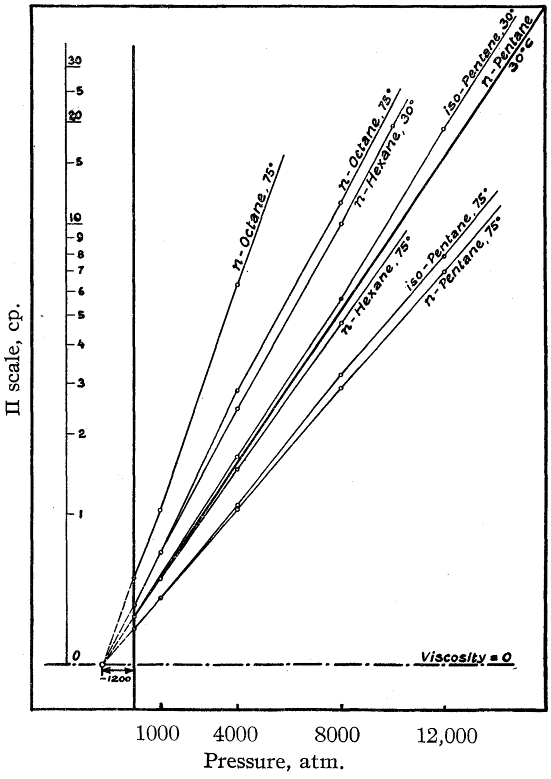

Fig. 11.

In the series of monohydric paraffin alcohols, an interesting regularity is found: the asymptotical intercepts, *i. e.*, the maximum internal pressures

---

(22) On the convexity of the curves which Bridgman obtained in absolute viscosity scale, he remarked: "This is unusual; most pressure effects become relatively less high at high pressures by a sort of law of diminishing return." The ϕ scale represents this "diminishing return" without inconsistencies and apparently in its true evaluation.

are identical for all members of the series (Fig. 12). It would seem, therefore, that the internal pressure is characteristic, not only for each liquid, but for whole homologous series.

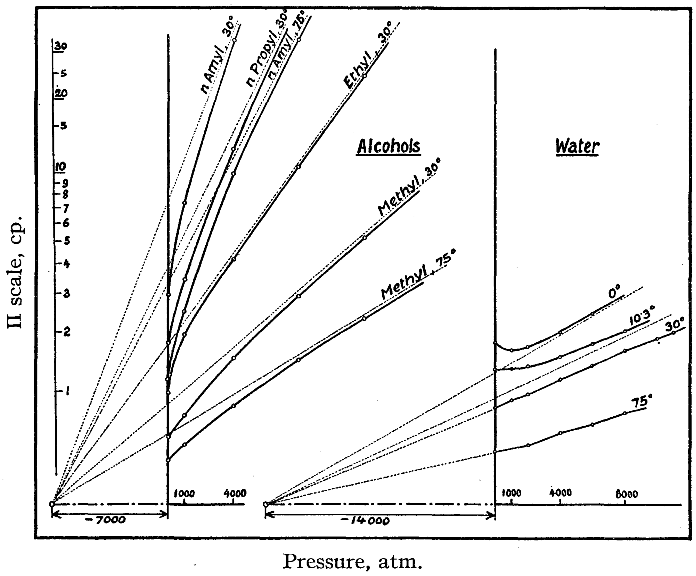

Fig. 12.

The isotherms of water, Fig. 12, run differently; they are convex, but their asymptotes also meet in one point on the pressure axis, with an intercept twice as large as that of the alcohols. Above 30°, the isotherms are straight lines.

TABLE II

		Internal pressures, atm.
All paraffin hydrocarbons		1200
Benzene		1200
Ethyl ether		1400
Chlorobenzene		1400
Alkyl benzenes		1500
Bromobenzene		2000
Chloroform		2300
Aniline		2400
Acetone		2500
Carbon disulfide		2700
Alcohols	(Limit)	7000
Water	(Limit)	14000
Glycerol	(Limit)	14000

IV. The General Viscosity Function; Constitution

The relations of viscosity to volume (dilution), temperature, and pressure must be considered special cases of the equation of state for liquids. The combination of these partial functions into the unknown general law is, of course, beyond the means of the graphical method. Nevertheless, the two functional scales, ϕ and Π, can be used for the computation of all viscosities of normal liquids if three elements are known. These are material factors characteristic for any given substance.

A complete rationalization would have to include that of constitutional additivity of these constants.

Whether the additivity of ϕ in terms of volume, or that of Π in terms of intermolecular attractions, also applies to the constituent parts of the chemical molecule; in other words, whether additive atomic values of ϕ or Π exist, cannot be definitely answered. This depends on precisely what may be understood under comparable conditions, and what kind of unit the "molecule" of a liquid really is.

For the time being, it must be realized that "constitution" to which viscosity phenomena may be related, is not necessarily that accepted in a purely chemical sense. The independently mobile entities whose movements or mobility viscosity records may, but again, may not be the individual chemical molecules.

All available facts point toward the necessity of a finer graduation of intermolecular relationships, apart from, and between complete independence and permanent association. If all these intermediate forms could be included into, and rationalized within a broader concept of constitution, the additive features of viscosity would reveal themselves more clearly.

Summary

Due to our insufficient knowledge of the structure of liquids it is impossible to formulate the basic and generally valid laws which relate liquid viscosity with variables of condition, such as volume (dilution), temperature and pressure. There is no real proof that such laws of broad validity exist, or that they are recognizable.

A method of graphical analysis was used in providing this evidence which may be summarized in three postulates:

1. A function of viscosity exists, $\phi(\eta)$, or the "ϕ scale," which is generally additive in terms of volume, *i. e.*, of dilution in ideal mixtures.

2. A function of viscosity exists which is generally additive in terms of temperature. This function or functional scale is identical with the above, ϕ; temperature and dilution

have the same quantitative effects upon viscosity.

3. Another function of viscosity exists, $\Pi(\eta)$, or the "Π scale," which is generally additive in terms of pressure.

If viscosities are plotted in these functional scales, all normal or "ideal" additivity is represented as a straight line. Deviations from this course are very accurately recognizable and significant.

Thus, the ϕ diagrams reveal "non-ideal" conditions, *i. e.*, associative or dissociative tendencies which could not be detected by other means. Extrapolation into the critical region suggests important conclusions regarding state discontinuity. The Π scale shows the correct magnitude of the internal pressures of liquids which, according to this evidence, are characteristic for whole series of related substances.

The Dielectric Properties of Acetylenic Compounds. X. Equipment for Measuring Dielectric Constants of Gases. The Polarity of Gaseous Monoalkyl Acetylenes

BY F. J. KRIEGER AND H. H. WENZKE

In order to determine accurately the low moments of the monoalkyl acetylenes it is necessary to abandon the method of solutions used in the previous papers of this series and employ the temperature variation method on the vapors of the materials to be investigated. This paper describes an apparatus for measuring the dielectric constants of gases and a method for determining their polarizations and gives data obtained for five homologs.

Description of Apparatus

The present apparatus for measuring the dielectric constants of gases was designed with a view to ruggedness and stability in operation. It is essentially a beat-frequency oscillator designed for measuring extremely small capacities with great accuracy. It offers as points of superiority over those described by Groves and Sugden[1] and by Zahn,[2] first, alternating current operation for convenience and maintained foolproof operation; second, excellent stability, combined with the comparison capacity method of eliminating residual drift, as mentioned by Zahn, but not used by Groves and Sugden; and, third, a direct-meter reading of zero beat which, because of precautions taken to eliminate entirely any tendency of the two oscillators in the circuit to "lock in," gives a much higher precision of setting than does either the resonance method of Groves and Sugden or the audible-beat method of Zahn.

Inspection of the circuit diagram, Fig. 1, indicates that the disposition of the circuit capacities, together with the capacity to be measured is similar to that used by Groves and Sugden. However, where they use the amplitude of the voltage developed at a particular point on a steep resonance curve as an indication of resonance, we use the heterodyne note between two oscillators. Frequency drift is eliminated by stabilizing one oscillator with a quartz crystal and furnishing the other oscillator with a suitable reference standard for correcting against the effect of drift should any occur.

Vacuum tube V_1, together with the inductance L_1, the capacity C_1, and the crystal X, form an oscillating circuit at a frequency of 500 kc. per second. The crystal is of the low temperature coefficient type and the oscillator is such that constancy may be assured to a precision of six cycles per degree C.

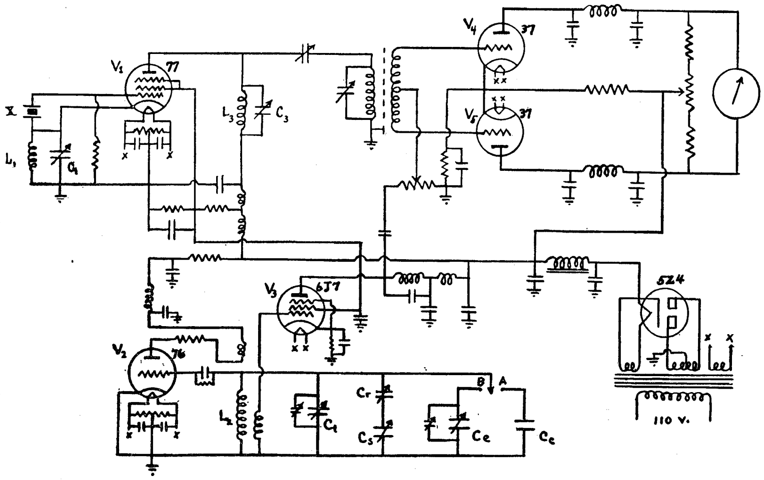

Fig. 1.—Circuit diagram of beat-frequency oscillator used in measuring dielectric constants of gases.

Vacuum tube V_2, the inductance L_2, and the capacities C_t, C_r, C_e and C_s, form the variable oscillator whose frequency is that of the second harmonic of the crystal oscil-

---

[1] Groves and Sugden, *J. Chem. Soc.*, 1094 (1934).

[2] Zahn, *Phys. Rev.*, **24**, 400 (1924).

lator. This oscillator is isolated from the crystal-controlled oscillator and from the detector by radio frequency amplifier circuits associated with the buffer tube V_3.

Tubes V_4 and V_5 form a balanced detector system in which the second harmonic of the crystal-controlled oscillator beats with the output of the variable oscillator for the indication of circuit adjustment. This is always done at zero beat, indicated by the meter in the plate circuit of the detector tubes. By this means frequency differences as small as a fraction of a cycle per second may be detected easily.

The variable oscillator contains, as a part of its variable capacity, a General Radio standard condenser, C_s, in series with a small variable capacity, C_r. This arrangement makes possible a maximum sensitivity of 0.000267 mmf. (micromicrofarad) per division, over a total range of 0.56 mmf., while the lowest sensitivity is 0.00186 mmf. per division, over a total range of 3.92 mmf.

Thermal stability is achieved by two general methods. The first of these is the choice of component parts of very low temperature coefficients, and the second is a complete segregation of all tuning elements within a thermally-insulated chamber and thorough ventilation of all heat-producing units. These precautions result in a thermal stability such that the zero-beat adjustment drifted an average of 0.01 mmf. per hour. The effect of even this small drift is, in practice, eliminated by including in the circuit a capacity arrangement which can be set equal to the initial capacity of the circuit under test. By inserting this capacity, the oscillator may be returned to its original adjustment at any time.

The instrument is operated as follows:

(a) The switch is set at A and the gas cell is evacuated.

(b) The standard condenser, C_s, and the range condenser, C_r, are set at values which will accommodate the change in cell capacity that will occur upon the introduction of the gas under test. The dial readings of both condensers are recorded.

(c) The tank condenser, C_t, is tuned until the beat note as indicated in the meter is very low. The auxiliary condenser C_t vernier, is used to bring the beat note to a zero.

(d) The switch is thrown to B.

(e) The equivalent condenser, C_e, is tuned for zero beat. Any slight drift is eliminated by means of the auxiliary condenser C_e vernier.

(f) The switch is reset at A and the gas to be measured is introduced into the cell.

(g) The standard condenser, C_s, is readjusted accurately to zero beat. This value is recorded as C_s'.

(h) Should there be considerable delay between steps (e) and (g), the switch is thrown to B, and if the beat is no longer zero, condenser C_t vernier is readjusted to give exactly zero beat just before step (g) is carried out. Thus, the equivalent capacity, C_e, serves as a standard equal to the evacuated cell in capacity by means of which the oscillator may be readjusted at any time and its residual drift eliminated.

From the capacity values read in steps (b) and (g) the capacity change of the cell due to the introduction of the gas under test may be determined as follows. The total variable capacities must have been equal in the two cases to give the same frequency. Thus

$$C_e + C_t + \frac{C_r C_s}{C_r + C_s} = C_e + C_t + \frac{C_r C_s'}{C_r + C_s} + \Delta C_c$$

where ΔC_c is the change in cell capacity produced by the introduction of the gas. On simplifying the above equation and solving for ΔC_c we obtain

$$\Delta C_c = \frac{C_r^2(C_s - C_s')}{C_r^2 + C_c(C_s + C_s') + C_s C_s'} \qquad \text{(I)}$$

If we make use of the relation

$$\epsilon - 1 = \Delta C_c / C_c$$

where ϵ is the dielectric constant and C_c the replaceable cell capacity, we obtain the expression

$$\epsilon - 1 = \frac{C_r^2}{C_c} \frac{(C_s - C_s')}{C_c^2 + C_r(C_s + C_s') + C_s C_s'} \qquad \text{(II)}$$

This equation is identical in form with that of Groves and Sugden. It is to be noted that in their work these investigators neglect the term C_r^2 in the denominator, stating that C_r as it appears in the denominator need not be known very accurately. This statement is open to question as the capacity, C_r, has some effect on the third figure following the decimal point. It is also to be noted that neither end of the capacity, C_r, is at ground potential, and the determination of the capacity of any condenser when operated under such conditions is an indefinite matter when direct methods are used. The value of the capacity C_r may be obtained indirectly by the use of gases of known dielectric constant.

The dielectric constant gas cell consists of a Pyrex glass-enclosed condenser made of three concentric chromium-plated brass cylinders each 6″ (15.5 cm.) long and 3″ (7.6 cm.), $2^3/_4$″ (7.0 cm.) and $2^1/_2$″ (6.35 cm.) in diameter, respectively, held rigidly in place by means of spring clips pressing against the outer glass wall. The outer and inner cylinders form one plate of the condenser which is maintained at ground potential. The condenser leads are of tungsten and are brought out at the top of the glass container. The top of the cell is furnished with a standard taper silver-clad joint to which is fitted a glass arm leading to a manometer, a vacuum pump and an inlet for the gases to be investigated. This arrangement is similar to that of Schwingel and Williams.(3)

The cell is mounted rigidly in a cottonseed oil-bath, the temperature of which is maintained

---

(3) Schwingel and Williams, *Phys. Rev.*, **35**, 855 (1930).

within 0.02° of the desired temperature by means of a mercury thermoregulator and relay-controlled heater system. The cell is connected with the beat-frequency oscillator by means of a special rigid concentric cable whose outer sheath is grounded to prevent capacity losses. In order to prevent condensation of the higher-boiling materials in the glass arm and in the manometer, those parts were wrapped with Chromel-A resistance wire and brought to a suitable temperature by means of an electric current. This precaution permits the measurement of higher pressures of high-boiling materials than would be possible at room temperature.

Calibration of Apparatus

From equation (II) it is seen that, in order to determine the dielectric constant of the cell contents, it is necessary to know the apparatus constants C_r and C_r^2/C_c and the initial and final readings of the standard condenser C_s. The value of cell capacity, C_c, was determined in the following manner. After the gas cell was brought to constant temperature it was evacuated and the oscillator was brought to zero beat. This zero beat was maintained with the equivalent capacity, C_e, in the circuit. Meanwhile the external cell capacity was replaced by a General Radio standard condenser which was tuned to zero beat. The reading of this standard condenser gave the value of the external capacity from which the value of the cell capacity was deduced.

The value of the capacity C_r was determined indirectly by making observations with gases of known dielectric constant. For this purpose the measurements of Bryan and Sanders,[4] Stuart,[5] and Zahn[6] on air and carbon dioxide were employed. The mean polarization of air was taken as 4.368 cm.^{3} and that of carbon dioxide as 7.317 cm.^{3}. Assuming that the polarization of these gases does not change with temperature and that the gas laws hold, the dielectric constants of these gases at a known temperature and pressure may be calculated by means of the relation

$$\epsilon - 1 = 4.810 \times 10^{-5} P_M p/T \qquad \text{(III)}$$

where P_M is the molecular polarization, p the pressure in mm. of mercury, and T the absolute temperature.

The air used in the calibration was passed through a train consisting of bottles containing potassium hydroxide solution, concentrated sulfuric acid, calcium chloride and phosphorus pentoxide in that order. The carbon dioxide used was obtained from a cylinder of the liquefied gas. It was passed through concentrated sulfuric acid and dried over calcium chloride and phosphorus pentoxide.

The values of the dielectric constants of air and carbon dioxide at 25°, obtained by means of equation (III), were substituted into equation (II), which was then solved for the term C_r. The value of the capacity C_r, which was chosen small, was found to be 12.81 mmf. Since the capacity of the gas cell changed with the temperature, it was necessary to determine the apparatus constant, C_r^2/C_c, for each of the temperatures employed. As the value of C_r remained the same throughout, it was necessary only to find the values of C_c.

Preparation of Materials.—The methyl- and ethylacetylenes were prepared by dropping the corresponding sulfates on sodium acetylide in liquid ammonia. The gas evolved was freed from ammonia by passing it through successive bottles of water and dilute sulfuric acid. The gaseous acetylenes were dried over calcium chloride and condensed by means of a dry ice–acetone bath. The liquid acetylenes were distilled through a Davis column,[7] recondensed, and

Technique and Results

The dielectric constants of the gases under consideration were determined by means of equation (II) at pressures, for the most part, above 100 mm. of mercury and at the three temperatures 25, 75, and 125°. In order to avoid the use of an equation of state for each of the gases in measuring its polarization, it was found expedient to plot $(\epsilon-1)/p$ against p and extrapolate to zero pressure. The values of the dielectric constants and of the factors $(\epsilon - 1)/p$ are given in Tables IV, V and VI.

The polarization at zero pressure and temperature T was obtained by multiplying the zero intercept, *i. e.*, $(\epsilon - 1)/p$ at $p = 0$, by $RT/3$ in accordance with the relation

$$P = \frac{\epsilon - 1}{\epsilon + 2} V = \frac{\epsilon - 1}{\epsilon + 2} \frac{RT}{p} = \frac{\epsilon - 1}{p} \frac{RT}{3} \qquad \text{(IV)}$$

where P is the polarization at temperature T, V the molar volume, p the pressure, R the gas constant and T the absolute temperature. The use of this perfect gas equation evidently is justified at zero pressure.

The electronic polarizations were obtained by determining experimentally the molar refraction for the sodium D line of propyl-, butyl- and amylacetylenes, and calculating the values for methyl- and ethylacetylenes on the basis of the refractions of their respective electron groups. As the

atomic polarizations could not be accurately determined, they were neglected in the calculations of the electric moments, which were obtained from the relation

$$\mu = 0.01273 \times 10^{-18}\sqrt{(P_{\mathrm{T}} - P_{\mathrm{E}})T} \qquad \text{(V)}$$

where P_{T} is the total polarization, P_{E} is the electronic polarization and T the absolute temperature. The moments at the various temperatures and their mean values are given in Table VIII.

TABLE VIII

ELECTRIC MOMENTS OF ACETYLENES ($\mu \times 10^{18}$)

Acetylene	25°	75°	125°	Mean
Methyl	0.768	0.778	...	0.77
Ethyl	.811	.789	0.799	.80
Propyl	.875	.847	.846	.85
Butyl	.899	.882	.858	.87
Amyl	...	.878	.847	.86

Watson and Ramaswamy,[8] using the temperature variation method, obtained for the moment of methylacetylene the value 0.72, which agrees well with the value obtained by the authors, 0.77, considering that the small atomic polarization was neglected in the calculation of the latter value. The data of Table VIII indicate that the moment induced in the alkyl chain is negligible beyond the third carbon atom from the triple bond.

Summary

1. An apparatus has been constructed for measuring accurately the dielectric constants of gases and vapors at various pressures and temperatures.

2. A method which obviates the necessity of equations of state is used in determining the polarizations of gases and vapors from their dielectric constants.

3. The dielectric constants, polarizations and electric moments have been determined for gaseous methyl-, ethyl-, propyl-, butyl- and amylacetylenes.

Alteration of Adsorption Properties of Charcoal: Activation of Charcoal in Different Gases at Different Temperatures

By F. E. Bartell and Lewis E. Lloyd

Three types of activated charcoal were prepared in this investigation, a "High Temperature Charcoal," activated at 1000° in an oxidizing atmosphere, a "Medium Temperature Charcoal," activated with oxygen at 400°, and a "Low Temperature Charcoal," activated below 250° in a strongly oxidizing gaseous atmosphere. For these charcoals, the following properties were determined: preferential adsorption of benzene–ethanol solutions, acid–base adsorption, and the sign of the particle charge of the charcoals.

Experimental

The ash-free sugar charcoal used in this investigation was prepared by charring recrystallized sucrose. After a preliminary grinding, the charred material was heated in nitrogen for two hours at 950°. It was then purified according to Miller;[1] and after the final heating in nitrogen at 950°, only that portion was used which passed a 300 mesh sieve but did not pass a 350 mesh sieve. The charcoal was stored in a wide-mouthed, screw-cap bottle until used. This charcoal will subsequently be referred to as "stock" charcoal.

The charcoal was activated in a quartz tube which was held in a horizontal position and could be rotated to give more complete mixing of the charcoal and activating gas. The quartz tube was heated by an electric furnace which could be removed from the tube by merely sliding it. This made it possible to cool the charcoal quickly at the end of an activation treatment. In all cases the charcoal was cooled in an atmosphere of the same gas as that used for the activation.

Preferential Adsorption Experiments.—The preferential adsorption which the different types of activated charcoal gave in benzene–ethanol solutions was determined by the interferometric method developed by Bartell and Sloan.[2] The method consists in placing a known amount of the adsorbent in each of several different concentrations of solutions of a pair of suitable liquids, and determining the change in fractional concentration of each solution by means of the interferometer. The data are plotted in terms of the $H\Delta x/m$ value against the mole fractional concentration of ethanol (x), where H is the number of milliequivalents of solution, Δx the change in fractional concentration, and m the weight of adsorbent. The $H\Delta x/m$ value is calculated from the data by the method of Bartell and Sloan.[2]

When the data are plotted in the manner described, an S-shaped curve is obtained. The point at which this S-shaped curve intersects the x-axis will be designated as the X_0 value. The X_0 value gives the maximum concentration at which ethanol is preferentially adsorbed, and since the concentration is given in mole fractions of ethanol, the X_0 value also gives the fraction of the entire concentration range (in molar units) over which ethanol is preferentially adsorbed. Those solids which adsorb polar ethanol over a major portion of the entire concentration range are less organophilic and more hydrophilic than solids which adsorb non-polar benzene over a major portion of the entire range. The X_0 value found by Bartell and Sloan[2] for organophilic charcoal with benzene–ethanol was 0.200. The X_0 value found by Bartell, Sloan, and Scheffler[3] for hydrophilic silica with benzene–ethanol was 0.850. The X_0 value gives, then, a comparative measure of the organophilic or hydrophilic nature of the solid; the higher the X_0 value, the more hydrophilic the solid. As yet no point has been established on the concentration axis dividing organophilic solids from hydrophilic solids. It is possible that such a point may be established by further experimentation.

"High Temperature Charcoal."—In order to make a comparison with the benzene–ethanol preferential adsorption curve of Bartell and Sloan[2] and to make measurements of other properties of a charcoal similar to that which they used, some charcoal was activated at 1000° in a slow stream of oxygen. The oxygen was passed through at the rate of 200 cc. per hour for seven and one-half hours. The S-shaped curve (see Fig. 1) obtained with this charcoal (Charcoal 1) crossed the x-axis at a value of 0.210 mole fraction of ethanol as compared to the 0.200 value obtained by Bartell and Sloan.[2] Their charcoal was activated in a stream of air, but, as was to be expected, air and oxygen gave about the same activation of charcoal at 1000°.

To avoid possible activation effects with oxygen over a temperature range during cooling, carbon dioxide was used as the activating gas in subsequent high temperature treatments. Charcoal 2 was activated for two hours in oxygen at 1000° and then for two hours in carbon dioxide at the same temperature. Charcoals 3 and 4 were activated in carbon dioxide at 1000° for five hours. The S-shaped curves for Charcoals 2, 3, and 4 are given in Fig. 1. The X_0 value for the preferential adsorption was shifted from 0.210 for Charcoal 1, which was cooled in oxygen, to 0.125 for Charcoals 3 and 4, which were cooled in carbon dioxide. The experimental data obtained for Charcoal 4, a typical "High Temperature Charcoal," are given in Table I.

The fact that the charcoals which were activated and cooled in carbon dioxide gave a lower X_0 value than the X_0 value of charcoal which was activated and cooled in air or oxygen indicates that during the process of cooling in oxygen some of the charcoal surface had been changed from the "High Temperature Charcoal" type. The

"1000° Charcoals" cited in the literature undoubtedly represent various degrees of completeness of 1000° activation, and although their properties are fairly similar, further experiment may show that the term "1000° Charcoal" lacks sufficient specificity to warrant this definite designation.

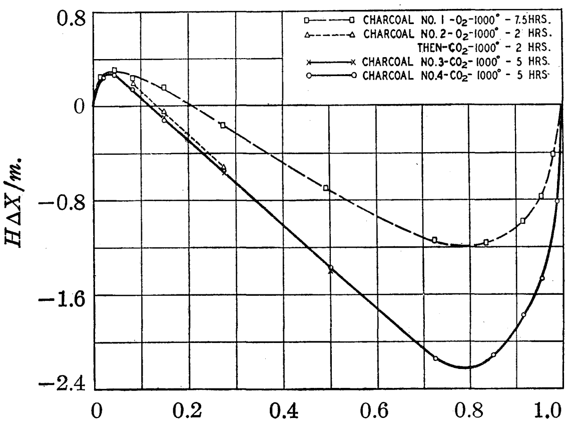

Fig. 1.—Preferential adsorption: Charcoal activated at 1000° in oxidizing atmosphere.

The concept that adsorption occurs at definite activated spots, which are probably unit cells at the crystal surface, has been accepted generally in explaining adsorption phenomena. According to this concept, an adsorbent becomes activated by having each of the spots or units of the surface changed into what constitutes the activated state. Thus, a "High Temperature Charcoal" would be one whose surface had all the unit spaces activated to that type. In actual practice complete activation of one type is probably never attained but may be approached. The exact properties of a given charcoal will depend both on the type of activation and also on the relative proportion of the surface which has the desired activation.

The "High Temperature Charcoal" was found to be quite stable at temperatures up to 150°. Part of the charcoal activated with and cooled in an atmosphere of carbon dioxide, when placed back in the activating tube and treated with dry oxygen for two hours at 150°, showed no change in X_0 value. The curve for the charcoal after this treatment was practically coincident with the one which the 1000° treatment gave.

"Medium Temperature Charcoal."—The first "Medium Temperature Charcoal" prepared during this investigation (Charcoal 5) was taken from the "stock" supply and activated directly at 400° in oxygen for seven and one-half hours without previous activation at 1000°. The preferential adsorption curve for Charcoal 5 is given in Fig. 2.

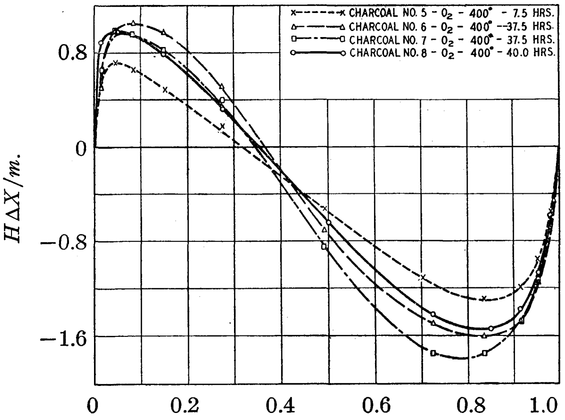

Fig. 2.—Preferential adsorption: Charcoal activated at 400° in oxygen.

This charcoal approached the characteristics which were expected except that the X_0 value, 0.315, was not so high as was expected in view of the fact that it had been predicted by other workers[4] that this charcoal would be hydrophilic. In the next two runs (Charcoals 6 and 7) the charcoal was first activated at 1000° in oxygen for seven and one-half hours and then for thirty-seven and one-half hours at 400° in oxygen. Charcoal 8 was first activated for five hours at 1000° in carbon dioxide and then in oxygen at 400°. The properties of Charcoals 6, 7, and 8 were quite similar to those of Charcoal 5. The preferential adsorption curves for Charcoals 6, 7, and 8 are shown in Fig. 2, and the experimental data for Charcoal 8 are given in Table II. The X_0 values for Charcoals 6, 7, and 8 are

very similar, the range being from 0.346 to 0.370. The X_0 value for Charcoal 5 is a little lower, being only 0.315. This difference in X_0 values is probably due to differences in the completeness of the medium temperature activation. As was suggested for the term *1000° Charcoal*, the term *400° Charcoal*, which also appears in the literature, may in the future be shown to lack the previously implied specificity.

A small change in the X_0 value of "Medium Temperature Charcoal" is effected by subsequent low temperature treatment. Some charcoal of this type was heated in oxygen at 125° for forty hours. The X_0 value was found to have been reduced by 0.013 unit. The charcoal was then further treated with oxygen (saturated with water vapor at 25°) at 150° for another forty hours. The X_0 value was reduced by 0.014 unit. The "Medium Temperature Charcoal" was fairly stable, then, since a total low temperature treatment with oxygen for eighty hours changed its X_0 value only by 0.027. At ordinary temperatures "Medium Temperature Charcoal" changes slowly and appears to revert to the "High Temperature Charcoal" type.

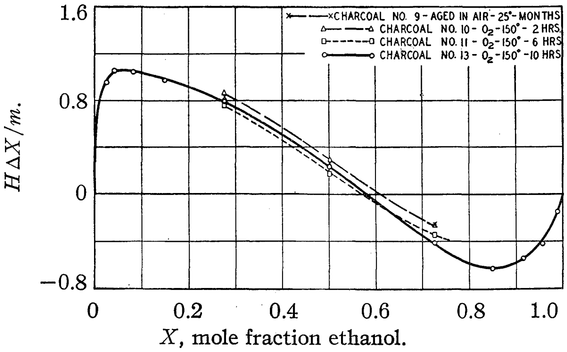

Fig. 3.—Preferential adsorption: Charcoal activated at 150° in oxidizing atmosphere.

"Low-Temperature Charcoal."—Some of our experiments had indicated that the "stock" charcoal had a larger X_0 value, and was more hydrophilic than the "Medium Temperature Charcoal." A special run was made, therefore, to determine the preferential adsorption of the "stock" charcoal. This untreated "stock" charcoal, No. 9, gave an X_0 value of 0.610, which is considerably higher than 0.370, the highest X_0 value for the "Medium Temperature Charcoal." The curve for Charcoal 9 is shown in Fig. 3. The "stock" charcoal was then heated in oxygen at 150° to see if such a low temperature oxidation would produce a more hydrophilic charcoal. Runs at 150° for two hours (Charcoal 10), six hours (Charcoal 11), and for ten hours (Charcoal 12) were made. The curves for these charcoals are given in Fig. 3. A low temperature treatment of the "stock" charcoal in oxygen for ten hours reduced the X_0 value from 0.610 to 0.580, and thus the "stock" charcoal, like the "Medium Temperature Charcoal," is changed slightly by a low temperature oxygen treatment and appears to revert toward a higher temperature type.

Some preliminary preferential adsorption runs on the "stock" charcoal just after it had been prepared and heated at 950° in nitrogen showed that at the time it was prepared the charcoal was organophilic, that is, it preferentially adsorbed benzene over the greater portion of the concentration range. The results on low temperature oxygen treatment of the "stock" charcoal and the "Medium Temperature Charcoal" show that oxygen alone would not be expected to change the "stock" charcoal from its original organophilic to a hydrophilic nature. It appeared that a catalytic effect must have brought about some type of activation during the time that the charcoal stood after its preparation. Oxides of nitrogen are known to be effective catalysts for oxidation reactions. Bartell and Bristol[5] found that traces of nitric oxide added to the oxygen stream greatly increased the oxidizing action on stibnite mirrors even at relatively low temperatures. It seems probable that traces of oxides of nitrogen were formed when the charcoal was heated and cooled in nitrogen during its preparation. Oxygen which is adsorbed on the surface of charcoal is known to be very difficult to remove, its complete removal requiring extreme outgassing.[6,7] Some of the oxygen which was adsorbed on the charcoal before the nitrogen treatment probably reacted with nitrogen during the 950° treatment and formed oxides of nitrogen. It seemed possible that traces of the oxides might have remained on the "stock" charcoal as it cooled, and catalyzed a slow oxidation at 25° as the "stock" charcoal stood in its container.

To test the above theory, some activation treatments were tried using strongly oxidizing gaseous mixtures at low temperatures. These treatments increased the X_0 values of the charcoals. Some "Medium Temperature Char-

coal" (with an X_0 value of approximately 0.370) was treated with a mixture of nitric oxide, oxygen, and water vapor at 150° for ten hours. The resulting product, Charcoal 13, was found to have an X_0 value of 0.545 and had, therefore, been made considerably more hydrophilic.

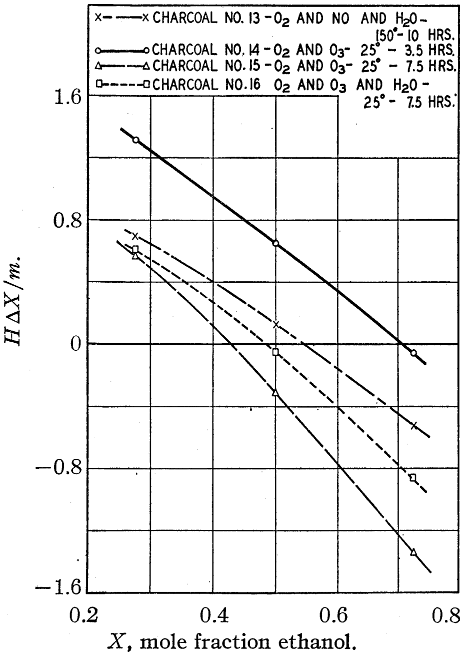

Fig. 4.—Preferential adsorption on charcoal activated at low temperature in oxidizing atmosphere.

Several runs were next made (Charcoals 14, 15, and 16) using ozone as oxidizing gas. Ozone, a fairly strong oxidizing agent, has the advantage that no foreign material other than that already used in the oxygen treatments, is exposed to the charcoal surface. The ozone was generated by a silent discharge apparatus which furnishes from 8 to 10% of ozone. In two of the runs, water vapor was excluded (Charcoals 14 and 15), and in one it was added (Charcoal 16). The starting material for Charcoal 14 was "stock" charcoal, and for Charcoals 15 and 16, it was "Medium Temperature Charcoal." In every case the charcoal thus treated was made more hydrophilic, that is, its X_0 value was increased. In the run in which the "stock" charcoal was treated with ozone (Charcoal 14), its X_0 value was increased from about 0.610 to 0.710. Nitric oxide produced greater effects than ozone, and had "stock" charcoal been activated with nitric oxide and oxygen as was the "Medium Temperature Charcoal" for Charcoal 13, and had the activation been continued for a sufficient period of time, it is possible that a charcoal with preferential adsorption properties approaching those of silica (X_0 = 0.850) might have been prepared. The curves for Charcoals 13, 14, 15, and 16 are given in Fig. 4. Experimental data for Charcoal 14 are given in Table III.

A graph showing the change in the preferential adsorption caused by different activation treatments of charcoal is shown in Fig. 5. (The data for these curves are given in Tables I–III.) On this graph is plotted also the curve for silica as given by Bartell, Sloan, and Scheffler.[3] The X_0 value for the most organophilic charcoal (Charcoal No. 3) is 0.125, while the X_0 value for silica, a very hydrophilic solid, is 0.850. The X_0 value of 0.125, which was found to be quite reproducible for charcoal heated in carbon dioxide at 1000°, appears to be characteristic of the "High Temperature Charcoal." A representative "Medium Temperature Charcoal" curve is given in Fig. 5 and is labeled "M. T. Charcoal." An X_0 value in the range of 0.350 to 0.370 is probably characteristic of the "Medium Temperature Charcoal." This indicates that "Medium Temperature Charcoal" preferentially adsorbs ethanol over a larger

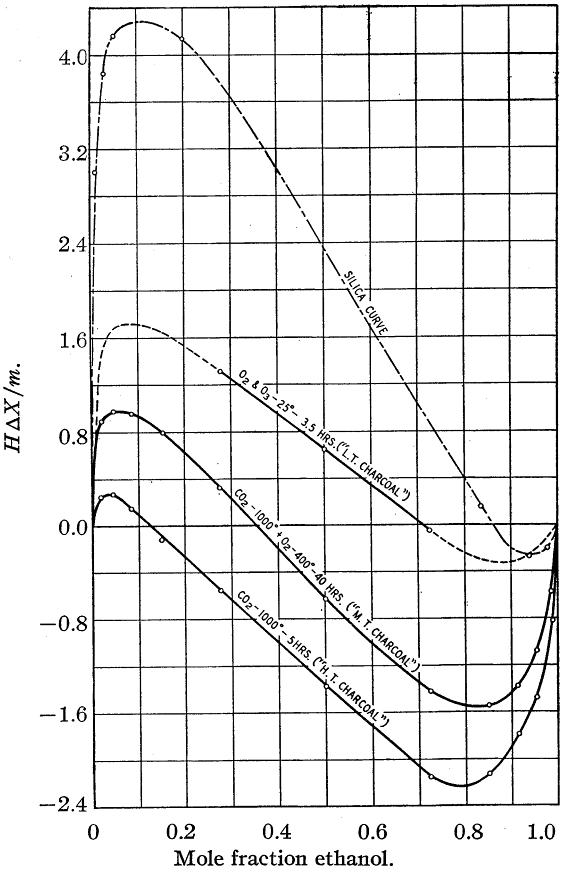

Fig. 5.—Comparison of different charcoals: preferential adsorption of ethanol from benzene.

portion of the concentration range than does "High Temperature Charcoal" and is less organophilic, *i. e.*, is more hydrophilic than the latter. A "Low Temperature Charcoal" curve, labeled "L. T. Charcoal," is also given in Fig. 5. A consideration of the curves which were obtained for "Low Temperature Charcoals" leads to the conclusion that none of them are characteristic of charcoal fully activated to the "Low Temperature Charcoal" type. Charcoal completely activated to this type would probably more nearly approach silica ($X_0 = 0.850$) in its preferential adsorption.

The X_0 values were found to be fairly reproducible for a given activation treatment, and, furthermore, the type of charcoal obtained was independent of the treatment given the charcoal before the final activation. This would seem to indicate that some definite surface structure—probably some definite carbon–oxygen complex such as an oxide—is responsible for the different types of activated charcoal.

Acid–Base Adsorption.—In the acid–base adsorption experiments, 0.01 *N* solutions of hydrochloric acid and sodium hydroxide were used. Methyl red was used as indicator. One-gram samples of the activated charcoal were weighed out and placed in dry flasks; to one-half of these flasks was added 50.00 cc. of 0.01 *N* hydrochloric acid, and to the other half, an equal volume of 0.01 *N* sodium hydroxide. Blanks were run with each set of experiments. The solutions stood with intermittent shaking for ten hours. They were then filtered, and 25.00 cc. of the filtrate pipetted off for titration. The blanks were filtered through the same kind of filter paper and titrated in the same manner. To the flasks containing the sodium hydroxide, 25.00 cc. of the 0.01 *N* hydrochloric acid was added directly and the excess back titrated.

The "High Temperature Charcoal," whether activated with oxygen or carbon dioxide, gave acid adsorption but no base adsorption from dilute solutions of strong inorganic acids and bases. A slight base adsorption which was evidenced by Charcoal 2 was undoubtedly due to the fact that there remained some carbon dioxide on the charcoal which was not chemisorbed. Any such carbon dioxide left on the charcoal would form carbonic acid in solution when the charcoal was suspended in water; this carbonic acid would neutralize some of the base during titration. The "Medium Temperature Charcoal" gave base adsorption, and when the activation was quite complete, it gave no evidence of acid adsorption. Several investigators, Bartell and Miller,[8] Schilow and co-workers,[9,10] and Kolthoff,[4] previously have run some experiments on activated charcoal, determining the acid and base adsorption. Their results on acid–base adsorption and those of the present investigation are in full agreement. Since our charcoals were activated to distinct and essentially pure types of charcoal, our data permit the following conclusion: "High Temperature Charcoal" adsorbs strong inorganic acids but not strong inorganic bases from dilute solutions. "Medium Temperature Charcoal" adsorbs strong inorganic bases but not strong inorganic acids from dilute solutions. Charcoal which is not completely activated to either of the above described types of surface would naturally give both acid and base adsorption. The "Low Temperature Charcoal" which we prepared showed some acid adsorption along with considerable base adsorption.

Charge on Particle.—The particle charge of the activated charcoals was determined by direct observation, with a microscope of the direction in which the particles moved when an electrical potential was applied. The apparatus and method is described by Bartell.[11] The "Medium Temperature Charcoal" and "Low Temperature Charcoal" gave only negatively charged particles in suspension. The "High Temperature Charcoal" showed both positive and negative particles when the suspension was first made up. If the observation was made at once, there were more

---

positive particles than negative ones. In a very short time, less than two minutes, only negative particles remained suspended. The positive particles, which could be seen to settle out very rapidly, apparently had all settled out and left only negatively charged particles. Kruyt and DeKadt[12] reported that charcoal activated at 1000° gave positively charged particles, while charcoal activated at 400° gave negatively charged particles. Kolthoff[4] observed the same relation between particle charge and temperature of activation. Frampton and Gortner[13] attempted to prepare positively charged charcoal but did not succeed in doing so; they reported only negatively charged particles for charcoal activated at 1000°. Wiegand[14] reported that lampblack which was collected by being attracted to a negative plate and, therefore, must have had a positive charge, proved to have a negative charge in an aqueous suspension. Further research regarding the charge of "High Temperature Charcoal" will probably clear up this apparent contradiction in the results on the particle charge for such charcoal.

A summary of the data obtained for all the charcoals is given in Table IV.

Summary

1. Preferential adsorption from benzene–ethanol solutions by charcoals activated at different temperatures and in different gases shows that charcoal can be changed from extremely organophilic charcoal to charcoal approaching in adsorptive properties the hydrophilic adsorbent, silica.

2. The characteristic S-shaped preferential adsorption curves for a series of increasingly hydrophilic charcoals have been plotted, and the points where these curves cross the X-axis, the X_0 values, are shown to be a measure of the relative organophilic or hydrophilic nature of the charcoals.

3. The organophilic "high temperature charcoal" (activated at temperatures near 1000°), when suspended in water, gave both positively and negatively charged particles. This charcoal gave acid adsorption but no base adsorption. The less organophilic "medium temperature charcoal" (activated at temperatures near 400°), when suspended in water, gave only negatively charged particles. This charcoal gave base adsorption. The "low temperature charcoal" (activated in a highly oxidizing atmosphere below 150°), approaching in adsorptive properties hydrophilic silica, when suspended in water, gave only negative particles. This charcoal showed both acid and base adsorption.

Physical Chemical Properties of *cis*- and *trans*-Decahydronaphthalene[1]

BY W. F. SEYER AND R. D. WALKER

Introduction.—Little is known of the chemical and physical properties of the dicyclic naphthalene hydrocarbons. An extensive investigation of these compounds can be undertaken only after a method has been found for obtaining these two compounds in a high state of purity and in suitable quantities. The wide variation in the physical data of the two isomeric forms as given by Hückel[2] in his summary of the literature dealing with this subject would indicate that in some of the methods of synthesis the two forms were produced simultaneously, but in varying amounts.

It was thought, therefore, that the most practical method of obtaining the two forms in sufficient quantity was to fractionate the commercial decalin.

Fractionating Apparatus.—It was discovered in a series of preliminary trials that reduced pressure must be used. Decomposition took place during distillation at atmospheric pressure even with a column length of only 1 meter. The complete apparatus used is shown in Fig. 1. The diagram is self-explanatory; hence only a few remarks are necessary to describe the mode of operation. By utilizing a magnet controlled receiving unit, stopcocks at this point were eliminated. The reflux was controlled by sealing a fine capillary tube to the head of the rectifying column. The lagged column was packed with No. 18 galvanized jack chain. The still had a capacity of 3000 cc. and was electrically heated. Water at 20° was pumped from a constant temperature bath to the condensers.

The reduced pressure of 10 mm. was maintained by a Cenco vacuum pump. At this pressure it was found that no pressure regulation device was required to keep the height of mercury in the manometer constant. A sulfuric acid manometer in connection with the one above showed variations in pressure of less than 1 mm.

Materials.—Decalin from various sources was used. Material from the Eastman Kodak Co. showed a consider-

---

[1] Original manuscript received August 20, 1937.

[2] Hückel, *Ann.*, **441**, 1 (1925).

able variation as judged by the density and refractive index. All samples showed some coloration when shaken with concentrated sulfuric acid. However, irrespective of whether or not the decalin had been treated with acid until no further coloration took place, the freezing points of the ultimate products were all the same within the limits of experimental error.

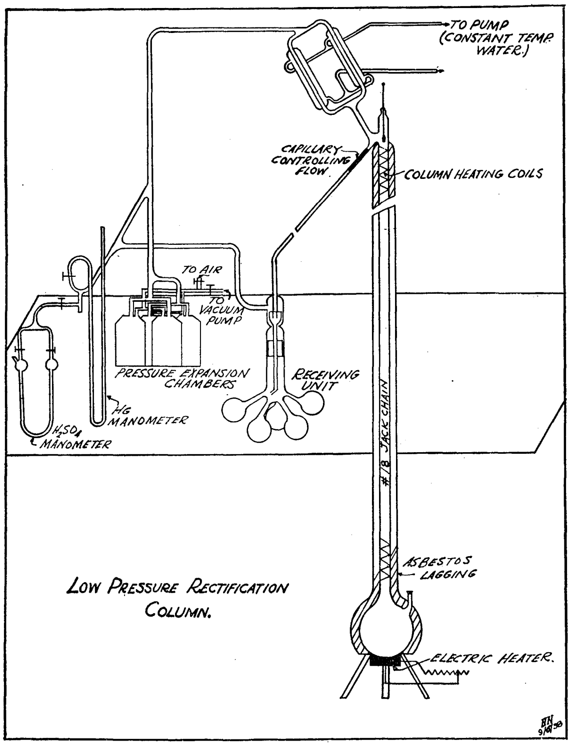

Fig. 1.

Methods of Purification and Procedure.—Two fractional distillations were carried out on each sample of decalin, followed by fractional crystallization until a constant freezing point was obtained. A summary of a typical distillation run is given below.

Table I

Charge, 2065 cc. of decalin about 45% *cis*. Distillation pressure 10 mm. Condenser water at 20°.

Fractions	1	2	3	4	5
Vol., cc.	205	440	483	460	310
Temp. at top of column, °C.	41.0–62.2	62.2–63.7	63.7–67.4	67.4–69.2	69.2–69.9
Time, hrs.	1.67	3.50	4.33	4.83	3.33
Rate, cc./hr.	123	126	112	95	93
$n^{20}\text{D}$	1.47050	1.47093	1.47404	1.47892	1.48082
Total time	17.66 hrs.		Total distillate		1900 cc.
Residue	120 cc.		Loss		45 cc.

Fractions 1 and 2 of this and other runs were then added together and again distilled. Nos. 4 and 5 were treated in a similar manner. The first lot upon the second distillation yielded a fraction of a little over 500 cc. with b. p. 60.3 to 62.7° and refractive index, $n^{20}\text{D}$ 1.46967, corresponding to the value given by Hückel for the *trans* form. A fraction totaling 425 cc. with b. p. 69.5 to 69.7° was selected as the pure *cis* form. The refractive index $n^{20}\text{D}$ was 1.48116 as compared with Hückel's value of 1.48054.

Freezing Point Determination.—The freezing point of the selected fractions was next determined with two Leeds and Northrup quartz encased potential terminal, platinum resistance thermometers of the following characteristics.

	R at ice point	F	δ
Thermometer I	2.5461	0.9941	1.504
Thermometer II	2.5117	.9732	1.502

Thermometer I has shown a change of only 0.0001 ohm in the ice-point over a period of ten years. Thermometer II, on the other hand, had shown a drift, and had therefore been sent to the Bureau of Standards for recalibration shortly before.

The freezing point apparatus consisted of two Dewar tubes. The outer one had a capacity of about 4 liters and was filled with dry ice. The inner tube, having a diameter of about 7 cm. and a depth of 20 cm., had attached to it a stopcock, such that the air pressure inside could be regulated at will, thereby giving any desired rate of cooling.

The change in the freezing point curves with progressive purification is shown in Figs. 2–4.

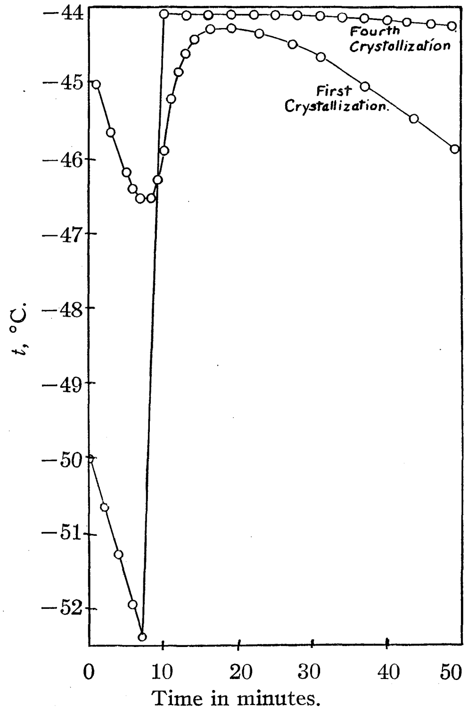

Fig. 2.—Cooling curves (*cis*).

If the slope of the freezing point curve is taken as a criterion of purity, the final (Fig. 4) curves of both the *cis* and the *trans* forms indicate a high state of purity. The final freezing point represents the ninth recrystallization and was taken only after the samples had been in contact with sodium wire for about ten days.

Inasmuch as the liquids were rather viscous at the freezing point it became of interest to find out just how accurately this point could be determined. Hence freezing point

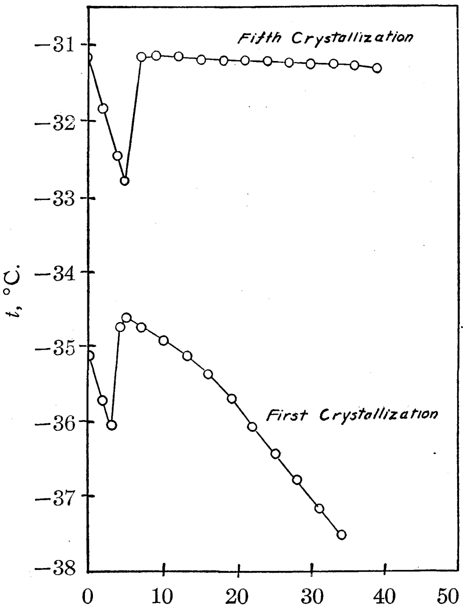

Fig. 3.—Cooling curves (*trans*).

determinations were made first with one thermometer and then with the other, next with constant rotary stirring by means of a propeller driven by a motor, then reciprocatory stirring by hand, and finally no stirring at all during the freezing period. The liquid was seeded with crystals in all cases. The results for the *cis* form were, respectively, −43.25, −43.26, −43.29, −43.23, −43.26°, with a deviation from the mean of 0.03°. The freezing point of the *cis* form is therefore given as −43.26 ± 0.04° and that of the *trans* form as 31.48 ± 0.04°. The last is an average of three determinations, −31.47, −31.46, −31.50°.

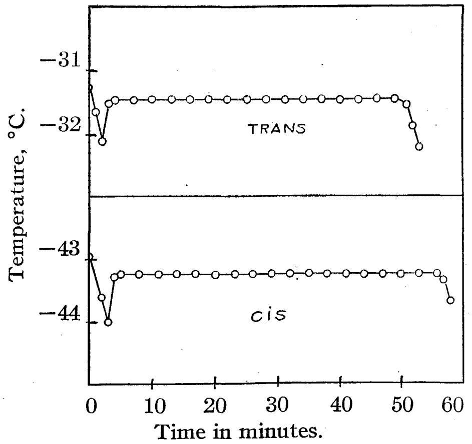

Fig. 4.—Final freezing point curves.

Boiling Point Determinations.—The method outlined in "Laboratory Methods of Organic Chemistry" by Gatterman (Macmillan) was followed closely. The thermometer used was one from an Anschütz set and was calibrated against one of the platinum resistance thermometers used in the previous determination. The boiling points corrected to 760 mm. were as follows; *cis*, 194.6°; *trans*, 185.5°.

Refractive Index.—The refractive indices were measured by a Hilger Pulfrich refractometer. Here two calibrated glass thermometers, graduated in tenths, were used. The one was in a constant temperature bath and the other in the refractometer itself.

Densities.—The densities of the pure compounds as well as the mixtures were measured by means of a modified Perkin pycnometer and are the average of three separate determinations.

Nine solutions of the two isomers were prepared by weight. The densities and refractive indices for D, C, G lines of these solutions were next measured. The results are given in Table II.

TABLE II

Concn. by wt. % *trans.*	d^{20}_4	n^{20}_{D}	n^{20}_{C}	n^{20}_{G}[1]
0	0.8963	1.48113	1.47869	1.49881
10.05	.8934	1.47991	1.47742	1.49762
19.66	.8910	1.47890	1.47632	1.49661
29.69	.8885	1.47770	1.47526	1.49533
39.41	.8858	1.47667	1.47413	1.49429
49.88	.8832	1.47550	1.47292	1.49318
59.84	.8808	1.47437	1.47188	1.49205
69.72	.8779	1.47323	1.47069	1.49098
79.85	.8752	1.47206	1.46956	1.48960
89.77	.8725	1.47092	1.46854	1.48854
100	.8699	1.46968	1.46720	1.48727

Upon examining the properties of these mixtures of known composition, it was found that both density and refractive index were linear functions of the concentrations (Figs. 5, 6). The relationship between the per cent. *trans* form and the density is given by the equation $C = 3395 - 3788d$ when C is per cent. *trans* form and d is the

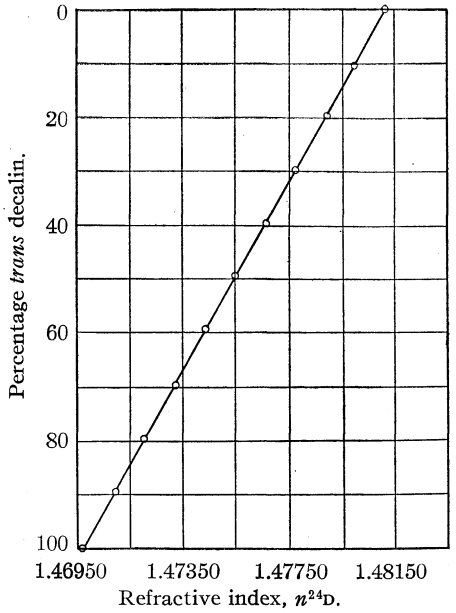

Fig. 5.

density at 20°, also $C = 12936 - 8734n$ when C is the same as above but n is the refractive index for the D line at 20°.

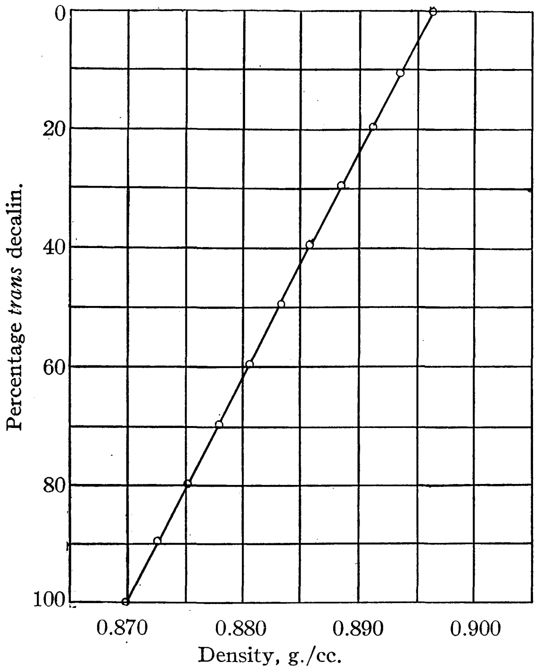

Fig. 6.

Attempts were made to determine the freezing points of the various mixtures by placing them in partially filled bulbs of about 20 cc. capacity. Because of the great amount of supercooling necessary and the low heat conduction of the hydrocarbons the results were only of qualitative significance. They indicated that the eutectic temperature lies between −60 and −70°.

A summary of the physical constants of the *cis* and *trans* forms of decahydronaphthalene is given in the following table.

TABLE III

	d^{20}_4	n^{20}_D	F. p., °C.	B. p. (760 mm.), °C.
cis form	0.8963	1.48113	− 43.26 ± 0.04	194.6
"Int. Crit. Tables"	.898			
Hückel[2]	.8952		− 51	
trans form	.8699	1.46968	− 31.47 ± 0.04	185.5
"Int. Crit. Tables"	.872	1.4701	−125	
Hückel[2]	.8695	1.46958	− 36	

Summary

1. Pure forms of *cis* and *trans* decahydronaphthalene have been prepared and some of their physical properties measured.

2. The freezing points were found to be higher than those so far recorded.

3. The densities and refractive indices of nine mixtures of the two forms were measured and it was shown that both these properties were linear functions of the compositions.

The Thermodynamics of Hydrochloric Acid in Dioxane–Water Mixtures from Electromotive Force Measurements. V. Properties of the 45% Dioxane Mixtures

BY HERBERT S. HARNED AND JOHN G. DONELSON

Measurements of the electromotive forces of the cells

$$H_2 \mid HCl\,(m),\ \text{dioxane}\,(X),\ H_2O\,(Y) \mid AgCl\text{–}Ag$$

in 45% dioxane–water mixtures and at acid concentrations varying from 0.003 to 0.1 M have been reported by Harned and Morrison.[1] These measurements have been extended so as to include concentrations from 0.003 to 3 M. From these results and the standard potential of the cell,[2] the activity coefficient, relative partial molal heat content and specific heat have been computed. Similar results have been obtained by Harned and Ehlers[3] in water and by us[4] in 20% dioxane–water mixtures which in conjunction with present results yield an accurate and very comprehensive study of the thermodynamics of this acid in media of dielectric constants of approximately 80, 60, and 40.

Experimental Results

No further changes in the technique described by Harned and Morrison[5,1] and modified in a few details by us[4] have been made. The present results were obtained with the same care and

[5] Harned and Morrison, *Am. J. Sci.*, **33**, 161 (1937).

accuracy as in the earlier investigations. The cell reproducibility at all concentrations was ±0.05 mv.

Six cells were measured at each concentration, all of which were equilibrated and measured at 25°. Three of these were measured at 5° intervals up to 50° and then brought back to 25°. The other three were measured at 5° intervals until 0° was reached and finally brought back to 25°. All results were finally accepted if and only if all the 25° readings at a given concentration checked to within ±0.05 mv.

The results at eleven temperatures were found to conform to the quadratic equation

$$E = E_{25} + a(t - 25) + b(t - 25)^2 \qquad (1)$$

The constants, a and b, obtained by the method of least squares, and the values of the electromotive forces at 25°, are given in Table I. The fifth column contains the maximum deviations in millivolts between the observed values and those calculated by equation (1). The last column contains the average deviation.

TABLE I

CONSTANTS OF EQUATION (1)

X = 45% by weight of dioxane

m	E_{25}	$-a \times 10^4$	$-b \times 10^6$	Δ(max.)	Δ(max.)
0.10943	0.30896	5.185	2.90	0.05	0.02
.19378	.28371	5.882	2.84	.05	.02
.32247	.26014	6.596	2.72	.05	.03

3.1105	.10209	8.850	1.80	.10	.04

Combined with the data of Harned and Morrison[1] suitable observations were available at eighteen concentrations between 0.003 and 3 M. These results were smoothed to round concentrations from suitable large scale plots. The values of a and b also were smoothed and the final values of all these quantities which subsequently were used for the computations are contained in Table II.

In the last row of the table are given the constants of the equation

$$E_0' = E_{0(25)}' + a_0(t - 25) + b_0(t - 25)^2 \qquad (2)$$

in which E_0' is the standard potential at a temperature t, $E_{0(25)}'$ the standard potential at 25°, and a_0 and b_0 empirical constants. These values were obtained from the standard potentials computed by Harned[2] by use of the Gronwall, La Mer, and Sandved extension of the Debye and Hückel theory. The values of $E_{0(25)}'$ and b_0 differ slightly from those obtained by Harned.

3	2285	.05561	2657	33.1

Relative Partial Molal Heat Content and Heat Capacity.—The heat data have been computed by the method described by Harned and Thomas[7] and mentioned by us.[4] The relative partial molal heat content, $\overline{L}_2$, is expressed by

$$\overline{L}_2 = \alpha + \beta T^2 \qquad (4)$$

α and β are given by

$$\alpha = -23{,}074[(E_{25} - E'_{0(25)}) - 298.1(a - a_0) + 88{,}864(b - b_0)] \qquad (5)$$

$$\beta = 23{,}074(b - b_0) \qquad (6)$$

respectively. $\overline{L}_2$ is in calories. The relative partial molal heat capacity may be computed by the equation

$$(\overline{C}_p - \overline{C}_{p0}) = 2\beta T \qquad (7)$$

Table IV contains the parameters α and β, from which $\overline{L}_2$ may be computed at all temperatures from 0 to 50° with an accuracy of the order of ±30 cal. by equation (4), and $(\overline{C}_p - \overline{C}_{p_0})$ with an accuracy of the order of ±1 cal. by equation (7). Values of $\overline{L}_2$ and $(\overline{C}_p - \overline{C}_{p_0})$ at 25° are given in the fourth and fifth columns of the table, respectively.

Summary

1. The electromotive forces of the cells

H_2 | HCl (m), Dioxane (45%), H_2O (55%) | AgCl–Ag

have been measured at 5° intervals from 0 to 50°, and from 0.1 to 3 M acid concentrations with an accuracy of ±0.05 mv.

2. From these and the results of Harned and Morrison in the dilute concentration range (0.003 to 0.1 M) the activity coefficient, the relative partial molal heat content and the heat capacity of the acid have been computed throughout these ranges of temperature and pressure.

The Thermodynamics of Hydrochloric Acid in Dioxane–Water Mixtures from Electromotive Force Measurements. VI. Extrapolations in the 70% Dioxane Mixtures and Standard Potentials

BY HERBERT S. HARNED AND CALVIN CALMON[1]

In an earlier communication in this series,[2] it was shown that accurate evaluations of the standard potentials of the cell

H_2 | HCl (m), dioxane (X), H_2O (Y) | AgCl–Ag

in mixtures containing 20 and 45% dioxane could be made by employing the Gronwall, La Mer and Sandved extension of the Debye and Hückel theory. At the same time, an extrapolation was made with the results obtained in a mixture of 70% dioxane–30% water at 25°. Since experimental results below 0.003 M were not available, a slight uncertainty in the extrapolation was suspected, and further calculations discontinued for the moment. This communication contains an attempt to obtain results at still lower concentrations, and to determine the lower limit of concentration at which reliable results can be obtained with the technique available.

Experimental Results

The preparation of solutions and the cell technique was carried out with all the precautions and in the same manner as that described by

---

[1] This communication contains material from a dissertation presented by Calvin Calmon to the Graduate School of Yale University in partial fulfilment of the requirements for the degree of Doctor of Philosophy, June, 1938.

[2] Harned, THIS JOURNAL, 60, 336 (1938).

Harned and Morrison.[3,4] The only difference which need be mentioned is the preparation and behavior of the silver–silver chloride electrodes. Electrodes of this type prepared electrolytically as described by Harned and Morrison[3] are reproducible to within ±0.1 mv. in solutions containing acid at 0.003 *M* or higher. Below this concentration, they fail to function satisfactorily. After proving this fact, electrodes made by mixing nine parts of silver oxide with one part of silver chlorate were employed. This mixture was spread on a platinum wire spiral and heated at a temperature of 450° for ten minutes as described by Rule and La Mer.[5,6] In solutions containing hydrochloric acid of concentrations 0.002 and 0.003 *M*, these electrodes behaved very satisfactorily. Equilibrium was attained in twelve hours and the electromotive forces agreed very closely at 0.003 *M* with those obtained by the electrolytically prepared electrodes of Harned and Morrison. Further, after measurements at different temperatures, the cells could be brought back to the initial temperature after a period of ten to twenty hours and the original electromotive force reproduced. In more dilute solutions, however, a longer period of time, from forty-eight to sixty hours, was required for equilibration. Also, at concentrations near 0.001 *M*, the reproducibility was found to be considerably less than at 0.002 *M*. Within the limit of ±0.5 mv., these electrodes would operate satisfactorily over periods of forty-eight hours, and after the temperature changes had been made.

Our experience may be summarized by the statement that an accuracy of ±0.1 mv. may be obtained at concentrations of 0.002 *M* and higher; that the reproducibility decreases with concentration decrease, and becomes approximately ±0.5 mv. at 0.001 *M*. These estimates will suffice to show the present experimental status of this subject.

The cells were run in triplicate. For each concentration, two series of measurements were made. Each series was begun at 25° and readings were taken at 5° intervals to 50° and finally at 25° again. The second series was also started at 25°, then readings were taken at 0° and at 5° intervals until 25° was reached. If at the end of each run the difference in readings at 25° was greater than 0.3 mv., the results were discarded. The vapor pressure data of Hovorka, Schaeffer and Dreisbach[7] were employed in making the usual correction for hydrogen pressure. Table I contains the electromotive forces.

TABLE I

ELECTROMOTIVE FORCES OF THE CELLS

H_2 | HCl (m), dioxane (X)–H_2O (Y) | AgCl–Ag

Reproducibility (mv.)	±0.1	±0.1	±0.5	±0.5	±0.5

Extrapolations and Evaluation of the Standard Electrode Potential.—The extrapolation was carried out in the manner described by Harned[2] by employing the function E', defined by the equation

$$E' = E + 2k \log m - \frac{2ku\sqrt{c}}{1 + A\sqrt{2c}} - 2k \log (1 + 0.002\, G_0 m) = E_0' + f(m) \quad (1)$$

E is the observed potential of the cell, k equals 2.3026 RT/F, u is the universal constant of the Debye and Hückel theory, A is the parameter which involves the mean distance of approach of the ions, a, G_0 is the mean molecular weight of the solvent (ref. 4, eq. (6)), and E_0' is the standard potential of the cell. m is the concentration of the acid in moles per 1000 grams of solvent, and c is its concentration in moles per liter of solution. The use of the Gronwall, La Mer and Sandved extension of the theory makes possible a more certain evaluation of E_0'. Arithmetical approximations showed that a value of "a" of 5.6 Å. at all temperatures gave satisfactory extrapolations. Thus, the values of $E' - E_{\text{Ex}}$, where E_{Ex} represents the contribution of the extended terms to the electromotive force, was very constant at concentrations between 0.002 and 0.02 *M*. At concentrations between 0.0008 and 0.002 *M*, the results are not as consistent, but in general indicate that the method is good.

Values of E' and $E' - E_{\text{Ex}}$ are plotted against the molal concentration in Fig. 1. The extrapolations at 10, 25 and 45° are given as typical. The plot at 10° is characteristic of the results at temperatures between 0 and 20°, inclusive, that at 25° is typical also of the results at 30, 35 and 40°, and that at 45° is similar to the result at 50°. The first thing to note is the characteristic "hump" in the plots of the Debye and Hückel function E' and the straight graphs for the functions, $E' - E_{\text{x}}$. $E' - E_{\text{x}}$ remains constant until a concentration of 0.02 M is reached which corresponds to a value of x or κa of the order of 0.7. The final values of E_0' have been computed from the more reproducible results at concentrations of 0.002 M or greater. With very few exceptions, the points computed from the results in the neighborhood of 0.001 M lie below the curves which indicates low values of the cell electromotive forces.

Values of the function $E' - E_{\text{Ex}}$ at the temperatures shown in the graph are given in Table III. The bottom row of the table contains the extrapolated values of E_0'. The consistency of the results between 0.002 to 0.03 M is excellent. The values in parentheses at the lower concentrations indicate a much larger error and were not used in the final evaluation of the standard potential.

A second method of extrapolation which will be described in a future communication dealing with 82% dioxane–water mixtures depends on a previous knowledge of the ionization constant of hydrochloric acid in the mixture. In Fig. 1, the dashed line represents a suitable function computed from the electromotive forces and a value of 0.0077 for the ionization constant of the acid, determined by Owen and Waters in this Laboratory. This extrapolates to the value previously obtained. Our experience indicates that the first method is the more satisfactory in these

E_0' ($m = 0$)	.08970	.06395	.02705

solutions where D equals approximately 20 and where the actual ionization in dilute solutions is high ($\alpha > 0.9$). In media of dielectric constant of 10 (82% dioxane), the second method seems to be more suitable than the one which employs the extended term theory since values of the ionization constant are known, and since the electrolyte is considerably weaker ($K \sim 0.0002$). Also in these solutions values of "a" computed by Bjerrum's theory are more reliable than in those of high dielectric constant.

In Table IV, the standard potentials at all temperatures are given. These results may be expressed by the equation

$$E_0' = 0.06395 - 17.67 \times 10^{-4}(t - 25) - 3.70 \times 10^{-6}(t - 25)^2 \quad (6)$$

The deviations between the observed values and those computed by this equation are given in parentheses immediately following the result. They are in hundredths millivolt and are positive when the calculated is greater than the observed value.

TABLE IV

STANDARD POTENTIAL OF THE CELL

H_2 | HCl (m), DIOXANE (70%), H_2O | AgCl–Ag

The Thermodynamics of Hydrochloric Acid in Dioxane–Water Mixtures from Electromotive Force Measurements. VII. Properties of the 70% Dioxane Mixtures

BY HERBERT S. HARNED, JOHN G. DONELSON AND CALVIN CALMON

Two earlier communications[1,2] contain electromotive forces of the cells

H_2 | HCl (m), dioxane (70%), H_2O | AgCl–Ag

at fourteen concentrations between 0.0008 and 0.2 M, and at temperatures from 0 to 50°. From these, the standard potentials of the cells have been computed throughout this temperature range.[2] To complete this study, measurements have been made at seven concentrations between 0.1 and 1.5 M. From the combined data, the activity coefficient, the relative partial molal heat content, and heat capacity of the acid have been computed. This completes the first comprehensive study of these properties of an electrolyte in a medium of dielectric constant of approximately 20.

Experimental Results

The results obtained from 0 to 50° at 5° intervals have been expressed by the equation

$$E = E_{25} + a(t - 25) + b(t - 25)^2 \quad (1)$$

The values of E_{25}, and the constants a and b are given in Table I. The fifth column of the table gives the maximum deviations in millivolts of the observed results from those calculated, and the last column contains the mean deviations.

These data were combined with those of Harned and Morrison[1] and Harned and Calmon[2] and

Activity Coefficients

The activity coefficients, computed by the equation

$$-\log \gamma = \frac{(E - E_0')F}{4.6052\ RT} + \log m \qquad (3)$$

are given in Table III at some of the temperatures. The last row contains the dielectric constants of the solvent at these temperatures.

Relative Partial Molal Heat Content and Heat Capacity.—The relative partial molal heat content, $\overline{L}_2$, and heat capacity are given by the equations

$$\overline{L}_2 = \alpha + \beta T^2 \qquad (4)$$

$$(\overline{C}_p - \overline{C}_{p0}) = 2\beta T \qquad (5)$$

where α and β are defined by equations (6) and (7) of Harned and Donelson's communication.[3] These equations have a range of validity from 0 to 50°, inclusive. The parameters α and β are given in Table IV. Values of $\overline{L}_2$ and $(\overline{C}_p - \overline{C}_{p0})$ at 25° are given in the fourth and fifth columns of this table.

Summary

1. Electromotive forces of the cells

H_2 | HCl (m), dioxane (70%), H_2O | AgCl–Ag

have been obtained from 0 to 50° at 5° intervals and at seven concentrations between 0.1 and 1.5 M.

2. These in combination with previous results through a concentration range of 0.0008

---

[3] Harned and Donelson, THIS JOURNAL, **60**, 339 (1938).

to 0.1 *M* have been employed to compute the activity coefficient, relative partial molal heat content and heat capacity of the acid in this solvent.

3. The accuracy of the experimental results is of the order of ±0.1 mv., leading to an error of about ±0.001 in the relative activity coefficient and ±30 cal. in the relative heat content. A greater source of error in these values may reside in the uncertainty of the extrapolation. A general discussion of these thermodynamics properties will be reserved until the investigation of the 82% dioxane–water mixtures of dielectric constant of approximately 10 is completed.

The Distribution Coefficients of Porphyrins between Ether and Hydrochloric Acid and Applications to Problems of Quantitative Separation

BY ANCEL KEYS AND JOACHIM BRUGSCH[1]

Differential solubility in various solvents is the basic means of separating porphyrins in mixtures.[2-6] The most useful solvents are ether, chloroform and hydrochloric acid.[7,8] These three reagents have been used to effect separation of biological porphyrins by a procedure involving repeated crystallizations.[9,10] No proof of the quantitative accuracy of this method has been given; in any case it suffers from three limitations: (1) it is very time-consuming; (2) it serves only to isolate the principal porphyrin in the mixture; (3) it is stated that at least 50 micrograms of porphyrin is needed, but the work reported has generally involved much more; these amounts are not always available in biological work.

The porphyrins known or believed to occur in the normal or pathological human metabolism are: protoporphyrin ($C_{32}H_{32}N_4(COOH)_2$), coproporphyrin ($C_{32}H_{34}N_4(COOH)_4$), mesoporphyrin ($C_{32}H_{36}N_4(COOH)_2$) deuteroporphyrin ($C_{28}H_{28}N_4(COOH)_2$), and uroporphyrin ($C_{32}H_{30}N_4(COOH)_8$). All but the last named (uro-) are soluble in ether acidified by glacial acetic acid. Except in extremely rare cases, uroporphyrin occurs naturally only in the most minute amounts. Traces of other unidentified porphyrins have been reported in biological materials but these questionable substances may be neglected for the present.

Most of the natural porphyrins are soluble in chloroform, but repeated trials convinced us that chloroform extraction is not suitable for quantitative separation of porphyrins from natural mixtures unless extraordinary precautions are taken. Traces of impurities, especially colloids, may enable some of the porphyrins to go into colloidal solution in chloroform, prevent their extraction or cause loss by adsorption on the walls of the vessels used.

Willstätter and Stoll[11] made a qualitative separation of the ether-soluble porphyrins by extraction of the ethereal solution with hydrochloric acid. Willstätter[12] has characterized as the "HCl number" that concentration of hydrochloric acid which will extract two-thirds of the porphyrin from an equal volume of porphyrin solution. The available information on hydrochloric acid solubility of the porphyrins is in terms of Willstätter's "HCl number."

Since the naturally occurring porphyrins are reported to differ widely from one another in their hydrochloric acid numbers, a quantitative separation on this basis should be feasible, provided: (1) the hydrochloric acid solubility is a fixed characteristic, (2) the hydrochloric acid solubility for a given porphyrin is independent of

the presence of other porphyrins, (3) suitable hydrochloric acid concentrations are chosen so as to effect the separation in a reasonable number of extractions and (4) a satisfactory means of estimating the amount of porphyrin in the extracts is at hand.

We can begin by stating that the last-named requisite is fulfilled. All the porphyrins with which we are concerned are fluorescent in ultraviolet light and, over a limited range of concentration, the intensity of the fluorescence under standard conditions is directly related to the concentration. The present paper is a study on the partition between ether and various concentrations of hydrochloric acid of the following pure crystalline porphyrins: copro-, hemato-, meso-, deutero-, protoporphyrin and phylloerythrin ($C_{33}H_{34}N_4O_3$).

Preparation of Pure Porphyrins.—Our pure porphyrins were checked by their absorption spectra in ether and in hydrochloric acid solution.[13] In the following paragraphs the wave lengths of the principal bands are given in mμ. The values in parentheses are taken from Kirstahler.[8]

Preparation of Protoporphyrin.—Fresh blood is run into ten times its volume of 0.25% hydrochloric acid, shaken gently and after an hour the brown hydrochloric acid pigment is taken up in glacial acetic acid–ether. The ether is reduced to a small quantity, preferably in a vacuum. With the addition of 4% hydrazine sulfate in strong acetic acid solution the complete conversion to protoporphyrin is brought about when the solution is boiled down to about a fourth the original volume. The protoporphyrin is separated by filtration, and shaken with acetic acid ether in a separatory funnel. By this procedure a part of the protoporphyrin goes over into the ether along with some impurities. From this solution the protoporphyrin is recovered by extraction with 10% hydrochloric acid. The rest is taken up in hydrochloric acid, concentrated and preferably precipitated as the sodium salt by the addition of sodium hydroxide. Purification is readily brought about by washing, re-solution and reprecipitation. Protoporphyrin prepared in this way has the following characteristic absorption bands:

In 5% Hydrochloric Acid
I, 608–594, *602* (601)
II, 575–545, *560* (557)

In Ether Solution
I, 643–629, *636* (633)
II, 594–574, *584* (585)
III, 549–533, *541* (537)
IV, 514–494, *504* (502)

Preparation of Mesoporphyrin.—Crystalline mesoporphyrin was prepared from protoporphyrin by the method of Fischer and Kögl (1924) in which the vinyl groups are reduced by the action of iodic acid. The mesoporphyrin had the following absorption bands:

In 5% Hydrochoric Acid
I, 598–591, *594* (593)
II, 562–544, *553* (549)

In Ether Solution
I, 626–621, *623* (623)
II, 571–567, *569* (577?)
III, 532–523, *528* (529)
IV, 506–489, *496* (495)

Hematoporphyrin.—We used the crystalline preparation made by the Nordmark Company which is known commercially as "Photodyn." This hematoporphyrin had the following bands in the absorption spectrum:

In 5% Hydrochloric Acid
I, 595–588, *592* (596)
II, 559–540, *550* (552)

In Ether Solution
I, 626–623, *625* (625)
II, 599–594, *597* (598)
III, 571–567, *569* (569)
IV, 536–526, *531* (531)
V, 507–487, *497* (497)

Preparation of Coproporphyrin.—We used crystalline synthetic coproporphyrin I supplied by the kindness of Prof. Hans Fischer, as well as a crystalline preparation from human excreta. The latter preparation involved extraction with acetic acid ether, transfer to 5% hydrochloric acid, transfer to ether and repeated fractionation by means of ether and 0.25% HCl. Our preparation had the following absorption bands:

In 5% Hydrochloric Acid
I, 594–578, (594, 575)
II, 553–543, *548* (551)

In Ether Solution
I, 626–621, *624* (624)
II, 598–594, *596* (597)
III, 571–567, *569* (568)
IV, 532–524, *528* (529)
V, 504–486, *495* (498)

Preparation of Phylloerythrin.—We prepared phylloerythrin from ox gallstones in the course of the preparation of bilirubin by the method of H. Fischer (1911). The combined washings were carried over into ether and after purification were taken up by 10% HCl which was then neutralized and the phylloerythrin was carried back to ether, from which typical crystals were obtained. The phylloerythrin had the following absorption spectra:[14]

In 10% Hydrochloric Acid
I, 628–604, *621* (620)
II, 577–565, *571* (568)

In Ether Solutions
I, 638–635, *637* (637)
II, 597–579, *588* (593, 584)
III, 564–554, *559* (561)
IV, 528–513, *521* (521)

---

[13] We are indebted to Dr. Charles Sheard for assistance in the determination of the absorption spectra.

[14] Comparison values in parentheses given by H. Fischer, in Oppenheimer, "Handbuch der Biochemie," 1933, 2d ed., Suppl. Vol. I (1), pp. 247, et seq.

Preparation of Deuteroporphyrin.—Deuteroporphyrin was prepared from deuterohemin by the action of hydrazine sulfate. We were unable to obtain sufficient material for recrystallization, but our preparation had the typical absorption spectra of deuteroporphyrin. Through the kindness of Dr. C. J. Watson we were able to check several of the hydrochloric acid solubility points with a solution of pure synthetic deuteroporphyrin from the laboratory of Prof. H. Fischer. However, since our preparation was not recrystallized, we prefer to term it simply "deutero type" porphyrin.

Measurement of Porphyrin Concentration in Hydrochloric Acid Solution

All our measurements of porphyrin concentration have been made in terms of the fluorescence in ultraviolet light. The intensity of fluorescence of a porphyrin solution in hydrochloric acid is stated to be linearly proportional to the porphyrin concentration in extreme dilution but not otherwise.[15—17] We have found this relation to be quantitative over the range 0.05 to 2 micrograms per ml. The fluorescence, however, is markedly affected by *p*H and, to a smaller extent, by temperature.[18] With the exception of phylloerythrin, we have measured the fluorescence of all our porphyrins in 5% HCl. With phylloerythrin we found it necessary to use 10% HCl. We have observed no effect of ordinary variations in room temperature, even in summer when some measurements were made at 30°.

The fluorescence spectra of the porphyrins studied here are not identical,[19] so the relative intensity of the fluorescence of the different porphyrins at equal concentration would be expected to differ slightly according to the system used for measurement. All of our measurements have been made by visual comparison, in some cases with the Zeiss "stufenphotometer."

Fluorescence is excited by the light from a quartz mercury vapor lamp. The ultraviolet light is passed through filters to cut out all radiation of a wave length longer than about 3800 Å. The "uviol" or Wratten No. 18A (ultraviolet) filters are satisfactory, especially when used as the windows of a copper sulfate cell. Wratten Nos. 15G and 18A make an excellent combination but a very powerful ultraviolet lamp must be used. The fluorescence of the porphyrin solutions may be studied in any type of quartz absorption vessels or ordinary glass vessels, provided these latter have relatively thin walls and possess no fluorescence of their own. Lacking more specialized apparatus, satisfactory comparisons can be made with matched test-tubes placed in the path of filtered ultraviolet light from an ordinary clinical ultraviolet lamp.

Standard coproporphyrin solution in 5% HCl was the standard of reference and all results here are expressed in terms of fluorescence equivalent to coproporphyrin. In general, the most useful concentrations for standard solutions are 0.2, 0.1 and 0.05γ of porphyrin per ml.

In the preparation of ethereal porphyrin solutions of known concentration dissolve from 2 to 20 micrograms of the pure crystalline material in about 30 ml. of 5% HCl. The exact concentration of porphyrin in the hydrochloric acid is determined, in terms of intensity of red fluorescence, by comparison with a stock standard solution of coproporphyrin. As soon as this measurement is completed, the acid solution is neutralized with solid sodium acetate and extracted with successive 25-ml. portions of ether until the aqueous phase no longer shows red fluorescence in ultraviolet light. It may be necessary to add a few drops of acetic acid in this process to keep the mixture slightly on the acid side of neutrality. The combined ethereal solution contains all the porphyrin originally dissolved in the 5% HCl.

For the purposes of quantitative analysis it is necessary that the partition between ether and hydrochloric acid be measured under conditions which are reproducible and easily applied. We add the hydrochloric acid to the ethereal solution in a separatory funnel and slowly shake back and forth by hand. Violent or prolonged agitation is unnecessary and may result in loss or oxidation of some of the porphyrin. The partition does not seem to be affected by the ordinary variations in room temperature in the range 20 to 26°. After the extraction, the hydrochloric acid extract was drawn off, the concentration brought up to 5% HCl and the fluorescence intensity measured at once. Finally, the ether was extracted with 5% HCl until all porphyrin had been removed from the ether. The fluorescence intensity was measured in these final extractions so that the total recovery of porphyrin from the ether was measured.

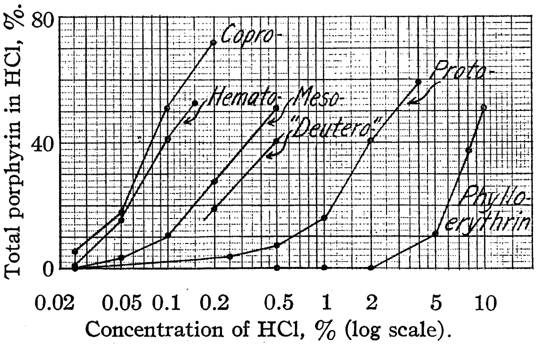

Fig. 1.—Extraction of porphyrins from ethereal solution by various concentrations of hydrochloric acid.

Figure 1 shows the results obtained when the volume relations were 1 part hydrochloric acid solution to 3 parts ethereal solution. Distribution coefficients for the several porphyrins over the useful range of hydrochloric acid concentration are given in Figs. 2 and 3. Most of these values were obtained using the volume relation 1 part hydrochloric acid to 3 parts ether. In a number of cases, however, the constancy of the distribution coefficient was checked by determinations made with the volume relation 1 part hydrochloric acid to 1 part ether.

Included in Fig. 2 are two points from an unknown porphyrin which occurs in very minute amounts in human feces. This porphyrin was soluble in chloroform and

was purified so far as possible with repeated fractionation by means of 0.25% HCl, ether, 5% HCl and chloroform. As can be seen from the distribution coefficient this porphyrin appears to be a separate entity. This appearance is fortified by the fact that the distribution coefficient did not change during six successive extractions.

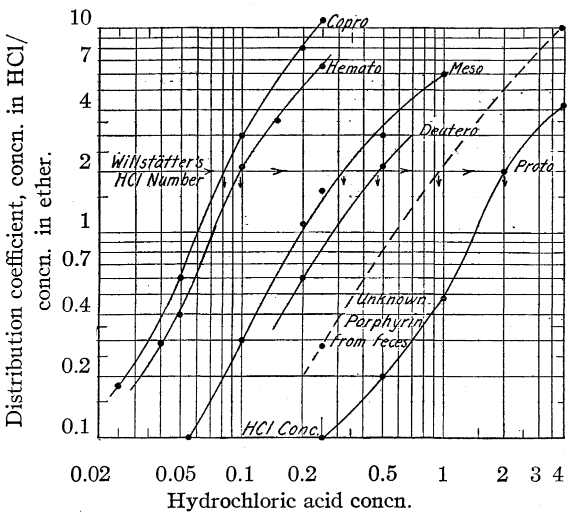

Fig. 2.—Distribution coefficients for the partition of porphyrins between ether and various concentrations of hydrochloric acid.

The distribution coefficient is simply the ratio of the concentration of the solute in the acid phase to that in the ether phase. If we let a = the percentage of the solute in the acid, and v the volume of the acid as percentage of the total volume, the distribution coefficient is

$$K = \frac{a/v}{(100 - a)/(100 - v)} \text{ and}$$

$$a = \frac{100\,Kv}{100 + Kv - v} \qquad \text{(I)}$$

Willstätter's hydrochloric acid number corresponds to a distribution coefficient of 2.0. In Table I we have given the previous values for the HCl number and the values calculated from the present results.

Quantitative analysis using distribution coefficients necessarily must involve successive extractions. It is requisite then that the experimental results with successive extractions conform to theory. General principles applicable to successive extractions were formulated by Herz[21] (1909). Let b_1 = the amount, in percentage terms, unextracted after the first extraction; *i. e.*, $b_1 = 100 - a$. Then

$$b_1 = 100\left(\frac{100 - v}{100 - v + Kv}\right)$$

TABLE I

HYDROCHLORIC ACID NUMBERS OF PORPHYRINS

Concentration of HCl which will extract two-thirds of the porphyrin from ether solution when equal volumes of HCl and ether are used in a single extraction. "Previous Values" taken from A. Treibs,[22] Fischer,[14] Fischer and Treibs[20] and A. Kirstahler.[8]

Porphyrin	Previous values	Present values	Uncertainty
Proto-	2	2.0	±0.1
Deutero-	0.3–0.4	0.47	± .05
Meso-	0.5	.32	± .05
Hemato-	0.1	.098	± .003
Copro-	0.08	.081	± .003
Phylloerythrin	about 9	8.5	± .5
Unknown porphyrin[a] from human feces	...	0.94	...

[a] This porphyrin is recovered in very small amounts from human feces by extraction in the following manner: extract with acetic ether, transfer to 5% HCl, transfer back to ether, extract with 0.25% HCl, neutralize, extract with chloroform, transfer to 5% HCl, carry back to ether, extract with HCl.

After n extractions the amount remaining in the ether (unextracted by the acid) will be

$$b_n = 100\left(\frac{100 - v}{100 - v + Kv}\right)^n \qquad \text{(II)}$$

Figure 4 shows the correspondence between experiment and theory for three successive extractions, using 3 volumes of ether and 1 volume of acid for each extraction. For this case equation II becomes

$$b_3 = 100\left(\frac{3}{3 + K}\right)^3 \quad \text{(IIA)}$$

In Fig. 4 the lines have been calculated from equation IIA and Figs. 2 and 3; the points are experimental observations.

Figure 4 shows that the agreement is good except at the highest hydrochloric acid concentrations where the extraction tends to be more complete than predicted. This is probably due to the fact that a small amount of hydrochloric acid is carried over in the ether to the succeeding extraction so that the hydrochloric acid is somewhat increased. This error is greatest with phylloerythrin and least with coproporphyrin.

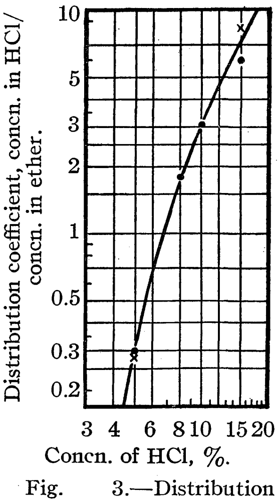

Fig. 3.—Distribution coefficient for the partition of phylloerythrin between ether and hydrochloric acid.

(22) A. Treibs, in Oppenheimer, "Handbuch der Biochemie," 2d ed., Ergänzungsband, 1930, pp. 104–116.

Accordingly it appears that successive extractions with the lowest effective hydrochloric acid concentration should be satisfactory.

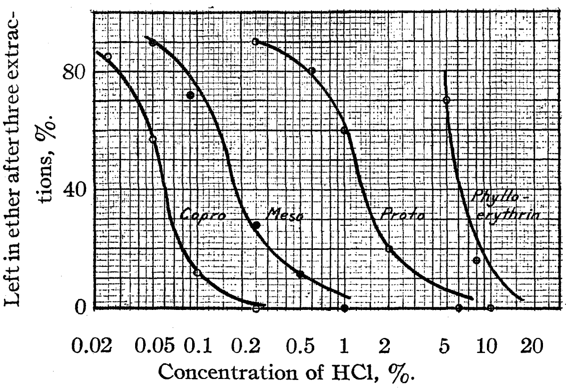

Fig. 4.—Constancy of the distribution coefficient in successive extractions. Lines calculated from distribution coefficients obtained in single extractions, points are experimental results with three successive extractions, using one volume hydrochloric acid to three volumes ether in each.

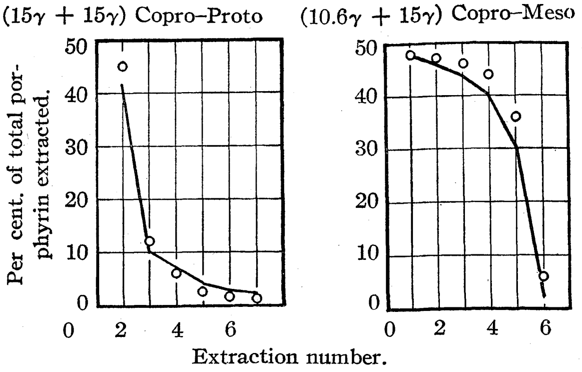
Finally, it is necessary to know whether the extraction of one porphyrin proceeds in quantitative independence of the presence of a second porphyrin. This question was studied with synthetic mixtures of porphyrins of known composition in terms of fluorescence equivalent to coproporphyrin. The results with two mixtures—copro- and protoporphyrin, and copro- and mesoporphyrin—are given in Fig. 5. In Fig. 5 the circles represent the experimental observations, the heavy lines were calculated from the distribution coefficients. The general agreement is good but there is a tendency to extract less than expected in some of the extractions. In all cases, however, the error is less than 4% of the total porphyrin.

The apparent small discrepancy between theory and observation with mixed porphyrins possibly may mean that the fluorescence intensities per unit concentration for the several porphyrins are not identical. It is generally assumed that the fluorescence intensities of the porphyrins studied here are equivalent per molecule. Our own studies indicate that this is approximately true when measurements are made in 5% HCl, but, owing to the excessively minute amounts of the materials available, an uncertainty of the order of 10% must be admitted.



(15γ + 15γ) Copro–Proto (10.6γ + 15γ) Copro–Meso

Fig. 5.—Successive extractions of mixtures of porphyrins. Extraction of ethereal solution by 0.25% HCl, one volume of hydrochloric acid to three volumes ether in each extraction. Points experimentally determined, lines calculated from distribution coefficients (Fig. 2).

Summary

The following pure porphyrins were prepared and studied: copro-, hemato-, meso-, deutero- and protoporphyrin, and phylloerythrin.

Distribution coefficients for the porphyrins between ether and hydrochloric acid were determined by fluorescence measurements, over the range 0.025 to 10% HCl.

For each of the porphyrins the distribution coefficient at a given hydrochloric acid concentration is constant over a range of porphyrin concentration from 0.05 to 2000 micrograms per ml.

The results of successive extractions of ethereal solution by hydrochloric acid are quantitatively predictable from the distribution coefficients, but the error becomes significant when over 85% of the total porphyrin has been extracted.

The results of extractions of mixed porphyrins conform approximately to expectations from the distribution coefficients, but the error in any single extraction may be as great as 5% of the total porphyrin.

The use of successive extractions with appropriate concentrations of hydrochloric acid provides a satisfactory basis for at least semiquantitative separation of the ether-soluble porphyrins when as much as 0.01 mg. of total porphyrin is available.

o-Methoxyphenylmalonic Acid and its Derivatives

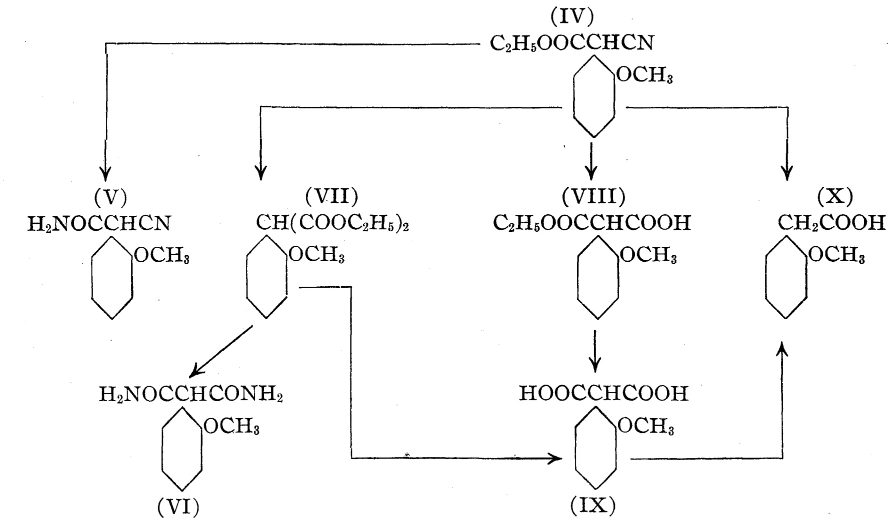
BY JOSEPH B. NIEDERL AND ROSLYN T. ROTH[1]

In a previous report of J. B. Niederl and coworkers,[2] the preparation of *p*-methoxyphenylmalonic acid and its derivatives was described and its general use in organic syntheses demonstrated. It was obvious that the preparation of its ortho isomer should be attempted. Unfortunately, due to the fact that in the diazotization of *o*-aminobenzyl·cyanide not the phenolic product but rather the indazole compound is formed,[3] a similar reaction scheme as for the para acid could not be utilized for the ortho isomer. Instead, the following series of reactions had to be employed

$$o\text{-}CH_3OC_6H_4CH_2OH\ (I) \xrightarrow{+HCl}$$
$$o\text{-}CH_3OC_6H_4CH_2Cl\ (II) \xrightarrow{+KCN}$$
$$o\text{-}CH_3OC_6H_4CH_2CN\ (III) \xrightarrow{+\text{ Claisen cond.}}$$
$$o\text{-}CH_3OC_6H_4CH(CN)COOC_2H_5\ (IV)$$

The ethyl *o*-methoxyphenylcyanoacetate (IV) was converted to the nitrile-amide (V) and the diester (VII). In the preparation of the latter compound, the monoethyl ester (VIII) was obtained as a by-product. On heating and saponification, it was converted into *o*-methoxyphenylacetic acid (X). The diester (VII) was converted into the diamide (VI) and the free dibasic acid (IX), which on heating also yielded *o*-methoxyphenylacetic acid (X). This latter acid was prepared by saponifying the *o*-methoxybenzyl cyanide (II) with alcoholic potassium hydroxide solution.[4]

The structural relationship of these compounds is as shown.



Experimental

***o*-Methoxybenzyl Chloride (II).**—Into a 500-cc. three-necked flask containing 100 g. of *o*-methoxybenzyl alcohol, a vigorous stream of dry hydrogen chloride was introduced. As soon as the temperature began to rise, the mixture was cooled externally with an ice–salt mixture, keeping the reaction temperature below 20°. Introduction of the gas was continued for about two hours, by which time the reaction was practically complete, as recognized by the attainment of constant weight or a fall of the temperature of the reaction mixture to about 2°. To the mixture was added crushed ice and ether. The ether extract was washed with water, 5% sodium carbonate solution and water. The washing was done rapidly to avoid hydrolysis. The ether was removed by distilling under reduced pressure, and the crude chloride was used directly for the preparation of the cyanide.

***o*-Methoxybenzyl Cyanide (III).**—The crude, freshly prepared *o*-methoxybenzyl chloride as prepared above was mixed with 100 cc. of ethyl alcohol and added dropwise over a period of an hour to a gently refluxing mixture of 46 g. of sodium cyanide in 42 cc. of water. Refluxing was continued for one and one-quarter hours (further refluxing decreased the yield due to the formation of high boiling and non-volatile products). The alcohol was removed from the reaction mixture under reduced pressure. The residue was dissolved in ether, the ether extract treated with water, then dried and distilled. The fraction boiling at 100–135° at 4 mm. was allowed to stand on ice for a week. Large prismatic crystals formed from which the oil was separated by placing the crystals on porous tile. The yield of crystals was 38 g.

In this process a large amount of *o*-methoxybenzyl ethyl ether always formed, due to interaction of the chloride with the ethyl alcohol used as solvent. Consequently,

[a] B. p. 133–135° (2 mm.); sp. gr. at 24°, 1.103; $n^{23°}_{D}$ 1.5020.

substitution of the ethyl alcohol by other organic, water-soluble solvents (acetone, dioxane, etc.) was attempted, leading to the formation of non-volatile high polymeric residues. No cyanide could be obtained under these reaction conditions.

Since the above method would constitute a simplification in the synthesis of alkoxyphenylmalonic acids, this same reaction was applied to *p*-methoxybenzyl alcohol, but in this case no *p*-methoxybenzyl cyanide could be obtained at all, either the *p*-methoxybenzyl ethyl ether (ethyl alcohol as solvent), or the polymer formed (dioxane as solvent), while with acetone as solvent no reaction whatsoever took place.

o-Methoxyphenylmalonic Acid. Ethyl Ester-Nitrile (IV).—A solution of 32 g. of the crystalline *o*-methoxybenzyl cyanide in 150 cc. of anhydrous ether was added dropwise, over a period of two and one-half hours, to a mixture of 5.1 g. of sodium shot, 20 cc. of ether, 26 g. of freshly dried and distilled ethyl carbonate. The mixture was allowed to stand overnight, and then after refluxing for two hours was acidified with ice-cold 25% sulfuric acid and extracted with ether. The ether extract was washed with water, 5% sodium carbonate solution, dried and distilled. The fractions from 150–175° (7 mm.) were collected. After standing, the lower fraction crystallized partly, and the higher fraction completely; yield 10 g. The ester-nitrile crystallized from alcohol in the form of large prisms.

In the preparation of the free *o*-methoxyphenylmalonic acid, 0.2 g. of the ester-nitrile in 10 cc. of ether was shaken for ten minutes with 8 cc. of 2% sodium hydroxide solution. Then the ether layer was removed and the ether allowed to evaporate. The residue thus obtained was unreacted ester-nitrile. Half of the alkaline solution, upon being acidified, yielded a mixture of acidic products. The other half of the alkaline solution, when allowed to stand overnight before being acidified, yielded the water-soluble *o*-methoxyphenylmalonic acid (IX).

o-Methoxyphenylmalonic Acid Amide-Nitrile (V).—Six-tenths of 1 g. of the ester-nitrile (IV) was melted and shaken for five minutes with 20 cc. of concentrated ammonia. Nearly all dissolved, and the rest was removed by filtration immediately. The amide-nitrile crystallized out from the filtrate in long needles; yield 0.3 g. It was recrystallized from hot water; mixed m. p. with the *p*-isomer, 114–126°.

o-Methoxyphenylmalonic Acid Mono and Diethyl Esters (VII and VIII).—A mixture of 4.45 g. of the ester-nitrile (IV), 7 cc. of ethyl alcohol, and 0.2 cc. of water was treated with dry hydrogen chloride, first while cold, then for fifteen minutes while refluxing, and then while being cooled in an ice–salt bath. It was allowed to stand overnight, and then refluxed for one hour, and poured into water. The ether extract of this solution was washed with 5% sodium carbonate solution and water, dried with calcium chloride and distilled, the product being the diethyl ester (VII). Neutralization and extraction with ether of the sodium carbonate washings yielded 0.24 g. of the monoethyl ester (VIII) which crystallized on long standing and was recrystallized from hot water. The monoester was identified by heating to drive off the free carboxyl group and saponification of the ester group by 3% sodium hydroxide. On acidification, the *o*-methoxyphenylacetic acid was obtained, confirmed by a mixed melting point with the same acid prepared from *o*-methoxybenzyl cyanide.

o-Methoxyphenylmalonic Acid Diamide (VI).—Three-tenths of a gram of the diethyl ester (VII) was shaken for several hours with 5 cc. of concentrated ammonia, filtered, and the filtrate allowed to evaporate at room temperature. The residue was recrystallized from absolute alcohol, in the form of flakes.

o-Methoxyphenylmalonic Acid (IX).—An ether solution of 0.24 g. of the diethyl ester (VII) was shaken for three hours with 1 cc. of sodium hydroxide solution. On acidification and extraction with ether, 0.15 g. of the free acid was obtained. It was recrystallized from ether–petroleum ether mixture in the form of prisms. The acid on melting gave off carbon dioxide. The residue when heated to 150° gave *o*-methoxyphenylacetic acid; mixed m. p. with the *p*-isomer, 122°.

The authors desire to express their appreciation to Reed and Carnrick, Jersey City, N. J., for a fellowship grant.

Summary

1. The preparation of *o*- and *p*-methoxybenzyl cyanide was studied.

2. *o*-Methoxyphenylmalonic acid and several of its derivatives were prepared and characterized.

NEW YORK, N. Y. RECEIVED JUNE 10, 1938

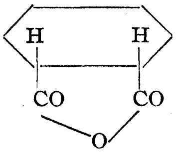
[Contribution from the Chemical Laboratories of Harvard University

The Reactions of Certain Gamma Ketonic Acids. V. Ketonic Beta Lactones and the Walden Inversion[*]

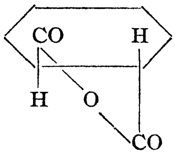
By E. P. Kohler and J. E. Jansen

In a previous paper[1] it was shown that the rates at which two diastereomeric β-bromo acids form β-lactones are dependent on the configurations of the bromo acids. The relations described did not provide a basis for determining whether the closure and opening of the β-lactone ring does or does not involve inversion. That problem is the subject of the present paper.

In order to secure substances of known configuration, it was necessary to resort to cyclic compounds in which the configuration is fixed by the structure and in which it can be determined by the methods that have been evolved for unsaturated ketonic acids.[2] To this end we began with two anhydrides of which the configuration is known, both from the relative ease with which they are formed and from the resolvability of the corresponding *trans* dibasic acid.

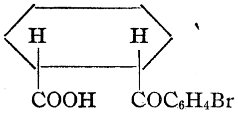


I

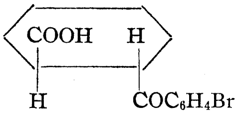


II

Both of these anhydrides were condensed with bromobenzene without difficulty and each gave only one γ-ketonic acid.

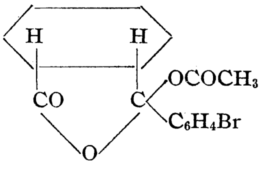


III

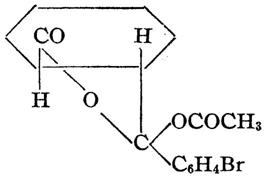


IV

The relative stability of these ketonic acids is the same as that of the corresponding dibasic acids, but, doubtless because of the greater tendency for ketones to enolize, the *cis* acid can be transformed into the *trans* by heating with bases as well as with acids. With the help of these acids of known configuration it was possible to ascertain whether a method which had been found reliable in the case of unsaturated ketonic acids can be employed for determining the configuration of their cyclic analogs. To this end each acid was dissolved in a cooled mixture composed of equal parts of acetic acid and acetic anhydride containing a trace of sulfuric acid, or each acid was dissolved in a warmed mixture of equal parts of acetic acid and acetic anhydride and, in each case, the *cis* acid was converted rapidly and completely into the compound which we assume to be the dicyclic acetate, whereas the *trans* acid was recovered unchanged. In order to convert the *trans* acid into a dicyclic acetate it was necessary to omit the acetic acid and employ only the anhydride. The configuration of these γ-keto acids can be established, therefore, by comparing the relative ease with which they form dicyclic acetates.



V



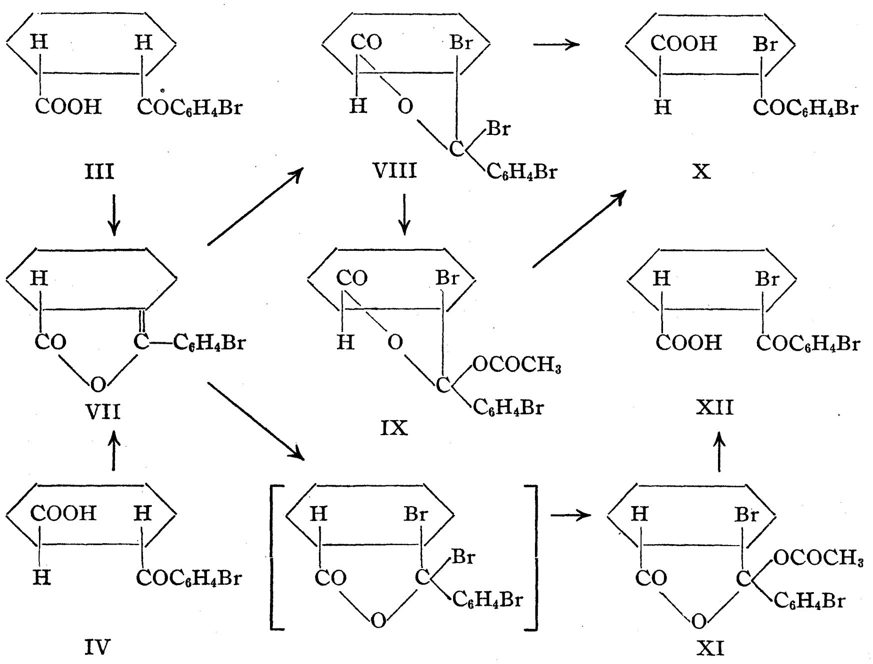
VI

The bromination of the cyclic ketonic acids proved to be unexpectedly troublesome. Neither of the acids could be brominated satisfactorily in non-polar solvents. In direct sunlight bromine reacts slowly with the *cis* acid in boiling chloroform, but the product is a mixture that is extremely difficult to separate. Under the same conditions the *trans* acid reacts still more slowly and forms only oily products. Both acids, however, can be dehydrated to an unsaturated γ-lactone which can be utilized for securing both bromo acids. This unsaturated lactone forms a dibromide which is converted into the dicyclic acetate of the *trans* bromo ketonic acid and when the unsaturated lactone is brominated in a mixture of acetic acid and acetic anhydride, it forms a mixture of the dicyclic acetates of the *cis* and *trans* bromo ketonic acids. The hydrolysis of the acetates to the corresponding bromo ketonic acids presents no difficulties. These relations are shown in the following chart.

(*) This paper was written by Professor Kohler a few months before his death. A few minor additions of experimental work, completed after the paper was written, have been included.—J. E. Jansen.

(1) Kohler, Peterson and Bickel, This Journal, **56**, 2000 (1934).

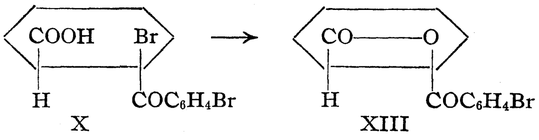
(2) Kohler and Peterson, *ibid.*, **56**, 2192 (1934).



This series of reactions, doubtless, accounts for the fact that both acids can be brominated in acetic anhydride and, also, in a mixture of acetic acid and anhydride. When they are brominated in acetic anhydride the sole product is the same dicyclic bromoacetate (IX) that is formed by the action of the anhydride on the dibromide, and when they are brominated in an acid and anhydride mixture they also form the mixture of bromoacetates that is formed by brominating the unsaturated lactone under the same conditions.

The configurations of the bromo ketonic acids were established without difficulty because they differ even more conspicuously than the unbrominated acids in the ease with which they form dicyclic acetates. The higher-melting bromo acid forms a dicyclic acetate when it is dissolved in cold acetic anhydride, in a warmed mixture of four parts of anhydride and one part acetic acid and when it is warmed with a mixture of equal parts of acetic acid and anhydride. The lower-melting bromo acid is not converted into its acetate in this manner; in order to prepare the dicyclic acetate it is necessary to employ acetic anhydride and sulfuric acid. In the higher-melting bromo acid, therefore, the carbonyl and bromobenzoyl groups are on the same side of the molecule as shown in formula XII. In these experiments two dicyclic acetates of the higher-melting bromo acid are obtained: one from the acetic anhydride solution and the other from the solutions of anhydride containing either acetic acid or sulfuric acid. The formation of two dicyclic acetates is attributable to the generation of a third center of symmetry in the molecule.

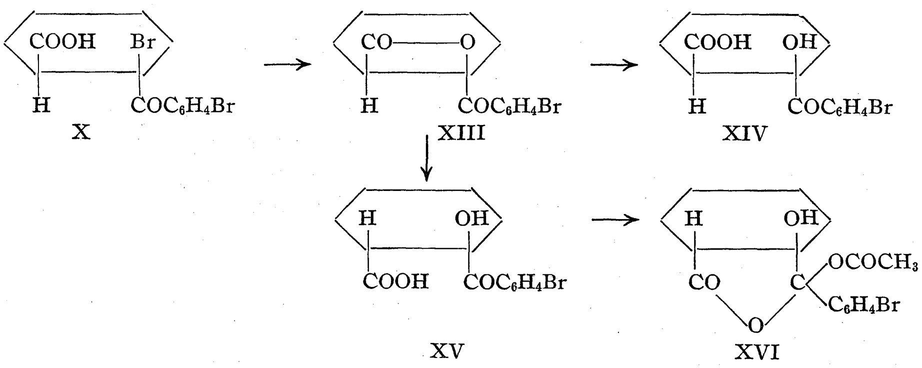
With these two bromo acids of known configuration in hand, it was possible to attack the problem of lactone formation. We found that these acids differ in their behavior toward bases precisely like the corresponding open-chained acids. The bromine derivative of the *trans* ketonic acid is extracted from an ether solution by dilute aqueous sodium bicarbonate, but its salt is converted rapidly and completely into a β-lactone. Under these conditions the bromine derivative of the *cis* ketonic acid is converted into a salt which undergoes no further change. Moreover, unlike the corresponding open chain compound, this bromo compound cannot be converted into a β-lactone by means of caustic alkalies. In this series, therefore, the β-lactone ring can be closed only when the bromine atom and the carboxyl group are on the same side of the molecule.



By analogy to cyclohexene oxide and to the cyclohexane dicarboxylic anhydrides, the β-lactone that is obtained from the bromo ketonic acid has the configuration shown in formula XIII. In view of its relative stability and the rapid cyclization, formation of a β-lactone with a *trans* configuration of the ring appears improbable and is inconsistent with the known properties of these bicyclic compounds. Also, since the isomeric bromo acid, in which the bromine and carboxyl groups are in the *trans* position, fails to form a β-lactone, it is unlikely that the reaction proceeds with inversion. If this were the case, it would be expected that this isomeric bromo acid would more readily form the β-lactone with a *cis* ring.

This β-lactone is exceedingly sensitive to bases. It is rapidly extracted from an ether solution by cold, dilute, aqueous potassium hydroxide, and more slowly by sodium carbonate, to yield, quantitatively, in each case, a salt of a single hydroxy acid. This hydroxy acid is not affected by dilute alkalies—it was recovered quantitatively from a solution of potassium hydroxide which had been boiled for four hours. In methyl alcohol containing a trace of sodium methylate, the β-lactone is opened quantitatively to a methyl ester of this same hydroxy acid. This methyl ester is also obtained from the hydroxy acid with methyl alcohol and sulfuric acid.

The methyl ester of a higher-melting isomeric hydroxy acid is obtained quantitatively when solutions of the β-lactone in methyl alcohol, containing sulfuric acid, are allowed to stand. This higher-melting hydroxy acid is also formed to some extent when the β-lactone is dissolved in methyl alcohol containing an excess of sodium methylate, or when it is boiled for a long time with dilute sulfuric acid. No isomerization of the lower-melting hydroxy acid, obtained from the β-lactone with bases, is observed in acid solutions. Thus, in this manner it was possible to secure the two isomeric hydroxy acids, though it was impossible to prepare more than one β-lactone.



The isomeric hydroxy acids, like all the other pairs of isomers that have been described, differed greatly in the ease with which they formed dicyclic acetates in acetic anhydride, but, unlike the bromo acids, in mixtures of acetic acid and anhydride satisfactory conversion to cyclic acetates could not be achieved. In acetic anhydride, the lower-melting hydroxy acid, which was formed by the action of bases on the β-lactone, failed to form the dicyclic compound, but the higher-melting isomer was converted into a dicyclic acetate without difficulty. On this basis, the latter acid is a derivative of the *cis* ketonic acid and the former is a derivative of the *trans* acid. However, these configurations have not been established with the certainty that was possible with the bromo acids.

The hydroxy groups in both the hydroxy acids were surprisingly resistant to attack. At the ordinary temperatures, with hydrogen bromide in acetic acid, the hydroxyl groups were not replaced with bromine and at elevated temperatures only thick oils resulted. Furthermore, it was not possible to prepare the corresponding methoxy acids by any of the ordinary methods.

With the configurations that are established, it is possible finally to decide whether the β-lactone is closed with or without inversion. Because the ring formation proceeds through closure of two groups in the *cis* position, with formation of a β-lactone of the same configuration, no inversion has occurred. The evidence obtained favors the same *cis* configuration for the hydroxy acid that is obtained from the β-lactone with bases and on this basis the ring opening with bases has also occurred without inversion. These reactions are shown in the chart.

Experimental

A part of the material employed in the investigations was prepared from dimethyl phthalate. The commercial ester was hydrogenated in the presence of Raney catalyst at a temperature of 225° and under a pressure of 2000 lbs. (133 atm.). As it was impossible to attain complete hydrogenation, the product had to be purified by fractional distillation before it was hydrolyzed to the dibasic acid from which the anhydride was made.

The rest of the material was made by adding maleic anhydride to butadiene[3] and hydrogenating the addition product. As the equipment for making butadiene[4] in quantity was available, we found it much more convenient to synthesize the anhydride by this method than to make it from the phthalate.

Tetrahydrophthalic Anhydride.—Diels and Alder operated in sealed tubes, but we found that with our much

---

[3] Diels and Alder, *Ann.*, **460**, 113 (1928).

[4] Fieser, *Org. Syntheses*, **17**, 25 (1937).

larger quantities it was quite feasible and much more convenient to operate in strong-walled flasks in the following manner. A suspension of 90 g. of maleic anhydride in 300 cc. of pure benzene was introduced into a suction flask equipped with a delivery tube that dipped under the surface of the liquid, and a Bunsen valve that was constructed out of heavy-walled tubing. The delivery tube was connected with a cooled vessel containing 70 g. of butadiene and the container was allowed to assume the temperature of the room. The gas was absorbed as fast as it was evolved, the temperature of the suspension rose rapidly and the anhydride disappeared before all of the diene had evaporated. The clear solution was allowed to remain under the pressure of butadiene until most of the addition product had separated, then cooled and filtered. The yield was 134 g. or 96%.

Hydrogenation: *cis* Cyclohexane Dicarboxylic Anhydride, I.—A suspension of 40 g. of the anhydride in 40 g. of glacial acetic acid was shaken with hydrogen in the presence of 0.1 g. of Adams catalyst. Hydrogen was absorbed rapidly, the reduction being complete in three to four hours. The catalyst was removed by filtration and the solvent by evaporation under diminished pressure. Nearly all of the residue was pure *cis* anhydride distilling at 161.7–161.9° (25 mm.) and melting at 31°. The yield was 93%.

***trans*-Cyclohexane Dicarboxylic Anhydride, II.**—The *cis* anhydride was heated for three hours at 180° with concentrated hydrochloric acid and the resulting *trans* acid was converted into its anhydride by treatment with acetyl chloride as directed by Baeyer.[5] The anhydride melted at 140–142° and the yield was 70%.

***cis-p*-Bromobenzoyl Cyclohexane Dicarboxylic Acid, III.**—To a solution of 50 g. of the *cis* anhydride in 250 g. of bromobenzene which was cooled to 10° was added, in a single lot, 94 g. of powdered aluminum chloride. The mixture was stirred and the temperature rose to 60–65°. After remaining at room temperature for forty-five minutes it was stirred into a mixture of ice and dilute acid and set aside to allow the acid to solidify. The solid was removed, washed with water and dissolved in sodium carbonate. After removal of the unchanged bromobenzene with ether, the carbonate solution on acidification deposited 98 g. of solid which was recrystallized from 75% acetic acid. It separated in fine needles melting at 169–171°. It is very sparingly soluble in ether, readily soluble in chloroform, benzene and acetone. The yield was 83 g. or 83%.

Anal. Calcd. for $C_{14}H_{15}O_3Br$: C, 54.0; H, 4.8. Found: C, 53.9; H, 4.9.

The methyl ester of the *cis* ketonic acid was prepared by means of diazomethane. It crystallized from ether–petroleum ether in small prisms melting at 60–61°. It also can be obtained by esterifying the acid with methyl alcohol and sulfuric acid but the yield is poor.

Anal. Calcd. for $C_{15}H_{17}O_3Br$: C, 55.4; H, 5.2. Found: C, 55.3; H, 5.2.

The Dicyclic Acetate, V.—(1) To a cooled solution of 1.0 g. of the *cis* ketonic acid in 60 cc. of acetic acid was added 20 cc. of acetic anhydride containing a trace of sulfuric acid (one drop of acid to 50 cc. of anhydride) which had been cooled to 0°. The solution was kept at 10° for half an hour, then stirred into ice water and left to itself for an hour. (2) One gram of the acid was dissolved in 40 cc. of equal parts of acetic acid and acetic anhydride and the solution kept at 60–65° for fifteen minutes. The solution was then treated as above. The resulting solid in each case was recrystallized from ether–petroleum ether. It separated in small prisms melting at 149°. The yields were 0.9 g. The mixed melting point of the two samples was not depressed.

Anal. Calcd. for $C_{16}H_{17}O_4Br$: C, 54.5; H, 4.9. Found: C, 54.5; H, 5.0.

Hydrolysis of the Acetate.—The acetate is hydrolyzed with great rapidity. In boiling moist ether it disappeared within three hours and it was removed from its ethereal solution by dilute sodium bicarbonate. In each case the *cis* ketonic acid was the only product.

***trans-p*-Bromobenzoyl Cyclohexane Carboxylic Acid, IV.**—By the same procedure that was employed for the preparation of the *cis* ketonic acid, the anhydride of *trans* cyclohexane dicarbonic acid was converted into the *trans* ketonic acid. The acid was recrystallized from ether–petroleum ether. It separated in irregular prisms melting at 164°. The yield was 60%.

Anal. Calcd. for $C_{14}H_{15}O_3Br$: C, 54.0; H, 4.8. Found: C, 54.2; H, 5.1.

The Methyl Ester.—The ester was prepared both with diazomethane and with methyl alcohol and sulfuric acid. It crystallized from methyl alcohol in prisms and melted at 98–99°. The yields were quantitative.

Anal. Calcd. for $C_{15}H_{17}O_3Br$: C, 55.4; H, 5.2. Found: C, 55.5; H, 5.4.

The Dicyclic Acetate, VI.—In experiments which were conducted exactly the same as that by which the *cis* ketonic acid was converted into the dicyclic compound, all of the *trans* acid was recovered. The acetic acid was omitted, therefore, and 1.0 g. of the *trans* acid was dissolved in 20 cc. of acetic anhydride containing a trace of sulfuric acid. The solution was kept at the ordinary temperature for fifteen minutes and then manipulated as described under the *cis* acetate. The result was 1.0 g. of the *trans* dicyclic acetate. It crystallized from ether–petroleum ether in small prisms and it melted at 96–97°. The *trans* acetate is more stable than the *cis* isomer in the presence of water but it is rapidly hydrolyzed by dilute acids, regenerating the *trans* acid.

Anal. Calcd. for $C_{16}H_{17}O_4Br$: C, 54.5; H, 4.9. Found: C, 54.6; H, 5.2.

Isomerization of the *cis* into the *trans* Ketonic Acid.—The *cis* ketonic acid, like the dibasic acid, can be isomerized with acids but unlike the dibasic acids it is isomerized much more rapidly with bases. Thus, after a solution of 15 g. of the acid in 400 cc. of 5% aqueous sodium carbonate had been boiled for three hours, it contained only the salt of the *trans* acid. The *trans* acid is, therefore, most easily secured by converting the *cis* anhydride into the corresponding ketonic acid and inverting this acid with sodium carbonate.

The Unsaturated γ-Lactone, VII.—A suspension of 10 g. of the *cis* ketonic acid in 50 cc. of acetic anhydride was cooled to 0°, stirred vigorously and treated with 3 drops of

---

[5] Baeyer, *Ann.*, **258**, 217 (1890).

concentrated sulfuric acid. The acid dissolved immediately and in a few moments a new solid appeared. After fifteen minutes the mixture was stirred into ice water where it was left for an hour. The solid was then collected, washed with water, dried and recrystallized from methyl alcohol. It separated in small cubes melting at 95°. The yield was 8 g. In a repetition with the same quantity of the *trans* acid, the same solid was formed in the same quantity and apparently with the same ease.

Anal. Calcd. for $C_{14}H_{13}O_2Br$: C, 57.3; H, 4.5. Found: C, 57.4; H, 4.8.

Hydrolysis.—The unsaturated lactone, like the corresponding monocyclic lactones, reverts to a ketonic acid when it is treated with bases. Thus a solution of 1 g. of the substance in 50 cc. of methyl alcohol containing a gram of potassium hydroxide was boiled for an hour, then diluted with water and acidified. The product was 0.6 g. of the *trans* ketonic acid, the only ketonic acid that is stable in the presence of bases.

Addition of Bromine: the Dibromide, VIII.—To a solution of 4 g. of the unsaturated lactone in 40 cc. of carbon disulfide, which was kept at 0°, was added 2.2 g. of bromine. The bromine disappeared as fast as it was added. After removing a part of the solvent, the residual solution was diluted with petroleum ether. It deposited 5.4 g. of a solid which, after recrystallization from ether–petroleum ether from which it separated in large tables, melted with decomposition at 119–122°.

Anal. Calcd. for $C_{14}H_{13}O_2Br_3$: C, 37.1; H, 2.9; Br, 53.0. Found: C, 37.3; H, 3.2; Br, 52.8.

Hydrolysis.—The dibromide is hydrolyzed slowly in contact with air, more rapidly when shaken with dilute acetic acid. After a suspension of 2 g. of the substance had been shaken with the dilute acid for eight hours it yielded 1.6 g. of pure *trans* bromo ketonic acid X.

Alcoholysis: the Dicyclic Bromomethyl Ether.—A solution of 0.5 g. of the dibromide in 10 cc. of methyl alcohol was kept at the ordinary temperature for three hours and then allowed to evaporate. The resulting oil was dissolved in ether. From the washed and dried ethereal solutions petroleum ether precipitated the solid ether in small hard prisms melting at 93°. The corresponding ethyl ether melts at 115°. These ethers are more stable than the bromide and the acetate but when they are digested with acetic acid and concentrated hydrochloric acid they likewise are hydrolyzed to the *trans* bromo ketonic acid.

Anal. Calcd. for $C_{15}H_{16}O_3Br_2$: C, 44.6; H, 4.0. Found: (93°) C, 44.5; H, 4.2. Calcd. for $C_{16}H_{18}O_3Br_2$: C, 46.0; H, 4.3. Found: (115°) C, 46.1; H, 4.6.

Reaction with Acetic Anhydride: the *trans* Dicyclic Bromoacetate, IX.—A solution of 0.5 g. of the dibromide in acetic anhydride almost immediately deposited 0.4 g. of the solid bromoacetate. It was crystallized from chloroform from which it separated in small, hard prisms melting with decomposition at 174–176°.

Anal. Calcd. for $C_{16}H_{16}O_4Br_2$: C, 44.5; H, 3.7. Found: C, 44.3; H, 3.8.

As this bromo compound can be obtained without difficulty by brominating either the *cis* or the *trans* ketonic acid, it was used as a source for the *trans* bromo ketonic acid. For this purpose it was prepared in the following manner: a solution of 39 g. of bromine in 50 cc. of acetic acid was added slowly to a solution of 75 g. of the *cis* ketonic acid in 200 cc. of acetic anhydride. The reaction started at once and proceeded rapidly. Hydrogen bromide was not evolved. The cyclic acetate began to precipitate before more than a third of the bromine had been added. In order to complete the precipitation the mixture was cooled for several hours in ice water before filtration. The solid was washed with dilute acetic acid, dried and recrystallized from chloroform or benzene. The yield was 94%. When the *trans* ketonic acid was brominated in the same manner the same dicyclic bromoacetate was obtained, the yield being 93%.

Hydrolysis: the *trans* Bromo Ketonic Acid, X.—The bromoacetate is not nearly so sensitive as the corresponding unsubstituted acetate, being unaffected when its ethereal solution is shaken with dilute solutions of bases. For the purpose of hydrolysis a suspension of 98 g. of the compound in 300 cc. of acetic acid and 40 cc. of concentrated hydrochloric acid was heated with constant stirring on a steam-bath for two hours. The clear solution, cooled and diluted with water, deposited a solid which, after recrystallization from ether, from which it separated in hard irregular prisms, melted at 147°. The yield was 94%.

Anal. Calcd. for $C_{14}H_{14}O_3Br_2$: C, 43.1; H, 3.6. Found: C, 43.1; H, 3.9.

The *cis* Dicyclic Bromoacetate, XI.—A solution of 2.6 g. of bromine in 20 cc. of acetic acid was added to a solution of 5.0 g. of the *cis* ketonic acid in 150 cc. of acetic acid and 75 cc. of anhydride. The reaction started slowly and required an hour for completion. When the solution was cooled it deposited 2.5 g. of the *trans* bromoacetate which was removed by filtration. The filtrate, on dilution with water, deposited 2.0 g. of solid that was separated by recrystallization from ether into 0.5 g. of *trans* and 1.5 g. of the *cis* bromoacetate. This *cis* compound crystallized from ether in flat needles melting at 149°.

Anal. Calcd. for $C_{16}H_{16}O_4Br_2$: C, 44.5; H, 3.7. Found: C, 44.3; H, 3.9.

Hydrolysis: the *cis* Bromo Ketonic Acid, XII.—The dicyclic acetate was hydrolyzed in the same manner as the *trans* compound. The product crystallized in fine needles and melted with decomposition at 185–187°.

Anal. Calcd. for $C_{14}H_{14}O_3Br_2$: C, 43.1; H, 3.6. Found: C, 42.8; H, 3.7.

The methyl ester of the *cis* bromo ketonic acid was obtained by means of diazomethane and with methyl alcohol and sulfuric acid. It crystallized from ether in small prisms and melted at 106°.

Anal. Calcd. for $C_{15}H_{16}O_3Br_2$: C, 44.6; H, 4.0. Found: C, 44.3; H, 4.4.

In the bromination of the *cis* ketonic acid the bromo derivatives of the *cis* and *trans* acids were formed in poor yields in the ratio of 30% of the former to 70% of the latter. Under the same conditions bromination of the unsaturated γ-lactone resulted in 25% of *cis* and 75% of *trans* compounds. No *cis* compounds were formed in the bromination of the *trans* ketonic acid but at least 20% of the product formed in the bromination of the methyl ester of the *trans* ketonic acid was the methyl ester of the *cis* bromo ketonic acid. Attempts to isomerize the *cis* bromo acid were unsuccessful.

Configuration of the Bromo Ketonic Acids.—Solutions of 0.5 g. of each bromo acid in 20 cc. of equal parts of acetic acid and acetic anhydride or in 20 cc. of one part acetic acid and four parts acetic anhydride were kept at 80° for forty-five minutes, then poured into ice water. The resulting solutions were stirred for an hour before filtration. The solid in each case from the bromo acid melting at 147° was unchanged bromo acid and the recovery of acid recrystallized from ether–petroleum ether was 80%. The solid from the bromo acid melting at 187° was the dicyclic acetate XI melting at 149° and the yield of pure recrystallized compound was 80%.

In another experiment in which solutions of equal quantities of the two bromo acids in acetic anhydride were kept at the temperature of the room for five hours and then manipulated as in the preceding experiment, the bromo acid melting at 147° was again recovered in an almost quantitative yield. The product from the higher melting bromo acid was a new dicyclic acetate which crystallized from ether–petroleum ether in small prisms which melted at 78°. When this acetate was hydrolyzed with acetic acid and hydrochloric acid it regenerated the bromo acid from which it had been formed.

Anal. Calcd. for $C_{16}H_{16}O_4Br_2$: C, 44.5; H, 3.7. Found: C, 44.5; H, 3.9.

These experiments show quite conclusively that the configuration of the higher-melting bromo acid is represented by XII and that of the lower-melting bromo acid by X.

The β-Lactone, XIII.—A solution of 5 g. of the lower-melting bromo acid in 250 cc. of alcohol-free ether was shaken for two hours with 250 cc. of 1% sodium bicarbonate. The ether layer was washed thoroughly with water, dried over sodium sulfate, concentrated and diluted with low boiling petroleum ether. It deposited a solid which, after recrystallization from methyl alcohol, melted at 83°. The lactone crystallizes in diamond-shaped plates and is soluble in all common solvents except petroleum ether. The yield was 97%.

Anal. Calcd. for $C_{14}H_{13}O_3Br$: C, 54.4; H, 4.3. Found: C, 54.6; H, 4.7.

The β-lactone is stable in methyl alcoholic solutions even with prolonged boiling. With hydrogen bromide in acetone solution the β-lactone was converted completely into the *trans* bromo acid from which it is formed. With ammonia in methyl alcohol only unidentified oily products were obtained.

Action of Bases: the *trans* Hydroxy Acid, XIV.—A solution of 5 g. of the lactone in ether was shaken with 300 cc. of 1% aqueous potassium hydroxide for twenty minutes. The resulting alkaline solution on acidification deposited 4.5 g. of a solid which, after recrystallization from ether–petroleum ether from which it separated in small, hard prisms, melted at 134°. The yield was 90%. As this acid is not affected by aqueous alkalies, it is also the only product that is formed when the bromo acid is shaken with dilute aqueous potassium hydroxide. Isomerization of this acid also was not detected in acid solutions.

Anal. Calcd. for $C_{14}H_{15}O_4Br$: C, 51.4; H, 4.6. Found: C, 51.3; H, 4.6.

The methyl ester, obtained by treating the *trans* hydroxy acid with diazomethane, crystallized from ether–petroleum ether in thick plates melting at 88°.

Anal. Calcd. for $C_{15}H_{17}O_4Br$: C, 52.8; H, 5.0. Found: C, 53.0; H, 5.5.

When a solution containing 2 g. of the β-lactone in 50 cc. of methyl alcohol containing 0.0007 mole of sodium methylate was allowed to stand for fifteen hours there was obtained after the usual manipulations 1.6 g. of a solid methyl ester which, after recrystallization from ether–petroleum ether, from which it separated in small prisms, melted at 142°.

Anal. Calcd. for $C_{15}H_{17}O_4Br$: C, 52.8; H, 5.0. Found: C, 52.6; H, 5.2.

This same 142° methyl ester also was obtained from the *trans* hydroxy acid with methyl alcohol and sulfuric acid in quantitative yields. When the 88° methyl ester is allowed to stand in methyl alcohol solutions containing either sulfuric acid or a trace of sodium methylate, it is converted completely into the 142° methyl ester. Both of these esters are hydrolyzed readily to the *trans* hydroxy acid with bases and less readily with acids. No evidence was obtained to show that one of them is a cyclic ether.

The *cis* Hydroxy Acid, XV.—A solution of 10 g. of the β-lactone in 600 cc. of methyl alcoholic sodium methylate containing 6 g. of sodium was left at room temperature. It deposited 5 g. of the sodium salt of the *trans* hydroxy acid. The filtrate from the salt, diluted with water and acidified, deposited 4 g. of the isomeric acid in nearly pure condition. The acid crystallized from ether in thin plates melting at 187°. The same acid was obtained in a yield of 68% when the lactone was boiled for thirty hours with 5% sulfuric acid. The methyl ester of this same hydroxy acid was also obtained in nearly quantitative yield when methyl alcoholic solutions of the β-lactone containing a few drops of sulfuric acid were allowed to stand at room temperature. This methyl ester was hydrolyzed readily with bases to the hydroxy acid.

Anal. Calcd. for $C_{14}H_{15}O_4Br$: C, 51.4; H, 4.6. Found: C, 51.2; H, 4.6.

The methyl ester obtained by treating the *cis* hydroxy acid either with diazomethane or with methyl alcohol and sulfuric acid, and from the β-lactone with methyl alcohol and sulfuric acid, crystallized from methyl alcohol in hard, irregular prisms, which melted at 54°.

Anal. Calcd. for $C_{15}H_{17}O_4Br$: C, 52.8; H, 5.0. Found: C, 53.1; H, 5.4.

Configuration of the Hydroxy Acids: the Dicyclic Hydroxy Acetate, XVI.—One gram of each of the hydroxy acids was shaken with 40 cc. of pure acetic anhydride until solution was complete—about fifteen minutes. The solutions were kept at the ordinary temperature for forty-five minutes, then poured into ice water. The resulting suspensions were stirred for an hour before the solid products were removed and purified. The solid from the lower-melting acid was unchanged hydroxy acid—the recovery of pure acid after recrystallization from ether–petroleum ether was 70%. The solid from the higher-melting hydroxy acid was a neutral compound which crystallized from ether–petroleum ether in short, stout needles melting at 95°. The yield was 77%.

Anal. Calcd. for $C_{16}H_{17}O_5Br$: C, 52.0; H, 4.6. Found: C, 51.7; H, 4.9.

In ether solution this neutral product was not hydrolyzed with sodium bicarbonate solution but when it was digested with a dilute solution of hydrochloric acid in acetic acid it regenerated the higher-melting hydroxy ketonic acid.

In solutions of acetic anhydride and acetic acid both hydroxy acids failed to react at the ordinary temperature. With heating in such solutions both hydroxy acids gave oils which invariably gave both the hydroxy acids on standing or when their ether solutions were extracted with dilute sodium bicarbonate. On the basis of the experiments with acetic anhydride only the higher-melting acid forms a dicyclic acetate and in this acid the carboxyl and bromobenzoyl groups are on the same side of the ring as shown in formula XV.

Summary

The configurations of two cyclic diastereomeric β-bromo γ-keto acids have been established. The bromo acid in which the bromine and carboxyl groups are in the *cis* position is the only one that will form a β-lactone. Evidence is given to show that this β-lactone formation has occurred without inversion. The β-lactone is opened with bases to give a single hydroxy acid. The evidence indicates that this hydroxy acid has the same configuration as the β-lactone and the bromo acid from which it is prepared.

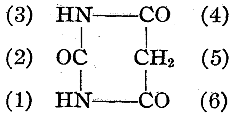
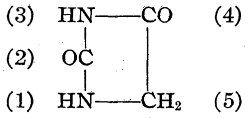
5,5-Dialkylhydantoins Containing a Dialkylamino Substituent[1,2]

By J. Wm. Magee with Henry R. Henze

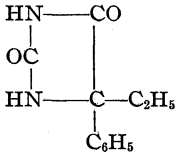
Attempts to relate chemical constitution to physiological activity have been of but moderate success and the information thus secured has been used in the development of the barbituric acid series of soporifics.[3,4] Synthesis of additional derivatives in this field has continued with the production of only a few new types. More recently interest has again been centered in the preparation of sedatives through the replacement of the hydrogen attached to the nitrogen of the barbituric acid nucleus by alkyl groups.[5,6] Here, particularly, the substitution of the methyl group for the imidic hydrogen has in certain instances produced compounds of extremely short but intense period of hypnotic activity.[7] A late publication includes evidence of success in the introduction of alkylamino groupings[8] into the alkyl commonly attached to the 5-position of the heterocycle.



I



II



III

A definite similarity exists in the structure of barbituric acid (I) and hydantoin (II), and rather close analogy is evident in the fact of the existence of compounds derived from substitution of identical groupings for the hydrogen atoms in the 5,5-, 1- and 3-positions of both the barbituric acid and hydantoin heterocycles.[4,6,9–11] Although, as yet, but one 5,5-disubstituted hydantoin[12] (III) has found clinical use, the hydantoin nucleus is innocuous and offers hope that additional compounds of value as sedatives may be derived from it by appropriate substitution. In this Laboratory attention has previously been directed to the utilization of alkoxyalkyl[13] and aryloxyalkyl[14] substituents and compounds of definite hypnotic power but unfavorable toxicity have been pro-

duced.[13] These hydantoin derivatives have been obtained from alkoxy- and aryloxy-dialkyl ketones and from alkoxyalkyl aryl ketones by adaptation of Bucherer's method[15] for synthesizing simple hydantoins. This process is much simpler and productive of better yields than is that of Bergs.[16]

The purpose of the present investigation was to obtain 5,5-dialkylhydantoins containing dialkylamino substituents. Although 1-alkyl-5,5-dialkylhydantoins[11] have been prepared, a thorough search of the literature fails to disclose the synthesis of 5-dialkylaminoalkyl-5-alkylhydantoins. In fact, Slotta, Behnisch, and Szyszka[17] reported that they were unable to convert dimethylaminoacetone and *bis*-dimethylaminomethyl ketone into the corresponding hydantoins by means of Bergs' procedure.[16] The former of these ketones, as well as nine other disubstituted aminoacetones, have been prepared in this research and all subsequently converted into 5-dialkyl- or diallyl-aminomethyl-5-methylhydantoins by adaptation of the method of Bucherer.[15]

Five of the dialkylaminoacetones had been synthesized previously but inadequately characterized. Marked discrepancies were found between the melting points of the semicarbazones of three of these ketones as recorded in the literature[18] and as determined in the course of this study.

Experimental

Bromoacetone.—The bromoacetone was prepared by slightly altering Levene's[19] modification of Nef's[20] method. It seemed advantageous to decrease by one-third the volume of water used and to heat on a steam-cone. Using an efficient mechanical stirrer, it was possible to add the required amount of bromine rapidly through a short separatory funnel. Experimental runs using 10 moles of acetone produced 800 g. of bromoacetone in about 55% of the theoretical yield and in sufficient state of purity to use without redistillation.

Preparation of the Disubstituted Aminoacetones.—Two general procedures were used for preparing the dialkylaminoacetones. In one method two moles of a specific secondary aliphatic amine, diluted with 20 volumes of ether, was treated with one mole of bromoacetone diluted with 2 volumes of ether. Usually the hydrobromide of the secondary amine separated as glistening, white leaflets from the reddish-brown colored solution. The ether solution was refluxed until the odor of bromoacetone was no longer evident, chilled in an ice-bath and filtered. The filtrate was fractionated under diminished pressure. In order to avoid the conversion of one-half of the secondary amine into the hydrobromide salt, a second method was developed. To one mole of the secondary amine, suspended in 5 volumes of water containing 2 moles of sodium carbonate, was added one mole of bromoacetone with vigorous stirring during thirty minutes or until the odor of bromoacetone could not be recognized. After filtration from the sodium bicarbonate formed, the filtrate was extracted with ether and the extract dried over anhydrous sodium sulfate before fractionation. Only in the cases of the di-*s*-propyl and di-*s*-butyl compounds was this second method unsuccessful. In these two instances the rate of reaction between the secondary amine and the bromoacetone seemed slower than the rate of decomposition of the bromoacetone by the alkali.

Although the di-*s*-butylaminoacetone was refractionated a number of times, and the analytical results seemed to indicate a state of satisfactory purity, the observed molecular refractivity and parachor did not check the calculated values very closely. Hence the liquid was treated with enough 6 *N* hydrochloric acid to dissolve 90–95% of the material; the acid solution was extracted with ether and then neutralized with sodium hydroxide. The regenerated amino ketone was treated with such a quantity of 6 *N* acid as to dissolve only 5–10% of the material. The residual liquid was washed free of any salt, dried and distilled. The physical properties of the fractionated material were not appreciably altered by this treatment.

All the ketones included in this study are colorless oils when freshly and carefully fractionated, possess a strong basic odor, but darken after standing even for a short time. Only one of the ketones, dimethylaminoacetone, is readily miscible with water but all are soluble in the usual organic solvents such as ether, acetone, alcohol, benzene, and chloroform. The amino ketones are readily dissolved by acids, as hydrochloric, sulfuric, and acetic.

Boiling points were taken with calibrated thermometers and the properly corrected values are reported for the disubstituted aminoacetones. Surface tensions were measured by means of Cassel's[21] precision capillarimeter at 20°. Densities were determined by means of a U-shaped glass tube weighing 1.7231 g. and containing 1.1384 cc. of water at 4°. The data resulting from the determination of physical constants, the values derived from these data by calculation and such information as was obtained through analysis of the substituted aminoacetones have been tabulated in Table I.

Preparation of Semicarbazones from Disubstituted Aminoacetones.—Solid, crystalline semicarbazones were obtained from all of the disubstituted aminoacetones. Those derived from dimethyl- and diethylaminoacetones, whose syntheses have not been reported previously, were so soluble in water as to present difficulty in their isolation. They were obtained best by making a

[a] Stoermer and Dzimski, *Ber.*, **28**, 2223 (1895), reported only the following boiling points for these ketones: dimethylaminoacetone, 123°; diethylaminoacetone, 155–156° with some decomposition.

[b] Stoermer and Pogge[18] reported for certain of these dialkylaminoacetones the following data which are noticeably at variance with the data included in Table I.

	B. p., °C.	d 17°
Di-*n*-propylaminoacetone	188	0.8337
Diisobutylaminoacetone	206–207	.8735
Diisoamylaminoacetone	219–220	.8911

concentrated solution of semicarbazide hydrochloride in the amino ketone, adding a slight excess of dilute aqueous solution of sodium hydroxide, and chilling in an ice-bath. Recrystallization of all semicarbazones is accomplished readily by solution in hot benzene and precipitation from the cooled solution by addition of several volumes of petroleum ether. The corrected melting points of, and the analytical constants for, the ten semicarbazones are collected in Table II. It is to be noted that the melting points of three of these semicarbazones, namely, of the di-*n*-propyl, diisobutyl and diisoamyl derivatives differ, as do the densities of the respective amino ketones, from those reported by Stoermer and Pogge.[18] In view of these discrepancies all three of the dialkylaminoacetones were resynthesized and their semicarbazones prepared again and carefully purified and dried. The melting points and analytical data checked closely those of the first preparations.

of potassium cyanide and ammonium carbonate in alcoholic solution according to directions of Bucherer.[15] To an Erlenmeyer flask fitted with an air condenser were added 0.10 mole of ketone, 0.30 mole of freshly powdered ammonium carbonate, 0.13 mole of potassium cyanide, and 7–8 volumes of 50% alcohol,[22] and the mixture heated for about eight hours. As the carbonate and cyanide gradually dissolved, gas was evolved and ammonium carbonate formed in the condenser tube. Near the end of the period of heating the condenser tube was removed and the temperature of the bath increased to evaporate the alcohol. Cooling in an ice–salt mixture caused most of the hydantoin to separate and only an additional, small amount was obtained when the solution was neutralized with dilute hydrochloric acid. Because of the dialkylamino substituent, all of the hydantoins are soluble in acid so an excess of the latter was avoided.

The hydantoins are easily recrystallized from dilute alcohol, are soluble in the ordinary organic solvents and, with the exception of the dimethyl homolog, very sparingly soluble in water. Because the compounds are amphoteric they are soluble in both acidic and alkaline solutions from which they are readily precipitated unchanged when such solutions are made exactly neutral. The disubstituted aminohydantoins are stable, white, crystalline solids which melt without decomposition to clear straw colored liquids. The temperatures reported as melting points of the hydantoins in Table III represent corrected values.

Summary

1. The series of 5,5-dialkylhydantoins has been extended by the synthesis of nine examples of dialkylamino derivatives. Likewise the production of 5-diallylaminomethyl-5-methylhydantoin represents the initial preparation of an additional type.

2. Although Slotta, Behnisch and Szyszka were unable to convert dimethylaminoacetone into 5-dimethylaminomethyl-5-methylhydantoin by means of the method of Bergs, this conversion has now been accomplished utilizing the closely related method of Bucherer.

3. Diallylaminoacetone and four new members of the series of dialkylaminoacetones have been prepared and five additional examples of this type have been resynthesized and all adequately characterized. The densities of three of the ketones are in definite disagreement with the data previously reported in the literature.

4. The yield of disubstituted aminoacetones, as based on the weight of the secondary amine used, has been doubled by using dilute alkali to prevent the formation of the secondary amine hydrobromide.

5. Semicarbazones, useful in the identification of the amino ketones, were obtained from each of the ten members of this series. The melting points of the semicarbazones of three of the disubstituted aminoacetones are quite different from those reported in a prior investigation.

6. For diallylaminoacetone and the series of dialkylaminoacetones studied in this investigation, the molecular refraction was found to be more sensitive than the parachor as an index to purity.

AUSTIN, TEXAS RECEIVED JUNE 13, 1938

[22] Due to the solubility of the dimethylaminoacetone no alcohol was used in the preparation of 5-dimethylaminomethyl-5-methylhydantoin.

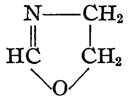
Syntheses from Ethanolamine. V. Synthesis of Δ^2-Oxazoline and of 2,2′-Δ^2-Dioxazoline

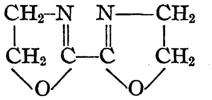
BY HENRY WENKER

As the lowest member of the series, Δ^2-oxazoline (I) is of theoretical interest. The compound has not been described hitherto; earlier attempts[1] to prepare it by dehydration of ethanol formamide resulted invariably in cleavage into carbon monoxide and ethanolamine.

The base has now been obtained by the action of alkali upon β-chloroethyl formamide; the latter was made from ethanol formamide[1,2] and thionyl chloride. Similarly, 2,2′-Δ^2-dioxazoline (II) was prepared from *s*-β,β′-dichlorodiethyl oxamide. The method in itself is not new; Gabriel and Heymann[3] obtained 2-phenyl-Δ^2-oxazoline from β-bromoethyl benzamide and alkali

I





II

Δ^2-Oxazoline is a colorless, mobile liquid which boils at 98° under atmospheric pressure and has a specific gravity of 1.075^{20}_{20}. Its odor is sweetish and somewhat pyridine-like, resembling that of the next higher 2-alkyl homologs. It is miscible with water, ethanol and ether; the aqueous solution reacts alkaline to phenolphthalein. It is less stable than the higher homologs. Boiling water hydrolyzes it to ethanol formamide. Anhydrous hydrogen chloride (in ether) forms an unstable hydrochloride which rearranges quickly to β-chloroethyl formamide, a characteristic reaction which it shares with the higher 2-alkyl homologs. Metallic sodium reacts with formation of sodium cyanide as one of the products. A picrate could not be obtained.

2,2′-Δ^2-Dioxazoline, on the other hand, is a stable, well crystallized compound. It dissolves in water with neutral reaction and forms a stable picrate. With dry hydrogen chloride it regenerates *s*-β,β′-dichlorodiethyl oxamide.

Experimental

β-Chloroethyl Formamide.—Due to its instability, this compound was not obtained in pure form. One hundred twenty-five grams of thionyl chloride was dropped into 89 g. of ethanol formamide with cooling; the charge was then heated on the water-bath for fifteen minutes and subjected to vacuum distillation. Forty-eight grams distilled between 130–155° (20 mm.); the residue then began to decompose. The distillate contained 25.0% of chlorine (theory 32.8%). Slow decomposition took place during the whole operation and made the maintenance of an adequate vacuum difficult. For the same reason, attempts at fractionating the first distillate with the aid of a column were unsuccessful. A second distillation gave 10 g. of material boiling between 137 and 140° (20 mm.) and having 28.5% chlorine; a third distillation gave 6 g. boiling at 137–138° (20 mm.) with 29.4% chlorine. The distillates represented colorless, odorless liquids miscible with water and with ethanol. Experiments in which a larger excess of thionyl chloride was used, gave smaller yields and showed an increased rate of decomposition.

The large amount of non-volatile residue apparently was caused by cleavage of β-chloroethyl formamide into carbon monoxide and β-chloroethylamine; the latter is protected by the dissolved hydrogen chloride from immediate decomposition. This explanation was supported by the following experiments. (a) Sodium hydroxide produced in a concentrated aqueous solution of the residue a liquid base which boiled up and decomposed after short standing; β-chloroethylamine shows the same spontaneous decomposition. (b) In a more dilute solution of the residue alkali produced ethylene-imine: 40 g. of residue was dissolved in a solution of 40 g. of sodium hydroxide in 350 g. of water; the clear solution was distilled, the first 20 cc. of distillate was carefully saturated, and then covered with dry sodium hydroxide, followed by distillation from a boiling water-bath. Two and two-tenths grams of ethylene-imine distilled over and was identified by its boiling point (56°).

Δ^2-Oxazoline.—Fifty-four grams of β-chloroethyl formamide, once distilled, was added to 150 g. of 50% potassium hydroxide contained in a 500-cc. distilling flask over a period of ten minutes. The mixture was shaken frequently and a temperature of 15–18° was maintained by external cooling with ice. Shaking was continued for about five minutes longer; by this time the crude oxazoline base had separated as an oily layer above the alkaline liquid. The flask was now connected with a condenser tube reaching into the bulb of a 250-cc. distilling flask; the latter was surrounded by ice. The base was distilled under a vacuum of 15 mm. from a water-bath heated to 45°. To the distillate, amounting to 25 g., 60 g. of dry potassium hydroxide was added under constant cooling with ice; the first additions had to be made in very small portions, since violent decomposition, due to overheating, occurred during one experiment at this stage. The charge was distilled *in vacuo* as before and the distillate (15 g.), which was already practically anhydrous and gave the correct nitrogen value, was covered again with 60 g. of potassium hydroxide and distilled *in vacuo*, giving 14 g. of the pure base.

Anal. Calcd. for C_3H_5NO: N, 19.7. Found: N, 19.6.

Reactions of Δ^2-Oxazoline. A. Boiling Point.—Two grams of oxazoline, heated in a test-tube over a free flame, boiled without decomposition at 98°. At the end of five minutes, the boiling point was unchanged.

---

[1] Wenker, THIS JOURNAL, **57**, 1080 (1935).

[2] French Patent 638,023 (1928).

[3] Gabriel and Heymann, *Ber.*, **23**, 2493 (1890).

B. Hydrolysis with Water.—Three grams of base and 3 g. of water was heated in a test-tube. Boiling began at 94° and continued, after removing the flame, for five minutes, while the temperature rose to 108°. The colorless liquid, which still smelled of oxazoline, was heated for thirty minutes more in the boiling water-bath and then dried *in vacuo* at 100°. A colorless, odorless oil remained which contained 14.9% nitrogen as compared with 15.7% calculated for ethanol formamide. A part of the oil was heated to 100° in oxalic acid solution for one hour; ethanol now precipitated the characteristic alcohol-insoluble ethanolamine oxalate.

C. Reaction with Hydrogen Chloride.—To 3 g. of oxazoline dissolved in 10 g. of ether, 15 g. of a 10% ethereal solution of hydrogen chloride was added with ice cooling. A white crystalline powder separated at once which at room temperature soon melted to a clear colorless liquid. After removing the ether and excess of hydrogen chloride *in vacuo* at 100°, the product contained 32.1% of chlorine; calculated for β-chloroethyl formamide, 32.8%.

D. Reaction with Sodium.—A piece of sodium in 1 g. of oxazoline caused a violent reaction with evolution of gas. The residue, a yellow amorphous mass, gave a precipitate of prussian blue by the usual test for cyanides.

E. Picrate.—The alcoholic solution of the base remained clear with picric acid. Ether precipitated an oil which did not crystallize.

***s*-β,β-Dichlorodiethyl Oxamide.**—Twenty grams of *s*-diethanol oxamide,[4] 100 g. of toluene and 42 g. of thionyl chloride was heated for thirty minutes to 60°, then for ninety minutes in a boiling water-bath. Without first dissolving, the diethanol oxamide changed to a thick white crystal sludge. After cooling, the crystals were filtered, washed subsequently with ethanol, boiling water, ethanol, and crystallized from 200 g. of boiling "cellosolve" (ethylene glycol monoethyl ether). The yield was 19 g. or 78%. The product forms white needles, insoluble in water, sparingly in hot ethanol, which melt at 203°.

Anal. Calcd. for $C_6H_{10}N_2O_2Cl_2$: Cl, 33.3. Found: Cl, 33.1.

2,2′-Δ^2-Dioxazoline.—Ten and six-tenths grams of the preceding compound in 100 cc. of *N* methyl alcoholic potassium hydroxide was boiled for one hour, the clear solution filtered from potassium chloride, evaporated on the water-bath and the crystalline residue recrystallized from 100 g. of toluene. The yield was 5.9 g. or 84%. 2,2′-Δ^2-Dioxazoline crystallizes from toluene in white, fern-like aggregates which melt at 213°. It is very soluble in water and in ethanol, almost insoluble in ether and in cold toluene.

Anal. Calcd. for $C_6H_8N_2O_2$: N, 20.0. Found: N, 19.9.

Reaction with Hydrogen Chloride.—One and four-tenths grams of dioxazoline was dissolved in methanol and 10 g. of a 10% solution of hydrogen chloride in ether was added. White crystals separated and were identified, after crystallization from "cellosolve," by melting point and mixed melting point (203°) as *s*-β,β-dichlorodiethyl oxamide.

Picrate.—Thirty-five hundredths of a gram of dioxazoline and 1.3 g. of picric acid both dissolved in hot ethanol gave a sparingly soluble picrate which crystallized in long needles and melted at 182°.

Summary

Thionyl chloride reacts with ethanol formamide and with *s*-diethanol oxamide with formation of β-chloroethyl formamide and of *s*-β,β-dichlorodiethyl oxamide. With alkali, the latter two compounds yield Δ^2-oxazoline and 2,2′-Δ^2-dioxazoline, respectively. Some characteristic reactions of the two oxazolines are described.

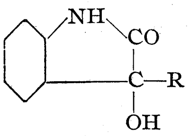
Reactions of Grignard Reagents with Isatin and N-Alkyl Isatins[1]

BY FREDERICK J. MYERS[2] AND H. G. LINDWALL

The reactions of several Grignard reagents with isatin and N-methylisatin have been reported by Kohn.[3] With isatin the Grignard reagents yield the respective 3-alkyl(or aryl)-3-hydroxy-oxindoles, as would be anticipated. These products have the general formula



I

Kohn prepared the 3-methyl, 3-phenyl and 3-benzyl derivatives of I, but did not investigate the chemical characteristics of these compounds.

Structure I suggested the possibility of the preparation of 3-alkylidene oxindoles through the action of dehydrating agents; using 3-benzyl-3-hydroxyoxindole as the representative of the group, various methods of dehydration were attempted, but without success. In most cases, the compound was recovered unchanged, or, under extremely strenuous conditions, suffered changes more complex than the simple splitting off of a molecule of water.

Kohn[4] also studied the action of phenylmagne-

---

[1] Presented in part at the Rochester meeting of the American Chemical Society, September, 1937.

[2] Present address: c/o Röhm and Haas Co., Bridesburg, Penna.

[3] Kohn and Ostersetzer, *Monatsh.*, **32**, 905 (1911); Kohn, *ibid.*, **31**, 747 (1910).

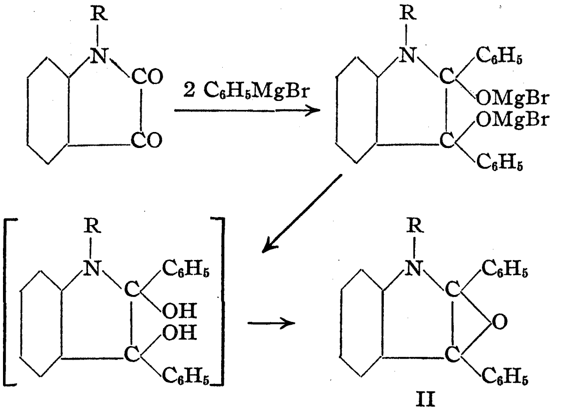
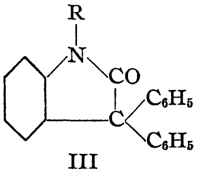
sium bromide upon N-methylisatin, and reported a single compound, 2,3-diphenyl-1-methylindole-oxide-2,3 (II), as the product. He postulated the mechanism



II

The reaction has been repeated; the product isolated was found to melt at 140–143°, which was in close agreement with the melting point (145°) reported for II by Kohn. However, upon repeated recrystallization of the product from dilute ethyl alcohol, it soon became apparent that two compounds were present; one (II) melting at 137.5–138.5°, was yellow and, as reported by Kohn for II, gave a marked fluorescence in solution, and the other (III) was almost white, melted at 171–171.5°, and gave no fluorescent effect in solution. Compound II was obtained as plates, while III was in the form of needles. The longer the period of time of exposure of the original Grignard complex to the hydrolytic agent (sulfuric acid), the larger was the relative amount of III obtained. Analyses showed II and III to be isomeric.

The oxide ring structure assigned by Kohn to II suggested that III might be a rearrangement product of II, and that III was possibly N-methyl-3,3-diphenyloxindole. Synthesis proved this structure for III to be correct. Inagaki's[5] method of preparation of 3,3-diphenyloxindole by the action of benzene upon 3,3-dichlorooöxindole in the presence of aluminum chloride was applied, substituting N-methyl-3,3-dichlorooöxindole. This Friedel–Crafts reaction proceeded smoothly, and yielded III.



III

Furthermore, phenylmagnesium bromide and N-ethylisatin were found to yield two products (IV and V) paralleling II and III. The higher melting compound (V) was shown, by synthesis as above, to be N-ethyl-3,3-diphenyloxindole, and compound IV was similar to II in general characteristics.

Experimental Part

2,3-Diphenyl-1-methylindole-oxide-2,3 (II).—Powdered N-methylisatin (0.05 mole) was added slowly, over the period of one hour, to a boiling solution of phenylmagnesium bromide (0.25 mole) in 150 cc. of ether and 150 cc. of benzene. After addition the mixture was kept at its boiling point with vigorous stirring for one-half hour, and then was poured into an ice and concd. sulfuric acid mixture. After standing overnight, 52% of crude product had separated; the residual liquid mixture was set aside for one week, in the course of which time further solid product appeared (see below).

The crude product, which had separated after overnight standing of the hydrolytic mixture, was obtained as a crystalline mass, green in tint, soluble in dilute ethyl alcohol, dilute methyl alcohol, and dilute acetic acid; thin plates from dilute ethyl alcohol, m. p. 140–143° (Kohn and Ostersetzer report 145°).

Repeated recrystallizations finally yielded II in purer form as thin plates, m. p. 137.5–138.5°, and showing a marked fluorescence in solution. Also (see below), another product (III) was isolated which differed from II in crystal form and did not show fluorescence in solution.

Anal. Calcd. for $C_{21}H_{17}ON$: N, 4.68. Found: N, 4.71, 4.80.

3,3-Diphenyl-1-methyloxindole (III). By the Action of Phenylmagnesium Bromide upon N-Methylisatin.—Repeated recrystallization of II (above) yielded small amounts of III, though not in very pure form (m. p. 167–168°). The residual hydrolytic mixture (see above for II), after removal of crude II and after one week of standing at room temperature, yielded a sample of III, which was easily purified by crystallization from aqueous alcohol; m. p. 171–171.5°; short stubby needles, showing no fluorescence in solution.

Anal. Calcd. for $C_{21}H_{17}ON$: N, 4.68. Found: N, 4.92, 4.52.

Compound III. By the Friedel–Crafts Reaction.—Powdered anhydrous aluminum chloride (0.0125 mole) was added slowly to 3,3-dichloro-1-methyloxindole (0.005 mole) in 20 cc. of absolute benzene, and the mixture was then heated at 50° for four hours. After removing the benzene by distillation under diminished pressure, the residue was treated with ice and dilute hydrochloric acid. A gummy mass resulted which was extracted with dilute methyl alcohol; the extract was decolorized with charcoal and cooled and the product (III) separated as white needles from methyl alcohol, m. p. 171–171.5°. Melting point methods showed samples of III to be identical with that obtained from the Grignard reaction.

2,3-Diphenyl-1-ethylindole-oxide-2,3 (IV).—N-Ethylisatin and phenylmagnesium bromide were allowed to react

---

[5] Inagaki, *J. Pharm. Soc. Japan*, **53**, 686 (1933).

following a procedure similar to that shown above for II. After hydrolytic treatment in the usual manner, the crystalline material that had formed in two hours was removed and purified by recrystallization from dilute methyl alcohol to which a little acetic acid had been added. Compound IV was thus obtained as short diamond-shaped crystals, greenish-yellow in color, and showing greenish fluorescence in solution; m. p. 116–117°; yield, 56%. The residual benzene–ether solution, from which the crude IV was obtained originally after the hydrolysis of the Grignard complex, was set aside for ten days, after which time compound V was isolated (see below).

Anal. Calcd. for $C_{22}H_{19}ON$: N, 4.47. Found: N, 4.29.

3,3-Diphenyl-1-ethyloxindole (V). By the Action of Phenylmagnesium Bromide upon N-Ethylisatin.—The residual benzene–ether solution, from which IV had separated (see above), was allowed to stand for ten days and then was concentrated by distillation. Compound V, yield 16%, separated and was purified by crystallization from dilute methyl alcohol; long white needles, m. p. 156–157°, giving no fluorescence in solution.

Anal. Calcd. for $C_{22}H_{19}ON$: N, 4.47. Found: N, 4.40.

Compound V. By the Friedel–Crafts Reaction.—Compound V was prepared by the reaction of benzene with 3,3-dichloro-1-ethyloxindole, as for III. The product was identical with the V obtained from the Grignard reaction in melting point and physical characteristics. A mixture of samples from the two sources showed no depression of the melting point.

Summary

3,3-Diphenyl-1-methyloxindole and 3,3-diphenyl-1-ethyloxindole accompany the respective 2,3-diphenyl-1-alkylindole-oxide-2,3 as products of the reaction of phenylmagnesium bromide with N-methylisatin and N-ethylisatin.

Friedel–Crafts Reactions on *m*-Diphenylbenzene[1]

BY H. GAINES GOODMAN, JR., AND ALEXANDER LOWY

In the process for the preparation of biphenyl from benzene, considerable amounts of high boiling products are produced. *m*-Diphenylbenzene is one of the constituents of this high boiling material. Wardner and Lowy[2] have reported references to the literature concerned with the preparation of this hydrocarbon and its derivatives up to 1932. Since then the additional articles[3] listed have dealt with the subject.

Because a search of the literature has revealed that no attempt has been made previously to apply the Friedel–Crafts type of reaction to *m*-diphenylbenzene, a study was undertaken, with the object of synthesizing and identifying several new compounds of the ketonic types, prepared by the action of acyl halides and anhydrides on *m*-diphenylbenzene in the presence of anhydrous aluminum chloride.

The Friedel–Crafts reaction needs no discussion here since it is covered admirably by several comprehensive reviews.[4]

The structure of the *m*-diphenylbenzene molecule is such that six theoretical monosubstitution products are possible. It was desirable, therefore, to determine the position of attack in the case of each reactant, and, in order to accomplish this, an oxidation of each acylation product was carried out and a study of the oxidation products made. The oxidation products isolated indicated that, in each reaction, the para position of an end ring had been attacked, except in the case of *m*-diphenylbenzene-phthaloylic acid,[5] the exact structure of which was not determined. This was in agreement with numerous examples contained in the literature, which indicated the para position of a substituted benzene ring to be the one generally attacked in the Friedel–Crafts syntheses.

Experimental

The writers are indebted to Mr. R. E. Bowman, of Wilmington, Delaware, who is investigating the high boiling material furnished by the Monsanto Chemical Co., for a generous supply of *m*-diphenylbenzene. The *m*-diphenylbenzene thus obtained was recrystallized twice from ethyl alcohol, producing white needle-shaped crystals, m. p. 85°. Redissolving these crystals in boiling ethanol, and filtering after cooling to 70°, resulted in the

separation from the cooled filtrate of crystals melting at 87°.

The apparatus described by Riddell and Noller[6] was used throughout the investigation.

In general, the procedures followed throughout the investigation were essentially the same, as is exemplified in the method used in the first experiment, described completely herewith.

Preparation and Identification of *p*-Acetyl-*m*-diphenylbenzene.—To a solution of 30 g. (0.13 mole) of *m*-diphenylbenzene in 100 cc. of nitrobenzene, a solution of 20.7 g. (0.15 mole) of anhydrous aluminum chloride in 100 cc. of nitrobenzene was added and mixed thoroughly. With the above mixture at 28°, 10.2 g. (0.13 mole) of acetyl chloride was added dropwise from the dropping funnel, stirring continuously. A vigorous evolution of hydrochloric acid gas continued for thirty minutes. Then the temperature was raised to 45° and held for five hours. The charge was hydrolyzed by the addition of ice, and the nitrobenzene layer separated and washed thoroughly with water. The nitrobenzene was removed by steam distillation and the resulting crude product dissolved in acetone and filtered. The acetone was then removed by evaporation and the residue subjected to a vacuum distillation. The distillate which passed over from 232 to 246° at 1 mm. pressure was further purified by three recrystallizations from ethanol, whereupon 10 g. of white *p*-acetyl-*m*-diphenylbenzene, melting at 104°, was obtained.

This compound was also produced by the use of acetic anhydride instead of acetyl chloride under the conditions given for experiment 2, Table I. Isolation of the reaction product was accomplished by the method described above.

One gram of *p*-acetyl-*m*-diphenylbenzene was refluxed for five hours with 5 g. of chromic anhydride and 40 cc. of glacial acetic acid. The charge was then poured into ice water, and the precipitated acid filtered and washed thoroughly with distilled water. The free acid was then dissolved in a small amount of 10% sodium hydroxide solution and filtered through asbestos. The filtrate was acidified with concentrated hydrochloric acid to reprecipitate the free acid which was washed thoroughly with distilled water and dried. The acid thus obtained was identified as terephthalic acid by conversion to dimethyl terephthalate, m. p. 140°, thus indicating that acylation had taken place in the para position of *m*-diphenylbenzene.

The essential data concerning each preparation are given in Table I. In this table the conditions are described by giving the initial and final temperatures, followed in parentheses by the duration of each temperature in hours. In each experiment the inert solvent was removed from the crude product by steam distillation. In Experiment 3, *p*-acetyl-*m*-diphenylbenzene, the product of Experiment 1, was used instead of *m*-diphenylbenzene in order to produce *p,p'*-diacetyl-*m*-diphenylbenzene. All efforts to produce this material from *m*-diphenylbenzene failed. After removal of the solvent, the crude product was extracted with ethyl ether and the residue recrystallized. This procedure also was used in working up the crude product of Experiment 4. In Experiment 5, after completion of the reaction, the inert solvent, carbon bisulfide, was decanted from the insoluble complex compound, which was then hydrolyzed, steam distilled to remove any residual carbon bisulfide, and the crude product extracted twice with 100 cc. of boiling ethanol. Upon cooling these extracts, crystals were deposited which were recrystallized from small amounts of ethanol. Benzenesulfonyl chloride was found to react very sluggishly upon *m*-diphenylbenzene if an inert solvent was used. In Experiment 6, therefore, the hydrocarbon and reactant were mixed, raised to 50°, and the aluminum chloride added in small increments. After hydrolysis, the crude product was boiled successively with several large portions of water to remove any remaining benzenesulfonyl chloride. The residue was then recrystallized from large quantities of ethanol. The procedure used in isolating the product of Experiment 7 differed so markedly from the others that it is given in detail, thus. The charge was hydrolyzed by pouring into a mixture of crushed ice containing 10% of concentrated hydrochloric acid. After hydrolysis, the solvent layer was separated and washed thoroughly to remove all the mineral acid, and the *o*-dichlorobenzene removed by steam distillation. The crude product was separated and boiled with 350 cc. of 10% sulfuric acid to remove any residual aluminum salts, and finally with several successive portions of water to remove any residual sulfuric acid and phthalic acid. The remaining solid matter was dissolved in 500 cc. of water containing 50 cc. of concentrated ammonium hydroxide, a small amount of boneblack added, and the solution boiled for one hour. After cooling, the boneblack and any insoluble hydrocarbon or phthalides were filtered off. The carboxylic acid was then reprecipitated by the addition of concentrated hydrochloric acid. After removal by filtration and washing to remove any residual hydrochloric acid or soluble chlorides, this product, 35.5 g., was dried over concentrated sulfuric acid, under reduced pressure. All efforts to purify this product by crystallization were futile. It is very soluble in methanol, ethanol, benzene, toluene,

Ring Closure of *m*-Diphenylbenzene-phthaloylic Acid.—Several experiments were performed with the idea of determining the susceptibility of *m*-diphenylbenzene-phthaloylic acid to ring closure, to form a substituted anthraquinone type. Of the five dehydrating agents used, acetic anhydride, anhydrous aluminum chloride, anhydrous ferric chloride, phosphorus pentoxide, and sulfuric acid, positive results were obtained only by the use of the last named reagent, when heated at 136°. Sulfonation, however, was shown to occur simultaneously. The resulting product was water soluble and when treated with zinc dust and 10% sodium hydroxide solution produced a deep red color, which disappeared upon blowing air through the solution.

***m*-Diphenylbenzene-*p*-carboxylic Acid.**—The method of oxidation described below is based upon that described by Bogert and Hasselström[8] for the preparation of retene-α-carboxylic acid from acetylretene.

One gram of *p*-acetyl-*m*-diphenylbenzene was dissolved in 50 cc. of hot methanol and, with stirring, 15 cc. of a strong sodium hypochlorite solution was added drop by drop. Stirring was continued for one hour. The formed suspension of white solid in methanol was poured into ice water and heated until the solid material had dissolved, filtered hot, and allowed to cool. The solid which crystallized was filtered and boiled with water to which sufficient hydrochloric acid had been added to convert the sodium salt to the free acid. This was cooled, filtered, and the residue washed thoroughly with water. The crude product, 0.9 g., was then recrystallized twice from benzene, after which 0.4 g. of white *m*-diphenylbenzene-*p*-carboxylic acid, melting at 221°, was obtained.

Anal. Calcd. for $C_{19}H_{14}O_2$: C, 83.21; H, 5.11; neut. equiv., 274. Found: C, 82.78, 83.03; H, 5.21, 5.26; neut. equiv., 274, 267.

The sodium salt is very insoluble in cold water, soluble in hot water.

Summary

1. The following hitherto undescribed compounds were prepared by means of the Friedel–Crafts synthesis, using *m*-diphenylbenzene as the hydrocarbon: (a) *p*-acetyl-*m*-diphenylbenzene, which was converted to *m*-diphenylbenzene-*p*-carboxylic acid; (b) *p,p'*-diacetyl-*m*-diphenylbenzene; (c) *p*-benzoyl-*m*-diphenylbenzene; (d) *p,p'*-di-(-ω-chloroacetyl)-*m*-diphenylbenzene; (e) *p*-(benzenesulfonyl)-*m*-diphenylbenzene; and (f) *m*-diphenylbenzene-phthaloylic acid.

2. Oxidation experiments upon (a), (b), (c), (d), and (e) yielded products which indicated that, in each case, the substitution had taken place in the para position of an end ring of the *m*-diphenylbenzene molecule. The structure of *m*-diphenylbenzene-*p*-carboxylic acid follows from its synthesis from (a) by oxidation. Most likely (f) is a mixture of two or more isomeric keto acids.

3. Attempts to form a substituted anthraquinone type by ring closure of (f) indicated that, of the five dehydrating agents tried, sulfuric acid alone gave positive results. Sulfonation, however, occurred simultaneously.

Structure of Gossypol. V.[1] Anilino Derivatives

BY ROGER ADAMS, C. C. PRICE AND W. R. DIAL[2]

Gossypol reacts readily with two molecules of aniline;[3] two molecules of water are eliminated and dianilinogossypol is formed. This product is purified easily, and as a consequence aniline has actually been used for the extraction of gossypol.[3]

The formation of this compound has led to the deduction that two keto groups are present in the gossypol structure. However, in a previous paper from this Laboratory it was pointed out that certain vinyl alcohol groups condense equally well with aniline with the elimination of water. There is reason for believing that gossypol contains groupings of this type.

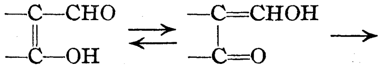
Anhydrogossypol reacts with aniline to give dianilinogossypol quantitatively; moreover, liquid ammonia reacts with gossypol or anhydrogossypol to give diaminogossypol. Both diaminogossypol and dianilinogossypol hydrolyze with unusual ease to give gossypol.

Substituted anilines have now been combined with gossypol. Some of them condense in a manner similar to aniline, β-naphthylamine and *o*-phenylenediamine. The derivative of *o*-phenylenediamine is of particular interest. Karrer and Tobler[4] reported the condensation product of gossypol and *o*-phenylenediamine as consisting of one molecule of gossypol and one of diamine with the loss of two molecules of water. From this they concluded that an *o*-quinone or 1,2-diketone might be present in the parent molecule. All the reliable reactions thus far described and many yet unpublished have conformed to the point of view of a symmetrical molecule for gossypol. An even number of molecules of reagent condense. It is not impossible that two ketone groups are adjacent and are symmetrically located in the molecule but as this seemed unlikely the condensation with *o*-phenylenediamine has been studied again. It has now been established that *o*-phenylenediamine when used in molecular amounts with gossypol gives a non-homogeneous product which agrees in properties with that reported by the above-mentioned authors. On the other hand, if two or more molecules of *o*-phenylenediamine are used, a readily purified, nicely crystalline compound is isolated in quantitative yield which consists of two molecules of *o*-phenylenediamine and one of gossypol with the elimination of two molecules of water. The presence of a 1,2-diketone grouping in gossypol, therefore, appears improbable.

Other substituted anilines condense readily with gossypol. However, in many cases (*o*-, *m*-, and *p*-toluidine, *p*-anisidine, *p*-chloroaniline) the analyses of the products do not conform to a simple derivative similar to the dianilinogossypol. They are more difficult to purify and it appears in some cases that an additional molecule of aniline is present in the product or that an oxygen has entered simultaneously. These compounds, however, all hydrolyze to gossypol. Similarly, the acetates of all but the dianilino compound are difficult to purify and give variable analyses.

Dianilinogossypol acetylates to a hexaacetyl derivative. Pyrolysis of this compound gives acetanilide and as a consequence it seems likely that two acetyls are attached to nitrogen atoms which would be possible only if the dianilinogossypol were so constituted that hydrogens were present on the nitrogen atoms.

Dianilinogossypol also can be methylated. Under certain conditions, a crystalline dimethyldianilinogossypol is sometimes produced. This substance is deep red. It has the methyl groups on the two nitrogens, if the fact that the Zeisel number of the derivatives is almost zero may be used as experimental evidence. Moreover, the compound cannot be hydrolyzed to gossypol under the conditions used for dianilinogossypol. These data and those on the acetylation product make it appear probable that the dianilino compound is tautomeric. The original dianilinogossypol which is yellow possibly may be a Schiff base which upon methylation is converted into a red N-methyl derivative of the hydroxymethylene type. These reactions may be explained by the presence of the following groupings



$$\begin{array}{l}\text{—C—CHO}\\ \ \ \|\\ \text{—C—OH}\end{array} \rightleftarrows \begin{array}{l}\text{—C=CHOH}\\ \ \ |\\ \text{—C=O}\end{array} \longrightarrow$$

---

$$\begin{array}{l} —C—CH{=}NC_6H_5 \\ \quad \| \\ —C—OH \end{array} \rightleftarrows \begin{array}{l} —C{=}CHNHC_6H_5 \\ \quad | \\ —C{=}O \end{array} \downarrow \begin{array}{l} —C{=}CH—N(CH_3)C_6H_5 \\ \quad | \\ —C{=}O \end{array}$$

Under slightly modified conditions of methylation, a crystalline dimethyldianilinooxogossypol is readily formed in which it appears that an atom of oxygen has replaced two hydrogens in dimethyldianilinogossypol or possibly merely an atom of oxygen was added. The compound does not hydrolyze to gossypol under the usual conditions. Its structure has not yet been investigated.

Experimental

Dianilinogossypol.—This compound previously described by Carruth[3] and by Clark[5] was prepared by dissolving crude gossypol-acetic acid in ten times its weight of boiling aniline. The orange crystals which separated on cooling were collected and washed thoroughly with ether. It was purified from chloroform–petroleum ether and yielded yellow-orange plates, m. p. 303°, with decomposition.

For hydrolysis, it was dissolved in concentrated sulfuric acid, the solution allowed to heat to 90° on a hot-plate (about two to two and one-half minutes), poured onto ice, filtered, and dried. The product was dissolved in hot glacial acetic acid and water was added dropwise to the boiling solution until crystals started to appear. The solution on cooling deposited gossypol-acetic acid which was usually in practically a pure state as golden platelets.

Dianilinogossypol, when heated on the steam cone for thirty minutes in 40% aqueous alkali, followed by methylation with dimethyl sulfate, gave a 60% yield of apogossypol hexamethyl ether.

By Zeisel methoxyl determination, gossypol is reported to give about 5% methoxyl. A repetition of this determination using a commercial grade of 47% hydriodic acid containing a small amount of preservative (1.5% H_3PO_2) gave less than 0.2% methoxyl. Dianilinogossypol also showed less than 0.2% methoxyl.

Hexaacetyldianilinogossypol.—A solution of 0.5 g. of dianilinogossypol in 10 cc. of pyridine and 5 cc. of acetic anhydride was warmed on a steam-cone for thirty minutes. About 10 cc. of acetic acid was added and the reaction mixture was poured into water. A bright yellow product separated which was purified by crystallization from methanol, m. p. 185°, decomposing vigorously without discoloration at 220°.

Anal. Calcd. for $C_{54}H_{52}N_2O_{12}$: C, 70.40; H, 5.70; N, 3.04; acetyl, 28.0. Found: C, 69.94; H, 5.82; N, 2.89; acetyl, 28.4.

The heat decomposition of this compound led to the isolation of a white crystalline compound, m. p. 112°, which sublimed in the cooler portions of the pyrolysis tube. It proved to be acetanilide. It may thus be deduced that two acetyl groups are probably attached to nitrogens in the starting material.

By hydrolysis with concentrated sulfuric acid, gossypol was recovered. The initial color in the acid is yellow which turns to olive-green in thirty seconds and to scarlet on addition of a drop or two of water.

Di-*o*-phenylenediaminogossypol.—A mixture of 2.5 moles of *o*-phenylenediamine and one of pure gossypol-acetic acid in chloroform solution was refluxed for thirty minutes. On cooling the solution, the product separated as orange crystals. It was recrystallized from chloroform, m. p. 246°.

Anal. Calcd. for $C_{42}H_{42}N_4O_6$: C, 72.13; H, 6.06; N, 8.02. Found: C, 72.01, 71.92; H, 5.84, 6.08; N, 8.18, 7.99.

By the use of one molecule of *o*-phenylenediamine, a non-crystalline substance was obtained which had properties similar to that reported by Karrer and Tobler.[4] An excess of diamine, however, readily converted it to the product reported above.

In the preparation of the di-*o*-phenylenediamine derivative, a product melting at 184° sometimes was obtained. This product, however, on drying and long standing acquires the higher melting point mentioned above.

Di-β-naphthylaminogossypol.—It formed bright orange crystals from chloroform, m. p. 310–313° with decomposition. It hydrolyzed to gossypol with sulfuric acid.

Anal. Calcd. for $C_{50}H_{44}N_2O_6$: C, 78.09; H, 5.97; N, 3.65. Found: C, 77.95; H, 5.78; N, 3.69.

The preparation of similar compounds was attempted from gossypol and *o*-, *m*-, and *p*-toluidine, *p*-chloroaniline and *p*-anisidine. In all these cases, crystalline products were obtained, more difficult to purify than the ones previously described. Analyses did not check the calculated values. In some cases, the analyses indicated that normal condensation took place and an additional molecule of the amine had added. In other cases, addition of one atom of oxygen to the condensation product of two molecules of amine agreed most satisfactorily. All these compounds, however, were hydrolyzed to gossypol. The acetyl derivatives were difficult to purify and did not give the expected values on analysis.

Dimethyldianilinooxogossypol.—To a solution of 1 g. of dianilinogossypol in 100 cc. of chloroform, were added 10 cc. of dimethyl sulfate and 6 cc. of pyridine in portions with shaking. The reaction mixture did not change color but separated into two phases in a few minutes. After standing at room temperature for five days to a week, 15 cc. of pyridine was added to decompose the excess dimethyl sulfate. The chloroform solution was washed twice with water, dried over sodium sulfate, and evaporated. It was purified by recrystallization from benzene as red microcrystals, m. p. 275–280°. It gave a brown color in concentrated sulfuric acid which turned red on standing for five to ten minutes.

Anal. Calcd. for $C_{44}H_{42}N_2O_7$: C, 74.33; H, 5.95; N, 3.94; OCH_3, 8.74. Found: C, 74.22, 74.46; H, 5.96, 5.82; N, 4.00, 3.99; OCH_3, 1.45.

The compound was recovered unchanged after eighteen hours in concentrated sulfuric acid by pouring on ice and recrystallizing from benzene–methanol. The resistance to

---

(5) Clark, *J. Biol. Chem.*, **75**, 725 (1927).

hydrolysis, as well as the low Zeisel number, indicates that the methyl groups are probably attached to nitrogens.

Dimethyldianilinogossypol.—By a similar procedure to the preparation of the oxo compound but refluxing overnight rather than allowing the reaction mixture to stand at room temperature resulted in a methylated but unoxidized product. It was purified from benzene and formed red crystals, m. p. 253–258°. It gave a dark red-brown color in sulfuric acid.

Anal. Calcd. for $C_{44}H_{42}N_2O_6$: C, 75.83; H, 6.36; N, 4.02; OCH_3, 8.89. Found: C, 75.70; H, 6.11; N, 4.09; OCH_3, 1.01.

Concentrated sulfuric acid does not hydrolyze this product. This and the low Zeisel number indicate the probability that the methyls are attached to nitrogen.

Summary

Gossypol condenses with β-naphthylamine or *o*-phenylenediamine in the same way as with aniline. Two molecules of amine react and two moles of water are eliminated.

Several other aniline derivatives gave products which did not analyze for simple condensation products. All of these hydrolyzed with sulfuric acid to give gossypol.

Dianilinogossypol can be acetylated to a hexaacetate. Two acetyls are attached to nitrogen. Methylation gives sometimes a dimethyldianilinogossypol or more commonly a dimethyldianilinooxogossypol.

It is deduced that there exist in gossypol two of the tautomeric residues

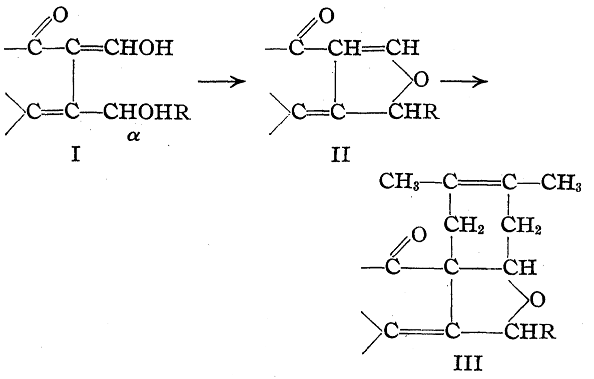
Structure of Gossypol. VI.[1] Addition Products with Butadienes

BY ROGER ADAMS, B. S. FRIEDMAN, C. C. PRICE, R. C. MORRIS AND E. C. KIRKPATRICK[2]

From a study of anhydrogossypol[3] and its reaction products and of the diamino- and dianilinogossypols[1] it was deduced that gossypol contains two similar groupings which are probably vinyl alcohols. Since the most common type of relatively stable vinyl alcohols possesses a carbonyl in place of one of the hydrogens of the methylene group $\left(-\overset{\displaystyle O}{\overset{\|}{C}}-CH=CHOH\right)$, the possibility of two such residues in gossypol has now been studied. The reaction used for this purpose was the Diels–Alder and the reagent, 2,3-dimethylbutadiene.

Gossypol condenses very readily in alcohol solution with the addition of two molecules of dimethylbutadiene and elimination of two molecules of water to give a beautifully crystalline product. In a similar way, anhydrogossypol or diaminogossypol in benzene condenses with two molecules of dimethylbutadiene to give the same derivative.

In the case of gossypol, the reaction involves the elimination of water; in the case of diaminogossypol the loss of ammonia; in the case of anhydrogossypol, however, the same derivative is formed by simple addition. Since anhydrogossypol adds the diene, it is a safe conclusion that the molecule probably contains α,β-unsaturated carbonyl linkages. The addition product, unlike anhydrogossypol itself, is not hydrolyzed. Consequently, the easily-opened oxygen ring which was postulated previously as being present in anhydrogossypol, must have been stabilized. This is no doubt due to the fact that the carbon–carbon double bond to which the diene adds is part of the oxygen-containing ring of the anhydrogossypol. Suggested nuclei which will account for the changes follow: gossypol (I), anhydrogossypol (II), dimethylbutadiene addition product (III).



It is probable that gossypol and diaminogossypol

---

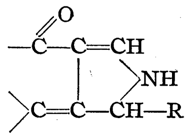
(3) Miller and Adams, THIS JOURNAL, **59**, 1736 (1937).

first lose water and ammonia, respectively, and then the diene adds to the anhydrogossypol formed.

The nucleus II accounts for the ease with which anhydrogossypol is hydrolyzed to gossypol, methylated or acetylated to gossypol hexamethyl ether or gossypol hexaacetate and converted by ammonia or aniline to the corresponding gossypol derivatives. Nucleus III indicates why the addition product is stable to hydrolysis as it no longer contains an easily-opened oxygen ring.

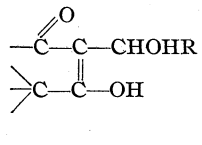
The dimethylbutadiene anhydrogossypol product is soluble in alkali and contains two acidic hydroxyls which are readily acetylated or methylated to form stable crystalline derivatives. It also gives a red color with pyroboroacetate, indicative of a phenol group *ortho* or *peri* to a carbonyl.

Still further deductions concerning the oxygen-containing ring formation when gossypol is converted to anhydrogossypol may be made. Liquid ammonia[3] converts anhydrogossypol to diaminogossypol and not to a molecule containing an imino nitrogen in place of the oxygen of the oxygen-containing ring in anhydrogossypol. It is difficult to believe that the nitrogen compound corresponding to II shown in IV would not be stable if the hydroxyl marked α in formula I were alcoholic in character. On the other hand, if it were phenolic, the non-formation of IV is explicable. For this reason, it is assumed that the oxygen-containing ring in anhydrogossypol is formed by elimination of water between the hydroxyl of an hydroxymethylene group and a phenolic group.

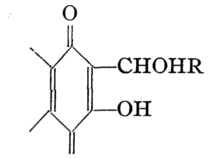


IV

The ease of condensation of anhydrogossypol or gossypol with the diene and the fact that neither gossypol hexamethyl ether nor tetramethyl ether undergoes such a reaction, makes it probable that the hydrogen on the carbon holding the vinyl hydroxyl is unsubstituted. The grouping should therefore be represented preferably by $>C{=}CHOH$ and not by  $>C{=}\overset{R}{\overset{|}{C}}{-}OH$. The ease of the reaction with the diene also tends to nullify the possibility of a structure isomeric with I shown in V and hence eliminates the likelihood of the presence of residues of a quinone-like structure (VI) in the gossypol molecule.



V



VI

The reaction is not limited to dimethylbutadiene. Anhydrogossypol also condenses with 2,3-butadiene to give an analogous product in which two molecules of diene have added, and two acidic hydroxyls remain unaffected. The product apparently is not as stable as the dimethylbutadiene derivative, as it dissociates upon standing in solution. It gives a diacetate similar to the dimethylbutadiene derivative.

From the study of the aniline and ammonia derivatives[1,3] and of the diene addition products, the presence in gossypol of two tautomeric hydroxyaldehyde residues seems fairly well established.

Experimental

The Addition of 2,3-Dimethylbutadiene-1,3 to Gossypol.—To a solution of 1 g. of gossypol in 25 cc. of absolute alcohol was added 1.5 cc. of freshly prepared dimethylbutadiene. The reaction mixture was refluxed for eight hours on the steam-bath, the condenser was then removed and the alcohol allowed to evaporate. After concentrating for a short time, crystals began to separate, the flask was cooled and the precipitate filtered. On further concentration of the mother liquor more product was obtained; yield 0.8 g. The material crystallized from acetone–methanol in bright yellow cubes, m. p. 244–245° with decomposition.

Anal. Calcd. for $C_{42}H_{46}O_6$: C, 78.00; H, 7.12. Found: C, 77.83; H, 7.09.

The crystals gave a bright yellow-brown color in concentrated sulfuric acid. Alcoholic ferric chloride gave a deep red color. Aqueous sodium hydrosulfite solution had no effect on an alcoholic solution of the addition compound. It gave a deep red with pyroboroacetate.

The addition reaction takes place equally well using benzene as the solvent.

The addition product would not condense with aniline. It was unaffected by heating for one-half hour on the steam-bath with 40% aqueous alkali. It decomposed when dissolved in concentrated sulfuric acid and allowed to stand overnight. It did not reduce catalytically with hydrogen and platinum oxide platinum black.

Methylation of the Dimethylbutadiene Addition Product.—To a solution of 0.4 g. of the addition product in 10 cc. of 30% methanolic potassium hydroxide was added an excess of dimethyl sulfate, in portions. When the reaction was complete the solution was made alkaline, diluted with water, and the precipitate filtered and washed. The product was air dried and crystallized from acetone-methanol; bright yellow needles, m. p. 227–229°, yield 0.32 g. It gave a yellow-brown color in concentrated sulfuric acid and gave no color with phenol reagents.

Anal. Calcd. for $C_{44}H_{50}O_6$: C, 78.3; H, 7.42. Found: C, 78.11; H, 7.35.

Acetylation of the Dimethylbutadiene Addition Product.—By heating for a half-hour a mixture of 0.075 g. of addition product, excess of acetic anhydride and sodium acetate, and then pouring into water, 0.065 g. of the acetylated compound was obtained. It crystallized in light yellow plates from acetone–methanol, m. p. 227–229°, and gave a brown color in concentrated sulfuric acid.

Anal. Calcd. for $C_{46}H_{50}O_8$: C, 75.5; H, 6.84. Found: C, 75.22; H, 6.95.

Saponification of this product yielded the original material as shown by melting point and mixed melting point.

The product was not affected by long refluxing (two and one-half hours) with acetic anhydride and sodium acetate.

Condensation of 2,3-Dimethylbutadiene-1,3 with Anhydrogossypol.—To a solution of 0.5 g. of anhydrogossypol in 25 cc. of dry benzene was added 1.5 cc. of freshly prepared dimethylbutadiene. The solution was refluxed overnight on the steam-bath, then evaporated to dryness. The residue was purified by crystallization from acetone–methanol; m. p. 244–245° with decomposition. A mixed melting point with the product from the addition of dimethylbutadiene to gossypol showed no lowering.

Condensation of 2,3-Dimethylbutadiene-1,3 with Diaminogossypol.—A solution of 0.425 g. of diaminogossypol in 25 cc. of dry benzene was refluxed on the steam-bath overnight with 1.5 cc. of freshly distilled dimethylbutadiene.

The material dissolved to give the red solution characteristic of diaminogossypol in benzene. At the end of eight hours the red color had faded to the yellow color common to a solution of gossypol.

The solution was evaporated and the residue crystallized from acetone–methanol, m. p. 244–245° with decomposition. This product was identical with that obtained in the reaction above using gossypol or anhydrogossypol.

Attempted Condensations with 2,3-Dimethylbutadiene-1,3.—Using the same procedure that was employed in the condensation of gossypol with dimethylbutadiene, attempts were made to condense hexaacetylgossypol, the white hexamethyl ethers of gossypol and apogossypol. In every case the starting material was recovered unchanged.

Condensation of Butadiene-1,3 with Anhydrogossypol.—A mixture of 3 cc. of pure butadiene-1,3,5 cc. of pure dry benzene and 0.5 g. of anhydrogossypol was heated in a sealed tube on a steam-bath for twelve hours. After evaporation of the excess butadiene by warming, the red solution was cooled and filtered from the precipitate. The solid thus obtained was purified by rapid crystallization from acetone–methanol; yellow crystals which darkened at 242° and melted with decomposition at 245–246°.

Anal. Calcd. for $C_{38}H_{38}O_6$: C, 77.2; H, 6.43. Found: C, 76.95; H, 6.46.

The product gave an orange color in concentrated sulfuric acid. If the addition compound was allowed to remain standing in solution, there was a reversion with regeneration of anhydrogossypol.

Acetylation of Butadiene Addition Product.—By a procedure similar to that described for the dimethylbutadiene product, a white diacetate was obtained. It was purified from aqueous methanol, m. p. 250–251° with decomposition. It gave a yellow color in concentrated sulfuric acid.

Anal. Calcd. for $C_{38}H_{36}O_4(OCOCH_3)_2$: C, 74.8; H, 6.24. Found: C, 74.91; H, 6.50.

Summary

Gossypol, anhydrogossypol, and diaminogossypol react with dimethylbutadiene to give a product which analyzes for the addition of two moles of diene to one of anhydrogossypol. During the reaction with gossypol or diaminogossypol, two moles of water or two moles of ammonia are eliminated simultaneously. The product contains two hydroxyls which can be methylated or acetylated.

Butadiene gives a similar product with anhydrogossypol though it is less stable than the dimethylbutadiene derivative.

The deduction from these experiments is that two α,β-unsaturated carbonyl groups are present in the anhydrogossypol molecule. Gossypol in forming anhydrogossypol probably loses water between hydroxymethylene groups and phenolic hydroxyls.

Structure of Gossypol. VII. Gossypol Dimethyl Ether

BY ROGER ADAMS AND T. A. GEISSMAN

Evidence has been presented in previous papers[1] that gossypol is a symmetrical molecule containing six hydroxyl groups and two tautomeric hydroxyaldehydic residues. Of the six hydroxyls, two are much less acidic than the other four. The stability of two of the ether linkages in gossypol hexamethyl ether should be different from that of the other four and this now has been tested experimentally.

The white and red hexamethyl ethers of gossypol are demethylated upon treatment with sulfuric acid in acetic acid with the formation of a dimethyl ether. This new product possesses many of the properties of gossypol. It dissolves in alkali to give solutions which oxidize in the air. It gives a green color with ferric chloride; it forms a compound with one molecule of acetic acid; it gives an orange-red color with pyroboroacetate and an orange-red color with stannic chloride. With concentrated sulfuric acid it gives the orange color characteristic of the hexamethyl ethers of gossypol in contrast to the tetramethyl ether which gives a scarlet color similar to that given by gossypol. This is assumed to mean that the two unmethylated hydroxyl groups in gossypol tetramethyl ether are those which are methylated in the dimethyl ether. This assumption has been supported further by a study of the demethylation of gossypol tetramethyl ether under conditions similar to those used in the demethylation of the hexamethyl ethers. Gossypol is the resulting product.

The hexamethyl and tetramethyl ethers of gossypol do not react with aniline but the new dimethyl ether does react to give a condensation product. Although this derivative appears from analysis to be one of complicated type similar to those obtained from gossypol and certain substituted anilines, it can be hydrolyzed by acids to the original dimethyl ether of gossypol.

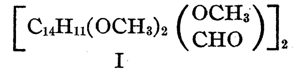
The dimethyl ether does not give an anhydro derivative under the conditions used for preparing anhydrogossypol from gossypol, and could not be converted to the red hexamethyl ether of gossypol either under the conditions used for preparing this compound from gossypol or under conditions which were modifications of these.

Gossypol dimethyl ether undergoes the apo reaction in a manner similar to gossypol, which again is in contrast to the tetra- and hexamethyl ethers which are stable under similar conditions.[2]

Remethylation of the dimethyl ether leads to the lower-melting form of the white hexamethyl ether.

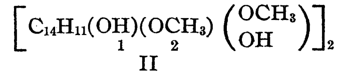
The white hexaethyl ether of gossypol can be deethylated to a gossypol diethyl ether analogous in structure and similar in properties to the dimethyl ether.

If gossypol hexamethyl ether in condensed form is accepted as having the structure indicated in I, and the tetramethyl ether II, then it may be concluded that III would be the structure for the dimethyl ether.



$$\left[C_{14}H_{11}(OCH_3)_2\begin{pmatrix}OCH_3\\CHO\end{pmatrix}\right]_2$$

I



$$\left[C_{14}H_{11}(\underset{1}{OH})(\underset{2}{OCH_3})\begin{pmatrix}OCH_3\\OH\end{pmatrix}\right]_2$$

II

$$\left[C_{14}H_{11}(\underset{1}{OCH_3})(\underset{2}{OH})\begin{pmatrix}OH\\CHO\end{pmatrix}\right]_2$$

III

The methylation of gossypol was reported to give a tetramethyl ether, two white hexamethyl ethers which were dimorphic and a red hexamethyl ether. It has now been found that the methylation conditions must be controlled very carefully in order to obtain the tetramethyl ether in a pure state. Moreover, it is possible to methylate gossypol-acetic acid to yield either the tetramethyl ether or the two white hexamethyl ethers.

Three different white gossypol hexamethyl ethers have now been isolated, m. p. 188, 225, 238–240°. The first two are apparently dimorphs but the highest melting appears to be diastereoisomeric or isomeric with the other two, if the depressed mixed melting point of the 225 and 240° forms is considered a proper criter-

[2] The apogossypol dimethyl ether could not be isolated in a pure state but upon methylation yielded apogossypol hexamethyl ether. This work will be reported in a subsequent paper.

ion. Fortunately, the chemical reactions of all these forms lead to the same products, so that their exact character is less significant.

The gossypol dimethyl ether can be oxidized in alkaline or acid medium. A solution in aqueous alkali when treated with air gives a deeply colored crystalline compound. This substance forms a violet salt the solution of which is decolorized by sodium hydrosulfite. The properties of this product indicate it to be a quinone. The dimethyl ether is also oxidized by ferric chloride in acetic acid or by dilute nitric acid to a deep orange crystalline compound. The mechanism by which these substances are produced has not yet been determined.

Experimental

Gossypol Dimethyl Ether.—To 1 g. of gossypol hexamethyl ether (m. p. 238–240°) dissolved in 40 cc. of hot acetic acid was added a solution of 10 drops of concentrated sulfuric acid in 10 cc. of acetic acid. The solution turned a deep red. After heating for thirty minutes on the steam-bath, 23 cc. of water was added carefully, with stirring and scratching of the walls of the flask. The initially flocculent precipitate soon became crystalline. It was filtered, washed with acetic acid and water and dried. The product was a yellow-green crystalline material and weighed 0.82 g. This crude product melted at about 155–165° with decomposition and obviously contained acetic acid. It was difficult to purify directly by further crystallization from acetic acid. By the action of aqueous alkali, a product was obtained which crystallizes from benzene–petroleum ether (b. p. 30–60°) as soft yellow needles, m. p. 191–193° (corr.), with decomposition. This is acetic acid free. The acetic acid also may be removed from the crude product merely by crystallization from benzene–petroleum ether without previous treatment with alkali. Recrystallization of this yellow crystalline form, m. p. 191–193° (corr.), from dilute acetic acid, results in the formation of a pure acetic acid derivative of gossypol dimethyl ether, m. p. 230–232° (corr.), with decomposition. The melting point varies considerably with the rate of heating.

Anal. Calcd. for $C_{30}H_{28}O_6(OCH_3)_2$: C, 70.33; H, 6.23. Found: (benzene–petroleum ether) C, 69.96; H, 6.01. (Removal of acetic acid by alkali) C, 70.48; H, 6.22. Calcd. for $C_{30}H_{28}O_6(OCH_3)_2 \cdot CH_3COOH$: C, 67.33; H, 6.26; OCH_3, 10.20. Found: C, 67.56; H, 5.99, 6.30; OCH_3, 14.2, 12.4, 13.5, 14.4.[3]

Aniline Derivative of Gossypol Dimethyl Ether.—A solution of 0.1 g. of the dimethyl ether of gossypol and 0.25 cc. of aniline in 4 cc. of benzene, was refluxed for thirty minutes. On dilution with petroleum ether (b. p. 30–60°), the aniline compound separated as orange prisms weighing 95 mg. Recrystallized from chloroform–petroleum ether (b. p. 30–60°), it formed bright orange prisms which melted at 268–270° (corr.) with decomposition.

Anal. Calcd. for $C_{44}H_{44}N_2O_6$: C, 75.86; H, 6.3; N, 4.0. Found: C, 74.92, 74.78; H, 6.30, 6.22; N, 5.20.

Deanilination of the Gossypol Dimethyl Ether–Aniline Compound.—To about 50 mg. of the aniline compound dissolved in 2 cc. of hot acetic acid was added one drop of concentrated hydrochloric acid. The clear orange solution was diluted drop by drop with water until crystallization started. The product was recrystallized from benzene–petroleum ether (b. p. 30–60°) (soft yellow needles, m. p. 187–189° (corr.) with decomposition), and then from dilute acetic acid (shining yellow leaflets, m. p. 229–230° (corr.) with decomposition). The latter sample showed no depression in melting point when mixed with a sample of dimethyl ether–acetic acid compound, m. p. 230–232° (corr.) with decomposition.

Gossypol Diethyl Ether.—To 0.1 g. of hexaethyl ether of gossypol in 4 cc. of hot acetic acid was added 1 cc. of acetic acid containing one drop of concentrated sulfuric acid. After heating on the steam-bath for fifteen minutes the solution was diluted with 2 cc. of water and cooled. The crude product was a yellow crystalline powder which weighed 95 mg. After one recrystallization from dilute acetic acid and a second from benzene–petroleum ether (b. p. 30–60°), it formed bright yellow needles, m. p. 193–195° (corr.) with decomposition.

Anal. Calcd. for $C_{34}H_{38}O_8$: C, 71.08; H, 6.62. Found: C, 71.17; H, 6.36.

The compound dissolves in alkali to give a yellow solution which slowly turns violet on standing in air. It gives a bright orange color with concentrated sulfuric acid and a brownish-green color with ferric chloride.

The fact that the material after a crystallization from dilute acetic acid melted at the same point as that from benzene–petroleum ether, indicates that an acetic acid compound analogous to the gossypol dimethyl ether derivative may not form.

Methylation of Gossypol Dimethyl Ether.—To a solution of 1.49 g. of the dimethyl ether in a mixture of 20 cc. of methanol and 20 cc. of dimethyl sulfate, 30 cc. of 10% methanolic potassium hydroxide was added slowly with cooling and the mixture was allowed to stand for forty-eight hours. The excess dimethyl sulfate was decomposed with 10% aqueous sodium hydroxide and the product collected. It formed white needles, weighing 1.5 g. Recrystallization from methanol gave white prisms, m. p. 209–211° (corr.).

Recrystallization from acetone–methanol gave small prisms which could be obtained melting as high as 221–223° (corr.), although it usually was possible to raise the melting point over 219° only by numerous recrystallizations. Recrystallization from ligroin (b. p. 90–110°) or from acetone–water gave long, crisp white needles which melted at 173° when heated quickly to this temperature, or at 223° when heated slowly (with shrinking at about 173°).

Anal. Calcd. for $C_{30}H_{26}O_2(OCH_3)_6$: C, 71.76; H, 6.97; OCH_3, 30.9; mol. wt., 602. Found: (prism form) C, 71.85; H, 6.93; OCH_3, 31.9, 33.3; (needle form) C, 71.78; H, 6.71; mol. wt. (Rast), 620.

This compound was proved by mixed melting point to be identical with the hexamethyl ether, m. p. 225°, obtained by methylating gossypol–acetic acid under suitable condi-

---

(3) Gossypol and most of its derivatives invariably give results from one to five per cent. high in the Zeisel determination. Compare Clark, THIS JOURNAL, **51**, 1479 (1929).

tions, and different from the hexamethyl ether, m. p. 240°, obtained by the methylation of the tetramethyl ether of gossypol (mixed m. p. 210–218° (corr.)).

Methylation of Gossypol–acetic Acid. (a) Gossypol Hexamethyl Ether (240° form).[4]—A solution of 10 g. of pure gossypol–acetic acid in a mixture of 50 cc. of dimethyl sulfate and 50 cc. of methanol was treated with 75 cc. of 10% methanolic potassium hydroxide with efficient cooling in an ice-bath. The solution was allowed to stand at 10–15° for about thirty-six hours and the excess dimethyl sulfate decomposed by the addition of 10% aqueous sodium hydroxide with ice cooling. The precipitate was washed well with water and with methanol, and consisted of buff needles weighing 5.95 g. and melting at 162–164°. It gave a scarlet color with concentrated sulfuric acid, indicating it to be crude tetramethyl ether.

This was remethylated to the hexamethyl ether according to the previously described procedure.[1c] It was recrystallized from acetone–methanol, when it formed colorless prisms, m. p. 238–240° (corr.). A sample recrystallized from ligroin (b. p. 90–110°) also formed prisms, m. p. 239–241° (corr.).

(b) Gossypol Hexamethyl Ether (225° form).—The proportions were the same as those just described for the first methylation, but the reaction mixture was cooled under the tap (*ca.* 20–25°) during the first addition of alkali and the final decomposition with 10% aqueous sodium hydroxide, and was allowed to stand for thirty-six hours at room temperature. The first product, methanol washed, weighed about 7.5 g., gave a deep orange color with concentrated sulfuric acid and melted at about 213°. Remethylated in the usual way,[1] it gave a product which melted (crude) at 211–213°, after one recrystallization from acetone–methanol at 216–218°, and after a second crystallization at 224–225° (corr.). A mixture of this with the product melting at 238–240° (corr.) melted at 212–217°.

This compound crystallized from ligroin (b. p. 90–110°) in clusters of white needles which sintered at about 179° and melted to a clear liquid at 221–224°. Plunged into a preheated bath at various temperatures it sintered at 185° and melted at 188°. At 198° it melted instantly, then resolidified, and remelted at 223–225° (corr.). The melted and resolidified samples of the *needle* form were found to have been converted to the *prism* form.

Both forms (m. p. 240° and 225°) were identical in their reactions.

Oxidation Products of Gossypol Dimethyl Ether. (a) Air Oxidation in Alkaline Solution.—Air was bubbled through a warm solution of 0.1 g. of the dimethyl ether in 25 cc. of 4% aqueous sodium hydroxide. After about five minutes the color became red and sodium hydrosulfite caused the reappearance of the initial yellow color. Continued treatment with air caused the solution finally to turn a deep violet and a purple sodium salt separated. The solution was acidified with sulfuric acid, extracted with ether, the ether solution dried and concentrated. The addition of petroleum ether caused the separation of 60 mg. of a compound crystallizing in tiny rosets. Recrystallized from ether–petroleum ether (b. p. 30–60°), the compound formed rosets of maroon prisms, m. p. 246° (corr.) with decomposition.

Anal. Calcd. for $C_{30}H_{30}O_8$: C, 69.50; H, 5.79. Found: C, 69.46, 69.51; H, 6.02, 6.10.

The compound gives a deep purple solution in sulfuric acid which changes through red to orange to yellow on dilution. The purple-red solution of the compound in dilute aqueous alcoholic alkali is changed to a yellow color by sodium hydrosulfite. Air reoxidizes the solution rapidly.

(b) Oxidation with Ferric Chloride.—To 0.8 g. of the dimethyl ether of gossypol dissolved in 80 cc. of hot glacial acetic acid was added 60 cc. of a 10% aqueous solution of ferric chloride. The solution turned deep greenish-brown and a small amount of tarry substance separated and was removed. The solution was heated on the steam-bath for a few moments and scratching of the walls of the flask caused orange crystals to form. These were collected and washed with acetic acid. They weighed 0.52 g. Recrystallized from acetic acid or dilute acetone the compound formed shining orange leaflets, m. p. 215–216° (corr.).

Anal. Calcd. for $C_{32}H_{30}O_{10}$: C, 66.90; H, 5.23. Found (acetone): C, 66.56; H, 5.19; (acetic acid): C, 67.02; H, 5.12.

The compound gives a red-brown color with ferric chloride and a red-brown color with concentrated sulfuric acid. It is soluble in dilute alkali, giving a red-violet solution which is unaffected by sodium hydrosulfite. It leaves no residue on ignition (not a Fe^{+++} salt).

(c) Oxidation with Nitric Acid.—Two attempts to isolate crystalline products after prolonged heating of the dimethyl ether with dilute nitric acid (1:4) were unsuccessful.

In another experiment 0.5 g. of the compound was dissolved in 10 cc. of benzene and 50 cc. of nitric acid (1:4) was added. The mixture was heated until the benzene had distilled off, the solid remaining suspended in the aqueous layer as a reddish, spongy mass. The heating was continued (gentle boiling) until this solid had turned a brick-red color. It was collected and washed free of nitric acid and crystallized three times from slightly diluted acetic acid; orange leaflets, m. p. 213–214° (corr.). Mixed with a sample of the ferric chloride oxidation product (m. p. 212–213°) it melted at 212–214°. Its color reactions with ferric chloride, concentrated sulfuric acid, and alkali were also identical.

Anal. Calcd. for $C_{32}H_{30}O_{10}$: C, 66.90; H, 5.23. Found: C, 66.70; H, 5.22.

Summary

Gossypol hexamethyl ethers are demethylated to gossypol dimethyl ether by the action of a drop of sulfuric acid in glacial acetic acid. Gossypol tetramethyl ether under similar conditions gives gossypol, which leads to the deduction that the two methoxyls in the dimethyl ether correspond to the two hydroxyls in the tetramethyl ether.

This dimethyl ether, in contrast to the tetra- and hexamethyl ethers, reacts with aniline or

---

[4] This product was reported in a previous paper to melt at 235°.

with alkali, and in general shows many of the reactions of gossypol. It may be remethylated to gossypol hexamethyl ether.

The color reactions and oxidation products of the dimethyl ether are described.

Structure of Gossypol. VIII.[1] Derivatives of the Ethers of Gossypol

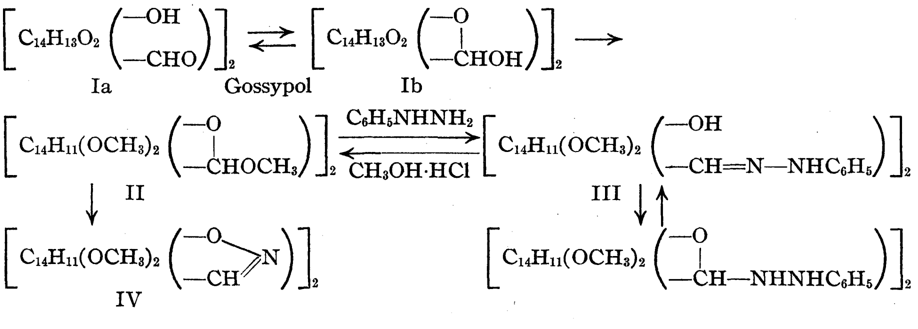
BY ROGER ADAMS AND T. A. GEISSMAN

The non-reactivity of gossypol tetra- and hexamethyl ethers with many carbonyl reagents leaves doubt concerning the presence of aldehyde groups in these molecules in spite of the fact that experiments indicate that six hydroxyls and two aldehyde groups are present in gossypol. This paper presents evidence which points to the belief that in the tetra- and hexaalkyl ethers of gossypol the systems involving the two aldehyde groups and two of the six hydroxyls may be stabilized in the lactol form by alkylation with the formation of two acetal (or lactol ether) linkages (formulas Ia, Ib, II).

Although gossypol (Ia and Ib) and its dimethyl ether form derivatives with aniline and with substituted anilines,[1,2] neither the hexamethyl ethers nor the tetramethyl ether of gossypol have been found previously to form any derivatives which showed unequivocally the presence in the molecule of a carbonyl group. In fact, all attempts to form such a derivative in alkaline or neutral solution have yielded negative results.[3] The white hexamethyl ether (either form) shows a remarkable stability in neutral or alkaline solution, being unattacked by permanganate in acetone or pyridine solution. In the latter case fairly vigorous treatment results in the complete degradation of a small percentage of the starting material with the recovery of the remainder unchanged.

Gossypol hexamethyl ether does not react with malonic acid in alcohol in the presence of piperidine or in pyridine solution.[4] With methylmagnesium iodide in benzene–ether solution some reaction seemed to occur, but a large proportion of starting material was recovered along with a small amount of an uncrystallizable oily product.

In acetic acid solution, however, the hexamethyl ether (II) behaves quite differently. It is attacked instantly by potassium permanganate (no crystalline products isolated), and it forms readily a crystalline condensation product with two molecules of phenylhydrazine (III) or with two molecules of hydroxylamine (IV). These latter condensation products appear to be formed by loss of two methylene groups due to hydrolysis of two methoxyls to hydroxyls followed by the loss of water between the resulting aldehyde groups and the reagents. The dihydroxylamine derivative was found by analysis to have lost an additional two molecules of water, probably through the formation of two orthoxazine rings. The unusual ease with which the methyl groups of two of the methoxyls in gossypol tetramethyl and hexamethyl ethers are eliminated in mildly acid solution leads to the deduction that acetal methoxyls are probably present. The chemical changes just described may be formulated structurally:



The phenylhydrazone can be reconverted to the hexamethyl ether by treatment with methanolic hydrogen chloride, and converted by treatment with ethanolic hydrogen chloride to a diethyl tetramethyl ether which presumably has

---

(4) Kuhn, *Ber.*, **63**, 2164 (1930).

two ethoxy groups of the acetal type. Attempts to convert it to a tetramethyl ether by hydrolysis in aqueous or non-alcoholic media were unsuccessful; treatment of the compound with dry hydrogen chloride in acetic acid led to a compound containing chlorine whose constitution has not yet been investigated.

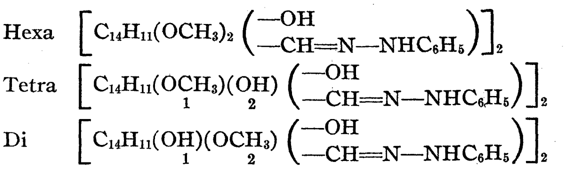
The tetramethyl ether of gossypol reacts with phenylhydrazine under conditions similar to those used for the hexamethyl ether and forms an analogous product, the diphenylhydrazone of a gossypol dimethyl ether. It can be reconverted into the gossypol tetramethyl ether or converted into a gossypol diethyldimethyl ether. The gossypol tetramethyl ether also reacts with two molecules of hydroxylamine. Two methoxyl groups are hydrolyzed and two molecules of water are lost followed by the elimination of two more molecules of water just as occurred in the gossypol hexamethyl ether derivative.

The facts presented in this paper favor the structures written for these compounds; the acetal structure for gossypol hexa- and tetramethyl ethers adequately explains the stability of these compounds toward alkaline reagents, their ready reaction in acid solution *with the hydrolysis of methyl groups from two of the ether linkages*, and the hydrolysis of the hexamethyl ether to the dimethyl ether by sulfuric acid in acetic acid solution.

The dimethyl ether of gossypol also forms a diphenylhydrazone and a dioxime, but as is to be expected no methyl groups are lost in the process. The dioxime, moreover, does not lose water. That acetic acid is not necessary in these condensations is indicated by the ready condensation of the dimethyl ether with aniline in benzene or chloroform solution.

It is significant that the diphenylhydrazone of the dimethyl ether of gossypol is isomeric with the diphenylhydrazone obtained from the tetramethyl ether. As was previously mentioned, two methyl groups are lost in the synthesis of the latter compound. That the two substances are not identical is to be expected from the fact that the two methoxyl groups in gossypol dimethyl ether are the ethers of the two free hydroxyl groups in gossypol tetramethyl ether, as was shown in a previous communication.[1]

The relationship between the phenylhydrazine derivatives of gossypol di-, tetra- and hexamethyl ethers may be formulated as follows

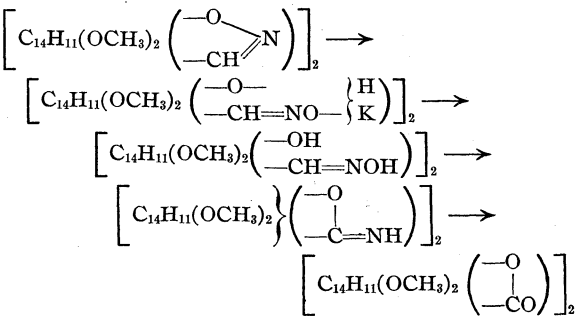


$$\text{Hexa}\quad\left[C_{14}H_{11}(OCH_3)_2\begin{pmatrix}-OH\\-CH{=}N-NHC_6H_5\end{pmatrix}\right]_2$$

$$\text{Tetra}\quad\left[C_{14}H_{11}(\underset{1}{OCH_3})(\underset{2}{OH})\begin{pmatrix}-OH\\-CH{=}N-NHC_6H_5\end{pmatrix}\right]_2$$

$$\text{Di}\quad\left[C_{14}H_{11}(\underset{1}{OH})(\underset{2}{OCH_3})\begin{pmatrix}-OH\\-CH{=}N-NHC_6H_5\end{pmatrix}\right]_2$$

The dehydro dioxime or orthoxazine derived from the hexamethyl ether and hydroxylamine forms a crystalline potassium salt when treated with alcoholic potassium hydroxide. This salt on treatment with acetic acid undergoes a change resulting in the formation of a compound which no longer contains nitrogen, formulated as a lactone



$$\left[C_{14}H_{11}(OCH_3)_2\begin{pmatrix}-O-\\-CH{=}\end{pmatrix}N\right]_2\longrightarrow\left[C_{14}H_{11}(OCH_3)_2\begin{pmatrix}-O-&\\-CH{=}NO-&\left\{\begin{matrix}H\\K\end{matrix}\right.\end{pmatrix}\right]_2\longrightarrow\left[C_{14}H_{11}(OCH_3)_2\begin{pmatrix}-OH\\-CH{=}NOH\end{pmatrix}\right]_2\longrightarrow\left[C_{14}H_{11}(OCH_3)_2\left\}\begin{pmatrix}-O\\ |\\-C{=}NH\end{pmatrix}\right.\right]_2\longrightarrow\left[C_{14}H_{11}(OCH_3)_2\begin{pmatrix}-O\\ |\\-CO\end{pmatrix}\right]_2$$

The reactions of this compound, which corresponds to the dilactone of a gossypol tetramethyl ether in which the two aldehyde groups are converted into carboxyls and then dehydrated with two hydroxyl groups to lactone residues, will be the subject of a later paper. It is proposed to call the molecule theoretically obtained by oxidizing the two aldehyde groups in gossypol to carboxyls, gossylic acid. This new compound would then be a gossylic acid lactone tetramethyl ether.

The fact that in this molecule there are only eight oxygens, the same number as in gossypol, lends additional weight to the conclusion that the oxygens in gossypol are present in the form of six hydroxyls and two aldehyde groups.

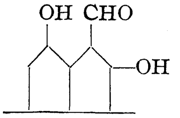
Speculation concerning the structure of the $(C_{14}H_{11})_2$ residue in gossypol may be made. On the basis of the available knowledge, the presence of two naphthyl or analogous residues directly or indirectly linked is indicated. This assumption is founded partly on the work of Schmid[5] and partly on absorption spectra data and on chemical data not yet published which have been accumulated in this Laboratory. Assuming the molecule to be symmetrical and that six hydroxyls and two aldehyde groups may replace eight hy-

---

(5) Schmid and Margulies, *Monatsh.*, **65**, 391 (1934).

drogens in the naphthalene nuclei, the residue becomes $(C_4H_9)C_{10}H_2–C_{10}H_2(C_4H_9)$ or an isomer of it, in which each of the C_4H_9 radicals represents more than one group. The two naphthyl groups, however, may be attached through an alkylene residue, thus $C_{10}H_3–(C_8H_{16})–C_{10}H_3$. Still another possible combination is that in which one or more alkyl groups are present in each of the naphthalene nuclei and the two naphthalene residues are connected by one or more methylene groups.

One type of hydroxyaldehyde which may explain many of the reactions of gossypol and its ethers is represented by the partial nucleus.



. A study of a naphthalene derivative with substituents of this type is now being made. An attempt to give a complete formula for gossypol is not yet justified as certain conflicting experimental facts must first be clarified.

Experimental

Condensation of Phenylhydrazine and Gossypol Hexamethyl Ether (a).—To a solution of 0.27 g. of pure gossypol hexamethyl ether (m. p. 239–241°) in 20 cc. of glacial acetic acid was added 1.5 cc. of phenylhydrazine. After heating for several minutes on the steam-bath bright yellow needles began to separate. After thirty minutes the solution was filtered hot and the product washed with acetic acid. It formed bright yellow needles, m. p. 266–267° (corr.) with decomposition, and weighed 0.25 g. No satisfactory method was found for recrystallization of this product.

(b). A solution of 0.25 g. of gossypol hexamethyl ether (m. p. 223–225°) was treated as in (a). The product weighed 0.28 g. In larger runs the yield was nearly quantitative.

Anal. Calcd. for $C_{46}H_{50}O_6N_4$: C, 73.22; H, 6.63; N, 7.43. Found: C, 72.78, 73.09; H, 6.59, 6.58; N, 7.40.

The compound is insoluble in alkali (aqueous or alcoholic) and gives no ferric chloride color. It gives an orange color with concentrated sulfuric acid.

To a suspension of 0.5 g. of the phenylhydrazone in 10 cc. of glacial acetic acid was added 5 drops of concentrated hydrochloric acid. The yellow-brown solution which rapidly formed, began to deposit clusters of yellow needles after standing for an hour at room temperature. The product was collected and washed with acetic acid and water. It could not be recrystallized successfully. It was insoluble in alkali and in ether, acetone and benzene. It was soluble in methanol and slightly so in acetic acid. It contained halogen (Beilstein test) and nitrogen. The compound melted at 257–262° (corr.) with decomposition.

When the solution of this material in methanol was saturated with dry hydrogen chloride a thick mass of short white needles separated. This compound is nicely crystalline, contains halogen and nitrogen, gives a yellow color with concentrated sulfuric acid, dissolves in warm alcoholic alkali to a bluish-red solution, and melts at 274–276° (corr.) with decomposition. It turns brown on standing in air and no method has yet been found for its purification.

Conversion of the Phenylhydrazine Derivatives of Gossypol Hexamethyl Ether to Gossypol Hexaalkyl Ethers

(a) With CH_3OH–HCl: Formation of Gossypol Hexamethyl Ether.—A suspension of 0.5 g. of the phenylhydrazone in 20 cc. of absolute methanol was treated with dry hydrogen chloride until the compound had gone into solution. The solution was allowed to stand overnight at room temperature. A crystalline product separated in clusters of stout prisms. It weighed 0.32 g. After recrystallization from ligroin, then from methanol it formed tiny white prisms, m. p. 219–221° (corr.), and mixed with gossypol hexamethyl ether (m. p. 221–223°), it melted at 221–223°.

(b) C_2H_5OH–HCl: Formation of Gossypol Tetramethyl Diethyl Ether.—A solution of 0.5 g. of the phenylhydrazone in 20 cc. of absolute ethanolic hydrogen chloride (prepared as in the case of the methanol) was allowed to stand at room temperature. Within two hours white needles began to separate from the solution. The crude product weighed 0.35 g. Recrystallized from ethanol–acetone, it formed white prisms, m. p. 229–230° (corr.).

Anal. Calcd. for $C_{30}H_{24}O_2(OCH_3)_4(OC_2H_5)_2$: C, 72.38; H, 7.30. Found: C, 72.19; H, 7.49.

A mixture of this compound (m. p. 229–230°) with the hexamethyl ether (m. p. 221–223°) melted at 203–208°. The compound gave the usual (for hexaalkylated gossypol) orange color with sulfuric acid.

Condensation of Hydroxylamine with Gossypol Hexamethyl Ether.—To 2.0 g. of gossypol hexamethyl ether dissolved in 30 cc. of hot acetic acid was added a solution of 1.0 g. of hydroxylamine hydrochloride in a very small quantity of water. The solution was heated on the steam-bath (five to ten minutes) until scratching of the walls of the flask caused crystallization to start. After allowing the mixture to stand until cool (overnight is preferable) the product was collected and washed with acetic acid and water. It formed greenish-yellow leaflets weighing 1.5 g.

Recrystallized from dilute acetic acid it forms flat buff needles and from benzene–petroleum ether it forms tiny buff platelets. Both forms when heated rapidly melt with decomposition at 192–204° but when heated slowly merely sinter at this temperature and do not melt below 280°.

Anal. Calcd. for (dioxime) $C_{34}H_{40}O_8N_2$: C, 67.5; H, 6.63; N, 4.64. Calcd. for (dioxime less $2H_2O$) $C_{34}H_{36}O_6N_2$: C, 71.82; H, 6.34; N, 4.92. Found (acetic acid): C, 71.83; H, 6.44. Found (benzene–petroleum ether): C, 72.05; H, 6.51; N, 4.83.

The oxime gives an orange color with concentrated sulfuric acid and no ferric chloride color. It is soluble in hot 10% methanolic potassium hydroxide, and the potassium salt crystallizes from the hot solution in clusters of bright yellow needles.

Degradation of the Hydroxylamine Derivative of Gossypol Hexamethyl Ether to a Lactone.—A suspension of 4.69

g. of the crude hydroxylamine derivative of gossypol hexamethyl ether in 60 cc. of 10% methanolic potassium hydroxide was heated to boiling with stirring. The compound gradually went into solution, then the potassium salt rapidly crystallized as a thick sludge of yellow needles. After being heated for a short time just below the boiling point to complete the reaction the mixture was allowed to cool and the product collected and washed with a small amount of alcoholic potassium hydroxide and with ether. The salt weighed 5.15 g. Purified hydroxylamine derivative gives a better yield but no over-all advantage is gained by such a procedure.

Analysis of the crude product for potassium indicated that it is a dipotassium salt.

Anal. Calcd. for $(C_{17}H_{19}O_4NK)_2$: K, 11.5. Calcd. for $(C_{17}H_{18}O_4NK_2)_2$: K, 20.6. Found: K, 10.8, 10.2.

A solution of 5.15 g. of crude potassium salt in 50 cc. of boiling glacial acetic acid was diluted carefully with water until crystallization started. It was then diluted with several times its volume of water and allowed to cool. The crude, crystalline product was collected and dried. It was found most convenient to recrystallize it from glacial acetic acid in the following way. The crude product was dissolved in 46 cc. (0.5 mole) of boiling acetic anhydride and the acetic anhydride carefully decomposed by the addition of 9 cc. of water dissolved in 10 cc. of acetic acid. As soon as the acetic anhydride had been hydrolyzed the product crystallized in shining leaflets. It weighed 4.05 g. and after recrystallization from acetic acid (in which it is difficultly soluble) or acetic anhydride it melted at 327–328° (corr.).

Anal. Calcd. for $C_{17}H_{17}O_4$: C, 71.58; H, 5.96; 2-OCH_3, 21.75. Found: C, 71.17; H, 6.11; OCH_3, 21.40.

The lactone is difficultly soluble in cold alcoholic alkali but dissolves readily on warming. It gives a yellow color with concentrated sulfuric acid and no ferric chloride color.

Condensation of Phenylhydrazine with Gossypol Tetramethyl Ether.—To a solution of 0.5 g. of gossypol tetramethyl ether in 20 cc. of hot glacial acetic acid was added 1 cc. of phenylhydrazine. On standing overnight the solution deposited 0.61 g. of a bright yellow crystalline product. Recrystallized from acetic acid it forms canary-yellow platelets, from benzene a bright yellow crystalline powder, and from benzene–petroleum ether bright yellow rosets of scale-like crystals which effloresce on drying at 100° to a yellow powder, m. p. 246–248° (corr.) with decomposition.

Anal. Calcd. for $C_{44}H_{46}O_6N_4$: C, 72.73; H, 6.34. Found (acetic acid): C, 73.07; H, 6.29. Found (benzene): C, 72.76; H, 6.52. Found (benzene–petroleum ether): C, 72.32; H, 6.53.

The compound gives a scarlet color with concentrated sulfuric acid, no ferric chloride color, and is soluble in alcoholic alkali with a reddish-yellow color.

Conversion of the Phenylhydrazine of Gossypol Tetramethyl Ether to Tetraalkyl Ethers

(a) **Gossypol Tetramethyl Ether.**—A solution of 0.5 g. of the phenylhydrazone from gossypol tetramethyl ether in 20 cc. of absolute methanolic hydrogen chloride was allowed to stand at room temperature overnight. A crystalline deposit weighing 0.30 g. was obtained and purified by recrystallization from acetone, m. p. 186–189° (corr.). It gave no depression in melting point when mixed with an authentic sample of gossypol tetramethyl ether.

(b) **Gossypol Dimethyl Diethyl Ether.**—A solution of 0.5 g. of the phenylhydrazone from gossypol tetramethyl ether in 15 cc. of absolute ethanolic hydrogen chloride began to deposit white needles after several hours at room temperature. The product was collected after diluting the solution and weighed 0.32 g. Recrystallized from dilute acetone it formed slender white needles, m. p. 160–162° (corr.).

Anal. Calcd. for $C_{30}H_{26}O_4(OCH_3)_2(OC_2H_5)_2$: C, 71.76; H, 6.98. Found: C, 71.49; H, 6.89.

The compound gives a scarlet color with concentrated sulfuric acid.

Condensation of Hydroxylamine with Gossypol Tetramethyl Ether.—To a solution of 0.5 g. of gossypol tetramethyl ether in 5 cc. of glacial acetic acid was added a solution of 0.25 g. of hydroxylamine hydrochloride in 0.5 cc. of water. After heating on the steam-cone for fifteen minutes, the solution was filtered and cooled. On scratching the walls of the flask the product separated as a yellow powder weighing 0.33 g. It can be recrystallized from benzene or benzene–petroleum ether from which it is obtained as fine canary-yellow platelets or prisms which melted poorly from 140–190° (with decomposition). Analysis indicated that it contained combined solvent. Recrystallized from ligroin (b. p. 90–110°) it formed short yellow needles which melted at 281–283° (corr.) with decomposition.

Anal. Calcd. for (dioxime less $2H_2O$) $C_{32}H_{32}O_6N_2$: C, 71.11; H, 5.92; N, 5.18. Calcd. for $C_{32}H_{32}O_6N_2 \cdot {}^1/_2C_6H_6$: C, 73.78; H, 6.15; N, 4.63. Found (ligroin): C, 70.93; H, 5.97. Found (benzene–petroleum ether): C, 73.56; H, 6.28; N, 4.79.

The compound dissolves in concentrated sulfuric acid to give an orange solution which turns deep wine-red on standing. It gives no color with ferric chloride. It dissolves readily in cold, dilute alcoholic potassium hydroxide to give a yellow solution which quickly turns wine-red. This red color is discharged by sodium hydrosulfite, giving the original yellow color.

Condensation of Phenylhydrazine with Gossypol Dimethyl Ether.—To a solution of 1.9 g. of the dimethyl ether in 20 cc. of glacial acetic acid was added 3 cc. of phenylhydrazine, and the mixture was warmed for fifteen minutes on the steam-bath. The solution was diluted carefully with water, with scratching, until crystallization began. The crude product weighed 2.0 g. Recrystallized from benzene, the compound formed rosets of yellow needles, m. p. 248–249° (corr.) with decomposition. From dilute acetic acid it forms yellow platelets, m. p. 246–248° (corr.) with decomposition. The melting point varies with the heating rate.

Anal. Calcd. for $C_{44}H_{46}O_6N_4$: C, 72.73; H, 6.34; N, 7.72. Found (benzene): C, 72.89; H, 6.58; N, 7.17.

The compound depressed the melting point of the isomeric phenylhydrazone from gossypol tetramethyl ether (mixed m. p. 232–234° corr.) with decomposition. It gives an orange-yellow color with concentrated sulfuric acid, and with ferric chloride a cherry-red which changes immediately to orange. It is soluble in cold alcoholic alkali.

Attempts to hydrolyze the compound by the procedure described for the phenylhydrazones did not yield a tetramethyl ether.

Condensation of Hydroxylamine with Gossypol Dimethyl Ether.—The product was prepared by treatment of an acetic acid solution of gossypol dimethyl ether with a neutralized solution of hydroxylamine hydrochloride in water, heating for thirty minutes on the steam-bath and diluting and scratching the hot solution. The hydroxylamine derivative was recrystallized from dilute acetic acid, from which it formed buff platelets, m. p. 229–232° (corr.) with decomposition.

Anal. Calcd. for $C_{32}H_{36}O_8N_2$: C, 66.66; H, 6.25; N, 4.85. Found: C, 66.33; H, 6.45; N, 4.38.

In contrast to the hydroxylamine derivative prepared from the hexamethyl ether, this substance has not lost the elements of water to form an orthoxazine.

The compound gives a yellow-orange solution in concentrated sulfuric acid, a green color with ferric chloride, and its yellow solution in aqueous alkali turns red on standing in the air.

Zeisel Determinations

The Zeisel numbers on gossypol and many of its derivatives appear to have very little significance, for the values found are usually too high. They are given in the table.

ZEISEL DETERMINATIONS ON GOSSYPOL ETHER DERIVATIVES

		Found	Calcd.
1	Phenylhydrazone from hexamethyl ether	17.8	16.4 (4-OCH_3)
2	Phenylhydrazone from tetramethyl ether	11.8 12.3	8.5 (2-OCH_3)
3	Phenylhydrazone from dimethyl ether	13.0 11.3	8.5 (2-OCH_3)

Although the found and calculated values are discordant, it is noteworthy that essentially the same values were obtained for the phenylhydrazones of the tetra- and dimethyl ethers and the compounds therefore are isomeric. This coincides with the other analytical data.

Summary

Gossypol hexamethyl ether and tetramethyl ether react with phenylhydrazine in acetic acid solution to give derivatives in which two molecules of water and methyl groups have been eliminated. Treatment of the products with ethanolic or methanolic hydrogen chloride results in the reconversion to hexa- or tetraalkyl ethers of gossypol.

The hexa and tetra ethers also react with hydroxylamine with elimination of four molecules of water and hydrolysis of two methoxyl groups. Apparently the two oxime groups initially formed lose water with formation of orthoxazine rings.

The phenylhydrazine derivatives of gossypol tetramethyl ether and of gossypol dimethyl ether are isomeric, as would be anticipated from the fact that the two methoxyls in gossypol dimethyl ether correspond to the two hydroxyls in gossypol tetramethyl ether.

The hydroxylamine derivative of gossypol hexamethyl ether by treatment with alkali, then with a mixture of acetic acid and acetic anhydride, gives a compound which appears to be a lactone and corresponds to a gossypol derivative in which the aldehyde groups have been converted to carboxylic acid groups.

Structure of Gossypol. IX.[1] Oxidation and Degradation of Gossypol Hexamethyl Ether; Gossic Acid

BY ROGER ADAMS, R. C. MORRIS AND E. C. KIRKPATRICK[2]

The experimental evidence previously published on the structure of gossypol has given much information concerning the functional groupings present in the molecule and some knowledge concerning the relative arrangement of these groups. On the other hand, it has not been demonstrated that the molecule contains two naphthyl residues or a binaphthyl residue as has been tentatively assumed.

It is only by obtaining degradation products and by identifying them that it may be hoped to clarify the complete structure of gossypol. The search for a convenient degradation reaction has, up to this time, been fruitless. Now, however, a most promising reaction has been discovered by which a smaller molecule can be isolated in a pure state and in reasonable yields.

The white gossypol hexamethyl ether (I) or gos-

---

[1] For previous paper in this field see Adams and Geissman, THIS JOURNAL, **60**, 2166 (1938).

[2] Abstract of a portion of a thesis submitted in partial fulfilment for the degree of Doctor of Philosophy by E. C. Kirkpatrick, Solvay Fellow 1936–1938.

sypol tetramethyl diethyl ether[1] can be oxidized with chromic acid, periodic acid or dilute nitric acid. By very short treatment with chromic acid, oxidation occurs to give chiefly a yellow crystalline compound (II) which for convenience may be looked upon as being formed by the hydrolysis of two methoxyl groups followed by replacement of four hydrogen atoms by two oxygens. This product will be called gossypolone tetramethyl ether since it is analogous to the compound described by Clark,[3] designated by him as tetraacetylgossypolone and obtained by the oxidation of gossypol hexaacetate; thus $C_{30}H_{24}O_2(OCOCH_3)_6$ to $C_{30}H_{22}O_6(OCOCH_3)_4$.

Along with the gossypolone tetramethyl ether was invariably found a very small amount of a second oxidation product $C_{30}H_{22}O_4(OCH_3)_4$, III, which proved to be a lactone and identical with the gossylic acid lactone tetramethyl ether described in a previous paper.[1]

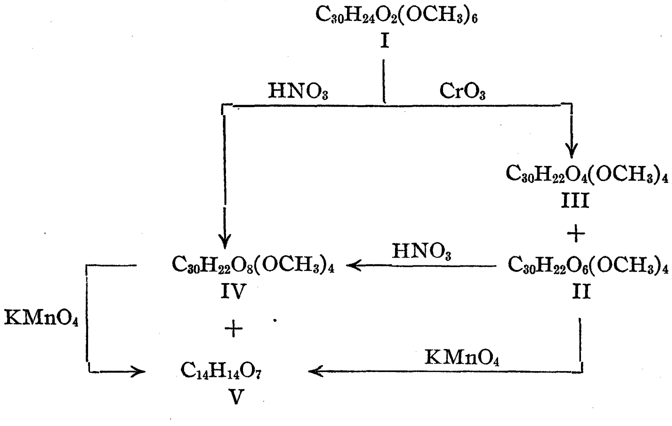
Gossypolone tetramethyl ether probably contains aldehydic carbonyls as shown by the condensation with two molecules of aniline. Preliminary tests indicate that it may also contain quinone groupings. It does not contain carboxyl groups, for the product could not be titrated electrometrically. If gossypol hexamethyl ether is accepted as containing two aldehyde and six methoxyl groups, there may have occurred in this oxidation the hydrolysis of two methoxyls to hydroxyls and the conversion of two phenolic residues to quinones. The product may well be a gossypoloquinone tetramethyl ether.

Gossypolone tetramethyl ether also could be obtained from gossypol hexamethyl ether by the action of periodic acid but this reaction was not nearly as satisfactory as the oxidation with chromic acid.

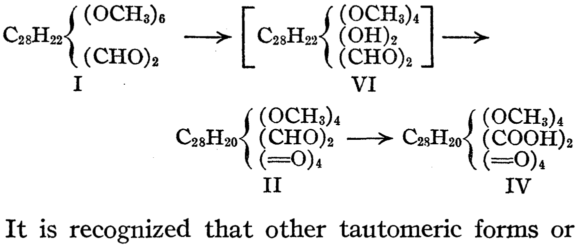
The oxidation of gossypol hexamethyl ether with dilute nitric acid is more deep-seated than with chromic or periodic acid. By this procedure, two products which account for essentially all of the starting material are formed, a yellow crystalline water-insoluble compound (IV), and a white crystalline water-soluble product (V). Approximately equal amounts of each are obtained.

The water-insoluble substance (IV) has a molecular weight comparable with that of the starting material and has two more oxygens than gossypolone tetramethyl ether (II). It is an acid and a tetramethyl ether and some indications are that it is a quinone. It will be called gossypolonic acid tetramethyl ether. Although stable to dilute nitric acid, it is readily oxidized with permanganate to give the same water-soluble compound (V), $C_{14}H_{14}O_7$, which results by the direct dilute nitric acid oxidation of gossypol hexamethyl ether. It is thus obvious that a close relationship in structure between these compounds exists. The oxidation of gossypol hexamethyl ether apparently takes place in two directions, one without degradation and the other with a cleavage to approximately a half molecule.

Moreover, these substances and gossypolone tetramethyl ether (II) are related as shown by the fact that the latter upon treatment with dilute nitric acid readily oxidizes to the water-insoluble product, gossypolonic acid tetramethyl ether (IV), obtained by direct nitric acid oxidation of gossypol hexamethyl ether. By treatment with permanganate gossypolone tetramethyl ether gives the water-soluble product (V) obtained either by the nitric acid oxidation of gossypol hexamethyl ether or by the permanganate oxidation of gossypolonic acid tetramethyl ether. These conversions are shown in the chart



A possible breakdown of these molecules with a postulated intermediate VI may be suggested



$$\underset{\text{I}}{C_{28}H_{22}\begin{cases}(OCH_3)_6\\(CHO)_2\end{cases}} \longrightarrow \underset{\text{VI}}{\left[C_{28}H_{22}\begin{cases}(OCH_3)_4\\(OH)_2\\(CHO)_2\end{cases}\right]} \longrightarrow$$

$$\underset{\text{II}}{C_{28}H_{20}\begin{cases}(OCH_3)_4\\(CHO)_2\\(=O)_4\end{cases}} \longrightarrow \underset{\text{IV}}{C_{28}H_{20}\begin{cases}(OCH_3)_4\\(COOH)_2\\(=O)_4\end{cases}}$$

It is recognized that other tautomeric forms or perhaps closely related isomeric forms of these structures may be the more nearly correct con-

---

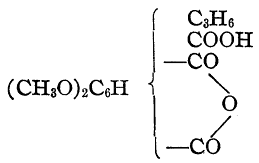
figurations but this will have to be determined after further experimentation.

The water-soluble product, because of its ease of preparation and of its molecular size of about 300, is a most promising derivative for immediate study to obtain a further insight into the gossypol structure. It will be called *gossic acid.* This product is a dimethyl ether and is acid in character as shown by its decomposition of aqueous sodium carbonate. It forms a monomethyl ester with diazomethane but titrates in aqueous solution approximately for a tribasic acid. Consequently a dibasic acid anhydride linkage in addition to a carboxyl group may be present. In all respects the compound acts like a substituted benzene. It gives none of the unusual color reactions of the higher molecular weight gossypol derivatives and has entirely normal solubility and crystallizing characteristics. From these meager results a partial breakdown of the gossic acid molecule may be postulated as follows



but the exact constitution must await further investigation.

It is significant that, under similar conditions, gossypol tetramethyl ether is oxidized by dilute nitric acid only to water-soluble acids which have not been obtained in a crystalline state. Neither could crystalline derivatives be obtained by the oxidation with chromic or periodic acid.

Experimental

Chromic Acid Oxidation of Gossypol Hexamethyl Ether or Gossypol Tetramethyl Diethyl Ether: Gossypolone Tetramethyl Ether (II).—To a solution of 2 g. of white gossypol hexamethyl ether in 50 cc. of boiling glacial acetic acid, was added rapidly with vigorous stirring 10 cc. of a 10% aqueous solution of chromic oxide and the mixture was allowed to boil for one minute. It was then poured onto a mixture of 100 g. of ice and 75 cc. of water. The product was filtered with suction and the yellow residue was washed with water until the washings were neutral. The air-dried residue was added to 40 cc. of boiling methanol. The material at first became gummy and then went gradually into solution, but, before solution was complete, a yellow material began to crystallize. By keeping warm on a steam-bath and breaking up the lumps with a stirring rod, all non-crystalline material went into solution. After standing for two hours at room temperature, the yellow crystalline product was filtered; yield 1.5 g. To purify, it was heated with 120 cc. of boiling methanol and filtered hot. The insoluble residue is described below. After cooling and allowing the filtrate to stand for two hours in an ice box, the yellow crystalline plates of gossypolone tetramethyl ether were filtered and washed with 20 cc. of petroleum ether (b. p. 30–60°). After two more crystallizations, the melting point was constant at 156–157°.

Anal. Calcd. for $C_{30}H_{22}O_6(OCH_3)_4$: C, 67.77; H, 5.64; $4CH_3O$, 20.59; mol. wt., 602. Found: C, 67.69, 67.42; H, 5.83, 6.06; CH_3O, 21.0, 20.8; mol. wt. (b. p. acetone), 664, 616.

Exactly the same substance was formed by a similar oxidation of gossypol tetramethyl diethyl ether.

The product gave a dark brown color in concentrated sulfuric acid which changed to a light orange on standing for a half hour. It gave no color with ferric chloride and a deep red with pyroboroacetate.

It was insoluble in 10% aqueous sodium hydroxide but was soluble in a 10% methanolic potassium hydroxide solution with decomposition.

This same product may also be made, though less conveniently, by the oxidation of gossypol hexamethyl ether with periodic acid.

By-Product from Oxidation with Chromic Acid: Gossylic Acid Lactone Tetramethyl Ether (III).—The material insoluble in the 120 cc. of boiling methanol was dissolved in 4 cc. of boiling acetone and the solution filtered. Upon standing, a yellow product separated. By crystallization from 4 cc. of acetone it formed yellow needles. A second crystallization this time from 15 cc. of boiling glacial acetic acid gave light yellow needles, m. p. 315–317°.

Anal. Calcd. for $C_{30}H_{22}O_4(OCH_3)_4$: C, 71.58; H, 5.96; CH_3O, 21.75. Found: C, 70.82; H, 5.84; CH_3O, 21.2.

It proved to be identical by mixed melting point determination with the lactone obtained by treating gossypol hexamethyl ether with hydroxylamine followed by alkali and acetic anhydride.

Oxidation of Gossypol Hexamethyl Ether with Dilute Nitric Acid

Water-Insoluble Oxidation Product: Gossypolonic Acid Tetramethyl Ether (IV).—A suspension of 0.40 g. of white gossypol hexamethyl ether in a mixture of 10 cc. of concentrated nitric acid (sp. gr. 1.42) and 40 cc. of water was refluxed for twelve hours. At the start of the reaction the material was a flocculent suspension, in about two hours it became a reddish-brown gummy mass which floated on the acid. Toward the end of the reaction, the mass had become hard. After cooling, the solid was filtered and the filtrate set aside for isolation of the water-soluble product.

The solid was dissolved in ether and the solution shaken repeatedly with sodium bicarbonate solution until all the alkali-soluble material was extracted. The bicarbonate extract was acidified, the yellow precipitate filtered, washed and dried. On crystallization from benzene, it formed small yellow plates, m. p. 249–251° with decomposition, yield 0.14 g. The product is essentially insoluble in methanol.

Anal. Calcd. for $C_{34}H_{34}O_{12}$: C, 64.4; H, 5.36; $(4OCH_3)$, 21.2; mol. wt., 634. Found: C, 64.33; H, 5.32; OCH_3, 20.9; mol. wt. (acetone), 644.

In concentrated sulfuric acid, the compound gave a deep red color, which rapidly faded to a yellow-brown. An alcohol solution gave no color with aqueous ferric chloride. It was not decolorized with sulfur dioxide or aqueous sodium hydrosulfite.

Although stable when dissolved in aqueous sodium bicarbonate, it was unstable in aqueous sodium hydroxide with the appearance of a green color and precipitation of a gummy mass.

It was unchanged by further refluxing (fifteen hours) with dilute nitric acid and was only very slowly affected by chromic acid in acetic acid solution.

When dissolved in concentrated sulfuric acid and the solution allowed to stand for one-half hour and then diluted with water, there was obtained only a brown amorphous powder which could not be made to crystallize.

Demethylation with constant boiling hydrobromic acid yielded no definite product.

The product can be nitrated with cold 100% nitric acid to give a crystalline nitro derivative which obviously has been oxidized also. Its chemical reactions will be reported later.

Water-Soluble Oxidation Product: Gossic Acid.—The dilute nitric acid filtrate from the oxidation reaction was neutralized with sodium carbonate, then acidified to Congo red with sulfuric acid, saturated with sodium chloride and extracted several times with ether. The crude brown product was crystallized twice from toluene from which it separates slowly in the form of long colorless needles, m. p. 184–186°. It may also be crystallized from petroleum ether (b. p. 60–110°), yield 0.16 g. A preferable method of purification for analysis is one crystallization from toluene, followed by sublimation at 15 mm. and then a second crystallization from toluene or petroleum ether (b. p. 60–110°).

Anal. Calcd. for $C_{14}H_{14}O_7$: C, 57.2; H, 4.76; $2OCH_3$, 21.0; neut. equiv., 98; mol. wt., 294. Found: C, 57.18; H, 4.95; OCH_3, 21.0, 20.6; neut. equiv., 104; mol. wt. (camphor), 316.

When larger amounts of gossypol hexamethyl ether were oxidized it was found an advantage to heat the sodium carbonate solution with potassium permanganate until the purple color had become permanent. The precipitate of manganese dioxide was destroyed with sulfur dioxide, the solution acidified with sulfuric acid and saturated with sodium chloride. Extraction in the way previously described gave a product very easily purified. The yields were equivalent to those obtained without the use of potassium permanganate.

The compound gave no color when dissolved in concentrated sulfuric acid. Such a solution after standing one-half hour gave unchanged product on dilution with water. It gave no color with aqueous ferric chloride solution.

Attempts to nitrate the compound with cold 100% nitric acid were unsuccessful and the product was recovered unchanged. The compound was very stable to chromic acid in acetic acid.

An aqueous solution was not oxidized by periodic acid. Refluxing for eight hours in nitric acid (1:1) did not affect the compound.

Permanganate Oxidation of Gossypolonic Acid Tetramethyl Ether: Gossic Acid.—To a suspension of 0.35 g. of gossypolonic acid tetramethyl ether in 200 cc. of water was added, in portions, 1.5 g. of solid potassium permanganate. The reaction mixture was heated on the steam-bath for five hours, at the end of which time there was still excess permanganate present. The flask was cooled, acidified with dilute sulfuric acid and sulfur dioxide was passed through until the excess permanganate and precipitate of manganese dioxide was destroyed. The solution was filtered, saturated with sodium chloride and extracted with ether. The ether extract was evaporated and the gummy residue crystallized from toluene. It formed long, colorless needles that became opaque on drying, m. p. 184–186°, yield 0.15 g. It proved to be gossic acid.

Oxidation of Gossypol Tetramethyl Ether.—Dilute nitric acid oxidation of gossypol tetramethyl ether, according to the directions used for the hexamethyl ether, gave only a nitric acid soluble product. Upon neutralizing and extracting with ether, an oily product, acidic in nature, was obtained. No crystalline substance was separated.

Methyl Ester of Gossic Acid.—To a solution of 0.10 g. of the acid in 5 cc. of ether was added an ether solution of diazomethane from 0.15 g. of nitrosomethyl urea. The reaction mixture was allowed to stand overnight at room temperature, then evaporated to dryness. The residue was purified by sublimation at 20 mm. and crystallized from petroleum ether (b. p. 30–60°) in long colorless needles, m. p. 106°.

Anal. Calcd. for $C_{15}H_{16}O_7$: C, 58.5; H, 5.19; $3OCH_3$, 30.2; mol. wt., 308. Found: C, 58.86; H, 5.25; OCH_3, 31.2; mol. wt. (Rast), 316.

The ester was saponified back to gossic acid by the following procedure. A suspension of 0.10 g. of the ester was refluxed gently with 5 cc. of 10% aqueous sodium hydroxide. The material was insoluble but gradually went into solution on heating. When solution was complete the reaction mixture was acidified, saturated with sodium chloride and extracted with ether. The ether was evaporated and the residue crystallized from petroleum ether (b. p. 60–110°), m. p. 184–186°.

Nitric Acid Oxidation of Gossypolone Tetramethyl Ether.—A suspension of 0.2 g. of gossypolone tetramethyl ether in 25 cc. of water and 8 cc. of concentrated nitric acid was refluxed for six and one-half hours. The insoluble product was worked up as described in the nitric acid oxidation of gossypol hexamethyl ether; yield 0.15 g. Recrystallized from benzene, it formed yellow needles, m. p. 237–238°. A mixed melting point showed it to be identical with gossypolonic acid tetramethyl ether.

Permanganate Oxidation of Gossypolone Tetramethyl Ether.—To a suspension of 0.1 g. of gossypolone tetramethyl ether in 20 cc. of water was added over a period of thirty minutes, 0.4 g. of potassium permanganate crystals. The mixture was heated under reflux for seven hours. Sulfur dioxide was then bubbled in till the manganese dioxide had dissolved and the solution was colorless. Unchanged gossypolone tetramethyl ether was filtered and 1 cc. of concentrated hydrochloric acid added to the filtrate. The filtrate was then extracted several times with ether, the ether extract dried with sodium sulfate, filtered and evaporated to remove the solvent. The gum obtained was dissolved in 10 cc. of boiling acetone, 10 cc. of petroleum ether (b. p. 60–110°) was added, and the mixture evaporated to 9 cc. The product was obtained as described previously and purified in a similar way: yield 0.045 g. of white needles; m. p. 183–184.5°. This product was gossic acid.

Anal. Calcd. for $C_{14}H_{14}O_7$: C, 57.1; H, 4.76. Found: C, 56.52; H, 4.85.

Concentrated aqueous ammonia converted gossypolone tetramethyl ether dissolved in a mixture of 5 cc. of acetone and 5 cc. of ethanol to a yellow crystalline material which separated from solution. It could not be recrystallized and was insoluble in all common organic solvents. It melted above 300°. It gave a deep yellow solution in concentrated sulfuric acid.

Reaction of Aniline with Gossypolone Tetramethyl Ether.—A solution of 0.5 g. of gossypolone tetramethyl ether in 100 cc. of methanol and 0.2 cc. of aniline was boiled gently on a steam-bath for about an hour. The solution was concentrated to 50 cc. and allowed to stand. The crude product which separated was crystallized from 20 cc. of acetone: yellow plates; m. p. 213–215°.

Anal. Calcd. for $C_{34}H_{32}O_8(NHC_6H_5)_2$: C, 73.37; H, 5.84; N, 3.72; $4CH_3O$, 16.45. Found: C, 73.54; H, 5.86; N, 3.70; CH_3O, 16.8.

The product was stable when dry. A solution, however, when exposed to air discolored.

It gave a light yellow color in concentrated sulfuric acid.

Action of Concentrated Nitric Acid on Gossypol Hexamethyl Ether.—By the action of cold 100% nitric acid, gossypol hexamethyl ether is nitrated and oxidized to a crystalline product, the nature of which will be reported later.

Summary

Gossypol hexamethyl ether has been oxidized by chromic acid, periodic acid and by dilute nitric acid. By the action of chromic acid or periodic acid a yellow crystalline product, gossypolone tetramethyl ether, is obtained which is formed by hydrolysis of two methoxyls followed by replacement of four hydrogens by two oxygens. Dilute nitric acid, however, gives two products, one which is water insoluble of a molecular weight comparable with the starting material, named gossypolonic acid tetramethyl ether and the other water-soluble, called gossic acid, of only about half the size. The former can be oxidized with permanganate to the latter. Gossypolone tetramethyl ether is oxidized with dilute nitric acid to gossypolonic acid tetramethyl ether and with permanganate to gossic acid. A discussion of the relationship of these compounds is given.

Gossic acid, $C_{14}H_{14}O_7$, appears to be a benzene derivative and contains a carboxyl, a dibasic acid anhydride linkage, and two methoxyls.

Structure of Gossypol. X.[1] Apogossypol and its Degradation Products

BY ROGER ADAMS AND D. J. BUTTERBAUGH[2]

Clark[3] discovered that by the action of hot concentrated alkali, gossypol, $C_{30}H_{30}O_8$, loses two carbon and two oxygen atoms with the formation of two moles of alkali formate and one mole of a white unstable compound, $C_{28}H_{30}O_6$, which he designated as apogossypol. He demonstrated by methylation and acetylation that this substance contained six hydroxyl groups, for the stable hexaacetyl and hexamethyl derivatives were prepared readily.

Clark did not attempt to speculate as to what occurred in the gossypol molecule by the action of alkali but it is quite obvious from the results published in papers V–IX of this series. The evidence is convincing that gossypol is a hexahydroxy dialdehyde and consequently the ready removal of the aldehyde groups by the action of alkali might be anticipated. Examples of the elimination of aldehyde groups from hydroxy aldehydes in this way are well-known. This is especially true also of easily tautomerized hydroxyaldehydes such as the conversion of hydroxymethylene camphor to camphor by alkali.[4]

It has been shown that two of the six hydroxyls in gossypol are more difficult to methylate than the other four. Moreover, two of the acetyls in gossypol hexaacetate are more difficult to saponify than the other four. Attempts to methylate or acetylate apogossypol to a tetramethyl ether or tetraacetate were unsuccessful but it was found by us that benzoylation yielded merely a tetrabenzoate.

Both apogossypol hexamethyl ether and hexa-

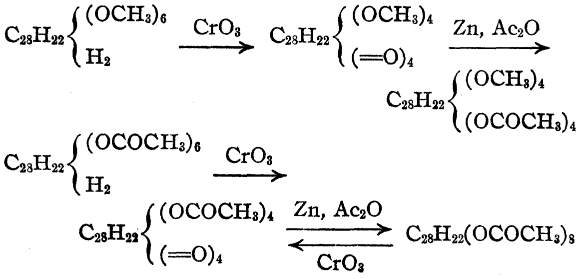
acetate may be oxidized by chromic acid. Clark designated the oxidation product from the hexaacetate as tetraacetylapogossypolone and assigned it the structure $C_{22}H_{16}O_2(OCOCH_3)_4$. To the product from the oxidation of the hexamethyl ether he gave the formula $C_{28}H_{22}O_4(OCH_3)_4$ and named it tetramethoxypseudogossypolone. Our results have demonstrated that these two compounds are analogous and the proper formula for Clark's tetraacetylapogossypolone is actually $C_{28}H_{22}O_4(OCOCH_3)_4$. It is proposed to avoid further confusion by naming both these compounds as apogossypolone derivatives, apogossypolone tetramethyl ether and apogossypolone tetraacetate. The analytical data on the oxidation product of the hexaacetate are equally satisfactory for Clark's assumed compound and the structure assigned it in this Laboratory.

These oxidation products were considered by Clark to be quinones but he offered no experimental evidence for this assumption. It has now been found that they are quinones, since both apogossypolone tetramethyl ether and tetraacetate may be reductively acetylated and the reduction product of the tetraacetate may be reoxidized to the quinone. The formulas, therefore, may be written as follows



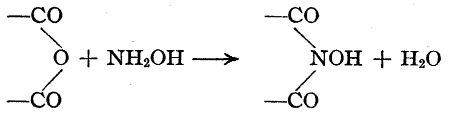
$$C_{28}H_{22}\begin{cases}(OCH_3)_6\\ H_2\end{cases}\xrightarrow{CrO_3}C_{28}H_{22}\begin{cases}(OCH_3)_4\\ (=O)_4\end{cases}\xrightarrow{Zn,\ Ac_2O}C_{28}H_{22}\begin{cases}(OCH_3)_4\\ (OCOCH_3)_4\end{cases}$$

$$C_{28}H_{22}\begin{cases}(OCOCH_3)_6\\ H_2\end{cases}\xrightarrow{CrO_3}C_{28}H_{22}\begin{cases}(OCOCH_3)_4\\ (=O)_4\end{cases}\underset{CrO_3}{\overset{Zn,\ Ac_2O}{\rightleftarrows}}C_{28}H_{22}(OCOCH_3)_8$$

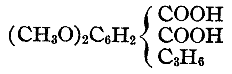
It is obvious that two methoxyl or two acetoxy groups are replaced by oxygens and two additional hydrogens are replaced by oxygens; or, interpreted in another way, two methoxyphenyl or acetoxyphenyl residues in the molecules are converted to quinones. Moreover, it is significant that these molecules differ from the corresponding gossypolone tetramethyl ether or tetraacetate by two carbon and two oxygen atoms. Since the apogossypolone derivatives are unquestionably quinones, this is indirect evidence for the assumed quinone structures of gossypolone derivatives. The analysis of the reductively acetylated apogossypolone tetraacetate does not agree with a formula derived from Clark's postulated structure of apogossypolone tetraacetate.

The apogossypolone tetraacetate is much more sensitive to reagents than the tetramethyl ether and consequently only the latter has been given an exhaustive investigation. Clark[5] oxidized apogossypolone tetramethyl ether with cold permanganate to a white acidic substance which he called apogossypolic acid. He believed this to have the formula $C_{20}H_{24}O_9$ and to be the trimethyl ether of a tricarboxylic acid, which on heating above its melting point lost one molecule of water to produce a trimethyl ether of a ketonic dibasic acid. The latter compound formed a hydrazone and a semicarbazone and hence the presence of a ketonic group was deduced.

A careful study of apogossypolic acid has led us to different conclusions concerning its structure. It proved by titration in aqueous solution to be a dibasic acid. Upon sublimation it lost water to give an anhydride and upon treatment with diazomethane it gave a dimethyl ester. Moreover, the molecular weight of the anhydride gave values which indicated the molecule to be most probably a simple benzene derivative. The molecular formula may be written as $C_{13}H_{16}O_6$ or $C_9H_8(OCH_3)_2(COOH)_2$. The formation of a semicarbazone of the anhydro product with the loss of a molecule of water does not necessarily imply the presence of a ketone group. It readily can be explained by analogy to other dibasic acid anhydrides which react with ketone reagents. Phthalic anhydride, for example, with hydroxylamine gives hydroxyphthalimide[6]



Apogossypolic acid therefore may be given the structural formula



$$(CH_3O)_2C_6H_2\begin{cases}COOH\\ COOH\\ C_3H_6\end{cases}$$

The problem is to determine the disposition of the C_3H_6 residue. It is obvious that in order to explain the facile formation of an anhydride, the two carboxyls must either both be in the *ortho* positions to each other in the ring or one may be in the ring *ortho* to a side-chain holding the carboxyl on the first carbon atom. This limits the structure to (1) a *n*-propyl or isopropyl group in the ring, (2) an ethyl and a methyl group in the ring, (3) a side-chain of the type —$CH(C_2H_5)$-

---

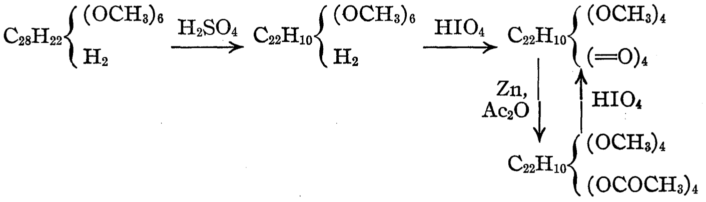
(6) Orndorff and Pratt, *Am. Chem. J.*, **47**, 88 (1912).

COOH or —$C(CH_3)_2COOH$, (4) a side-chain —$CH(CH_3)COOH$ with a methyl group in the ring, (5) a side-chain —CH_2COOH with one ethyl or two methyl groups in the ring. The determination of its exact structure will be the subject of a subsequent communication.

Apogossypol hexamethyl ether undergoes a very unusual reaction under the influence of concentrated sulfuric acid at room temperature. A white stable crystalline substance is formed containing no sulfur and still retaining the six methoxyl groups. This substance will be designated as desapogossypol hexamethyl ether. The molecular weight and analyses agree unusually well for the loss of the residue C_6H_{12} from the starting material and this assumption was confirmed by a study of its oxidation products which apparently are analogous to those of apogossypol hexamethyl ether. Desapogossypolone tetramethyl ether is obtained by a periodic acid oxidation and this product may be reductively acetylated. This latter substance may be reoxidized to the quinone. Both the quinone and its reduction product have C_6H_{12} less than the corresponding apogossypol hexamethyl ether derivatives, and the reaction thus may be formulated as follows



$$\begin{tikzcd}
C_{28}H_{22}\begin{cases}(OCH_3)_6\\ H_2\end{cases} \arrow[r, "H_2SO_4"] & C_{22}H_{10}\begin{cases}(OCH_3)_6\\ H_2\end{cases} \arrow[r, "HIO_4"] & C_{22}H_{10}\begin{cases}(OCH_3)_4\\ (=O)_4\end{cases} \arrow[d, shift right, "{Zn,\ Ac_2O}"'] \\
 & & C_{22}H_{10}\begin{cases}(OCH_3)_4\\ (OCOCH_3)_4\end{cases} \arrow[u, shift right, "HIO_4"']
\end{tikzcd}$$

Assuming that apogossypol is a symmetrical molecule just like gossypol, the elimination of C_3H_6 from each half of the molecule has taken place. Since the reagent for this degradation is cold sulfuric acid, it appeared likely that propyl or isopropyl acid sulfate might be the by-product. The diluted sulfuric acid reaction mixture therefore was distilled and the distillate treated with potassium dichromate and mercuric sulfate. After boiling for one to two minutes, an orange precipitate separated similar to that obtained by the use of acetone. Moreover, the iodoform test of the original distillate is positive. The quantities of material available were so small as to lack the desired convincing proof, but tentatively it has been postulated that two isopropyl groups have been removed from the original molecule. No exact parallel for such a reaction has been found but it is interesting to note that isopropylnaphthalene can be dealkylated by means of hydriodic acid.[7]

The orange quinone, desapogossypolone tetramethyl ether, undergoes oxidation by means of cold permanganate to give a water-soluble dibasic acid which was identified as *m*-hemipinic acid, 1,2-$(CH_3O)_2C_6H_2(COOH)_2$-4,5, by comparison of it, its anhydride and its N-ethylimide with synthetic samples.

The isolation of *m*-hemipinic acid proves definitely that apogossypol hexamethyl ether and therefore gossypol hexamethyl ether contain two pairs of *ortho* methoxyl groups.

Since both *m*-hemipinic acid and apogossypolic acids are formed by permanganate oxidation of quinones, it may be inferred that the *o*-methoxyl groups are not in the quinone rings of the apogossypolone or desapogossypolone tetramethyl ethers since the quinone portions of the molecules probably account for two carboxyl groups found in the oxidation products.

The analogy between the degradation reactions of apogossypol and desapogossypol and the possible identification of acetone in the formation of desapogossypol hexamethyl ether make the assumption inviting that two isopropyl groups have been removed and, hence, that apogossypolic acid and *m*-hemipinic acid differ only by an isopropyl residue.

Apogossypol hexaethyl ether can be prepared readily, but it did not undergo the transformation to the desapogossypol hexaethyl derivative under the conditions used. The discussion of the reagents and conditions employed for preparing these different compounds is given in the experimental part. Suffice it to say here that the yields in the degradation reactions are usually not good and only if the conditions are carefully controlled can crystalline, easily purified compounds be obtained.

Experimental

Apogossypol.—The method employed for the preparation of apogossypol was that described by Clark[3] except for minor modifications. In place of pure gossypol as a raw material, it was found possible to use crude gossypol-acetic acid. To the alkaline solution sodium hydrosulfite, to the extent of about one-fifth the weight of the gossypol-acetic acid, was added to inhibit air oxidation. The apogossypol is unstable and turns dark on standing even in a nitrogen atmosphere in a desiccator. It must be converted immediately after preparation to a hexamethyl ether or a hexaacetate.

---

[7] Meyer and Bernhauer, *Monatsh.*, **54**, 721 (1929).

Freshly prepared apogossypol gives a yellow color in concentrated sulfuric acid, a dark green with ferric chloride and an orange-red with pyroboroacetate. The nickel acetate, diethyl malonate, thiophene-sulfuric acid and stannic chloride tests were all negative. Attempts to prepare an anhydro compound by the method employed for preparing anhydrogossypol were unsuccessful.

Apogossypol Hexamethyl Ether.—The apogossypol was converted to its hexamethyl ether by the method of Clark.[8] A 40% yield of crystalline apogossypol hexamethyl ether or a 60% yield of methanol-insoluble material suitable for oxidation purposes could be obtained from crude gossypol-acetic acid. Pure apogossypol hexamethyl ether was purified by dissolving in the smallest possible volume of benzene, concentrating to one-half the volume and adding three volumes of methanol, m. p. 259°. Clark also reports 259°.

Apogossypolone Tetramethyl Ether.—This product was prepared from crude gossypol hexamethyl ether by oxidation with Kiliani's reagent according to the directions of Clark[8] (called by him tetramethoxy pseudogossypolone).

It could also be obtained by the oxidation with periodic acid. To a solution of 2.0 g. of (methanol-insoluble) apogossypol hexamethyl ether in 90 cc. of dioxane was added 30 g. of periodic acid in 20 cc. of water. The mixture was refluxed for four hours. During this period a 5-g. portion of periodic acid was added at the end of two hours and another at the end of three hours. The bright red solution changed to light yellow. After cooling, the solution was poured into 300 to 400 cc. of water and part of the dioxane removed by a current of air. The orange solid separating during this concentration was collected on a filter, dried and treated with just enough methanol to cover the solid. A bright orange solution resulted from which apogossypolone tetramethyl ether precipitated as a bright yellow solid. For further purification the material was recrystallized from a small volume of methanol in preference to an ether–acetic acid mixture recommended by Clark: m. p. 212–214°; yield 0.37 g.

Anal. Calcd. for $C_{28}H_{22}O_4(OCH_3)_4$: C, 70.3; H, 6.23; mol. wt., 546. Found: C, 70.30, 70.20; H, 6.27, 6.27; mol. wt., 538.

No crystalline products could be obtained by the action of *o*-phenylenediamine or by demethylation with hydrobromic acid in acetic acid.

It gave in concentrated sulfuric acid a dark orange color changing rapidly to bright purple. With the diethyl malonate–ammonia reagent it gave a blue-green.

Reductive Acetylation of Apogossypolone Tetramethyl Ether; Hydroapogossypolone Tetramethyl Ether Tetraacetate.—A mixture of 0.02 g. of pure apogossypolone tetramethyl ether, 0.02 g. of anhydrous sodium acetate, 1.0 g. of zinc dust and 2.0 cc. of acetic anhydride was refluxed for twenty-five minutes. Small additions of zinc dust were made intermittently during this time. The mixture was filtered hot, the residue washed twice with small portions of acetone and the filtrate poured into water to decompose the acetic anhydride. A few drops of glacial acetic acid aided materially in this decomposition. The white hydroapogossypolone tetramethyl ether tetraacetate was purified by crystallization from anhydrous ethanol, m. p. 229–230.5°, yield 0.015 g.

Anal. Calcd. for $C_{28}H_{22}(OCOCH_3)_4(OCH_3)_4$: C, 66.85; H, 6.41. Found: C, 66.93; H, 6.44.

Apogossypolic Acid.—This product was prepared according to unpublished directions of Clark.[9] A solution of 1.0 g. of crude apogossypolone tetramethyl ether (methanol-insoluble material) in 100 cc. of acetone distilled from potassium permanganate was cooled to 0° in an ice-bath. To this was added with stirring in three portions one hour apart 1.7 g. of potassium permanganate. The mixture was stirred, kept cold for twenty-four to thirty hours, after which time the manganese dioxide was collected on a gravity filter and washed free of any excess permanganate with acetone. After *thorough* air drying of the manganese dioxide precipitate, it was covered with water to which two or three drops of ethanol were added to decompose any permanganate that might not have been removed. It was then heated on a steam-bath for fifteen minutes. The manganese dioxide was removed by filtration and the alkaline solution acidified with dilute sulfuric acid. The yellow semi-solid material which separated was extracted with ether. The ether solution was dried and then concentrated to a few cubic centimeters. After addition of 15 cc. of dry benzene and concentration until the product started to separate (about 5–8 cc.), the solution was allowed to stand a day for crystallization. The apogossypolic acid obtained is essentially pure but may be purified further by dissolving in dry ether, pouring into benzene and concentrating till crystallization begins: white crystals, m. p. 162–165°, but the value obtained is very dependent on the rate of heating.

Anal. Calcd. for $C_{13}H_{16}O_6$: C, 58.2; H, 5.97; neut. equiv., 2COOH, 134. Found: C, 58.10, 58.00; H, 5.89, 5.90; neut. equiv., 134.

Dimethyl Ester of Apogossypolic Acid.—To an ether solution of 0.07 g. of apogossypolic acid was added an ether solution of diazomethane prepared from nitrosomethyl urea. At the end of twenty-four hours at room temperature, the solution was filtered and concentrated by evaporation. The oil obtained required about twenty days in an ice box before it became crystalline. For purification, it was twice sublimed at 25 mm.: white crystals; m. p. 45–46.5°.

Anal. Calcd. for $C_{15}H_{20}O_6$: C, 60.8; H, 6.76. Found: C, 60.49; H, 6.77.

Apogossypolic Acid Anhydride.—Sublimation of apogossypolic acid at 25 mm. with a bath temperature of 170–180° gave the anhydride in quantitative yields. After a second sublimation at 90–100°, a white product, m. p. 93–94° (Clark, 95°), resulted.

Anal. Calcd. for $C_{13}H_{14}O_5$: C, 62.40; H, 5.60; neut. equiv., 2COOH, 125; $2OCH_3$, 24.8. Found: C, 62.10; H, 5.39; neut. equiv., in H_2O, 123; OCH_3, 23.6.

The Action of Semicarbazide Hydrochloride on Apogossypolic Acid Anhydride.—A mixture of 0.075 g. of apogossypolic acid anhydride, 0.075 g. of semicarbazide hydrochloride, 0.112 g. of sodium acetate and 1.2 cc. of 95% ethanol was immersed in a bath of hot water and left while

---

(8) Clark, THIS JOURNAL, **51**, 1475 (1929).

(9) Private communication from E. P. Clark.

the bath cooled. After standing for five hours, a few drops of water was added and the sides of the container scratched. The product crystallized and was purified by dissolving in a little methanol and adding an equal volume of water. Fine white crystals separated in the course of a few hours, m. p. 221–223°, yield 0.055 g. Clark reported 233°.

Anal. Calcd. for $C_{14}H_{17}O_5N_3$: C, 54.8; H, 5.54; N, 13.68. Found: C, 54.91; H, 5.60; N, 13.58.

Action of Concentrated Sulfuric Acid on Apogossypol Hexamethyl Ether; Desapogossypol Hexamethyl Ether.—To 80 cc. of concentrated sulfuric acid was added with vigorous stirring to aid solution, 4.0 g. of apogossypol hexamethyl ether. The mixture was allowed to stand for thirty minutes at room temperature and then poured onto ice. A fine purple-tinted amorphous material precipitated which was extremely difficult to filter. The dilute sulfuric acid suspension was therefore shaken with 25 to 50 cc. of ether, the two layers separated and the ether suspension poured into water. As the ether was evaporated on the steam-bath, a gray-white granular precipitate was obtained; yield 3.3 g. The product was purified by dissolving it in the smallest possible volume of boiling benzene, concentrating to about 40% of its original volume and adding two volumes of methanol. Crystallization was complete in about three hours; yield 1.6 g. An additional treatment in benzene with Norite followed by concentration and addition of methanol as previously described gave a white crystalline product, m. p. 295–296°.

Anal. Calcd. for $C_{28}H_{30}O_6$: C, 72.70; H, 6.50; mol. wt., 462; OCH_3, 40.2. Found: C, 72.62, 72.73, 72.68; H, 6.79, 6.56, 6.56; mol. wt., 425; OCH_3, 36.1, 35.8, 36.3, 37.8, 37.7, 35.8, 36.7.

In preparing the above compound in larger quantities, crude (methanol-insoluble) apogossypol hexamethyl ether proved satisfactory. Once recrystallized sulfuric acid compound was satisfactory for degradation purposes.

The product gave an orange-yellow color in concentrated sulfuric acid.

Periodic Acid Oxidation of Desapogossypol Hexamethyl Ether; Desapogossypolone Tetramethyl Ether.—A solution of 2.0 g. of desapogossypol hexamethyl ether in 140 cc. of dioxane was prepared by heating to boiling. After cooling to 40–50°, a saturated aqueous solution of 30 g. of periodic acid was added. The mixture was heated gently for a half hour during which time the solution refluxed vigorously and turned a dark red-brown color. The solution was then heated till it refluxed and after another thirty minutes a second 30-g. portion of periodic acid was added. After two more hours of refluxing, during which period the solution generally changed to orange in color, the solution was cooled to 60–70° and poured into 400 cc. of water. An orange flocculent precipitate formed. The major portion of the dioxane was removed by a current of air and the orange powder filtered; yield 1.5 g. This crude product was digested with 10 cc. of warm methanol for thirty minutes during which time all the lumps were crushed thoroughly with a glass rod. After standing for one hour, an orange powder weighing 0.53 g. was obtained. This was further purified by dissolving in a small volume of acetone, adding two volumes of methanol and concentrating till crystals appeared. The product formed orange spikes, softening at 199° and melting at 236–238° with decomposition. This product retained a small amount of solvent which was very difficult to remove; consequently, it was dissolved in benzene and concentrated to one-half volume, diluted with benzene and again concentrated. Petroleum ether (b. p. 60–110°) was then added, the mixture concentrated to one-half and this procedure repeated till practically all the benzene was removed. On cooling, an orange microcrystalline product separated, m. p. 245–248° with decomposition. This was used for analysis.

Chromic acid and Kiliani's reagent could not be substituted for periodic acid. With these reagents an orange product resulted but could not be obtained crystalline.

Anal. Calcd. for $C_{26}H_{22}O_8$: C, 67.5; H, 4.76; $4OCH_3$, 26.8. Found: C, 67.20; H, 4.98; OCH_3, 23.5, 23.3.

It gave a permanent dirty brown color in concentrated sulfuric acid. The *o*-quinone test with thiophene-sulfuric acid was negative.

Reductive Acetylation of Desapogossypolone Tetramethyl Ether; Hydrodesapogossypolone Tetramethyl Ether Tetraacetate.—A mixture of 0.4 g. of *pure* desapogossypolone tetramethyl ether, 5 cc. of acetic anhydride, 0.4 g. of fused sodium acetate and 2 g. of zinc dust was refluxed gently for twelve minutes. Small additions of zinc dust were made from time to time during this period. The solution was then filtered, the zinc washed with acetone and the filtrates poured into water. The fine white crystalline powder was purified by crystallization from methanol, m. p. 264–266°, yield 0.36 g.

Anal. Calcd. for $C_{34}H_{34}O_{12}$: C, 64.40; H, 5.37; $4CH_3CO$, 27.1. Found: C, 64.03, 64.28; H, 5.50, 5.18; CH_3CO, 25.8, 25.8.

Periodic Acid Oxidation of Hydrodesapogossypolone Tetramethyl Ether Tetraacetate.—Excess (2 to 3 g. in 2 cc. of water) periodic acid was added to a dioxane solution of 0.030 g. of hydrodesapogossypolone tetramethyl ether tetraacetate and the solution warmed gently on a steam-bath for fifteen to twenty minutes. During this time a colorless to yellow to orange-red change was observed. The orange product, precipitated by the addition of water to the dioxane solution, was collected on a filter, dried, digested with a small volume of methanol and crystallized from a hot mixture of benzene and methanol. The orange crystals so obtained proved to be identical with desapogossypolone tetramethyl ether obtained by the periodic acid oxidation of desapogossypol hexamethyl ether.

Permanganate Oxidation of Desapogossypolone Tetramethyl Ether; *m*-Hemipinic Acid.—To a cold (0°) solution of 0.5 g. of desapogossypolone tetramethyl ether in 130 cc. of acetone (distilled from permanganate) was added portionwise over a period of five hours, 1 g. of potassium permanganate. The solution was stirred and maintained at 0° for forty-eight hours. The manganese dioxide was filtered and washed to remove excess permanganate. The manganese dioxide precipitate was air-dried, then covered with water to which two to three drops of ethanol and 0.5–1 cc. of 10% aqueous sodium bicarbonate had been added. After heating on a steam-bath for fifteen minutes, the manganese dioxide was filtered and a dark orange solution remained. Dilute sulfuric acid precipitated a tan flocculent material which was extracted with ether. After drying the ether solution with sodium sulfate, a little benzene was added and the mixture concentrated. After the ether was removed, a light colored crystalline product began to separate. After standing for several hours, it was filtered and purified by a Norite treatment in acetone solution, followed by concentration after the addition of benzene, m. p. 191°, yield 0.13 g.

To complete the purification of this slightly colored material, it was sublimed at 60 mm. in a bath at 195°. A perfectly white crystalline product resulted, m. p. 179–181°, which apparently was the anhydride of the unsublimed material. This substance proved to be *m*-hemipinic acid anhydride. Carr and Pyman[10] report m. p. 176° for this substance.

Anal. Calcd. for $C_{10}H_8O_5$: C, 57.70; H, 3.85; mol. wt., 208. Found: C, 57.82; H, 4.14; mol. wt. (Rast), 215.

This anhydride was dissolved in 5% aqueous sodium hydroxide and the solution acidified with acid, keeping the mixture below 20°. The white insoluble *m*-hemipinic acid was extracted with ether, the ether solution dried and mixed with an equal volume of petroleum ether (b. p. 30–60°). Upon evaporation at room temperature long white needles of *m*-hemipinic acid separated, m. p. 191°. Carr and Pyman report a melting point of 192°.

Anal. Calcd. for $C_{10}H_{10}O_6$: C, 53.20; H, 4.43; neut. equiv., 113; mol. wt., 226. Found: C, 53.29; H, 4.65; neut. equiv., 115; mol. wt. (Rast), 224.

N-Ethylimide.—The acid just described was dissolved in an excess of ethanolic ethylamine containing 30–40% water. The product obtained by evaporating the solution to dryness on a steam-bath was sublimed at 60 mm. and a bath temperature of 235–240°. The fine white needles were then recrystallized from methanol, m. p. 229–231°. Carr and Pyman report a variety of melting points of the N-ethylimide of *m*-hemipinic acid ranging from 228–234°.

Anal. Calcd. for $C_{12}H_{13}O_4N$: C, 61.35; H, 5.54; N, 5.96. Found: C, 61.49; H, 5.68; N, 5.92.

m-Hemipinic acid, its anhydride and N-ethylimide were synthesized from veratric aldehyde[11] by Perkin's[12] method. The melting points are recorded in Table I.

TABLE I

COMPARISON OF *m*-HEMIPINIC ACID FROM APOGOSSYPOL AND BY SYNTHESIS

	Acid	Anhydride	N-Ethylimide
Synthetic	190–191	176–177	228–231
Mixture	190–191	176–178	229–231
From apogossypol	190–191	179–181	229–231

Apogossypol Dimethyl Ether.—To a small pressure bottle filled with nitrogen was added 12 cc. of 30% methanolic potassium hydroxide and 0.5 g. of gossypol dimethyl ether.[13] The flask was closed and heated at 100° for four hours after which period it was cooled and the contents poured into 8 cc. of water and acidified immediately with concentrated sulfuric acid. A light cream colored precipitate formed which could not be separated by filtration. The suspension was extracted with ether, dried and evaporated to yield a light brown amorphous solid. No method of purification was discovered. Methylation of this product in 20% aqueous alkali gave apogossypol hexamethyl ether, m. p. 259°.

Apogossypol Hexaethyl Ether.—To a solution of 2.0 g. of freshly prepared dry apogossypol in 10 cc. of methanol was added 12 cc. of pure diethyl sulfate and then dropwise with stirring a saturated methanolic solution of potassium hydroxide until the mixture was alkaline to moist litmus. After standing for several hours, the mixture was poured into water and the brown powder filtered. It was purified by dissolving in the smallest possible amount of benzene followed by addition of four volumes of methanol. This was repeated several times until the melting point was constant, 176–180°; yield 0.8 g.

Anal. Calcd. for $C_{28}H_{24}(OC_2H_5)_6$: C, 76.15; H, 8.57. Found: C, 75.82; H, 8.36.

Apogossypol Hexaacetate.—This product was prepared by the method of Clark[3] in yields of 62% of crystalline material, using crude gossypol-acetic acid for the conversion to apogossypol.

Apogossypolone Tetraacetate.—Clark's[3] procedure was used in this preparation. It was found that crude apogossypol hexaacetate gave satisfactory results. The product was purified from methanol, m. p. 230–232°. Clark reports 230°.

It gave in concentrated sulfuric acid a dark orange color changing rapidly to bright purple; with diethyl malonate–ammonia reagent, it gave a reddish-purple.

Reductive Acetylation of Apogossypolone Tetraacetate; Hydroapogossypolone Octaacetate.—A mixture of 0.62 g. of apogossypolone tetraacetate, 10 cc. of acetic anhydride, 0.3 g. of fused sodium acetate and 2 g. of zinc dust was refluxed gently for twelve minutes. The product was isolated as described for hydroapogossypolone tetramethyl ether tetraacetate; yield quantitative. After crystallization from ethanol it formed white crystals, m. p. 225–229°.

Anal. Calcd. for $C_{44}H_{46}O_{16}$: C, 63.8; H, 5.32. Found: C, 63.74; H, 5.33.

Oxidation of hydroapogossypolone octaacetate gave apogossypolone tetraacetate. To a hot solution of 0.2 g. of octaacetyl product in 10 cc. of glacial acetic acid was added 1 cc. of 10% aqueous chromic acid. The mixture was heated for one minute and poured onto ice. The bright orange apogossypolone tetraacetate melted at 230–232°.

Apogossypol Tetrabenzoate.—To 45 cc. of a cooled 20% aqueous sodium hydroxide solution of 2.5 g. of apogossypol was added in portions with stirring and cooling 18 cc. of benzoyl chloride. A light yellow product separated and was purified by dissolving in a small volume of hot benzene, concentrating one-half, adding an equal volume of methanol and allowing to stand. The benzoate crystallizes as white crystals with a faint pinkish tint: m. p. 314–316°; yield 1.9 g.

Anal. Calcd. for $C_{28}H_{24}(OCOC_6H_5)_4$: C, 76.55; H, 5.24. Found: C, 76.42; H, 4.89.

Gossypol Tetrabenzoate.—In a previous article[14] gossypol hexabenzoate was described. The analysis of this sub-

stance was poor for the hexa but it conforms satisfactorily to a tetrabenzoate which we now believe it to be. This opportunity is therefore taken to correct the error appearing in the earlier paper.

Summary

Apogossypol formed by the action of concentrated aqueous sodium hydroxide on gossypol yields a stable hexaacetate and a stable hexamethyl ether.

Both these products are oxidized to quinones, apogossypolone tetraacetate and apogossypolone tetramethyl ether. During this reaction, two acetoxy groups in the acetate and two methoxyl groups in the ether have been eliminated.

The presence of two quinone nuclei in each was proven by reductive acetylation. Hydroapogossypolone octaacetate and hydroapogossypolone tetramethyl ether tetraacetate are thus produced and the former could be reoxidized readily to apogossypolone tetraacetate.

The apogossypolone tetramethyl ether is oxidized with permanganate to a water-soluble acid, called apogossypolic acid, $C_{13}H_{13}O_6$. It contains two methoxyls and two carboxyl groups.

Apogossypol hexamethyl ether by the action of cold concentrated sulfuric acid loses the residue C_6H_{12} with the formation of a product called desapogossypol hexamethyl ether. This product is oxidized with periodic acid to desapogossypolone tetramethyl ether which corresponds to apogossypolone tetramethyl ether in being a quinone but with C_6H_{12} lost. Reductive acetylation gives hydrodesapogossypolone tetramethyl ether tetraacetate which can be reoxidized to desapogossypolone tetramethyl ether. This reductively acetylated product also analyzes for C_6H_{12} less than hydroapogossypolone tetramethyl ether.

When apogossypolone tetramethyl ether is oxidized with permanganate, *m*-hemipinic acid is formed as proved by a comparison with an authentic sample. It is thus demonstrated that two methoxyls are adjacent and since gossypol or apogossypol are symmetrical molecules, two pairs of *o*-methoxyls must be present.

Since apogossypolic acid and *m*-hemipinic acid differ by a C_3H_6 or half the C_6H_{12} lost in conversion of apogossypol tetramethyl ether to desapogossypol tetramethyl ether, it is a reasonable assumption that the difference is merely an isopropyl or propyl residue. The difference between the apo and desapo series would then be two isopropyl or propyl residues. Evidence is presented to indicate these groups to be isopropyl.

Structure of Gossypol. XI.[1] Absorption Spectra of Gossypol, its Derivatives and of Certain Dinaphthalene Compounds

BY ROGER ADAMS AND E. C. KIRKPATRICK[2]

Previous work on the structure of gossypol has involved the preparation of derivatives and degradation products. While much information has thus been obtained concerning the functional groups present, little evidence is available as yet to indicate the nature of the basic nucleus of gossypol. Ultraviolet absorption offers a method of procuring such knowledge.

An examination of the spectra of gossypol[3] and many of its derivatives shows them all to be characterized by an absorption maximum at approximately 2500 Å. with the logarithm of the molal extinction coefficient close to 5 and a maximum or point of inflection near 3000 Å. with a log *e* of 4. Thus, gossypol is a very intense absorbent which can be explained only by assuming the presence of aromatic rings.

A comparison of the absorption spectrum of gossypol with those of substituted naphthalenes indicates that it is of the same general shape but with subdued detail.[4] The peaks of the gossypol curve are regularly more intense. If this intensity were due merely to auxochromes or other

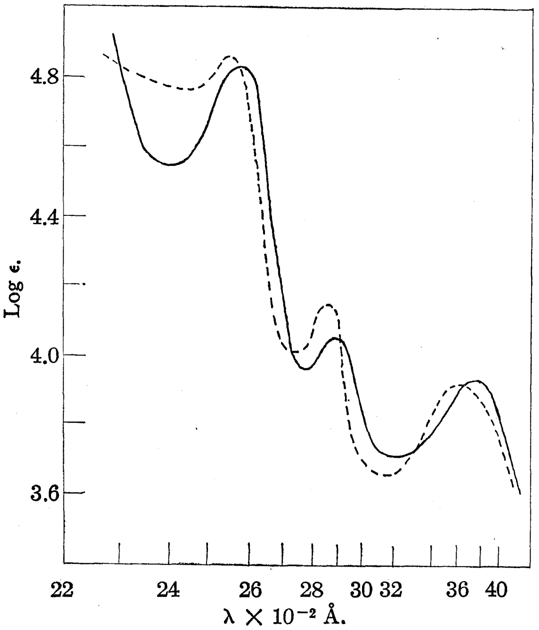
chromophores in the molecule, the peaks of the curves of the various derivatives of gossypol in which the functional groups have been modified or eliminated, should vary considerably from those of gossypol and in general should be less intense. This has been found not to be the case. Thus, for example, the absorption spectrum of apogossypol hexamethyl ether (Figs. 1 and 4) which has two aldehyde groups less than gossypol shows only minor differences in the two main peaks from that of gossypol, instead of approaching in resemblance more closely that of naphthalene.

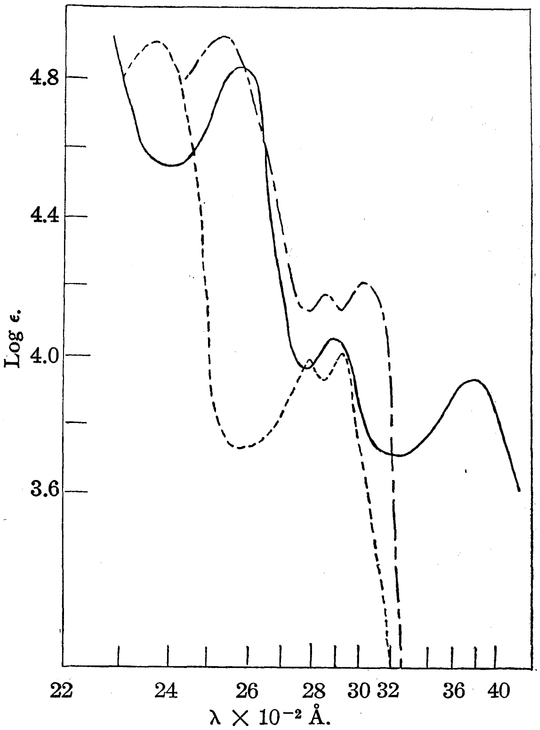


(1) —, Gossypol; (2) - - -, gossypol dimethyl ether.

Fig. 1.

The spectra of compounds with more complex condensed ring systems such as phenanthrene, anthracene, chrysene, naphthacene, benzanthracene, etc., are quite different from those of naphthalene derivatives or of gossypol. Both absorption regions, log e = 4 and log e = 5, become much broader, contain many more peaks shifted toward the visible and in general show no sharp distinction between the two regions. Closely-packed ring systems such as pyrene and perylene enhance this effect so that they both have strong absorption in the visible. Fluorene, as illustrative of a molecule containing separated benzene rings, has much less intensity of absorption than gossypol. Oxygen-containing rings and quinones also have distinctly different spectra.[5]

The difference between the two principal peaks in gossypol and in naphthalene derivatives is one of intensity. The enhancement of the intensity in the gossypol spectrum is by an amount which could be satisfactorily explained by assuming double the number of naphthalene rings per mole.



(1) —, Gossypol; (2) — -, β,β-binaphthyl; (3) - - -, α,α-binaphthyl.

Fig. 2.

Consequently, the absorption spectra have been determined of four dinaphthalene compounds: α,α-binaphthyl, β,β-binaphthyl, *sym*-di-α-naphthylethane, and *sym*-di-β-naphthylethane (Figs. 2 and 3). These all have absorption regions of the same character and intensity as gossypol but nearer the ultraviolet. Because of the many substituents in gossypol, it is impossible to identify its absorption spectrum with any one of the four. However, the log e = 5 absorption region is closer to the visible in the two binaphthyls than in the two dinaphthylethanes and consequently the position and character of the peaks

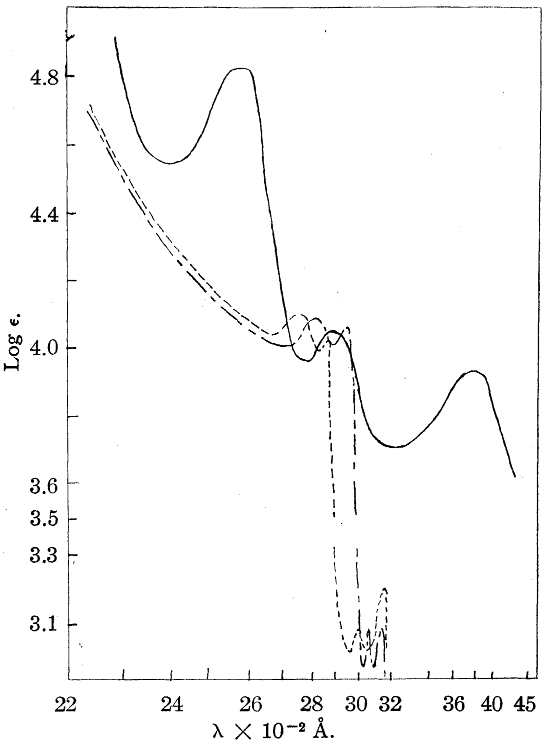
in the curves of the former two resemble more closely those of gossypol. The conclusion is that either an α,α-binaphthyl or a β,β-binaphthyl is probably the basic nucleus of gossypol.

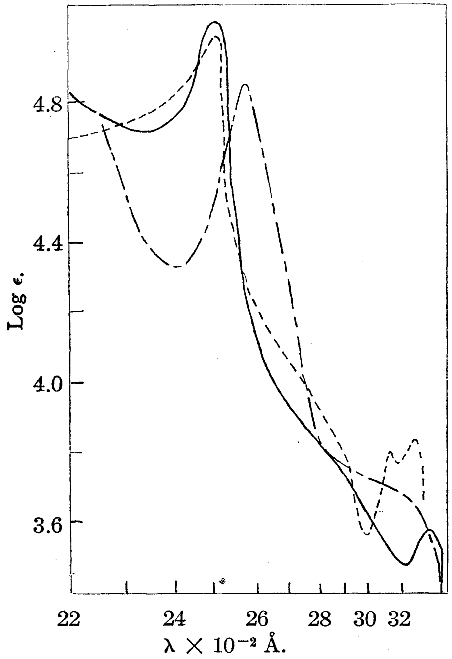


(1) —, Gossypol; (2) - - -, *sym*-di-β-naphthylethane; (3) — -, *sym*-di-α-naphthylethane.

Fig. 3.

Gossypol and gossypol dimethyl ether, which resemble each other chemically, have very similar absorption spectra, Fig. 1, with an absorption maximum at 3600 Å. This maximum was not found in the spectra of gossypol tetramethyl ether, hexamethyl ether or hexaacetate. All of these gossypol derivatives show none of the characteristic aldehyde reactions of gossypol and are in general less reactive. The fact that the region of strong absorption in or near the visible is a low energy excitation coupled with its complete disappearance in the more highly methylated or the acetylated derivatives points strongly to a tautomeric structure in gossypol and gossypol dimethyl ether. Tautomerism is also to be inferred from the fact that ordinary analogous hydroxy and methoxy compounds differ from each other in absorption spectra only slightly whereas a marked change occurs in these gossypol derivatives when methylation or acetylation has been effected.

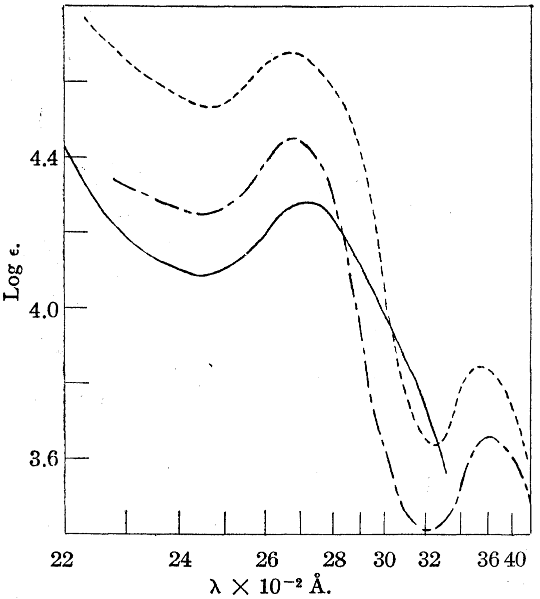
The absorption spectra of gossypol hexamethyl ether, apogossypol hexamethyl ether and desapogossypol hexamethyl ether are shown in Fig. 4. The basic nuclei must be very similar or identical in all of these. Apogossypol hexamethyl ether is converted into desapogossypol hexamethyl ether by the action of cold sulfuric acid. The alteration which takes place in this transformation as deduced from absorption spectra comparisons must be in the substituents and not in the nucleus. This is confirmatory of the deductions from chemical information.



(1) —, Apogossypol hexamethylether; (2) - - -, desapogossypol hexamethyl ether; (3) — -, gossypol hexamethyl ether.

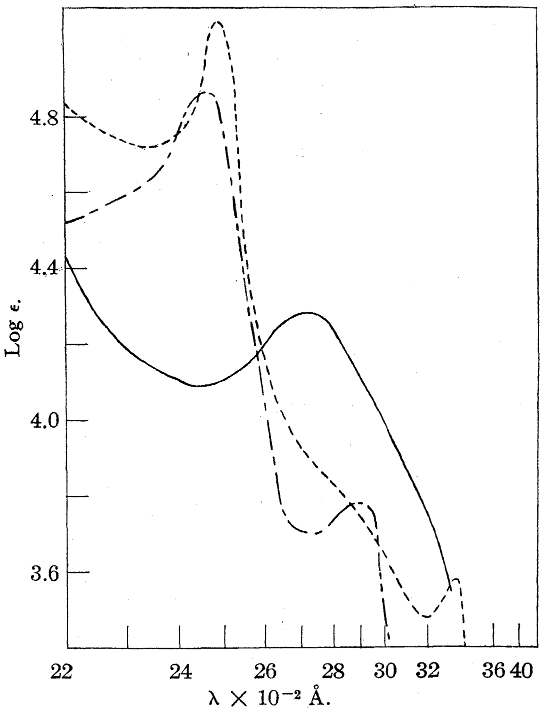
Fig. 4.

Gossypol hexamethyl ether is oxidized first to gossypolone tetramethyl ether, then to gossypolonic acid tetramethyl ether. Apogossypol hexamethyl ether is oxidized to apogossypolone tetramethyl ether. The molecular weights of all these oxidation products are not far different from the parent compounds. The absorption spectra, however, are materially different. In place of the sharp peak near 2500 Å. in the unoxidized substances, these products have less intense broad bands at a position nearer the visible, (Fig. 5). Solubility difficulties prevented the study of apogossypolone tetramethyl ether at higher concentrations which would allow observation of the second less intense maximum. The curve obtained, however, is less intense though very similar to that of the gossypolone tetramethyl ether or gossypolonic acid tetramethyl ether. The difference in the absorption spectra between the unoxidized and oxidized products resembles the difference between the absorption spectrum of naphthalene and 1,4-naphthoquinone. Broad bands appear with decrease in intensity indicating a change in ring structure.[5c,d] These facts substantiate the chemical experiments which gave evidence of quinone nuclei.



(1) —, Apogossypolone tetramethyl ether; (2) - - -, gossypolone tetramethyl ether; (3) — -, gossypolonic acid tetramethyl ether.

Fig. 5.

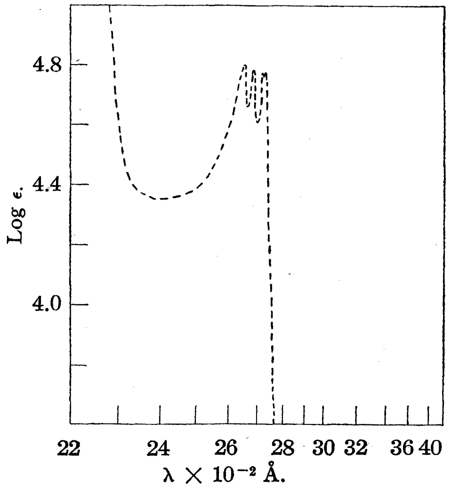


(1) - - -, Apogossypol hexamethyl ether; (2) —, apogossypolone tetramethyl ether; (3) — -, hydroapogossypolone octaacetate.

Fig. 6.

Reductive acetylation of apogossypolone tetramethyl ether results in hydroapogossypolone tetramethyl ether tetraacetate and the latter product[6] has a spectrum resembling that of apogossypol tetramethyl ether, thus suggesting a return to the original ring structure. These changes are shown in Fig. 6. Conversion of a naphthalene to a naphthoquinone then reconversion to a naphthalene may be inferred from the absorption spectra of this series of compounds.

Anhydrogossypol (Fig. 7) has a spectrum entirely different from those of other gossypol derivatives tested. It may be concluded that loss of water when gossypol is converted to anhydrogossypol involves a deep-seated change such as the formation of a new ring containing unsaturation and the alteration of the electronic configuration of the basic ring structure.



Anhydrogossypol.

Fig. 7.

---

[6] In taking the absorption spectra, hydroapogossypolone octaacetate was the substance actually used. Since, however, the acetates and the ethers in the apogossypol series resemble each other very closely, the curve given in Fig. 6 must be essentially the same as that of the tetramethyl ether tetraacetate.

Experimental

The absorption spectra were taken on a Bausch and Lomb ultraviolet spectroscope using a hydrogen discharge tube operating under 15,000 volts as a light source. The calibration of wave length was made from the lines Hα, Hβ and Hγ from this source. A quartz cell exactly 1 cm. thick was used throughout with a slit width of 60 μ and appropriate exposure. Stock solutions 5×10^{-4} molar were diluted to yield a series of seven concentrations between this and 5×10^{-6} molar. These concentrations covered the critical concentrations in all cases.

Gossypol and all its derivatives except anhydrogossypol were dissolved in alcohol for these determinations. Anhydrogossypol was dissolved in absolute alcohol and the absorption spectrum taken immediately. Of the α,α-binaphthyl, β,β-binaphthyl, *sym*-di-α-naphthylethane and *sym*-di-β-naphthylethane only the first two were sufficiently soluble in alcohol; as a consequence purified dioxane[7] was used as a solvent for all four. That dioxane gives absorption spectra comparable to those taken in alcohol was shown by the fact that α,α-binaphthyl gave identical curves in both solvents.

Summary

On the basis of the comparison of the ultraviolet absorption spectra of gossypol and its derivatives with known spectra of aromatic ring systems and with four dinaphthalene compounds, α,α-binaphthyl, β,β-binaphthyl, *sym*-di-α-naphthylethane, *sym*-di-β-naphthylethane, it was concluded that gossypol probably contains a binaphthyl nucleus.

The following deductions were drawn from a study of the absorption spectra of gossypol derivatives. (a) Gossypol and gossypol dimethyl ether have a third absorption maximum not found in gossypol tetramethyl ether, hexamethyl ether or hexaacetate. (b) The difference between the absorption spectra of the oxidation products of gossypol hexamethyl ether or apogossypol hexamethyl ether resembles the difference between the naphthalene and 1,4-naphthoquinone. Quinone structures for the oxidation products were thus deduced.

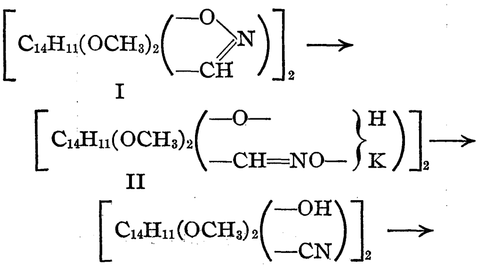
The Structure of Gossypol. XII.[1] Gossylic Acid Lactone Tetramethyl Ether

BY ROGER ADAMS AND T. A. GEISSMAN

When the compound (I) obtained by treatment of gossypol hexamethyl ether with hydroxylamine hydrochloride in acetic acid is dissolved in methanolic potassium hydroxide, a crystalline potassium salt (II) is obtained. This salt when heated in acetic acid solution undergoes a change which is assumed to follow the course formulated below, resulting in the formation of a lactone (III)[2]



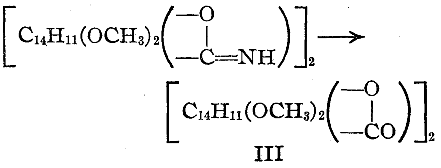
$$\left[C_{14}H_{11}(OCH_3)_2\left(\begin{matrix}-O-\\ -CH=\end{matrix}N\right)\right]_2 \longrightarrow$$

I

$$\left[C_{14}H_{11}(OCH_3)_2\left(\left.\begin{matrix}-O-\\ -CH=NO-\end{matrix}\right\}\begin{matrix}H\\ K\end{matrix}\right)\right]_2 \longrightarrow$$

II

$$\left[C_{14}H_{11}(OCH_3)_2\left(\begin{matrix}-OH\\ -CN\end{matrix}\right)\right]_2 \longrightarrow$$



$$\left[C_{14}H_{11}(OCH_3)_2\left(\begin{matrix}-O\\ |\\ -C=NH\end{matrix}\right)\right]_2 \longrightarrow$$

$$\left[C_{14}H_{11}(OCH_3)_2\left(\begin{matrix}-O\\ |\\ -CO\end{matrix}\right)\right]_2$$

III

The same compound is obtained in small yields as a by-product in the oxidation of gossypol hexamethyl ether with chromic acid in acetic acid.[3]

In this communication evidence is presented that this substance not only is a lactone but that it is formed from a carboxyl and a *phenolic* hydroxyl group. This information along with the results reported in previous papers and additional evidence since accumulated in this Laboratory leads to the conclusion that a lactone structure between the *peri* positions of a naphthalene nucleus (IV) is actually in hand.

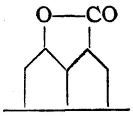
[3] Adams, Morris and Kirkpatrick, *ibid.*, **60**, 2170 (1938).



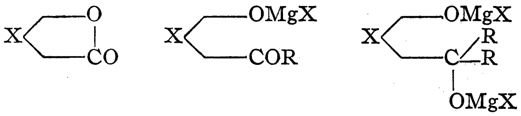
IV

The lactone ring can be opened by warming the compound in 10% methanolic potassium hydroxide solution; acidification of the alkaline solution gives the hydroxy acid (V). It can be converted into the lactone merely by warming in acetic anhydride.

By treatment of the hydroxy acid in methanolic alkali with dimethyl sulfate, the hydroxyl and carboxyl groups are methylated leading to the dimethyl ester of gossylic acid hexamethyl ether (VI). Moreover, the hydroxy acid may be methylated in ether solution with diazomethane to give the same compound (VI). This latter reaction is significant in that alcohols do not ordinarily methylate with this reagent and, hence, it may be inferred that the hydroxyls are phenolic groups. Attempts to hydrolyze the ester (VI) to the corresponding acid were unsuccessful, lending support to the conclusion that ortho substituents to the carbomethoxy groups are present, which hinder saponification. Added confirmation of this is found in the fact that attempts to esterify the hydroxy acid (V) in methanol–sulfuric acid or methanol–hydrochloric acid were equally unsuccessful. Attempted esterification by the methanol–mineral acid procedure resulted in the formation of the lactone.

Methylmagnesium iodide reacts with the lactone to give a compound in which each lactone residue has added one mole of reagent (VII); this substance will be called homogossypol tetramethyl ether since it is homologous with a tautomeric form of one of the possible gossypol tetramethyl ethers. The product is soluble in methanolic alkali and can be methylated in two ways with the formation of isomeric methyl ethers. Upon treatment of an alkaline solution of homogossypol tetramethyl ether (VII) with dimethyl sulfate, the ether produced is formulated as a methoxy methyl ketone (VIII), while treatment with methanol containing a few drops of sulfuric acid gives an isomeric ether probably of the acetal type (IX).

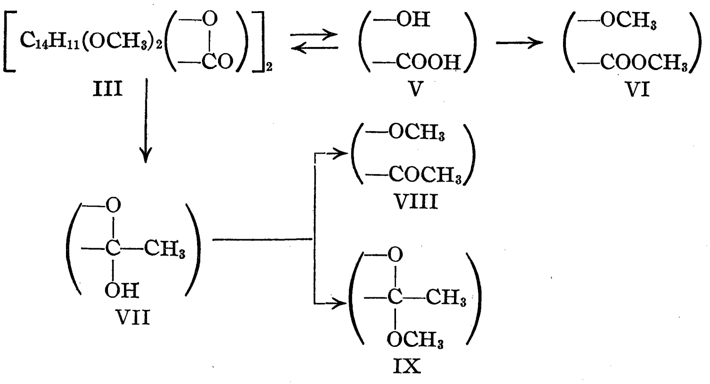
Considerable significance can be attached to the fact that a large excess of Grignard reagent did not bring about the addition of more than one mole to each of the two lactone linkages. The usual course of the reaction between a lactone and a Grignard reagent is as follows



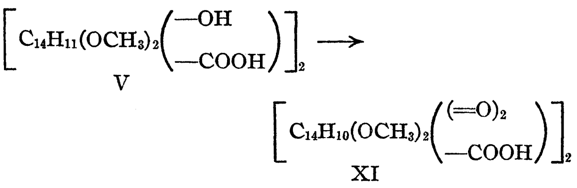
Xa Xb

Since in the present case the keto group represented by step Xa does not undergo further addition (Xb), a reasonable assumption is that it is present in the molecule with ortho substituents on each side as in a 2-substituted 1-naphthyl methyl ketone. The same explanation accounts for the resistance of the ester (VI) to saponification.

The lactone (III) was surprisingly stable to oxidizing agents; it was unattacked by potassium permanganate under most conditions, severe treatment resulting in complete destruction of the molecule. Chromic acid did not oxidize the molecule, which indicates that in the chromic acid oxidation of gossypol hexamethyl ether,[3] the lactone is formed as a by-product and not as an intermediate. The lactone was not affected by dilute nitric acid of a strength which readily oxidized gossypol hexamethyl ether. It was found impossible also to reduce the lactone although a variety of reagents was employed.



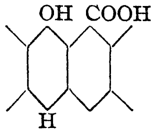
The hydroxy acid (V) differs from the lactone in that it can be oxidized by dilute nitric acid ($1HNO_3{:}4H_2O$) and the product (XI) is gossypolonic acid tetramethyl ether, the water-insoluble compound obtained by a similar oxidation of gossypol hexamethyl ether. It is probable that the ring containing the *peri* hydroxyl is converted to a quinone and since only two hydrogens for each quinone ring formed are lost in the process, a hydrogen in the



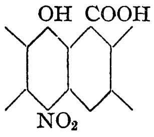
$$\left[C_{14}H_{11}(OCH_3)_2\left(\begin{matrix}-OH\\-COOH\end{matrix}\right)\right]_2 \longrightarrow \left[C_{14}H_{10}(OCH_3)_2\left(\begin{matrix}(=O)_2\\-COOH\end{matrix}\right)\right]_2$$

V XI

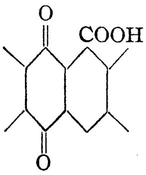
ortho position or more probably in the para position to the hydroxyl in the original ring must be unsubstituted (XII). The para hydrogen seems the more likely since the series of quinones in the gossypol and apogossypol series are all yellow in color while the vast majority of *o*-quinones are red or at least not yellow. The quinone produced by this oxidation may be assumed to have the structure shown in XIII.



XII



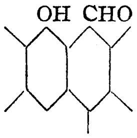
XIV



XIII

The lactone, however, when treated with the proper concentration of nitric acid was readily nitrated and two nitro groups were introduced (XIV). The corresponding diamine was formed by reduction and this was characterized through the acetyl derivative. The nitro group generally enters a 1-naphthol in the 4-position, if unoccupied, and this is in agreement with the results of the oxidation of the hydroxy acid.

Since the carboxyl group in the lactone which has been studied unquestionably has been formed from the corresponding aldehyde, three positions in each of the naphthalene rings in gossypol can be considered as definitely established (XV): 1-aldehydo, 5-hydrogen, 8-hydroxyl.



XV

Experimental

Gossylic Acid Lactone Tetramethyl Ether.—This was prepared by the method previously described.[3]

Gossylic Acid Tetramethyl Ether (V).—To a solution of 1.10 g. of gossylic acid lactone tetramethyl ether in 30 cc. of 10% methanolic potassium hydroxide was added about a gram of zinc dust and 10 cc. of water. The solution (deep red at first) was boiled until the color had faded to yellow and filtered into dilute sulfuric acid. The hydroxy acid was extracted with ether, the ether solution dried over anhydrous sodium sulfate and concentrated. Dilution with petroleum ether (b. p. 30–60°) caused the compound to crystallize in soft white needles weighing 0.85 g. Recrystallized from ether–petroleum ether, the compound formed soft white needles which, when heated slowly, melted at the melting point of the lactone, but when plunged into a bath preheated to 290° melted with vigorous decomposition, resolidified and then remelted at the melting point of the lactone.

Anal. Calcd. for $C_{28}H_{22}(OCH_3)_4(OH)_2(COOH)_2$: C, 67.33; H, 6.27. Found: C, 67.34; H, 6.20.

Dimethyl Gossylate Tetramethyl Ether (VI)

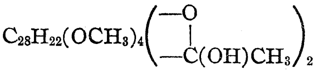
(1) With Dimethyl Sulfate.—To a hot solution of 0.5 g. of gossylic acid lactone tetramethyl ether in 10 cc. of 10% methanolic potassium hydroxide was added slowly 1.65 cc. of redistilled dimethyl sulfate. Then 15 cc. of potassium hydroxide and 1.7 cc. of dimethyl sulfate were added in that order and the mixture heated on the steam-bath for five minutes longer. After dilution with water, the mixture was allowed to stand for an hour and filtered. The air-dried solid obtained was recrystallized twice from dilute acetic acid, yielding 0.46 g. of white plates, m. p. 215–216.5°, to a yellow liquid which did not decompose when heated to 300°.

Anal. Calcd. for $C_{28}H_{22}(OCH_3)_6(COOCH_3)_2$: C, 68.89; H, 6.94; OCH_3, 37.5. Found: C, 69.18; H, 6.80; OCH_3, 35.6, 35.4.

The compound gives a pale yellow color in concentrated sulfuric acid. It is insoluble in alkali.

(2) With Diazomethane.—A solution of 0.18 g. of gossylic acid lactone tetramethyl ether in 10 cc. of 10% methanolic potassium hydroxide was diluted with 80 cc. of water and acidified with hydrochloric acid. The precipitated hydroxy acid was taken up in ether, extracted from the ether solution with sodium carbonate solution, and after acidification of the sodium carbonate solution extracted with 10 cc. of ether. The ether solution was added to 10 cc. of a solution of diazomethane in ether prepared from 0.2 g. of nitrosomethyl urea. Nitrogen was evolved for about ten minutes. The solution was allowed to stand overnight and then evaporated on the steam-bath. The yellow gum remaining was crystallized from dilute acetic acid by careful dilution of an acetic acid solution held at the boiling point. Recrystallized from 62% acetic acid, the compound formed colorless crystals which gave no depression in melting point when mixed with the compound obtained by methylating the lactone with dimethyl sulfate.

Homogossypol Tetramethyl Ether (VII).—To a solution of methylmagnesium iodide prepared from 10 g. of methyl iodide and 1.7 g. of magnesium in 50 cc. of dry ether was added a suspension of 3.5 g. of gossylic acid lactone tetramethyl ether in 40 cc. of dry ether. Reaction took place immediately with moderate refluxing of the solution, which acquired an orange color. Refluxing was continued for thirty minutes, at the end of which time the lactone had all dissolved. The solution was poured into an iced solution of ammonium chloride, and the ether layer was separated and concentrated. The product separated as a white crystalline powder as the ether evaporated. After washing with fresh ether the product weighed 3.07 g. Recrystallized from chloroform–petroleum ether (b. p. 90–110°) it formed a white crystalline powder, and from dilute pyridine it formed rosets of pinkish-white prisms, m. p. 308–309° (corr.), with decomposition.



Anal. Calcd. for $C_{28}H_{22}(OCH_3)_4\left(\begin{array}{l}—O\\ \ \ |\\ —C(OH)CH_3\end{array}\right)_2$: C, 71.76; H, 6.98. Found: C, 71.97; H, 7.10.

It gives a deep yellow color with concentrated sulfuric acid and no ferric chloride color. It is readily soluble in alcoholic alkali to a rose-pink solution which is decolorized by sodium hydrosulfite. The compound is insoluble in sodium carbonate solution.

Phenylmagnesium bromide and gossylic acid lactone tetramethyl ether gave only oily products.

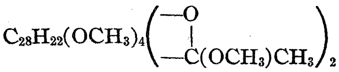
Methylation of Homogossypol Tetramethyl Ether

(1) Dimethyl Sulfate and Alkali (VIII).—To a solution of 0.5 g. of homogossypol tetramethyl ether in 5 cc. of 30% ethanolic potassium hydroxide, dimethyl sulfate was added until the solution was no longer alkaline. Alcoholic alkali and dimethyl sulfate were each added in slight excess several times; the solution was finally made alkaline, diluted and filtered. The crude product was white and crystalline and weighed 0.5 g. After two recrystallizations from methanol and two from dilute dioxane the compound was obtained as tiny clusters of white needles, m. p. 242–243° (corr.), to a colorless liquid which was stable up to 270°.

Anal. Calcd. for $C_{28}H_{22}(OCH_3)_6(COCH_3)_2$: C, 72.38; H, 7.30. Found: C, 72.61; H, 7.58.

The compound is insoluble in alcoholic alkali and gives a yellow color with concentrated sulfuric acid.

(2) Methanol–Sulfuric Acid (IX).—To a suspension of 0.2 g. of homogossypol tetramethyl ether in 10 cc. of methanol was added 8 drops of concentrated sulfuric acid. On warming, the compound dissolved with the formation of an emerald green solution and after a few moments' refluxing, colorless prisms began to separate from the solution. After cooling, the product was collected. It was obtained as colorless flat prisms and weighed 0.2 g. After several recrystallizations from dilute acetone it was obtained as flat white prisms, m. p. 255–256° (corr.), to a pink liquid. The same product was obtained by methylation in methanol with dimethyl sulfate and alkali but with an excess of dimethyl sulfate. In this case to a solution of 0.5 g. of homogossypol tetramethyl ether in 4 cc. of methanol and 4 cc. of dimethyl sulfate was added 6 cc. of 10% methanolic potassium hydroxide and the mixture was allowed to stand overnight. The solid (product and methyl potassium sulfate) was collected on a filter, the potassium salt washed out with water, and the water-insoluble portion recrystallized from dilute acetone. It formed flat white prisms, m. p. 255–256°, and gave no depression in melting point when mixed with the product obtained by the use of methanol–sulfuric acid.



Anal. Calcd. for $C_{28}H_{22}(OCH_3)_4\left(\begin{array}{l}—O\\ \ \ |\\ —C(OCH_3)CH_3\end{array}\right)_2$: C, 72.38; H, 7.30. Found: C, 72.52; H, 7.23.

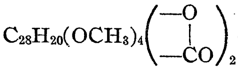
A mixture of IX (m. p. 255–256°) and VIII (m. p. 242–243°) melted at 221–236°.

The compound is insoluble in alcoholic alkali and gives a deep yellow color with concentrated sulfuric acid.

Oxidation of Gossylic Acid Tetramethyl Ether.—The directions followed for this oxidation were those previously described for the oxidation of gossypol hexamethyl ether. One gram of the lactone was converted to the hydroxy acid as described above, and the latter compound was refluxed for four hours with a mixture of 10 cc. of concentrated nitric acid and 40 cc. of water. The solid first became gummy, then gradually formed a hard pale yellow mass (with spots of red-brown gum). After cooling, the solution was neutralized and extracted with ether, the solid dissolved in this ether solution and the solvent removed and replaced with methanol. On standing, 0.48 g. of bright yellow needles separated. Recrystallized from benzene–ligroin (b. p. 60–110°), the compound formed soft yellow needles which gave no depression in melting point when mixed with the product obtained in a similar oxidation of gossypol hexamethyl ether, and gave identical color reactions in sulfuric acid (brownish-red) and methanolic alkali (blue-green).

Dinitrogossylic Acid Lactone Tetramethyl Ether (XIV).—A suspension of 0.95 g. of the lactone in a mixture of 20 cc. of glacial acetic acid and 3 cc. of concentrated nitric acid was heated to boiling on a hot-plate. The lactone dissolved in the course of several minutes to a clear brownish-yellow solution. Water was added carefully. The solution was kept at the boiling point until crystallization started, and the mixture was allowed to cool. The product separated in pale yellow, flat needles melting at 246–248°, and weighed 0.87 g.

Recrystallized from acetone–methanol, ether–petroleum ether or ethyl acetate–petroleum ether, the compound formed pale yellow prisms which melted at 238–239° (corr.), resolidified, and then remelted at 247–248° (corr.). Recrystallized from dilute acetic acid the compound formed flat, slender, pale yellow needles which melted sharply at 247–248°.



Anal. Calcd. for $C_{28}H_{20}(OCH_3)_4\left(\begin{array}{l}—O\\ \ \ |\\ —CO\end{array}\right)_2(NO_2)_2$: C, 61.82; H, 4.85; N, 4.25. Found (methanol–acetone): C, 61.97; H, 5.03; N, 4.43. Found (dilute acetic acid): C, 62.16; H, 5.06; N, 4.48.

The compound gives a yellow color with concentrated sulfuric acid and no ferric chloride color. It is insoluble in aqueous alkali, but dissolves readily in cold methanolic alkali to a deep orange-red solution.

Diaminogossylic Acid Lactone Tetramethyl Ether.—Reduction of the nitro compound with zinc dust in acetic acid, sodium hydrosulfite in alkali or iron in acetic acid yields the same compound.

To a hot solution of 0.5 g. of the nitro compound (XIV) in 5 cc. of acetic acid was added 0.5 g. of iron powder. The pale yellow color of the solution changed quickly to a deep orange. After the addition of a drop of hydrochloric acid the solution was heated for thirty minutes on the steam bath. A heavy precipitate of orange needles formed after a few minutes.

At the end of thirty minutes some acetic acid was added to dissolve the product which had separated and the solution was filtered, several small portions of boiling acetic acid being used to extract the product which was admixed with the iron. The hot solution was diluted carefully until crystallization started. On cooling, there was obtained

0.38 g. of bright orange platelets, and on dilution of the mother liquors there was obtained an additional 80 mg. of what was largely unreduced nitro compound.

Recrystallization of the main portion several times from slightly diluted acetic acid (with the addition of a small amount of iron) resulted in the formation of bright orange platelets, m. p. 293–294° (corr.), with decomposition.

Anal. Calcd. for  $C_{28}H_{20}(OCH_3)_4\left(\begin{array}{c}\text{—O}\\ |\\ \text{—CO}\end{array}\right)_2(NH_2)_2$: C, 68.00; H, 6.00; N, 4.67. Found: C, 67.52; H, 6.09; N, 4.54.

The compound gives a pale yellow color with concentrated sulfuric acid and is readily soluble in methanolic hydrochloric acid (but not in methanol) or in a mixture of acetic acid and hydrochloric acid. Upon the addition of hydrochloric acid to the orange solution of the compound in acetic acid the color fades to pale yellow. It dissolves with some difficulty in warm alcoholic alkali with the formation of a yellow solution which rapidly turns deep blue in air.

Acetylation of Amino Derivative.—A solution of 0.27 g. of the diamine and 0.1 g. of anhydrous sodium acetate in 5 cc. of acetic anhydride was refluxed for one hour. The initially deep orange solution soon became a pale yellow. The excess acetic anhydride was decomposed with water and the product, which weighed 0.29 g., was recrystallized twice from methanol, from which it formed pearly-white leaflets, m. p. 252–253° (corr.).

Anal. Calcd. for  $C_{28}H_{20}(OCH_3)_4\left(\begin{array}{c}\text{—O}\\ |\\ \text{—CO}\end{array}\right)_2(NHCOCH_3)_2$: C, 66.66; H, 5.85; N, 4.10. Calcd. for  $C_{28}H_{20}(OCH_3)_4\left(\begin{array}{c}\text{—O}\\ |\\ \text{—CO}\end{array}\right)_2[N(COCH_3)_2]_2$: C, 65.63; H, 5.73; N, 3.65. Found: C, 66.03; H, 5.71; N, 3.71.

The compound is insoluble in alcoholic hydrochloric acid.

Summary

Gossylic acid lactone tetramethyl ether has been shown to be a *peri*-naphthalene lactone. It can be hydrolyzed to the corresponding hydroxy acid which can be methylated with diazomethane or alkali and dimethyl sulfate to the ether ester. The hydroxy acid is oxidized with dilute nitric acid to gossypolonic acid tetramethyl ether, the same water-insoluble quinone obtained by the oxidation of gossypol hexamethyl ether with nitric acid. The color indicates a *p*-quinone which demonstrates the probability of unsubstituted hydrogens para to the hydroxyls in the hydroxy acid.

The lactone is resistant to oxidation but is nitrated to a dinitro derivative. The nitro groups presumably occupy the unsubstituted positions para to the hydroxyls.

Gossypol can be considered as having two naphthalene nuclei each containing the following substitutions: 1-aldehydo, 5-hydrogen, 8-hydroxyl.

Structure of Gossypol. XIII.[1] Conversion of Gossic Acid to Apogossypolic Acid

BY ROGER ADAMS AND R. C. MORRIS

Two products are obtained by oxidation of gossypol hexamethyl ether with nitric acid, a water-insoluble, gossypolonic acid tetramethyl ether, and a water-soluble, gossic acid. The former is converted into the latter by the action of potassium permanganate.[2] Gossic acid has approximately half the molecular weight of the original compound and consequently knowledge of its structure would be of unusual value in clarifying the structure of gossypol.

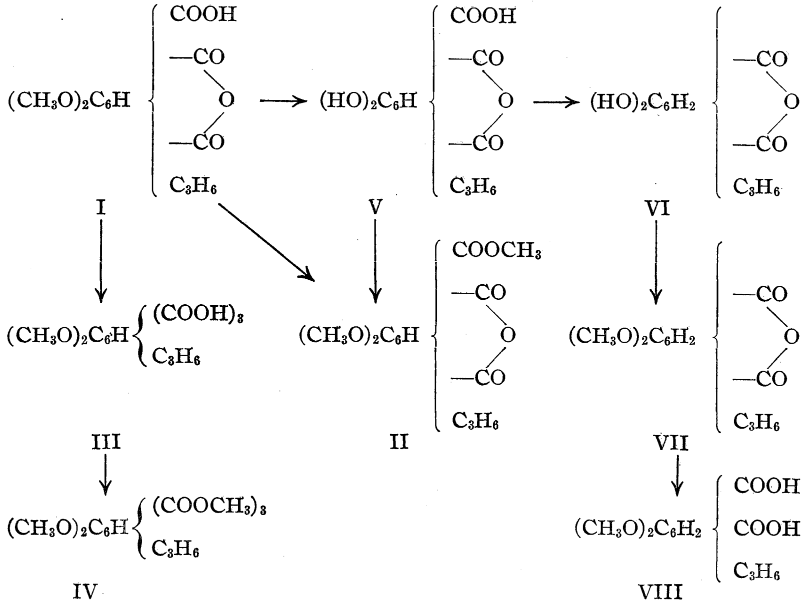
It was shown previously that gossic acid contains two methoxyls, one carboxyl, and one dibasic acid anhydride linkage formulated as I. These facts were deduced from a Zeisel determination, titration for a tribasic acid in aqueous solution, formation of a monomethyl ester (II) by the action of diazomethane and a molecular weight determination. Various derivatives and degradation products now have been prepared. Gossic acid is hydrolyzed by alkali to a tribasic acid (III) which could not be isolated in a pure state due to its tendency to revert to gossic acid. However, an ether solution of the hydrolyzed gossic acid was methylated with diazomethane and a stable crystalline trimethyl ester (IV) obtained. This confirms the presence of a carboxyl and a dibasic acid anhydride residue in gossic acid. By demethylation of gossic acid, the corresponding dihydroxy acid (V) was isolated readily. That no rearrangement was involved was indicated by the action of diazomethane on the demethylated product. The methyl ester

---

[1] For previous paper in this series see Adams and Geissman, THIS JOURNAL, **60**, 2184 (1938).

[2] Adams, Morris and Kirkpatrick, *ibid.*, **60**, 2170 (1938).

of gossic acid (II) previously prepared from gossic acid resulted. The demethylated gossic acid, when heated with quinoline and copper bronze, lost carbon dioxide to give a dihydroxy dibasic acid anhydride, $C_{11}H_{10}O_5$ (VI). This in turn, upon methylation with diazomethane, gave a dimethoxy dibasic acid anhydride (VII), which proved to be identical with apogossypolic acid anhydride and which hydrolyzed to apogossypolic acid (VIII).[3] This series of reactions is shown as



There are several interesting deductions which may be drawn from these experiments. Gossic acid is derived from gossypol hexamethyl ether, and apogossypolic acid from apogossypol hexamethyl ether. The difference between gossic and apogossypolic acids is merely a single carboxyl group. Since gossypol has two aldehyde groups and apogossypol none, and since the oxidation products are obtained by not dissimilar reactions, it is a reasonable speculation that one of the aldehyde groups in the gossypol hexamethyl ether accounts for the carboxyl group which is present in gossic acid and which is not found in apogossypolic acid anhydride.

The dihydroxy compounds (V and VI) both give a green color with ferric chloride indicative of two ortho hydroxyls. These compounds are oxidized by blowing air through the alkaline solutions. Upon acidification of the oxidized solutions they both yield the same red crystalline compound, which has the formula $C_9H_{10}O_4$, and which appears to be a quinone, since it can be reduced with sodium hydrosulfite and the colorless solution thus obtained can be reoxidized by shaking in air.

Experimental

Trimethyl Ester of Hydrolyzed Gossic Acid.—A solution of 0.100 g. of gossic acid in 5 cc. of 10% aqueous sodium hydroxide was prepared by warming for a few minutes on the steam-bath and then cooling in an ice–salt mixture. The cooled solution was acidified carefully with dilute hydrochloric acid and extracted a number of times with ether. The ether extracts were combined and washed with cold water. To this solution was added an ether solution of diazomethane from 0.5 g. of nitrosomethyl urea. The reaction mixture was allowed to stand overnight at room temperature, then washed with dilute sodium hydroxide. The ether was evaporated and the residue purified by crystallization from petroleum ether (30–60°), m. p. 70–71°.

Anal. Calcd. for $C_{17}H_{22}O_8$: C, 57.6; H, 6.21. Found: C, 57.56; H, 5.92.

Demethylation of Gossic Acid.—A suspension of 0.15 g. of gossic acid was refluxed very gently with 5 cc. of constant boiling hydrobromic acid for twenty to twenty-five minutes. The material dissolved in a short time and at the end of the reaction the solution had only a light yellow color. The reaction mixture was diluted with water, neutralized with sodium carbonate, acidified to congo red with dilute sulfuric acid, and extracted with ether. The ether was evaporated and the residue crystallized from acetone–petroleum ether (b. p. 60–110°). Long colorless needles formed, m. p. 140–141°.

Anal. Calcd. for $C_{12}H_{10}O_7$: C, 54.2; H, 3.76; mol. wt., 266. Found: C, 54.43; H, 3.80; mol. wt. (Rast), 280.

This product gave a green color with alcoholic ferric chloride, and a very light yellow color when dissolved in cold concentrated sulfuric acid. The material dissolved easily in 10% aqueous sodium hydroxide to give a light yellow solution, which became bright red upon shaking with air.

Action of Diazomethane on Demethylated Gossic Acid.—To an ether solution of 0.10 g. of the demethylated gossic acid was added an ether solution of diazomethane from 0.15 g. of nitrosomethyl urea. The reaction mixture was allowed to stand overnight at room temperature, then the ether was evaporated and the residue purified by sublimation at 15 mm., followed by crystallization from petroleum ether (b. p. 30–60°); white needles, m. p. 106°. The mixed melting point gave no lowering with the ester of gossic acid previously described.

Oxidation of Demethylated Gossic Acid.—A solution of 0.10 g. of the demethylated gossic acid in 5 cc. of 10%

---

(3) Adams and Butterbaugh, THIS JOURNAL, **60**, 2174 (1938).

aqueous sodium hydroxide was oxidized by blowing a stream of air through it. The alkaline solution was at first a bright yellow, changing to a deep orange, and finally to a bright red. After nine hours the solution was acidified with dilute sulfuric acid and the flocculent precipitate filtered, washed, and dried. The residue was purified by sublimation at 15 mm., and subsequent crystallization from benzene; large red plates, m. p. 179–181°.

Anal. Calcd. for $C_9H_{10}O_4$: C, 59.5; H, 5.49. Found: C, 59.56; H, 5.55.

Sodium hydrosulfite causes the red color to disappear from an aqueous alkaline solution of the compound; on shaking in the air the red color reappears immediately.

Decarboxylation of Demethylated Gossic Acid.—To a solution of 0.20 g. of demethylated gossic acid in 0.8 cc. of dry quinoline was added 0.1 g. of copper bronze. The reaction mixture was heated in a Wood's metal bath at 160–165°. At this temperature there was a vigorous evolution of gas.

When the evolution of gas ceased, the tube was cooled and the reaction mixture diluted with ether. The ether solution was filtered and washed a number of times with dilute hydrochloric acid. The ether was evaporated and the residue purified by sublimation at 15 mm. It crystallized from ether–petroleum ether (b. p. 60–110°) in white plates, m. p. 165–166°.

Anal. Calcd. for $C_{11}H_{10}O_5$: C, 59.5; H, 4.52. Found: C, 59.62; H, 4.40.

The compound gave a green color with alcoholic ferric chloride. It dissolved in aqueous alkali to a yellow solution which changed to red on standing. It was soluble in water and a spontaneous evaporation formed long needles.

Oxidation of Demethylated Decarboxylated Gossic Acid.—Air was blown through a solution of 0.10 g. of demethylated decarboxylated gossic acid in 5 cc. of 10% aqueous sodium hydroxide for nine hours. The material dissolved to give a yellow solution which quickly turned to a bright red on passing through the air.

The solution was acidified with dilute sulfuric acid and extracted with ether. The ether was evaporated and the residue purified by sublimation and crystallization from benzene, m. p. 179–181°. It was shown by mixed melting point to be identical with the product obtained by the alkaline–air oxidation of the demethylated gossic acid.

Diazomethane on Demethylated Decarboxylated Gossic Acid; Apogossypolic Acid Anhydride.—To a solution of 0.10 g. of the demethylated decarboxylated gossic acid in 10 cc. of ether was added an ether solution of diazomethane from 0.15 g. of nitrosomethyl urea. The reaction mixture was allowed to stand at room temperature overnight.

The ether was evaporated and the residue purified by sublimation at 15 mm., followed by crystallization from petroleum ether (b. p. 30–60°); white needles, m. p. 93–94°. The compound gave no depression in melting point when mixed with apogossypolic acid anhydride.

Anal. Calcd. for $C_{13}H_{14}O_5$: C, 62.4; H, 5.60; $2OCH_3$, 24.8. Found: C, 62.1; H, 5.39; OCH_3, 23.6.

A solution of 0.050 g. of this product in 10% aqueous sodium hydroxide was cooled in an ice-bath and carefully acidified with dilute sulfuric acid. The suspension that formed was extracted with ether, the ether extract dried and evaporated. The residue was crystallized from petroleum ether (b. p. 30–60°), m. p. 170–171° with decomposition. This compound gave no depression in melting point when mixed with *apogossypolic* acid.

Anal. Calcd. for $C_{13}H_{16}O_6$: C, 58.3; H, 5.97; neut. equiv., 134. Found: C, 58.31; H, 6.24; neut. equiv., 134.

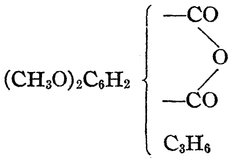
On sublimation at 15 mm. dehydration takes place with formation of apogossypolic acid anhydride as shown by melting point and mixed melting point.

Apogossypolic acid was very stable to alkaline permanganate and was recovered unchanged even on long refluxing.

Summary

Gossic acid, 
$$(CH_3O)_2C_6H_2\left\{\begin{array}{l} COOH \\ -CO \\ \qquad \diagdown \\ \qquad\quad O \\ \qquad \diagup \\ -CO \\ C_3H_6 \end{array}\right.$$

, obtained by oxidation of gossypol hexamethyl ether has been degraded through (1) demethylation with hydrobromic acid followed by (2) heating with quinoline and copper bronze and subsequent (3) methylation with diazomethane. The final product proved to be apogossypolic anhydride,



$$(CH_3O)_2C_6H_2\left\{\begin{array}{l} -CO \\ \qquad \diagdown \\ \qquad\quad O \\ \qquad \diagup \\ -CO \\ C_3H_6 \end{array}\right.$$

, the product obtained by oxidation of apogossypol hexamethyl ether. It appears likely that the carboxyl group in gossic acid is produced from an aldehyde group in gossypol.

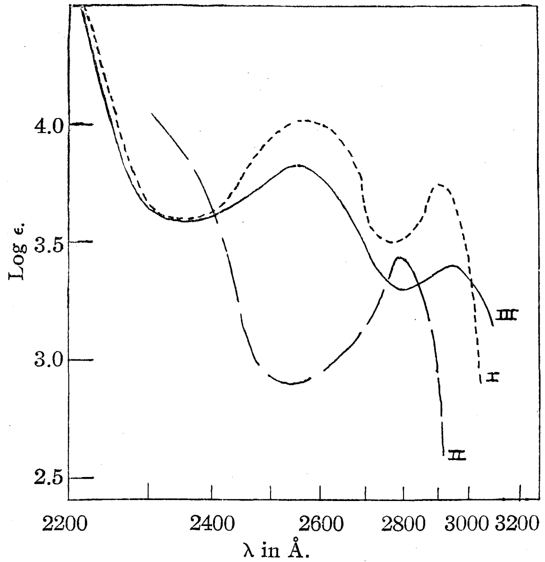
Structure of Gossypol.[1] XIV. Apogossypolic Acid

By Roger Adams, R. C. Morris, D. J. Butterbaugh[2] and E. C. Kirkpatrick[2]

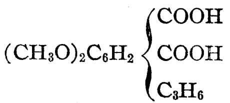
Apogossypolic acid[1,3] which can be obtained from gossypol hexamethyl ether by oxidative and degradation reactions and from apogossypol hexamethyl ether by oxidation has the formula shown in I. The possible position or positions for the C_3H_6 residue have been discussed previously.[3]



I, Veratric acid; II, homoveratric acid; III, decarboxylated apogossypolic acid.

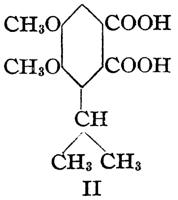
Fig. 1.

The two most likely structural formulas are assumed to be II and III.

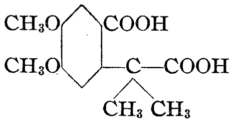


$$(CH_3O)_2C_6H_2\left\{\begin{array}{l}COOH\\COOH\\C_3H_6\end{array}\right.$$

I

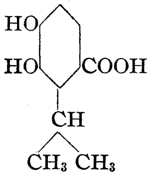


II

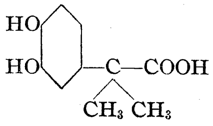


III

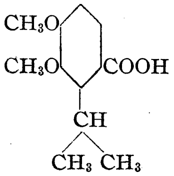
By extended boiling with hydrobromic acid, two methoxyls are converted to hydroxyls and one molecule of carbon dioxide is lost. The compound thus produced is postulated as IV or V. Upon treatment of this substance with diazomethane, methylation of the hydroxyl and carboxyl groups occurs and upon saponification the dimethoxy acid (VI or VII) results. The fact that the ester saponifies with reasonable ease is in favor of structure VI, for esters of the type of the acid shown in VII saponify only with great difficulty. This monobasic acid (VI or VII) is surprisingly resistant to oxidation and no satisfactory results were obtained after repeated experiments. Moreover, the carboxyl from compound IV or V could not be eliminated by any of the usual procedures which decarboxylate 1,2-dihydroxy-4-benzoic acid.



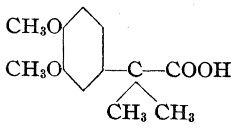
IV



V



VI



VII

The absorption spectra of homoveratric acid (VIII) and of veratric acid (IX) were compared with that of compound VI or VII. The results are shown in Fig. 1. It is clearly apparent that the absorption spectra of veratric acid and the acid from gossypol resemble each other closely and differ from that of homoveratric acid. Formula V, therefore, was assumed to be that of decarboxylated apogossypolic acid. The presence of the isopropyl group ortho to the carboxyl may account for the difficulty in eliminating the carboxyl in compound IV. The difficulty with which the compound apparently is

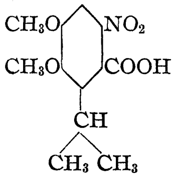
[1] For previous paper in this field see Adams and Morris, This Journal, **60**, 2188 (1938).

[2] Portions of theses submitted in partial fulfilment of the degree of Doctor of Philosophy by D. J. Butterbaugh, Chemical Foundation Fellow 1935–1938, and E. C. Kirkpatrick, Solvay Process Fellow, 1936–1938.

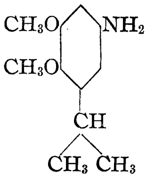
[3] Adams and Butterbaugh, This Journal, **60**, 2174 (1938).

oxidized may be explained by the hindrance of the isopropyl group by ortho substitutents.

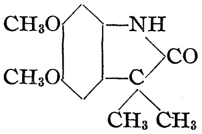
Apogossypolic acid reacts with nitric acid and a carboxyl group is replaced by a nitro. Two alternative structures, based on formula V, are possible but compound X is the more likely because oxidation of the nitro compound failed and oxidation might have been expected if the nitro were ortho to the isopropyl group. This replacement is analogous to that reported for the substitution of the carboxyl group in veratric acid by a nitro group.[4] Upon reduction of the mononitromonocarboxylic acid (X), an amino compound was formed which was purified by sublimation. The product proved to be not the expected amino acid but an amine (XI) due to loss of carbon dioxide. A lactam (XII) undoubtedly would have resulted if the structure of the apogossypolic acid was III. The decarboxylation of the amino compound upon sublimation resembles the reaction of *o*-aminobenzoic acid under similar conditions. These facts leave little doubt that the C_3H_6 is present in the molecule as a propyl or isopropyl substituent in the benzene ring. It cannot be present as two groups, an ethyl and methyl, because apogossypolic acid may be formed from gossic acid which contains in the ring two methoxyls and three carboxyls and hence only a single position for the C_3H_6 residue is available. The group is probably isopropyl since experimental evidence indicated that isopropyl alcohol was lost in the conversion of apogossypol hexamethyl ether to desapogossypol hexamethyl ether.



X



XI



XII

It is true that the experimental facts available do not allow a conclusive deduction concerning the relative positions of the methoxyl, isopropyl, and carboxyl groups in apogossypolic acid. However, indirect evidence adduced from the study of the various degradation products of gossypol and apogossypol is very helpful[5] and practically limits the structures of gossic acid to XIII, apogossypolic acid to XIV and decarboxylated apogossypolic acid to XV. The absolute proof of these must await synthesis.

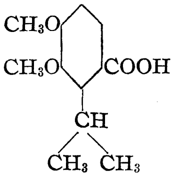
XIV



XV

Experimental

Action of Hydrobromic Acid on Gossic Acid, Apogossypolic Acid or Apogossypolic Acid Anhydride.—The same product was obtained by the action of constant boiling hydrobromic acid on gossic acid, apogossypolic acid or its anhydride. Since from a preparative standpoint gossic acid is the most convenient raw material, the detailed directions below involve this product. The procedure for the other compounds is exactly the same except that only two hours of boiling with hydrobromic acid instead of four is necessary.

A suspension of 0.10 g. of gossic acid was refluxed for four hours with 5 cc. of constant boiling hydrobromic acid. At the end of this time the reaction mixture was poured into a beaker. On cooling there separated a precipitate of light pink crystals. The product was filtered and purified by sublimation and crystallization from benzene or toluene. It formed colorless plates, m. p. 216–217°. The product may be heated until it distils and is recovered unchanged.

Anal. Calcd. for $C_{10}H_{12}O_4$: C, 61.2; H, 6.12. Found: C, 61.21; H, 6.55.

The compound gave a green color with alcoholic ferric chloride. A solution of the compound in dilute aqueous sodium hydroxide rapidly becomes yellow and on standing longer changes to deep orange.

Diazomethane on Demethylated Decarboxylated Apogossypolic Acid.—To a solution of 0.02 g. of the demethylated decarboxylated apogossypolic acid in ether was added an ether solution of diazomethane. The reaction was allowed to stand overnight at room temperature. The ether solution was then washed with cold 2% aqueous sodium hydroxide and evaporated. The residue was purified by sublimation and then crystallization from petroleum ether (b. p. 30–60°); colorless prisms, m. p. 106–107°.

Anal. Calcd. for $C_{13}H_{18}O_4$: C, 65.6; H, 7.56. Found: C, 65.42; H, 7.20.

Saponification of the Methyl Ester of Decarboxylated Apogossypolic Acid.—A suspension of 0.10 g. of the ether was refluxed with 10% aqueous sodium hydroxide until solution was complete. The reaction mixture was then cooled, acidified with dilute sulfuric acid, and extracted with ether. The ether was evaporated and the residue

purified by sublimation followed by crystallization from benzene; colorless plates, m. p. 167–169°.

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 64.4; H, 7.15. Found: C, 64.85; H, 7.42.

Action of Dilute Nitric Acid on Apogossypolic Acid.—A mixture of 0.15 g. of apogossypolic acid, 3 cc. of concentrated nitric acid and 9 cc. of water was refluxed for two hours. Upon cooling, fine white crystals separated. These were purified by crystallization from cyclohexane, m. p. 155–158°; yield 0.105 g.

Anal. Calcd. for $C_{12}H_{15}O_6N$: C, 53.55; H, 5.58; N, 5.21; neut. equiv., 269. Found: C, 53.79; H, 5.75; N, 5.19; neut. equiv., 268.

Reduction of the Nitric Acid Product of Apogossypolic Acid.—The product just described was reduced with Raney nickel and hydrogen under 2.5 atm. pressure in ethanol solution. The product was purified by twice subliming at 25 mm.; white crystals, m. p. 74–76°, that turn dark after standing a few hours in air.

Anal. Calcd. for $C_{11}H_{17}O_2N$: C, 67.7; H, 8.72; N, 7.18. Found: C, 67.84; H, 8.62; N, 6.96.

This material was insoluble in dilute aqueous sodium hydroxide but soluble in 5% aqueous hydrochloric acid. It diazotized with nitrous acid and the solution gave a red color on treatment with a solution of β-naphthol.

Acetylation of the Amine.—A mixture of 30 mg. of the amine just described, 2 cc. of acetic anhydride and 50 mg. of fused sodium acetate was refluxed gently for thirty minutes. After cooling, the excess acetic anhydride was decomposed by the addition of three to four volumes of water. The solution was evaporated to dryness under a stream of air and the amine acetate extracted from the sodium acetate by means of ether. From this extract a colorless oil was obtained which crystallized after standing for two to three hours. Purification of this crystalline material was accomplished by two sublimations at a bath temperature of 100–125° (18 mm.). This was followed by a dilute acid wash and by a third sublimation; white crystals, m. p. 85–86°.

Anal. Calcd. for diacetate, $C_{15}H_{21}O_4N$: C, 64.52; H, 7.53; N, 5.02. Found: C, 64.73; H, 7.49; N, 5.11.

Summary

Apogossypolic acid is decarboxylated and demethylated by the action of hydrobromic acid. The product, upon methylation with diazomethane and subsequent saponification gives a monobasic acid, decarboxylated apogossypolic acid. A discussion of the structure of this latter product is given.

Apogossypolic acid is converted to a mononitro monocarboxylic acid by the action of nitric acid. The nitro compound upon reduction followed by sublimation gives an aromatic amine containing no carboxyl group. This must be a dimethoxy *n*- or isopropyl aminobenzene. Its structure and the analogous compounds from gossypol are discussed.

The absorption spectrum of decarboxylated apogossypolic acid is similar to that of veratric and dissimilar to homoveratric acid.

Structure of Gossypol. XV.[1] An Interpretation of its Reactions

BY ROGER ADAMS, R. C. MORRIS, T. A. GEISSMAN, D. J. BUTTERBAUGH AND E. C. KIRKPATRICK

A large number of reactions of gossypol and of its degradation products have been studied. As the result of this accumulation of experimental evidence, it is now possible to formulate deductively a reasonable structure for the gossypol molecule. The purpose of this communication is to correlate and interpret the physical and chemical properties of gossypol in terms of this structure.

The absorption spectra of gossypol[2] and its derivatives and the formation of many of its degradation products are indicative of a molecule containing two naphthalene nuclei connected either directly or through an alkylene chain. The formula for gossypol must be essentially symmetrical and probably completely so, for an even number of moles of reagent reacts in every instance. The diverse and unusual reactions of gossypol as well as the absorption spectra show every indication that the molecule is tautomeric.

The postulated structure of gossypol is represented by Ia with Ib and Ic representing two possible tautomeric forms.

The structural configuration of gossypol will be discussed and formulas will be assigned for all the significant derivatives and degradation products.

Ia

Ib

Ic

Wherever structural formulas are used, only half the molecule will be written in order to conserve space. It must be remembered, however, that in all cases double the number of moles of reagents react than is indicated by the half molecules and double the number of groups are introduced.

Color Reactions and Salts.[3]—Gossypol gives (1) a green color with ferric chloride, (2) a deep red with pyroboroacetate and (3) a purple red with stannic chloride. These colors have been shown previously to be rather characteristic, particularly in the naphthalene series, (1) of two phenolic hydroxyls ortho to each other, (2) and (3) of a hydroxyl peri or ortho to a carbonyl. These colors may be expected of a molecule with formula Ia. Gossypol forms a stable compound with stannic chloride which was isolated and analyzed. It has a Sn:Cl ratio of 1:2. Naphthalene molecules with two peri hydroxyls and a ketone or aldehyde group form similar compounds. It is not unreasonable to believe that an arrangement of hydroxyls and aldehyde groups as shown in formula Ia would give the same result though no simple naphthalene derivatives with hydroxyls and aldehyde thus placed have been tested.

Gossypol titrates dibasic and forms a dipyridyl salt. Many hydroxyaldehydes show a similar acidity for the phenol group possibly due to the vinylogous relationship of an *o*- or *p*-hydroxyaldehyde to a carboxylic acid.

Aniline and Ammonia Derivatives.[4]—Gossypol condenses readily with two moles of aniline with the elimination of two moles of water. Several substituted anilines, including *o*-phenylenediamine, also condense in the same ratio; others give products which do not analyze for simple derivatives. All these products, however, are readily hydrolyzed by acid to gossypol.

Liquid ammonia reacts similarly to give an easily hydrolyzed diaminogossypol.

Of importance from the structural standpoint are the methylation and acetylation of the yellow dianilinogossypol.[4] Under proper conditions a red dimethylated compound is isolated which has the methyl groups attached to nitrogens since they cannot be removed by hydriodic acid; the methylated compound cannot be hydrolyzed to gossypol. The hexaacetyldianilinogossypol has two acetyls attached to nitrogens since acetanilide is obtained by pyrolysis. These experiments establish the probability of the dianilino compound existing not as a simple Schiff base but as a tautomeric structure such as might be formed from an hydroxymethylene compound, the tautomeric form of an *o*-hydroxy aldehyde. The anilino compound of gossypol therefore is formulated as IIa, IIb, IIc and the hexaacetate possibly as III though it could be based on structure IIc.

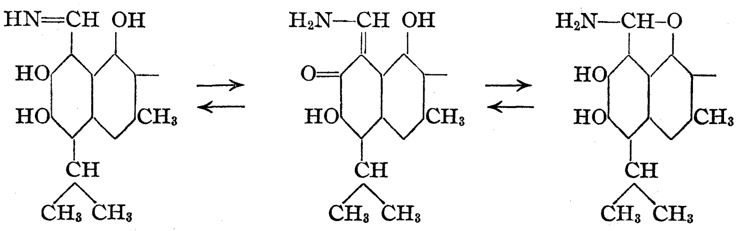
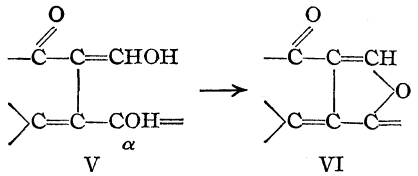
of liquid ammonia probably have analogous formulas, IVa, IVb, IVc.



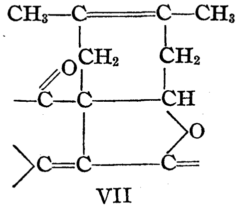
IVa IVb IVc

Anhydrogossypol.[5]—Anhydrogossypol is produced by heating gossypol above its melting point or by the use of a mild dehydrating agent in an inert solvent. It is very sensitive to hydrolysis, regenerating gossypol. The reactions which were attempted such as methylation, acetylation or treatment with liquid ammonia or amines even under strictly anhydrous conditions result not in anhydrogossypol derivatives but in derivatives of gossypol. In the case of anhydrogossypol, the reactions always involve simple addition; in the case of gossypol, the same derivatives are obtained by elimination of water, acetic acid or analogous molecules but never by simple addition. A very easily opened oxygen-containing ring must therefore be present in anhydrogossypol.

The anhydro compound reacts with both butadiene and dimethylbutadiene[6] to give addition products. This indicates the probability of the presence of an α,β-unsaturated carbonyl grouping. The stability of the diene addition compounds to hydrolysis leads to the conclusion that the unstable oxygen-containing ring of anhydrogossypol has been modified and stabilized. It is probable, therefore, that the carbon–carbon double bond of the α,β-unsaturated carbonyl grouping is part of the oxygen-containing ring of anhydrogossypol. Nuclei postulated to account for these transformations are shown in V (gossypol), VI (anhydrogossypol), and VII (diene addition product).



V VI

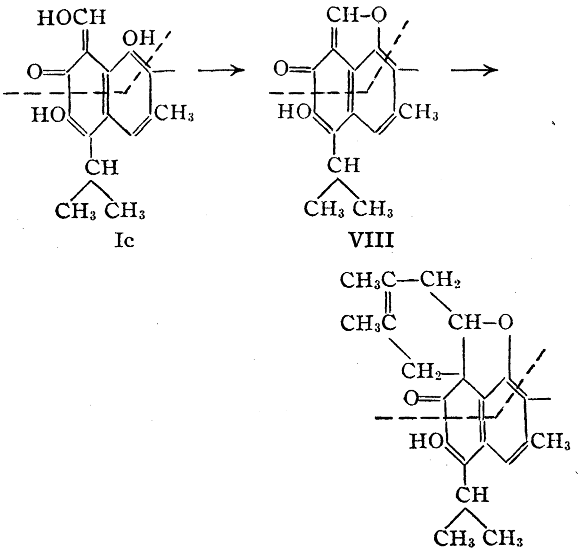


VII

Gossypol also adds dienes but with the simultaneous loss of water to give the same compound obtained from anhydrogossypol.

The α-hydroxyl in formula V must be phenolic since otherwise a nitrogen-containing ring[4] analogous to VI should be produced upon treatment with anhydrous ammonia.

The tautomeric formula of gossypol (Ic) contains just such a nucleus as is shown in V and the formula of anhydrogossypol may thus be VIII and the dimethylbutadiene addition product IX. The portions of the molecules above the dotted lines in Ic, VIII and IX are identical with the corresponding nuclei V, VI and VII.



Ic VIII IX

The oxygen-containing ring structure in VIII probably would hydrolyze readily and that in IX would undoubtedly be stable.

The diene addition products also contain two phenolic hydroxyls which are readily methylated or acetylated. These are shown in IX. The red color which the addition products give with pyroboroacetate is found in molecules with an hydroxyl ortho or peri to a carbonyl.

From a survey of the literature of hydroxy aldehydes of the benzene and naphthalene series, it was impossible to find any record of a derivative

---

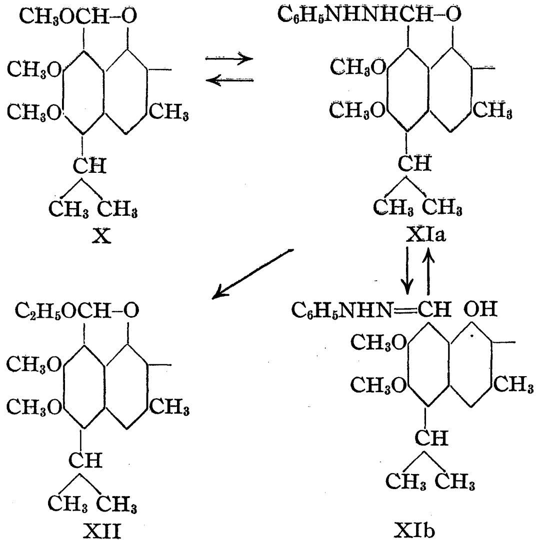
[6] Adams, Friedman, Price, Morris and Kirkpatrick, *ibid.*, **60**, 2160 (1938).

of the tautomeric forms of the hydroxymethylene type. On the other hand, it seems likely they should exist, especially in certain types of polyhydroxy naphthaldehydes and an attempt is now being made to prepare such derivatives. It is worthy of note that Windaus[7] on the basis of sound experimental evidence postulated the hydroxymethylene form of an aromatic hydroxy aldehyde for the structure of colchicine.

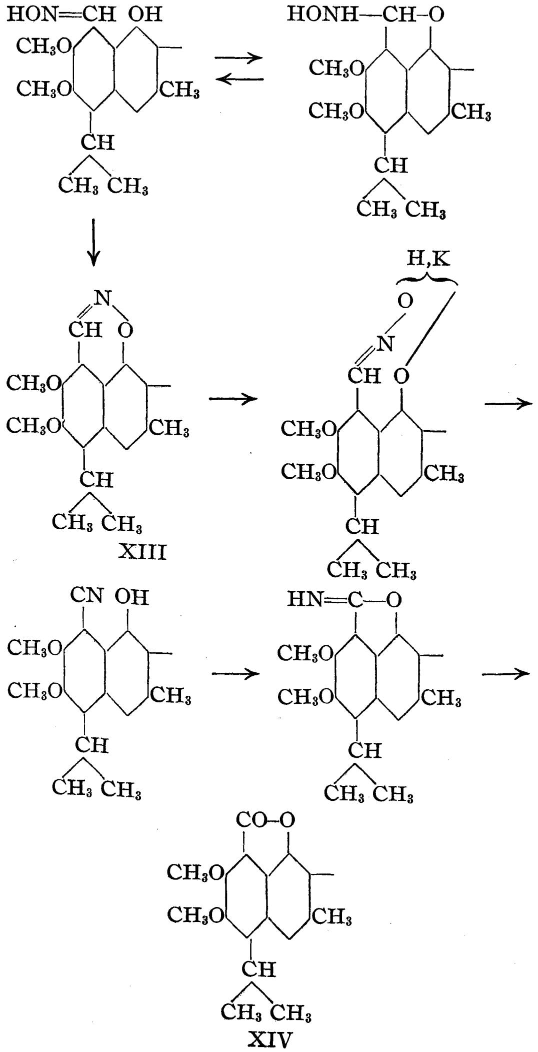
Ethers of Gossypol.[8]—A white tetramethyl ether of gossypol is obtained by the action of dimethyl sulfate on gossypol under conditions which exclude degradation due to the presence of alkali. Further methylation of this compound gives a white or a red hexamethyl ether, depending on the experimental conditions. Moreover, it acetylates to a gossypol tetramethyl ether diacetate.

The tetramethyl ether and the white hexamethyl ether are very stable to alkali or alkaline oxidizing agents in contrast to gossypol. They do not react with aldehyde reagents in neutral solvents. In the presence of acetic acid, however, condensation reactions with aldehyde reagents take place.[9] The substances produced no longer contain six methoxyls. Two apparently are hydrolyzed to hydroxyls and then two moles of reagent react in the normal way with the aldehyde groups. The phenylhydrazine derivative of gossypol hexamethyl ether is a diphenylhydrazone of a gossypol tetramethyl ether; of gossypol tetramethyl ether a diphenylhydrazone of a gossypol dimethyl ether. By means of methanolic hydrochloric acid, the diphenylhydrazone of gossypol tetramethyl ether is reconverted to gossypol hexamethyl ether or by ethanolic hydrochloric acid to gossypol tetramethyl diethyl ether.

It is thus obvious that two of the methoxyls in gossypol hexamethyl ether differ from the other four and their reactivity suggests they are of an acetal type. A lactol structure of a *peri*-hydroxynaphthaldehyde is written to account for these results. Gossypol hexamethyl ether (X) is thus based on structure Ib. The phenylhydrazine derivative is represented by XIa and XIb and the gossypol tetramethyl diethyl ether by XII.



The reaction of hydroxylamine[9] in acetic acid solution with gossypol tetramethyl and hexamethyl ethers also involves the hydrolysis of two methoxyl groups. Two moles of reagent then condense in the usual way, followed however by loss of two more molecules of water. These



---

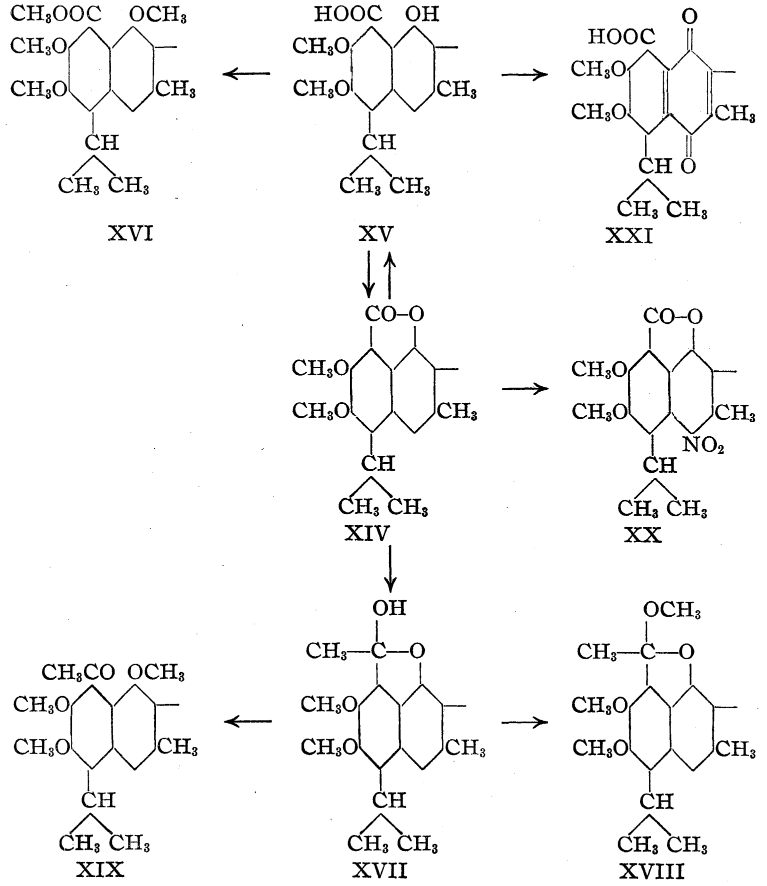
[8] Morris and Adams, This Journal, **59**, 1931 (1937).

[9] Adams and Geissman, *ibid.*, **60**, 2166 (1938).

reactions may best be interpreted by the assumption that orthoxazine rings have formed XIII.

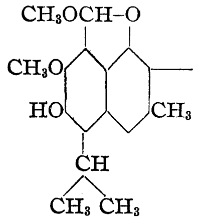


Hydrolysis of the orthoxazine (XIII) followed by treatment with acetic acid results in a lactone, gossylic acid lactone tetramethyl ether (XIV). The hypothetical intermediates in this transformation, the structures of which are given but not numbered, were not isolated.

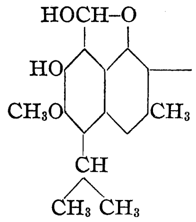
The lactone[10] (XIV) is hydrolyzed to the hydroxy acid (XV), which can be methylated by treatment either with diazomethane, thus indicating that a phenolic hydroxyl is involved in the lactone, or by dimethyl sulfate and alkali, to give dimethyl gossylate hexamethyl ether (XVI). The fact that XVI could not be hydrolyzed under any usual conditions constitutes evidence for the presence of orthosubstituted groups.

Additional reactions of the lactone (XIV) were also carried out. It reacts with one molecule of methylmagnesium iodide instead of two, as is common to ordinary lactones which are not hindered, and gives homogossypol tetramethyl ether (XVII). Upon methylation with methanolic sulfuric acid, this yields the ether (XVIII) whereas dimethyl sulfate and alkali gives the isomeric ether (XIX). Nitration of the lactone (XIV) results in a dinitro compound (XX). The action of dilute nitric acid upon the hydroxy acid (XV), however, oxidizes it to the quinone, gossypolonic acid tetramethyl ether, shown in XXI.

Gossypol hexamethyl ether[11] can be demethylated partially by means of a drop of sulfuric acid in acetic acid. A dimethyl ether is formed which, unlike the tetra- and hexamethyl ethers, shows many of the characteristic reactions of gossypol. It condenses readily with aniline in neutral solution and undergoes loss of two carbons and two oxygen atoms by treatment with concentrated aqueous sodium hydroxide. Gossypol tetramethyl ether, when demethylated in a similar way, is converted to gossypol. This shows conclusively that the two hydroxyls in gossypol tetramethyl ether are those which are methylated in gossypol dimethyl ether. In view of these facts the formula for the tetramethyl ether is XXII and of the dimethyl ether XXIII.



XXII



XXIII

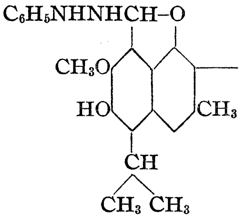
It becomes obvious why the phenylhydrazine derivatives of gossypol tetramethyl ether (XXIV) and of the dimethyl ether (XXV) are isomeric and not identical.[9]

The structure assigned the hexamethyl ether (X) accounts satisfactorily for the existence of two stereoisomeric forms.[11] The two lactol carbon atoms are asymmetric and, therefore, allow two stereoisomers. Stereoisomers could

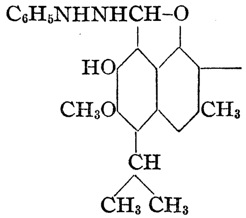
---

[10] Adams and Geissman, THIS JOURNAL, **60**, 2184 (1938).

[11] Adams and Geissman, *ibid.*, **60**, 2163 (1938).



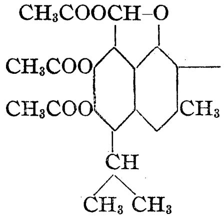
XXIV



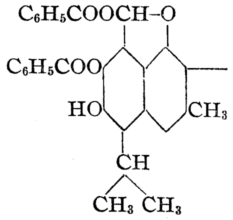
XXV

also be explained on the basis of formula Ia due to restricted rotation between the naphthalene nuclei. Since, however, stereoisomers were isolated only in the case of gossypol hexamethyl ether, the first explanation seems preferable. The formula (X) also explains why its absorption spectra[2] and that of the tetramethyl ether (XXII) differ from those of gossypol and the dimethyl ether (XXIII). The third peak in the spectra of the latter two compounds is missing in the first two. This peak is presumably due to the tautomeric *o*-hydroxyaldehyde nucleus and confirms the structures written for those molecules.

Esters of Gossypol.—Gossypol hexaacetate[12] is formed from gossypol, acetic anhydride and sodium acetate under very mild conditions. In addition to the white hexaacetate, a yellow product is obtained. This latter product is also formed upon heating the white hexaacetate with acetic anhydride. The yellow substance has not been obtained in an analytically pure state so that its character is undetermined. It is natural to assume that the white gossypol hexaacetate has a structure analogous to the hexamethyl ether and is, therefore, XXVI, though other formulas may be written based on the other tautomeric forms of gossypol. Benzoylation of gossypol[13] results merely in a tetrabenzoate and is represented by XXVII.

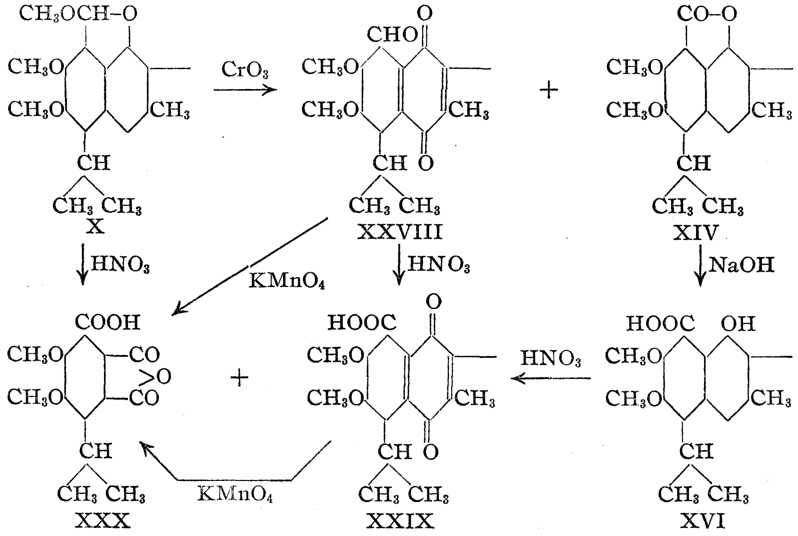


XXVI



XXVII

Oxidation Reactions of Gossypol Hexamethyl Ether.[14]—Gossypol hexamethyl ether (X) upon oxidation with chromic acid yields primarily a compound, gossypolone tetramethyl ether (XXVIII), in which two methoxyls have been hydrolyzed and two hydrogens have been replaced by an oxygen. As a minor by-product the lactone (XIV) is formed. Oxidation of X by dilute nitric acid yields two products in about equal amounts, the first, the water-insoluble gossypolonic acid tetramethyl ether (XXIX) of molecular size about that of the starting material, the second the water-soluble gossic acid (XXX) of about half the molecular size. Gossypolonic acid tetramethyl ether (XXIX) by the action of permanganate gives gossic acid (XXX). Moreover, gossypolone tetramethyl ether (XXVIII) is oxidized by nitric acid to gossypolonic acid tetramethyl ether (XXIX) and by permanganate to gossic acid (XXX). The lactone (XIV) is stable to nitric acid but the corresponding acid (XVI) is oxidized with nitric acid to gossypolonic acid tetramethyl ether (XXIX).



It is obvious how gossic acid (XXX) is produced. The quinone rings of gossypolonic acid tetramethyl ether (XXIX) are oxidized to two *o*-carboxyls which form the anhydride linkage. On the other hand, it is not so clear why gossypolonic acid tetramethyl ether (XXIX) cannot be oxidized with nitric acid to gossic acid (XXX) and still gossic acid is formed directly and simultaneously along with (XXIX) by the nitric acid oxidation of gossypol hexamethyl ether (X). An oxidation with degradation of the naphthalene

XXX XXXI XXXII

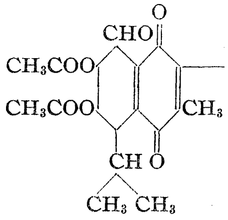
XXXVI XXXV XXXIV XXXIII

nucleus can take place apparently without quinone formation as an intermediate.

An extended study of the reactions of gossypolone tetramethyl ether (XXVIII) or of gossypolonic acid tetramethyl ether (XXIX) has not yet been completed. It has been shown, however, that the former contains no carboxyl groups while the latter contains two. Evidence yet unpublished is that they are quinones. Gossic acid (XXX), on the other hand, by degradation studies has been shown to be a benzene derivative with two methoxyls, a carboxyl, a dibasic acid anhydride and an isopropyl group. The evidence for this last group will be discussed under the heading "Desapogossypol."

Gossic acid[15] (XXX) is converted to apogossypolic acid (XXXIV) through the following intermediates, all of which can be isolated in a pure state, (1) demethylated gossic acid (XXXI), (2) demethylated decarboxylated gossic acid (XXXII), (3) decarboxylated gossic acid or apogossypolic acid anhydride (XXXIII), (4) apogossypolic acid (XXXIV). Other derivatives of gossic acid are also shown, methyl gossate (XXXV) by the action of diazomethane on gossic acid and the trimethyl ester (XXXVI) of hydrolyzed gossic acid by treatment of gossic acid with alkali, followed by acidification and methylation.

Gossypol hexaacetate[16] acts similarly to gossypol hexamethyl ether and undergoes oxidation with chromic acid to gossypolone tetraacetate (XXXVII). Further degradations of this molecule are not feasible because of the tendency for the acetyls to hydrolyze and thus to give products which are unstable and which rapidly decompose.



XXXVII

Apogossypol and its Derivatives.—Gossypol (Ia or Ic) loses two carbons and two oxygens by the action of concentrated aqueous sodium hydroxide.[5,13] The unstable compound produced, apogossypol (XXXVIII), is undoubtedly formed by the loss of the two aldehyde groups. Such a reaction is common to many hydroxyaldehydes of the benzene and naphthalene series. The instability of the product is explicable if compared with many polyhydroxynaphthalenes. The hexaacetate (XXXIX) and hexamethyl ether (XLII) of apogossypol, however, are stable compounds. Both of these derivatives oxidize, the first to apogossypolone tetraacetate (XL) and the second to apogossypolone tetramethyl ether (XLIII). Two methoxyls or two acetoxyls are lost during these reactions and the products are quinones as shown by reductive acetylation to hydroapogossypolone octaacetate (XLI) and hydroapogossypolone tetramethyl ether tetraacetate (XLIV). In the case of the hydroapogossypolone octaacetate (XLI) reoxidation to the quinone takes place readily. It is important to note that parallel series of derivatives are formed from the hexaacetate and hexamethyl ether.

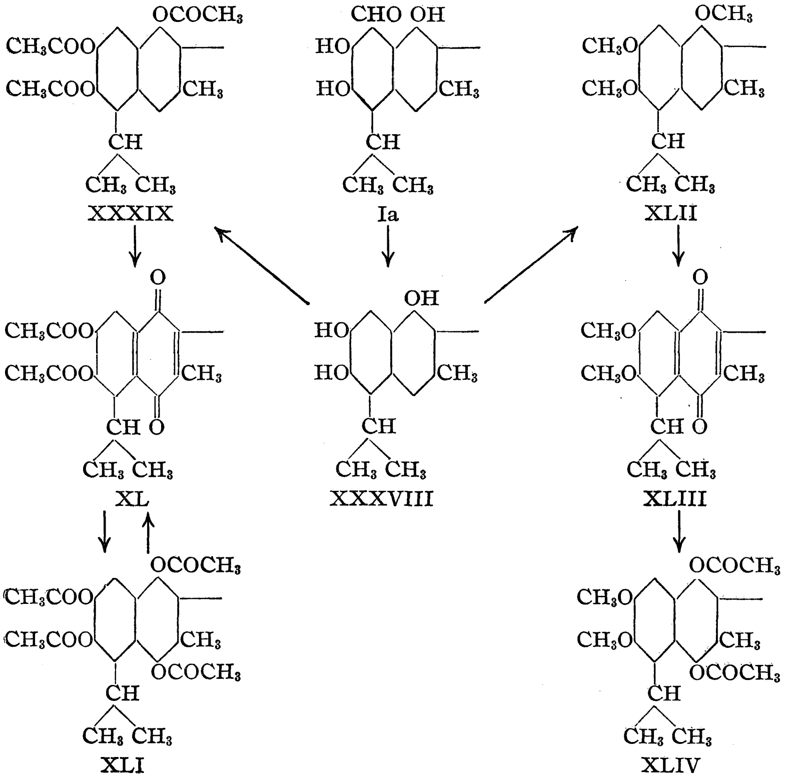
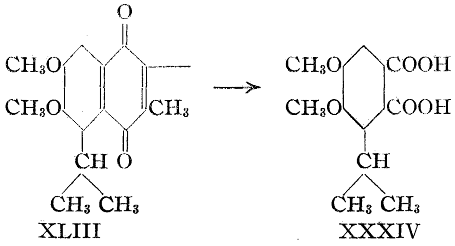
[15] Adams and Morris, THIS JOURNAL, 60, 2188 (1938).

[16] Clark, *ibid.*, 51, 1475 (1929).



The quinone,[13,17] apogossypolone tetramethyl ether (XLIII), upon oxidation with permanganate gives the water-soluble apogossypolic acid (XXXIV) described in connection with the degradation reactions of gossic acid (XXX). This transformation is shown below, the quinone ring oxidizing to two carboxyl groups.



It is significant that apogossypol (XXXVIII), apogossypol hexamethyl ether (XLII) and apogossypolone tetramethyl ether (XLIII) correspond exactly to gossypol Ia, gossypol hexamethyl ether (X), and gossypolone tetramethyl ether (XXVIII). There are two aldehyde groups less in each of the members of the former series, and consequently no condensation with aniline occurs. With the latter series aniline derivatives are formed. Apogossypolic acid (XXXIV) from the first series and gossic acid (XXX) from the second series differ merely by a carboxyl group[18] which presumably has formed from the aldehyde group by oxidation. Observation of this parallelism in the gossypol and apogossypol series leads to the conclusion that gossypolone tetramethyl ether and apogossypolone tetramethyl ether must have analogous structures. Since the latter has been shown unquestionably to be a quinone, the former is almost certain to be one also. This is confirmed by comparison of their absorption spectra.

Apogossypolic acid (XXXIV) has been degraded in a number of ways.[1] Methylation gives a dimethyl ester (XLV), and sublimation, the anhydride (XXXIII). Hydrobromic acid hydrolyzes the methoxyl groups and at the same time a carboxyl group is eliminated as carbon dioxide giving compound (XLVI). Methylation of (XLVI) gives the dimethoxy ester (XLVII) and saponification of the latter the acid (XLVIII).

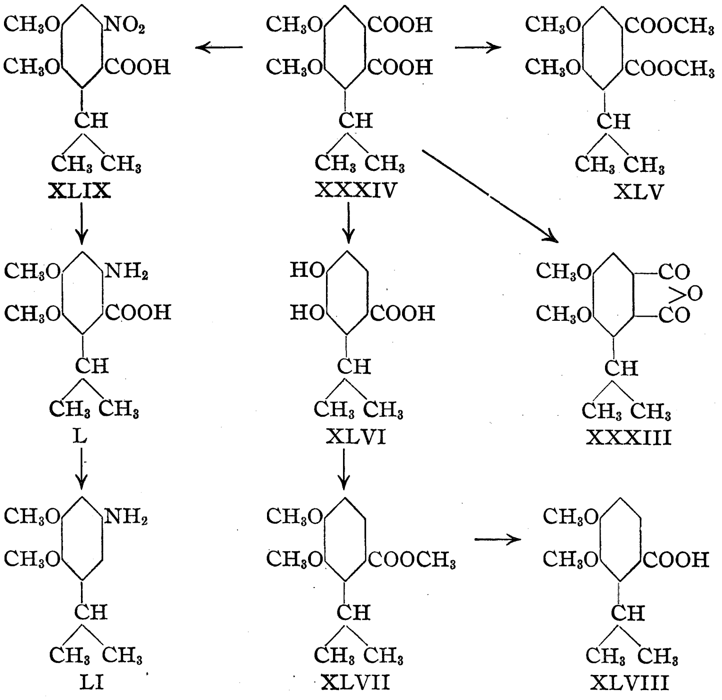
Apogossypolic acid upon treatment with nitric acid is converted to a compound in which one carboxyl has been replaced by a nitro group, postulated as XLIX. Reduction of this substance gives the amino acid (L) which was not isolated as such, for attempted purification by sublimation results in the loss of carbon dioxide with the formation of the amine (LI). This series of reactions has eliminated both of the carboxyl groups in apogossypolic acid and has thus demonstrated that they must be directly attached to the benzene nucleus.

The structures of these substances are assigned on the basis of indirect evidence or by analogies and not upon experimental data. Further study may necessitate changes in them. Thus, the nitro derivative (XLIX) of apogossypolic acid may have the nitro group in place of one or the other of the two carboxyls. Moreover, by hydrobromic acid treatment of apogossypolic acid,

---

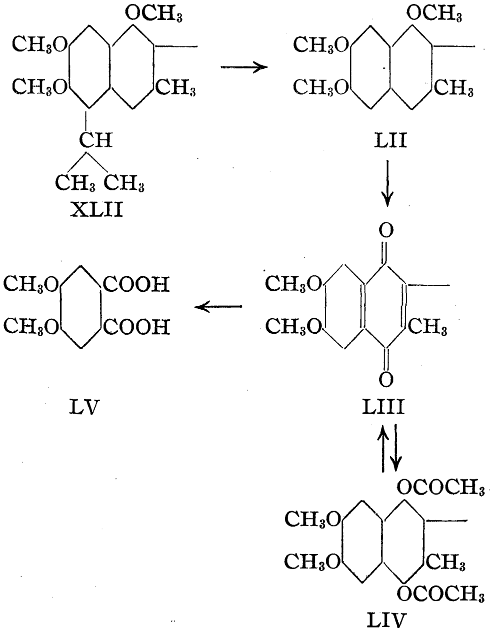
(17) Clark, *Oil & Fat Industries*, **6**, 7, 15 (1929).

(18) The fact that two carboxyls stabilize themselves as an anhydride linkage in gossic acid is of secondary importance.



the resulting molecule will be different depending upon which carboxyl is lost. The relative positions of the methoxyls and isopropyl group from indirect evidence appear indisputable and are the important factor in these molecules. The position of the other groups is less significant.

Desapogossypol and its Derivatives.[13]—Apogossypol hexamethyl ether (XLII) reacts with cold concentrated sulfuric acid and a loss of C_6H_{12} occurs. The product, which still contains six methoxyl groups, is desapogossypol hexamethyl ether (LII). It is not unlike the corresponding apo compound in its reactions for it oxidizes to a quinone, desapogossypolone tetramethyl ether (LIII), with loss of two methoxyls. Moreover, the quinone is reductively acetylated to hydrodesapogossypolone tetramethyl ether tetraacetate (LIV) which in turn can be reoxidized to the quinone (LIII).



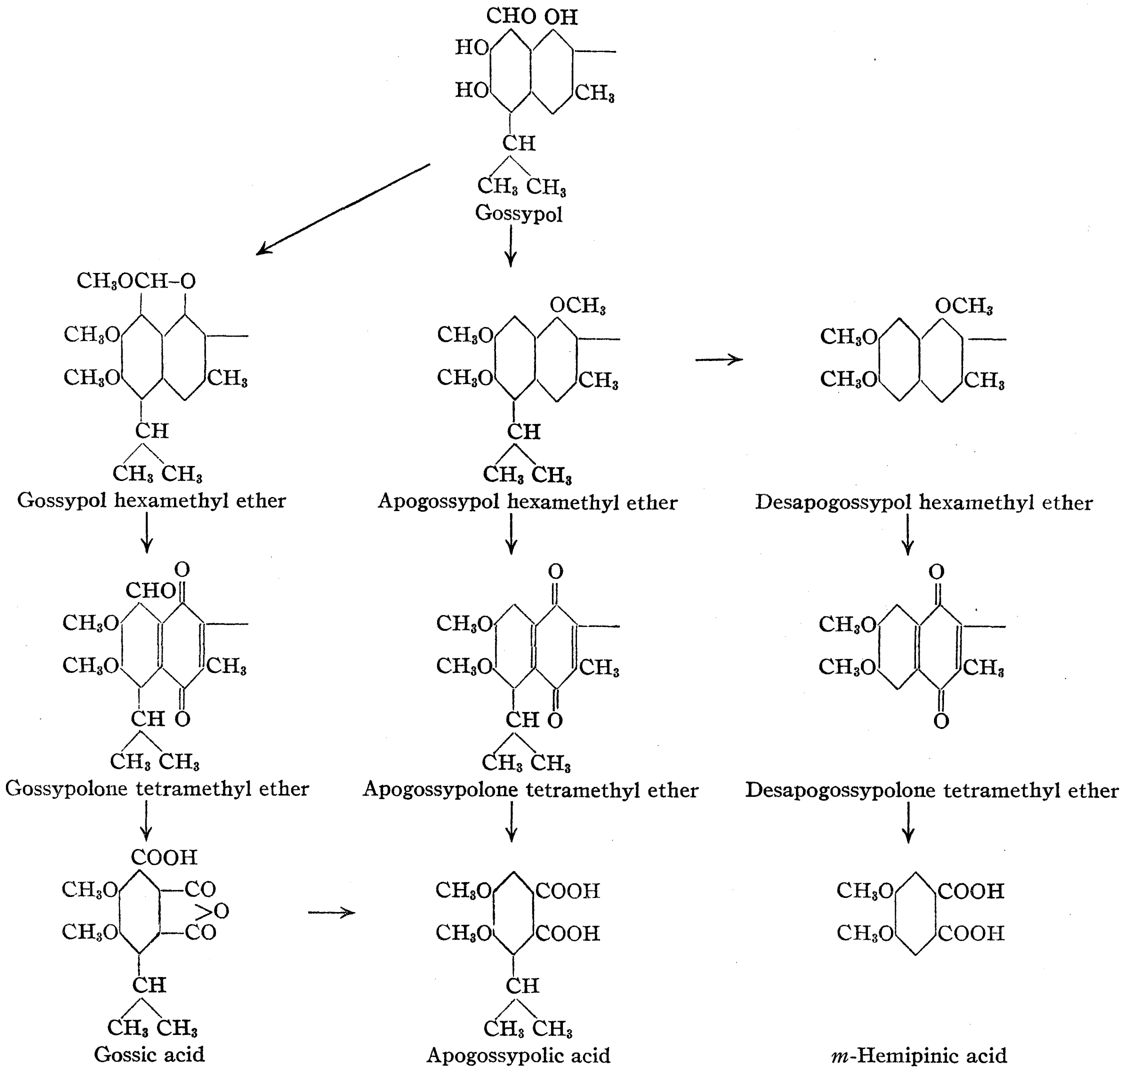
Desapogossypolone tetramethyl ether oxidizes with permanganate to *m*-hemipinic acid (LV), the only known product from gossypol which has yet been isolated. The difference between the molecular formula of *m*-hemipinic acid and apogossypolic acid (XXXIV) is a C_3H_6 residue. Between the corresponding but less degraded compounds of the desapogossypol and the apogossypol series, there is a difference of C_6H_{12} and between those of the desapogossypol and gossypol series C_6H_{12} and 2CO. It is, therefore, reasonably certain that the C_6H_{12} residue merely corresponds to two C_3H_7 groups, one in each naphthalene nucleus. By distilling the dilute sulfuric acid filtrate from the preparation of desapogossypol, a distillate is obtained which on oxidation gives a test for acetone. This demonstrates that the groups are isopropyls and are being removed directly from the naphthalene nuclei by hydrolysis.

The deductive evidence that has just been submitted for assuming gossypol to contain two naphthalene nuclei and that the functional groups present are of the kind and in the location shown in Ia, can best be summarized by a table of formulas (Table I) in which the relationships between the most important derivatives of gossypol are clearly apparent. All intermediates are omitted.

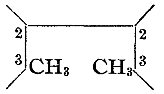
The experimental facts discussed in this communication have established without much question the functional groups in the 1, 5, 6, 7 and 8-positions of the two naphthalene nuclei. There is reasonable certainty of a hydrogen in the 4-position as deduced by the yellow color of the quinones; the possibility that the hydrogen may be in the 2-position is not absolutely excluded. No direct evidence is yet in hand from which the linkages and groups in the 2,3-positions may be

TABLE I

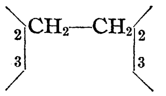
CORRELATION OF GOSSYPOL, APOGOSSYPOL AND DESAPOGOSSYPOL DERIVATIVES



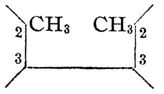
assigned. Alternative isomeric structures for that portion of the molecule associated with the linkage of the two naphthalene rings are shown in LVIa, LVIb, LVIc, LVId.



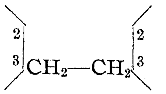
LVIa



LVIb



LVIc



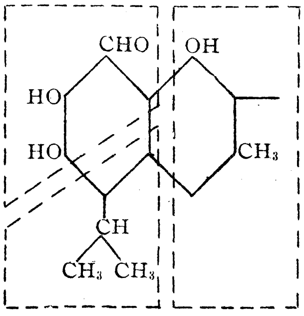
LVId

All four of these structures could be formed from isoprene units of which so many natural products appear to be built. Thus, two examples are given in formulas LVII and LVIII.

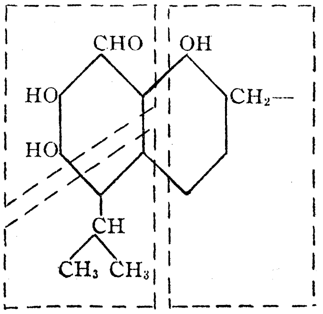
Numerous naturally-occurring compounds contain methyl and isopropyl groups in the relative positions 3,5 in naphthalene skeletons. Only formula LVIa has such a structure though LVId might result from the oxidation of a methyl group in the 3-position. A most important fact is that a substantial quantity of acetic acid can be isolated along with formic and isobutyric acids, by the limited permanganate oxidation of gossypol.[19] The aldehyde group may be the source of the formic acid and the isopropyl group with a carbon atom from the ring the source of the isobutyric acid. The formation of the acetic acid can be explained only on the basis of LVIa and LVIc. Attempted isolation of suc-

---

(19) Clark, *J. Biol. Chem.*, **77**, 81 (1928).



LVII (Ia)



LVIII

cinic acid which should result from LVIb and LVId by a similar oxidation was unsuccessful. Since LVIc is less likely because it does not have the 3-methyl-5-isopropyl arrangement, LVIa is considered as the most acceptable. It is obvious that other combinations in the 2,3-positions may be written but none other than those mentioned would result in a completely symmetrical molecule.

In view of these facts, formula Ia has been tentatively adopted for gossypol and is 2,2-bi-1,6,7-trihydroxy-5-isopropyl-8-aldehydonaphthyl.

The structure of gossypol (Ia) accounts for the anomalous results found by Clark[20] in carrying out a Zeisel determination. Gossypol gave a value of 5.7% though it contains no methoxyls. In the investigations from this Laboratory, methoxyl values of most of the gossypol derivatives were very frequently high. These can be accounted for by the fact that hydriodic acid removes, partially at least, the isopropyl groups as isopropyl iodide. The removal of an isopropyl group from a naphthalene by means of hydriodic acid is not entirely to be unexpected for it is reported in the literature that α-isopropylnaphthalene can be converted by means of hydriodic acid into naphthalene and isopropyl iodide.[21]

The definite establishment of structure Ia for gossypol must await (1) the synthesis of one or more of the benzene derivative degradation products, (2) a further study of gossypolone tetramethyl ether and gossypolonic acid tetramethyl ether, (3) knowledge concerning the arrangement of linkages and groups at the 2,3-positions.

Two oxidation products of gossypol dimethyl ether which have not been discussed are (1) that obtained by passing air through an alkaline solution, and (2) that resulting from treatment with ferric chloride.[11] These are of less significance in connection with the gossypol structure and consequently their further investigation is of secondary importance. The same is true of the oxidation product of demethylated apogossypolic acid in alkaline solution by means of air.[15]

The red gossypol hexamethyl ether requires further study.[3] This substance is not easily isolated in a pure state and consequently there is some doubt as to its exact empirical formula. The yellow product formed along with gossypol hexaacetate or from the latter by the action of acetic anhydride falls into the same category.[12] The complex compounds[4] from gossypol and certain substituted anilines need clarification. The character of the nitration products of gossypol hexamethyl ether and gossypolonic acid tetramethyl ether has not yet been determined. The structure of red gossypol may be Ic though no evidence for this is available.[22]

No simple naphthalene compounds have ever been isolated by degradation of gossypol except that reported by Schmid[23] as β-isoamylnaphthalene, obtained by exhaustive hydrogenation of gossypol and distillation of the reaction mixture with excess zinc dust. The identification of the product mentioned was not convincing and the formula for gossypol proposed would not give β-isoamylnaphthalene by the procedure used. Schmid also reported the isolation of *n*-butyric acid, a compound which could not be obtained from formula Ia.

The character of gossypolic acid reported by Karrer and Tobler[24] cannot be determined until a satisfactory method is found for its preparation.

The authors desire to express their sincere thanks to the Proctor and Gamble Company for furnishing through their subsidiary, the Buckeye Cotton Oil Company, the cottonseed meats from which the gossypol is being extracted for use in these investigations.

Summary

1. The correlation of the results of the study of gossypol has been made. The deductions from (1) the color reactions and salts, (2) the anilino

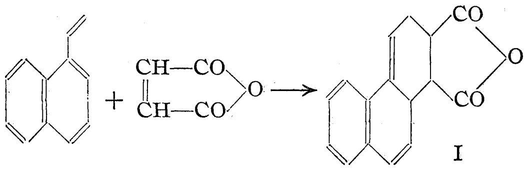
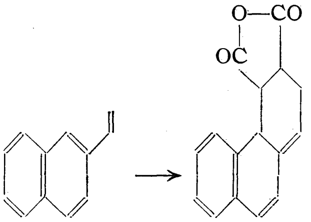
The Diels–Alder Reaction between Naphthylcyclopentenes and Maleic Anhydride

By W. E. Bachmann and M. C. Kloetzel[1]

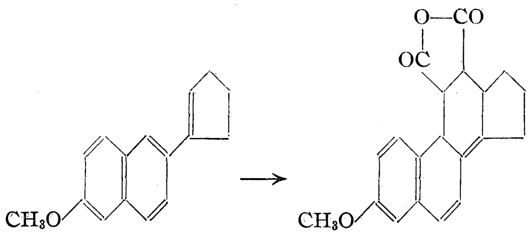
Cohen and Warren[2] have shown recently that 1-vinylnaphthalene and 2-vinylnaphthalene undergo the Diels–Alder reaction with maleic anhydride to give 1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid anhydride (I) and 2,3,4,4a-tetrahydrophenanthrene-3,4-dicarboxylic acid anhydride (II), respectively. A similar addition of maleic anhydride to 1-(6′-methoxy-2′-naphthyl)-cyclopentene-1 (III) would be expected to form a compound (IV) having the sterol skeleton, but it has been reported by Bergmann and Bergmann[3] that maleic anhydride reacts neither with 1-(α-naphthyl)-cyclopentene-1 (V) nor with (III). We have now found that (III) and (V) can be made to react practically quantitatively with maleic anhydride. Similarly, 1-(β-naphthyl)-cyclopentene-1 (VI) can be made to react with maleic anhydride to the extent of 92%.



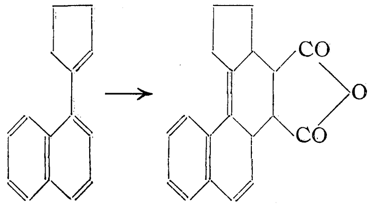
I



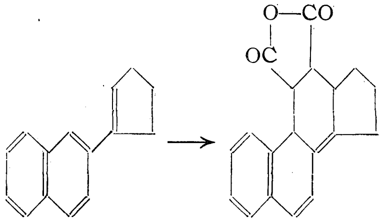
II



III IV



V Va



VI VIa

When a xylene solution of equimolecular proportions of (V) and maleic anhydride was refluxed for two hours and allowed to cool, a mixture of 3,4-cyclopentano-1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid and the corresponding acid anhydride (Va) was deposited. Under these conditions, reaction was found to have gone to the extent of 63%. A quantitative yield of the adduct could be obtained by fusing (V) with ten mole equivalents of maleic anhydride for twenty hours on a steam-bath.

When 1-(β-naphthyl)-cyclopentene-1 (VI) was refluxed for two hours in xylene solution with maleic anhydride and the solution was allowed to cool, 1,2-cyclopentano-2,3,4,4a-tetrahydrophenanthrene-3,4-dicarboxylic acid anhydride (VIa) was deposited as a resin, but (VIa) and (IV) were best prepared by fusing (VI) or (III), respectively, with ten mole equivalents of maleic anhydride on a steam-bath for twenty hours, dissolving the adduct in aqueous potassium hydroxide and precipitating by acidification with hydrochloric acid.

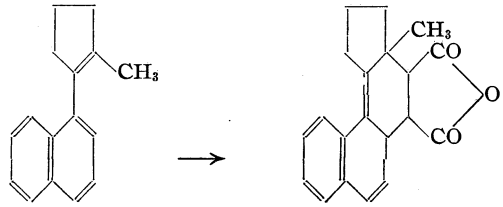
---

[1] Du Pont Post-Doctorate Fellow.

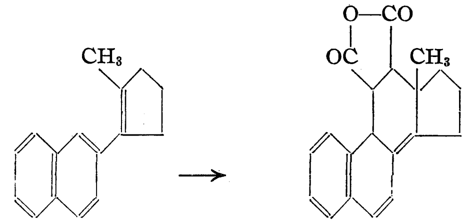
[2] Cohen and Warren, *J. Chem. Soc.*, 1318 (1937).

[3] Bergmann and Bergmann, This Journal, **59**, 1443 (1937).

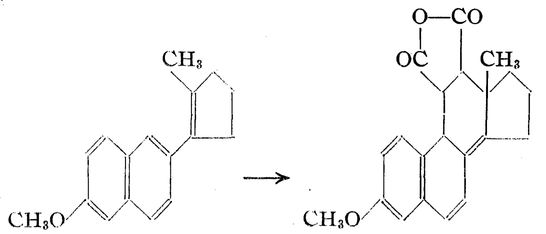
We have shown recently[4] that methyl groups in the *meso* positions of anthracene derivatives markedly activate the diene systems involved in the reaction with maleic anhydride. We therefore prepared 1-(α-naphthyl)-2-cyclopentene-1 (VII), 1-(β-naphthyl)-2-methylcyclopentene-1 (VIII) and 1-(6′-methoxy-2′-naphthyl)-2-methylcyclopentene-1 (IX) and tested their reactivity with maleic anhydride. These naphthylcyclopentenes reacted to give (VIIa), (VIIIa) and (IXa), respectively, but, contrary to expectation, the presence of the methyl groups actually decreased the rates of reaction.



VII VIIa



VIII VIIIa



IX IXa

The compounds (IV), (Va), (VIa), (VIIa), (VIIIa) and (IXa) are in each instance proposed as the primary addition products with the realization that they may be isomerized to the corresponding naphthalenic isomers. This isomerization was actually demonstrated by Cohen and Warren,[2] who converted (I) into (X) by the action of hot acetic acid saturated with hydrogen chloride.

The extent of reaction of each of these naphthylcyclopentenes with maleic anhydride was determined by refluxing a xylene solution (2 cc. of xylene/g. of cyclopentene) containing equimolecular proportions of the reactants for periods of one and two hours, respectively. In each instance, also, the naphthylcyclopentene was fused with ten mole equivalents of maleic anhydride on a steam-bath for twenty hours. The results, which are based upon the weight of unreacted cyclopentene recovered, are presented in Table I. It is important, however, that in most instances of long refluxing, although the extent of reaction is greater, the adduct is contaminated with decomposition products, so that a shorter period of reflux is generally desirable for preparative purposes.

TABLE I

THE EXTENT OF REACTION OF NAPHTHYLCYCLOPENTENES WITH MALEIC ANHYDRIDE

	Percentage of reaction after		
	Period of reflux		Fusion
Naphthylcyclopentene	1 hour	2 hours	20 hours
1-(α-Naphthyl)-cyclopentene-1 (V)	45	63	98
1-(α-Naphthyl)-2-methylcyclopentene-1 (VII)	9	16	32
1-(β-Naphthyl)-cyclopentene-1 (VI)	55	58	92
1-(β-Naphthyl)-2-methylcyclopentene-1 (VIII)	18	19	77
1-(6′-Methoxy-2′-naphthyl)-cyclopentene-1 (III)	45	56	98
1-(6′-Methoxy-2′-naphthyl)-2-methylcyclopentene-1 (IX)	12	14	94

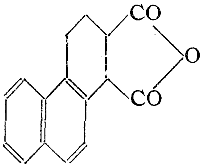
The naphthylcyclopentenes necessary for this investigation were all prepared in a similar manner. First of all, the tertiary cyclopentanols were prepared by means of the Grignard reaction: thus, α-naphthylmagnesium bromide with cyclopentanone and 2-methylcyclopentanone gave 1-(α-naphthyl)-cyclopentanol-1 and 1-(α-naphthyl)-2-methylcyclopentanol-1, respectively; β-naphthylmagnesium iodide with the same two ketones gave 1-(β-naphthyl)-cyclopentanol-1 and 1-(β-naphthyl)-2-methylcyclopentanol-1, respectively; and 6-methoxy-2-naphthylmagnesium bromide gave 1-(6′-methoxy-2′-naphthyl)-cyclopentanol-1 and 1-(6′-methoxy-2′-naphthyl)-2-methylcyclopentanol-1, respectively. These carbinols were then dehydrated to the corresponding naphthylcyclopentenes by warming for a short time with anhydrous formic acid.

It may be observed that the use of (VIII) and (IX) in the reaction with maleic anhydride offers a convenient method of obtaining compounds containing angular methyl groups; thus, (IXa) is an isomer of the methyl ether of deoxoequilenin-11,12-dicarboxylic acid anhydride. It was therefore of interest to attempt the decarboxylation of our adducts with the hope of obtaining derivatives closely related to naturally occurring compounds.

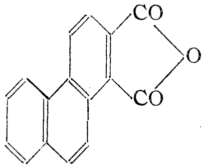
---

(4) Bachmann and Kloetzel, THIS JOURNAL, **60**, 481 (1938).

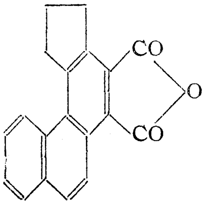
When a mixture of (I) or (Va) with the theoretical amount of sulfur necessary to remove four hydrogen atoms was heated to 250–270° for a period of thirty to forty-five minutes, phenanthrene-1,2-dicarboxylic acid anhydride (XI) or 3,4-cyclopentenophenanthrene - 1,2 - dicarboxylic acid anhydride (XII) were obtained, respectively. Dehydrogenation of (IV), (VIa), (VIIa), (VIIIa) or (IXa) with sulfur did not proceed smoothly under these same conditions.



X



XI

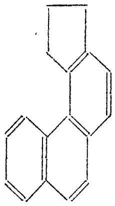


XII

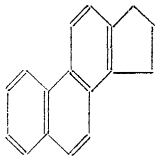
An attempt then was made to decarboxylate (XII) by refluxing in quinoline solution with basic copper carbonate. This method gave erratic results, however, and in no case was the yield of 3,4-cyclopentenophenanthrene (XIII) greater than 19%. Dry distillation of the dipotassium salt of 3,4 - cyclopentenophenanthrene - 1,2 - dicarboxylic acid with potassium hydroxide at 430° likewise gave 3,4-cyclopentenophenanthrene in extremely poor yield. When, however, the calcium salt of (XI) was dry distilled with a mixture of calcium oxide and zinc dust, a 30% yield of phenanthrene was obtained.

When the latter method of decarboxylation was applied to the adducts themselves it was found that dehydrogenation as well as decarboxylation took place, even when no zinc dust was employed in the distillation of the calcium salts. Dry distillation of the calcium salt of 1,2,3,10a-tetrahydrophenanthrene - 1,2 - dicarboxylic acid (from I) with calcium oxide alone gave a 67% yield of phenanthrene. When zinc dust was included in the distillation mixture, the yield of phenanthrene was reduced to 28%, and the product, moreover, was contaminated with impurities which were difficult to remove. The calcium salt of 3,4-cyclopenteno-1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid (from Va) was distilled with a mixture of calcium oxide and zinc dust, resulting in a 62% yield of 3,4-cyclopentenophenanthrene (XIII). Addition of 1-(α-naphthyl)-cyclopentene-1 to maleic anhydride, followed by decarboxylation of the resulting adduct, therefore offers a second convenient synthesis of 3,4-cyclopentenophenanthrene.[5]

In like manner, the addition of 1-(β-naphthyl)-cyclopentene-1 to maleic anhydride, followed by decarboxylation of the resulting adduct, offers a convenient synthetic route to 1,2-cyclopentenophenanthrene (XIV), for the dry distillation of the calcium salt of 1,2-cyclopentano-2,3,4,4a-tetrahydrophenanthrene-3,4-dicarboxylic acid (from VIa) with a mixture of calcium oxide and zinc dust resulted in an 80% yield of 1,2-cyclopentenophenanthrene, even when crude adduct was employed.



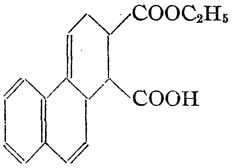
XIII



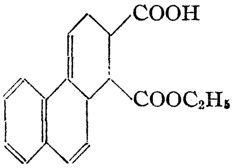
XIV

When this method of decarboxylation was extended to 2-methyl-1,2-cyclopentano-2,3,4,4a-tetrahydrophenanthrene-3,4-dicarboxylic acid anhydride (VIIIa), a good yield of distillate was obtained. Although the product formed a picrate (m. p. 123–124°), its identity was not ascertained. Similarly, the distillation of the calcium salts of those adducts containing methoxyl or angular methyl groups produced no identifiable products.

The reaction of 1-vinylnaphthalene with ethyl hydrogen maleate was investigated in the hope of obtaining an adduct which might be readily decarboxylated without simultaneous aromatization. When a mixture of equimolecular proportions of the hydrocarbon and ester was heated on the steam-bath for fifteen hours, addition took place to the extent of 72%, and the adduct, (XV) or (XVI), was isolated as a colorless solid. Dehydrogenation of this with sulfur gave phenan-



XV



XVI

---

[5] Bachmann and Kloetzel, This Journal, **59**, 2207 (1937).

threne-1,2-dicarboxylic acid anhydride (XI). Attempted decarboxylation by refluxing in quinoline solution with basic copper carbonate gave, however, only an unidentified, crystalline product.

Experimental

The effect of concentration, time and temperature on the yields of adducts was determined by means of a procedure outlined in a previous paper.[4] Xylene solutions containing equivalent quantitites of the reactants (2 cc. of xylene/g. of naphthylcyclopentene) were heated to the boiling points of the solutions for periods of one hour and two hours, respectively. Forty per cent. potassium hydroxide solution was then added to hydrolyze the addition product (anhydride) and the potassium salt of the dicarboxylic acid was dissolved in hot water. Benzene was added to dissolve unreacted naphthylcyclopentene and the two solutions were separated. Evaporation of the benzene in a weighed container gave the amount of unreacted naphthylcyclopentene; acidification of the aqueous solution with dilute hydrochloric acid precipitated the dicarboxylic acid.

Experiments also were carried out in which the naphthylcyclopentene and ten mole equivalents of maleic anhydride were fused together on a steam-bath for twenty hours without the addition of any solvent. These reaction mixtures were worked up as before in order to determine the extent of reaction. The results of these experiments, which are accurate to a few per cent., are presented in Table I.

1-Vinylnaphthalene and Maleic Anhydride.—The adduct of 1-vinylnaphthalene was prepared according to the method of Cohen and Warren[2] with some modifications. The yellow solution obtained by heating 8.5 g. of 1-vinylnaphthalene, 5.7 g. of maleic anhydride and 17 cc. of anhydrous xylene on a steam-bath began to deposit the adduct within ten minutes. Heating was continued for three hours, after which the mixture was allowed to stand at 0° for twelve hours and the precipitate was filtered off; yield 13.0 g. This crude product began to sinter at 130° and finally melted with decomposition at 185–190°. A portion of the product was soluble in hot acetic acid, and on being cooled the solution deposited colorless crystals of **1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid.** The portion insoluble in acetic acid was presumably the corresponding dicarboxylic acid anhydride (I).[3]

Decarboxylation and Dehydrogenation of 1,2,3,10a-Tetrahydrophenanthrene-1,2-dicarboxylic Acid to Phenanthrene.—A 2.5-g. sample of the crude adduct from 1-vinylnaphthalene and maleic anhydride was dissolved by warming in 80 cc. of water containing 1.0 g. of sodium hydroxide, 1.5 g. of calcium oxide was added, and the mixture was boiled for five minutes in order to form the calcium salt of 1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid. The suspension was evaporated to dryness and the calcium salt was mixed intimately with 8.5 g. of calcium oxide and dry distilled in a hard glass test-tube. The yellow, crystalline product (1.2 g.) which condensed in the cold part of the tube was sublimed in vacuum (130° at 0.6 mm.) and crystallized from ethanol, yield 0.8 g., m. p. 97–98°, giving no depression of melting point when mixed with an authentic sample of phenanthrene. The picrate (m. p. 144–145°) was likewise identical with phenanthrene picrate.

In a similar experiment, when the calcium salt of the dicarboxylic acid was dry-distilled with a mixture of 8.5 g. of calcium oxide and 6.3 g. of zinc dust, the phenanthrene obtained (0.5 g.) was contaminated with other products.

Phenanthrene-1,2-dicarboxylic Acid Anhydride (XI).—A mixture of 1.0 g. of the crude adduct obtained from 1-vinylnaphthalene and maleic anhydride was mixed with 260 mg. of sulfur and heated to 255° for forty minutes. The product was sublimed in vacuum (240° at 1 mm.) and recrystallized from chlorobenzene; yield, 320 mg. of yellow needles; m. p. 310–311° (Fieser and Hershberg[6] give 311–312°).

The **diethyl ester of phenanthrene-1,2-dicarboxylic acid** was prepared by refluxing for six hours a mixture of 200 mg. of phenanthrene-1,2-dicarboxylic acid anhydride, 10 cc. of absolute ethanol and 1 cc. of concentrated sulfuric acid. A clear yellow solution was obtained within one hour. Most of the alcohol was evaporated and the ester was precipitated with water. When the precipitate was warmed with a small quantity of ethanol the ester dissolved, leaving behind some unchanged dicarboxylic acid anhydride which was filtered off. The ester was vacuum sublimed (140° at 0.6 mm.) and crystallized from ethanol in pale yellow needles, m. p. 132°; yield, 63 mg.

Anal. Calcd. for $C_{20}H_{18}O_4$: C, 74.5; H, 5.6. Found: C, 74.0; H, 5.8.

Decarboxylation of Phenanthrene-1,2-dicarboxylic Acid.—A 0.47-g. sample of phenanthrene-1,2-dicarboxylic acid was converted to the calcium salt in the same manner as described for the conversion of 1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid, and was then dry distilled with a mixture of 1.7 g. of calcium oxide and 1.3 g. of zinc dust. The crude **phenanthrene** (100 mg.) was purified by picration, and was identical with an authentic sample.

1-Vinylnaphthalene and Ethyl Hydrogen Maleate.—A mixture of 2.6 g. of 1-vinylnaphthalene and 2.5 g. of ethyl hydrogen maleate[7] was heated on a steam-bath for fifteen hours. Water, potassium carbonate and benzene were then added and the layers were separated. Evaporation of the benzene left 0.74 g. of unreacted vinylnaphthalene, indicating 72% reaction. Acidification of the aqueous layer with dilute hydrochloric acid precipitated the adduct (XV or XVI) as a pale yellow solid (4 g.), which was digested with warm ether and filtered. The colorless powder so obtained is very soluble in ethyl acetate, chloroform, acetic acid or hot ethanol; insoluble in ether, hot benzene or hot *n*-butyl ether. Partial purification of the adduct was accomplished by solution in hot acetone (in which it is slightly soluble) and reprecipitation with ether, but the compound was not successfully crystallized.

When a sample of the aforementioned adduct (1.5 g.) was heated at 250–260° for thirty minutes with sulfur (330 mg.) and the product vacuum sublimed, there was obtained 100 mg. of **phenanthrene-1,2-dicarboxylic acid anhydride** (XI).

---

[6] Fieser and Hershberg, THIS JOURNAL, **57**, 1508, 1853 (1935).

[7] Shields, *J. Chem. Soc.*, **59**, 740 (1891).

A solution of the aforementioned adduct (2 g.) in quinoline (20 cc.) was refluxed with basic copper carbonate (400 mg.) for thirty minutes, and after being cooled was diluted with ether and filtered. The ethereal solution was washed with dilute hydrochloric acid, dilute sodium carbonate and finally with water. Evaporation of the ether left only a yellow crystalline compound which crystallized from acetic acid in broad, yellow needles; m. p. 246–247°; yield 600 mg. The compound (C, 81.1; H, 4.3) gives a red-orange color with concentrated sulfuric acid, and is soluble in hot, aqueous potassium hydroxide with difficulty.

1-(α-Naphthyl)-cyclopentanol-1 was prepared by adding 42 g. of cyclopentanone dropwise to a solution of α-naphthylmagnesium bromide prepared from 116 g. of α-bromonaphthalene, 12.5 g. of pure magnesium ribbon and 300 cc. of anhydrous ether. The cyclopentanone was added at such a rate that the mixture refluxed gently from heat of reaction. The crystalline addition product which separated after standing at 0° for twelve hours was filtered off and hydrolyzed with ice water and ammonium chloride. When an ethereal solution of the hydrolyzed product was allowed to evaporate spontaneously at room temperature the carbinol was obtained in colorless crystals which were then washed with petroleum ether (60–70°); yield, 50 g. (42%). From 30–40° petroleum ether **1-(α-naphthyl)-cyclopentanol-1** crystallized in colorless, rectangular prisms, m. p. 75.5–76°. Concentrated sulfuric acid gives a purple-red color with this carbinol.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.9; H, 7.6. Found: C, 84.5; H, 7.1.

1-(α-Naphthyl)-cyclopentene-1 (V) was obtained when the corresponding naphthylcyclopentanol was dehydrated with either potassium acid sulfate or anhydrous formic acid.

A mixture of 5 g. of the carbinol and 7.5 g. of potassium acid sulfate was heated in a Pyrex test-tube at 165° for forty-five minutes. Water and benzene were then added, the benzene layer was separated and evaporated and the residual oil was distilled in vacuum (165–168° at 1 mm.); yield, 3.7 g. (81%) of a colorless oil which solidified when placed in a refrigerator at −2°.

Dehydration with anhydrous formic acid was accomplished by dissolving 20 g. of finely powdered 1-(α-naphthyl)-cyclopentanol-1 in 50 cc. of the acid at room temperature. Within several minutes the solution became cloudy and the hydrocarbon separated as an oil. After warming the mixture on a steam-bath for five minutes to complete the reaction, 200 cc. of water was added and the 1-(α-naphthyl)-cyclopentene-1 was extracted with benzene; yield, 18 g. (98%).

The naphthylcyclopentene prepared by either method yielded a picrate which crystallized from methanol in vermilion needles, m. p. 79–80°.[3]

Anal. Calcd. for $C_{21}H_{17}O_7N_3$: N, 9.93. Found: N, 9.98.

1-(α-Naphthyl)-cyclopentene-1 and Maleic Anhydride.—A solution of 8.5 g. of 1-(α-naphthyl)-cyclopentene-1 and 4.5 g. of sublimed maleic anhydride in 17 cc. of anhydrous xylene was refluxed for two hours, the solvent was evaporated and the residue was dissolved in 13 cc. of hot acetic acid. After standing for twelve hours the solution deposited 2.8 g. of a mixture of **3,4-cyclopentano-1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid** and the corresponding acid anhydride (Va). The dicarboxylic acid crystallizes from acetic acid in colorless, diamond-shaped plates, m. p. 211–213° dec. (in nitrogen).

Anal. Calcd. for $C_{19}H_{18}O_4$: C, 73.5; H, 5.8. Found: C, 73.2; H, 5.9.

The dicarboxylic acid is soluble in acetone, dioxane or hot benzene, slightly soluble in cold benzene, and insoluble in ether. It dissolves in dilute potassium hydroxide and the cold alkaline solution reduces potassium permanganate instantaneously. Acidification of the alkaline solution yields the dicarboxylic acid as a yellow gum. Recrystallization from acetic acid or from acetic anhydride partially converted the acid to the corresponding anhydride, as was shown by analysis.

3,4-Cyclopentenophenanthrene-1,2-dicarboxylic Acid Anhydride (XII).—A mixture of 500 mg. of 3,4-cyclopentano-1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid and 100 mg. of sulfur was heated to 230–240° for forty-five minutes in an atmosphere of carbon dioxide. The product was sublimed in vacuum (250–280° at 0.4 mm.) and crystallized from chlorobenzene (65 cc./g.) in yellow needles; m. p. 321°; yield, 270 mg. (54%).

Anal. Calcd. for $C_{19}H_{12}O_3$: C, 79.1; H, 4.2. Found: C, 78.9; H, 4.2.

3,4-Cyclopentenophenanthrene (XIII). (a) Decarboxylation and Dehydrogenation of 3,4-Cyclopentano-1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic Acid.—A 1.2-g. sample of 3,4-cyclopentano-1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid was converted to the calcium salt as in the case of 1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid, and dry distilled with 4 g. of calcium oxide and 3 g. of zinc dust. The yellow distillate obtained (0.56 g.) was dissolved in 4 cc. of absolute ethanol and 0.6 g. of picric acid was added to the hot solution. When the solution was cooled, 1.0 g. of **3,4-cyclopentenophenanthrene picrate** crystallized; m. p. 133–134° alone and when mixed with an authentic sample of the same melting point.

The picrate was decomposed with dilute ammonium hydroxide, and the **3,4-cyclopentenophenanthrene** liberated was crystallized from acetone–methanol, m. p. 69–71° alone and when mixed with an authentic sample.[5]

(b) Decarboxylation of 3,4-Cyclopentenophenanthrene-1,2-dicarboxylic Acid Anhydride.—A mixture of 70 mg. of 3,4-cyclopentenophenanthrene-1,2-dicarboxylic acid anhydride, 14 mg. of basic copper carbonate and 2 cc. of quinoline was refluxed for thirty minutes, a large volume of ether was added and the solution was filtered from a dark sludge. The ethereal solution was shaken with dilute hydrochloric acid, dilute potassium hydroxide and finally with water. Evaporation of the ethereal solution left a residue which, when dissolved in acetone–alcohol, yielded 10 mg. of yellow needles of m. p. 240°. These were discarded and the remaining residue was sublimed in vacuum (up to 150° at 0.4 mm.) and crystallized from acetone–alcohol; yield, 10 mg. of **3,4-cyclopentenophenanthrene** in colorless plates, m. p. 71.5–72° alone and when mixed with an authentic sample. The picrate of the hydrocarbon obtained was likewise identical with an authentic sample of 3,4-cyclopentenophenanthrene picrate.

3,4-Cyclopentenophenanthrene-1,2-dicarboxylic acid also was decarboxylated with poor yield by dry distillation of its dipotassium salt. A mixture of 100 mg. of 3,4-cyclopentenophenanthrene-1,2-dicarboxylic acid anhydride, 100 mg. of potassium hydroxide and 5 cc. of water was heated in a test-tube until complete solution was obtained. The solution was then evaporated to dryness and the residue was heated for thirty minutes at 430°. The white sublimate obtained from the cool part of the tube was dissolved in ethanol and picric acid was added; yield, 5 mg. of **3,4-cyclopentenophenanthrene picrate**, m. p. 134–135°.

1-(α-Naphthyl)-2-methylcyclopentene-1 (VII).—To the cooled solution of α-naphthylmagnesium bromide prepared from 31 g. of α-bromonaphthalene, 3.8 g. of pure, powdered magnesium and 100 cc. of anhydrous ether, was added dropwise a solution of 15 g. of 2-methylcyclopentanone[8] in 15 cc. of anhydrous benzene. The clear green solution obtained was refluxed on a steam-bath for two hours, cooled and then hydrolyzed with cold, aqueous ammonium chloride. To the residual 1-(α-naphthyl)-2-methylcyclopentanol-1 obtained when the organic layer was evaporated was added 85 cc. of anhydrous formic acid, and the resulting blue-green solution was warmed on a steam-bath for ten minutes. The solution was poured into 400 cc. of water, ether was added and the ethereal extract was washed with 10% sodium carbonate. After removal of the ether the residue was fractionated three times in vacuum, and the fraction boiling at 165–168° (1 mm.) finally was collected as **1-(α-naphthyl)-2-methylcyclopentene-1**; yield, 6 g. of pale yellow oil. Concentrated sulfuric acid gives a red color with this hydrocarbon. The compound was not obtained analytically pure.

1-(α-Naphthyl)-2-methylcyclopentene-1 and Maleic Anhydride.—A mixture of 1.0 g. of 1-(α-naphthyl)-2-methylcyclopentene-1 and 4.7 g. of maleic anhydride was heated on a steam-bath for twenty hours. **3-Methyl-3,4-cyclopentano-1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid** (0.25 g.) was obtained in the form of a brown gum when the reaction mixture was extracted with aqueous potassium hydroxide and the extract was acidified with dilute hydrochloric acid.

1-(β-Naphthyl)-cyclopentene-1 (VI).—To the solution of Grignard reagent prepared by refluxing 25.4 g. of β-iodonaphthalene, 2.5 g. of pure magnesium powder and 75 cc. of anhydrous ether for three hours, was added dropwise a solution of 8.5 g. of cyclopentanone in 10 cc. of ether. The mixture was allowed to warm up from heat of reaction, and then allowed to stand at room temperature for two hours. To the crude 1-(β-naphthyl)-cyclopentanol-1 obtained by hydrolysis of the Grignard reaction mixture was added 50 cc. of anhydrous formic acid, and the solution was heated on a steam-bath for ten minutes. **1-(β-Naphthyl)-cyclopentene-1** separated in crystalline form when the solution was cooled. The crude hydrocarbon was crystallized twice from ethanol (separating from a yellow, insoluble by-product) and formed thin, colorless plates, m. p. 85–86°; yield, 5.2 g. The compound gives a rose-red color with concentrated sulfuric acid.

Anal. Calcd. for $C_{15}H_{14}$: C, 92.7; H, 7.3. Found: C, 92.6; H, 7.35.

1-(β-Naphthyl)-cyclopentene-1 and Maleic Anhydride.—A mixture of 1.0 g. of 1-(β-naphthyl)-cyclopentene-1 and 5 g. of maleic anhydride was fused on a steam-bath for twenty hours. A red color was produced immediately when the reactants were mixed. The reaction product was hydrolyzed with water and potassium hydroxide, the aqueous solution was extracted with benzene to remove unreacted hydrocarbon, and was then acidified with dilute hydrochloric acid; yield, 1.4 g. (92%) of cream-colored adduct.

Decarboxylation and Dehydrogenation of 1,2-Cyclopentano-2,3,4,4a-tetrahydrophenanthrene-3,4-dicarboxylic Acid.—The calcium salt of 1,2-cyclopentano-2,3,4,4a-tetrahydrophenanthrene-3,4-dicarboxylic acid was prepared as before from a 2.0-g. sample of the crude adduct, and was dry distilled with 8 g. of calcium oxide and 6 g. of zinc dust. **1,2-Cyclopentenophenanthrene** (1.2 g.) crystallized in the cold part of the tube, and was recrystallized from ethanol; yield, 0.6 g. of nearly colorless leaflets, m. p. 135–136° alone and when mixed with an authentic sample of hydrocarbon melting at 134°. **1,2-Cyclopentenophenanthrene picrate** was prepared and crystallized from ethanol in orange-yellow needles, m. p. 130–132°.

1-(β-Naphthyl)-2-methylcyclopentene-1 (VIII) was prepared in the same manner as its α-naphthyl isomer, from β-naphthylmagnesium iodide and 2-methylcyclopentanone. The crude hydrocarbon was fractionated four times in vacuum, and the fraction boiling at 180–182° (1 mm.) finally was collected as **1-(β-naphthyl)-2-methylcyclopentene-1**; yield, 5.5 g. of yellow oil (from 38 g. of β-iodonaphthalene). Concentrated sulfuric acid produces a red color with this hydrocarbon. Like its α-naphthyl isomer. the hydrocarbon was not obtained analytically pure.

1-(β-Naphthyl)-2-methylcyclopentene-1 and Maleic Anhydride.—The adduct was prepared by fusing the naphthylmethylcyclopentene with ten mole equivalents of maleic anhydride on a steam-bath for twenty hours, as described for 1-(β-naphthyl)-cyclopentene-1; yield, 58% of cream-colored powder.

1-(6′-Methoxy-2′-naphthyl)-cyclopentene-1 (III).—1-(6′-Methoxy-2′-naphthyl)-cyclopentanol-1 was prepared from 6-methoxy-2-naphthylmagnesium bromide and cyclopentanone, and then dehydrated with anhydrous formic acid as described in the preparation of 1-(β-naphthyl)-cyclopentene-1. The crude product was fractionated in vacuum, and the fraction boiling at 200–240° (1 mm.) was crystallized from ethanol. Boiling for fifteen minutes with an equivalent weight of maleic anhydride in xylene solution removed the last traces of colored impurities, and the **1-(6′-methoxy-2′-naphthyl)-cyclopentene-1** finally crystallized from ethanol in colorless leaflets, m. p. 141–142°; yield, 10 g. from 22 g. of 6-bromo-2-methoxynaphthalene. Bergmann and Bergmann,[3] who prepared this hydrocarbon by dehydrating the carbinol with potassium acid sulfate, reported a melting point of 148° for this compound.

1-(6′-Methoxy-2′-naphthyl)-cyclopentene-1 and Maleic Anhydride.—When 1.0 g. of 1-(6′-methoxy-2′-naphthyl)-cyclopentene-1 and 4.4 g. of maleic anhydride were melted together on a steam-bath the mixture quickly became brown-red. Heating was continued for twenty hours and

---

[8] Cornubert and Borrel, *Bull. soc. chim.*, (*IV*) **47**, 310 (1930).

the reaction mixture was hydrolyzed as previously described. Acidification of the alkaline solution precipitated 0.52 g. of **7-methoxy-1,2-cyclopentano-2,3,4,4a-tetrahydrophenanthrene-3,4-dicarboxylic acid** in the form of a cream-colored solid. The adduct was not crystallized successfully, but was partially purified by solution in cold acetic acid and reprecipitation with xylene. It then formed a colorless powder which sintered and darkened at 280° and finally melted at 310°, dec. The compound is nearly insoluble in hot xylene or hot chlorobenzene, but is readily soluble in cold acetic acid. Molecular weight (by neutralization) was 300; calculated, 340.

1-(6′-Methoxy-2′-naphthyl) - 2 - methylcyclopentene - 1 (IX).—This compound was prepared in the usual manner by dehydrating the carbinol obtained from 6-methoxy-2-naphthylmagnesium bromide and 2-methylcyclopentanone. The crude product was distilled twice in vacuum, and the fraction boiling at 200–205° (0.9 mm.) was crystallized from ethanol. Boiling for one hour with an equivalent weight of maleic anhydride removed the colored impurities and the **1-(6′-methoxy-2′-naphthyl)-2-methylcyclopentene-1** finally crystallized from methanol in clusters of colorless needles; m. p. 74–75°; yield 4.0 g. The compound gives an orange-red color with concentrated sulfuric acid.

Anal. Calcd. for $C_{17}H_{18}O$: C, 85.7; H, 7.6. Found: C, 85.6; H, 7.7.

1-(6′-Methoxy-2′-naphthyl) - 2 - methylcyclopentene - 1 and Maleic Anhydride.—When a mixture of 0.7 g. of the methoxy derivative and 2.94 g. (ten mols) of maleic anhydride was heated on a steam-bath for twenty hours and the alkaline solution of the hydrolyzed product was acidified with dilute hydrochloric acid, 0.9 g. (92%) of **7 - methoxy - 2 - methyl - 1,2 - cyclopentano - 2,3,4,4a - tetrahydrophenanthrene-3,4-dicarboxylic acid** was obtained in the form of a colorless, granular precipitate. The adduct is practically insoluble in hot xylene but is readily soluble in cold acetic acid. It was partially purified by solution in cold acetic acid, and reprecipitation with xylene: the colorless powder so obtained sintered and darkened at 275° and finally melted at 292°, dec.

Summary

Maleic anhydride reacts with 1-(α-naphthyl)-cyclopentene-1, 1-(α-naphthyl)-2-methylcyclopentene-1, 1-(β-naphthyl)-cyclopentene-1, 1-(β-naphthyl)-2-methylcyclopentene-1, 1-(6′-methoxy-2′ - naphthyl)-cyclopentene - 1 and 1-(6′ - methoxy-2′- naphthyl) - 2 - methylcyclopentene-1. In these reactions one of the double bonds of the diene system is part of the aromatic naphthalene ring.

Dry distillation of the calcium salt of 3,4-cyclopentano-1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid or 1,2-cyclopentano-2,3,4,4a-tetrahydrophenanthrene-3,4-dicarboxylic acid with a mixture of calcium oxide and zinc dust produces excellent yields of 3,4-cyclopentenephenanthrene or 1,2-cyclopentenophenanthrene, respectively. This reaction offers a convenient route to the synthesis of these two hydrocarbons.

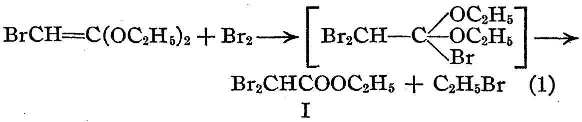
Ketene Acetals. III. The Bromination of Bromoketene Diethylacetal. Other Halogenated Ketene Acetals

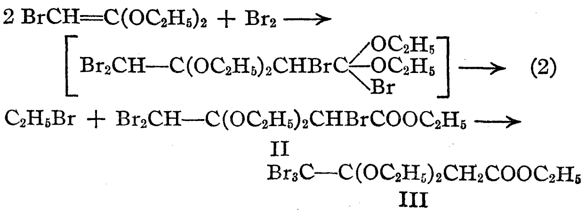
BY ARTHUR MAGNANI[1] AND S. M. MCELVAIN

A continuation of the study of various halogenated ketene acetals led to an investigation of the bromination of bromoketene diethylacetal.[2] Although the bromination did not prove to be of any value from the standpoint of preparing other ketene acetals, it seems to be of sufficient interest to report at this time.

Bromoketene diethylacetal absorbs bromine rapidly at 0–5° but the absorption stops abruptly after approximately 0.7 of an equivalent of bromine has reacted. No further absorption of bromine occurs even if the temperature of the reactants is allowed to rise to 25°. The products that were isolated from the resulting reaction mixture can be explained on the basis that slightly less than one-half of the bromoketene acetal reacts according to reaction (1) while somewhat more than one-half of the acetal follows the course shown in reaction (2)



$$BrCH{=}C(OC_2H_5)_2 + Br_2 \longrightarrow \left[Br_2CH{-}C\begin{matrix} OC_2H_5 \\ OC_2H_5 \\ Br \end{matrix} \right] \longrightarrow \underset{\text{I}}{Br_2CHCOOC_2H_5} + C_2H_5Br \quad (1)$$



$$2\,BrCH{=}C(OC_2H_5)_2 + Br_2 \longrightarrow \left[Br_2CH{-}C(OC_2H_5)_2CHBrC\begin{matrix} OC_2H_5 \\ OC_2H_5 \\ Br \end{matrix} \right] \longrightarrow \quad (2)$$

$$C_2H_5Br + \underset{\text{II}}{Br_2CH{-}C(OC_2H_5)_2CHBrCOOC_2H_5} \longrightarrow \underset{\text{III}}{Br_3C{-}C(OC_2H_5)_2CH_2COOC_2H_5}$$

---

[2] Beyerstedt and McElvain, THIS JOURNAL, **59**, 2266 (1937).

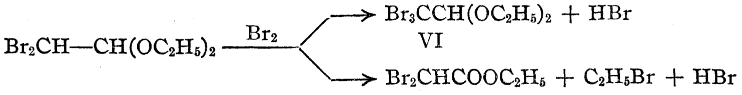
In addition to these main reaction products, small and practically equivalent amounts of ethyl tribromoacetate (IV) and the dibromoacetoacetic ester acetal (V) were found in the reaction mixture. These products appear to have been formed by the interaction of I and II, thus

$$\mathrm{Br_2CHCOOC_2H_5 + Br_2CHC(OC_2H_5)_2CHBrCOOC_2H_5 \longrightarrow \underset{IV}{Br_3CCOOC_2H_5} + \underset{V}{Br_2CHC(OC_2H_5)_2CH_2COOC_2H_5}} \quad (3)$$

It may be seen that reaction (1) requires one equivalent of bromine per mole of the bromoketene acetal while reaction (2) requires only one-half of this quantity of bromine. These ratios of reactants explain the failure of the ketene acetal to absorb more than about 0.7 of an equivalent of bromine.

The brominated acetic esters (I and IV) were identified as amides; the brominated acetals of acetoacetic ester (III and V) were hydrolyzed to the corresponding brominated acetones which were identified.

The other halogenated ketene acetals which have been prepared in this work are monochloro-, dichloro-, and dibromoketene diethylacetal. Each of these ketene acetals was prepared by the procedure which has been used previously in this Laboratory, *viz.*, the elimination of hydrogen halide from the properly halogenated acetaldehyde acetal. Dichloroacetal was prepared by the direct chlorination of acetal. Trichloroacetal was prepared by treating α,β,β,β-tetrachlorodiethyl ether ($Cl_3CCHCl\text{-}O\text{-}C_2H_5$) with alcohol; the tetrachloro ether was obtained by the action of phosphorus pentachloride on chloral alcoholate.[3] Tribromoacetal VI could not be prepared successfully by the procedure which was used for the corresponding chloro compound. It was finally prepared by the bromination of dibromoacetal. This reaction gave a very low yield (12–15%) of the desired tribromoacetal, partly because of the fact that the hydrogen attached to the carbon atom carrying the ethoxyl groups was replaced by bromine as easily as was the hydrogen on the carbon carrying the bromine atoms, thus



$$\mathrm{Br_2CH{-}CH(OC_2H_5)_2 \xrightarrow{Br_2} \begin{cases} \underset{VI}{Br_3CCH(OC_2H_5)_2} + HBr \\ Br_2CHCOOC_2H_5 + C_2H_5Br + HBr \end{cases}}$$

The yield of ethyl bromide (90%), however, was very much greater than that of ethyl dibromoacetate (17%). This discrepancy in yields, and the fact that a large amount of bromal (45%) was found among the reaction products, indicate that the main reaction that takes place is the splitting of the acetal linkages of tribromoacetal or some of the starting acetal by the hydrogen bromide to yield ethyl bromide and the free aldehyde which, in the case of dibromoacetaldehyde, is brominated further to bromal.

The halogenated acetaldehyde acetals are converted smoothly by potassium in *t*-butyl alcohol into the corresponding halogenated ketene diethylacetals. The yields range from 55 to 85% of the theoretical. These ketene acetals show the same vigorous reaction with water and alcohol that was observed with ketene diethylacetal[4] and bromoketene diethylacetal.[2]

In the second paper of this series[2] it was pointed out that these ketene acetals are ethers of the enolic forms of esters and their boiling points, in general, are considerably higher than those of the corresponding esters.[5] The table below lists the analyses and properties of the halogenated ketene acetals and compares their boiling points with those of the corresponding esters. The monobromoketene diethylacetal is included for comparison.

Experimental

Bromination of Bromoketene Diethylacetal.—In a 1-liter 3-necked flask, fitted with a stirrer, a dropping funnel and a reflux condenser carrying a drying tube, was placed 176 g. (0.90 mole) of bromoketene diethylacetal.[2] The flask was cooled in an ice–salt bath until the contents reached a temperature of 0–5° and then a solution of 145 g. (0.90 mole) of bromine in 150 cc. of carbon tetrachloride was added to the stirred solution at such a rate that the temperature did not rise above 5°. After about one and a half hours, when 0.61 mole of bromine (68% of the theoretical) had been added, the bromine was no longer decolorized.

The contents of the reaction flask were allowed to come to room temperature and the ethyl bromide and carbon tetrachloride were distilled from the slightly yellow solution at atmospheric pressure. The remaining products were then fractionated through a Widmer column (26 cm. spiral) under reduced pressure. The following compounds, in the amounts indicated, were obtained: 64.3 g. (0.59 mole) ethyl bromide, b. p. 37–38°; 81.9 g. (0.33 mole) of ethyl dibromoacetate, b. p. 66–70°

(5) Due to an oversight a ketene acetal which has been described in the recent literature was omitted from the table of known ketene acetals that appeared in this paper. This ketene acetal is dicarbomethoxylketene dimethylacetal, $C(COOCH_3)_2{=}C(OCH_3)_2$, which was described by Martius and Arndt [*Ann.*, **499**, 268–270 (1932)] as boiling at 142–145° (13 mm.). The corresponding ester, tricarbomethoxymethane ($HC(COOCH_3)_3$), boils at 130° (16 mm.).

(7 mm.); 11.9 g. (0.038 mole) of ethyl tribromoacetate, b. p. 65–69° (2 mm.); 17.4 g. (0.048 mole) of ethyl β,β-diethoxy-γ,γ-dibromobutyrate (V), b. p. 114–117° (3 mm.); and 77.2 g. (0.175 mole) of ethyl β,β-diethoxy-γ,γ,γ-tribromobutyrate (III), b. p. 135–139° (3 mm.).

The ethyl bromide was identified by its boiling point and by its conversion to propionanilide, m. p. 105–106°, through the formation of ethylmagnesium bromide and the reaction of this compound with phenyl isocyanate. Both ethyl dibromoacetate and ethyl tribromoacetate were converted to the corresponding amides, m. p. 154–155°[6] and 119–120°,[7] respectively. These amides were compared with authentic specimens obtained from known esters and found to be identical. The tribromo ester was identified further by hydrolysis with dilute sodium hydroxide into bromoform which was characterized by conversion into carbon tetrabromide, m. p. 91°.[8]

Ethyl β,β-diethoxy-γ,γ-dibromobutyrate, as obtained from the reaction, contained 45.50% of bromine (calcd. 44.20) and showed a molecular weight of 356 (calcd. 362) in benzene. Hydrolysis in 40% sulfuric acid for three hours yielded a dibromoacetone, b. p. 90–93° (12 mm.), which contained 75.44% (calcd. 76.23) of bromine. Reduction of this dibromoacetone with zinc and hydrochloric acid yielded acetone, identified as the dibenzilidene derivative, m. p. 110–111°. Both bromine atoms were assumed to be on the same carbon atom of the dibromoacetone and its precursor on account of the report[9] that the symmetrical dibromoacetone is a solid and also because of their analogy to ethyl β,β-diethoxy-γ,γ,γ-tribromobutyrate.

Ethyl β,β-diethoxy-γ,γ,γ-tribromobutyrate.—This product showed a bromine content of 57.10% (calcd. 54.42) and a molecular weight in benzene of 482 (calcd. 441). On hydrolysis with 40% sulfuric acid, 13.7 g. of this ester yielded 3.75 g. of tribromoacetone,[10] b. p. 105–108° (8 mm.), which contained 81.07% (calcd. 81.36) of bromine. This tribromoacetone was reduced to acetone as described above and was converted by alkaline hydrolysis into bromoform.

Dichloroacetal.—Into a 3-liter 4-necked flask fitted with a condenser carrying a calcium chloride tube, a thermometer, an efficient stirrer and a 7-mm. inlet tube for chlorine, was placed 745 g. of anhydrous acetal. Chlorine was passed into the acetal at such a rate that a temperature of 34–36° was maintained by the heat of the reaction for about two hours. The acetal was stirred vigorously throughout the entire run. An exit tube from the condenser led to a 1-liter flask in which the characteristic green chlorine color could be seen against a white background.

At the end of two hours the rate of chlorine addition was increased until the temperature of the acetal reached 70° where it was held by the heat of the reaction for about six hours. After this time the temperature began to drop, whereupon heat was supplied from a steam-bath to maintain a temperature of 70° in the flask while chlorine was added slowly over an additional four-hour period. After this chlorination period the acetal was cooled to room temperature. The volume amounted to approximately 1000 cc. It was washed once with water, three times with 300 cc. of a 10% solution of sodium bicarbonate, once with 250 cc. of a 10% solution of sodium thiosulfate, and twice with water. The volume of the reaction product at this point amounted to approximately 800 cc. After drying over anhydrous potassium carbonate the product was fractionated through a 38-cm. Widmer column.

From this fractionation 314 g., b. p. 35–66° (12 mm.), and 440 g., b. p. 66–71° (12 mm.), were obtained. This latter fraction is practically pure dichloroacetal. The yield amounts to 37% of the theoretical. This acetal boils at 178–181° at atmospheric pressure. On standing dichloroacetal appears to decompose to a slight extent to yield hydrogen chloride. Chlorine analyses are generally high on freshly distilled material unless the latter portion of the distillate is taken. Three fractions collected at 69–70, 70–70.5 and 70.5–71° (12 mm.) showed chlorine contents of 46.75, 40.88 and 38.98%, respectively (calcd. 37.94). Each of these fractions, however, gave practically the same yields of chloroketene acetal (see below).

Several attempts to prepare dichloroacetal by the procedure of Fritsch[11] were made. This method involves simply the chlorination of ethyl alcohol. In none of these attempts was an appreciable amount of the dichloroacetal obtained.

Trichloroacetal (Chloral Diethylacetal).—This compound was prepared by the procedure of Paternò and Pisati,[3(a)] from chloral, by first preparing the alcoholate, converting this compound into α,β,β,β-tetrachlorodiethyl ether by the action of phosphorus pentachloride, and finally treating the tetrachloro compound with absolute alcohol. The yield of the alcoholate from the chloral is quantitative, of the tetrachlorodiethyl ether from the alcoholate 25–33% of the theoretical, and of the chloral acetal from the tetrachloro ether about 70%. The acetal so obtained boils at 84–85° (10 mm.).

Tribromoacetal (Bromal Diethylacetal).—In a 1-liter 3-necked flask carrying a reflux condenser, a stirrer and a dropping funnel was placed 552 g. (2 moles) of dibromoacetal.[2] The flask was heated on a steam-bath while 320 g. (2 moles) of bromine was added over a period of two hours. After approximately one-half of the bromine had been added, the evolution of hydrogen bromide started and ethyl bromide began to reflux in the condenser. A carbon dioxide snow trap was used to catch any ethyl bromide that was carried from the reaction by the hydrogen bromide. After all of the bromine had been added the reaction mixture was fractionated. The following compounds, in the amounts indicated, were obtained from this fractionation: 1.8 mole of ethyl bromide, b. p. 36–38°; 0.29 mole of dibromoacetaldehyde, b. p. 46–54° (19 mm.); 0.90 mole of bromal, b. p. 69–73° (19 mm.); 0.34 mole of ethyl dibromoacetate, b. p. 88–95° (19 mm.); 0.14 mole of recovered dibromoacetal, b. p. 105–112° (19 mm.); 0.23 mole of tribromoacetal, b. p. 132–135° (19 mm.).

The tribromoacetal upon refractionating boiled at 85–86° (1 mm.). It contained 68.18% (calcd. 67.61) bromine and 25.29% (calcd. 25.35) ethoxyl; n^{25}_D 1.5158; d^{25}_{25} 1.8721.

Halogenated Ketene Acetals.—Chloro-, dichloro- and dibromoketene diethyl acetals were prepared in yields of 85, 76 and 56%, respectively, from the corresponding halogenated acetals by means of potassium in *t*-butyl alcohol.[2] The properties of these compounds are listed in the table in the introductory portion of this paper.

The authors wish to acknowledge their indebtedness to Mr. Donald G. Kundiger for the development of the preparation of dichloroacetal.

Summary

The bromination of bromoketene diethylacetal has been carried out and the course of the reaction elucidated. The preparation and properties of chloro-, dichloro- and dibromoketene diethyl acetals and of the intermediate halogenated acetaldehyde acetals have been described.

The Enol Content of Some β-Keto Esters

BY ARTHUR B. NESS AND S. M. MCELVAIN

Over a period of years a number of β-keto esters have accumulated in this Laboratory from studies of the acetoacetic ester condensation. It seemed worth while to determine the enol content of certain of these esters in the hope that some correlation between this property and the structure of the keto ester might be revealed.

The esters which were studied in this work are of two general types, (a) alkyl acetoacetates[1] and (b) ethyl α,γ-dialkyl acetoacetates.[2] In this latter group are two keto-esters, ethyl α-isovalerylisovalerate and ethyl α,γ-di-*t*-butylacetoacetate, that are of special interest on account of the fact that they cannot be made from the condensation by means of sodium ethoxide,[3] of the substituted acetic ester, $RCH_2COOC_2H_5$, but are readily formed from these esters by the action of mesitylmagnesium bromide.[2c]

The determinations of the enol content were made in 0.1 *M* hexane solution at 25° since the work of Conant and Thompson[4] indicates that this particular solvent has the least solvation effect on the true thermodynamic equilibrium between the keto and enol forms. For the β-keto esters carrying no α-substituent the indirect method[5] of titration was used, while for the α-substituted esters the direct method[5] was employed.

The results that were obtained are summarized in the following table. Data for ethyl acetoacetate, ethyl α-butylacetoacetate, and ethyl α-benzylacetoacetate (nos. 2, 8 and 9) are included for comparison with results obtained by previous workers.

It may be seen from the above table that the alkyl acetoacetates, with the exception of the ethyl ester, have practically the same enol content. The ethyl ester stands out in striking contrast to the other esters of this type by having a decidedly lower enol content.

α-Substitution, as expected, lowers considerably the enol content of the β-keto esters. Distribution of the substituent carbon atoms between the α- and γ-carbon atoms of the keto ester appears to have about the same effect as having

[a] Values for the keto esters nos. 2, 8 and 9 as reported by Conant and Thompson[4] are 48.0–50.0, 9.0–11.0 and 11.0–13.0%, respectively; in alcoholic solution these workers reported 9.0–11.0, 5.7–6.4 and 5.0–5.5% enol content, respectively, for the same esters. [b] In alcoholic solution these esters show no enol content. [c] The sample of this keto ester that was used was not pure in that it contained small amounts of the corresponding ketone.[2]

all of them (as a normal chain) on the α-carbon (*cf.* nos. 8 and 11). An increase in size of the normal α- and γ-alkyl substituents causes a progressive lowering of the enol content of the substituted β-keto ester (nos. 10–12, 15–17). The work of Conant and Thompson shows that an increase in the size of a single normal α-alkyl substituent does not produce the same progressive lowering of the enol content of the β-keto ester.[6] Branching of the carbon chain that substitutes the α- and γ-carbons of the keto ester causes a further lowering of the enol content (*cf.* nos. 13 and 14 with 12 and 15). Conant and Thompson found that a similar effect was produced by branched substituents.[7]

It should be noted that ethyl isovalerylisovalerate (no. 13) contains almost as much of the enol form as does ethyl myristyl-myristate (no. 17). The latter ester may be prepared with sodium ethoxide as the condensing agent but the former ester (as well as no. 14) cannot be so prepared.[3] It must be concluded, therefore, that the failure of these esters that contain branched substituents, to be formed from condensations using sodium ethoxide cannot be attributed to their inability to enolize. It should be pointed out also that these keto esters with branched substituents seem to enolize very slowly as compared to those having *n*-alkyl substituents. In the direct titration of the latter type of keto esters the bromine coloration disappears in less than one minute after the end-point has been reached. With the branched chain substituted keto esters (13 and 14), however, the bromine coloration persisted for several (three to five) minutes before it was finally discharged. That this slow loss of the bromine color was due to a slow rate of enolization rather than to bromine substitution seems likely for the reason that neither of these keto-esters (13 and 14) showed any measurable absorption of bromine when absolute alcohol instead of hexane was used as a solvent. This observation is in line with that of previous investigators[4] who found that β-keto esters in general are enolized to a considerably less extent in alcohol than they are in hexane (*cf.* footnote *a* of the above table).

The present work has demonstrated that ferric chloride cannot be depended upon as an indicator when the enol content of a β-keto ester is low. At some point between an enol content of 7–8 and 4–5% it fails. Ethyl α-butyrylbutyrate (no. 11) gives a satisfactory ferric chloride test in aqueous suspension or alcoholic solution. The keto esters, nos. 12 to 16, inclusive, in the above table, give no coloration with ferric chloride under these conditions, nor do they show any coloration at the interface when their solutions in hexane, which have stood for several days, are treated with an aqueous or aqueous-alcoholic solution of ferric chloride.

Experimental

The β-keto esters that were used in this work were freshly distilled from samples that had been prepared[2] previously in this Laboratory. Two hundred and fifty cc. of a 0.1 *M* solution of each of these esters in hexane was made and allowed to stand for at least seventy-two hours to attain equilibrium. A 20-cc. sample of this hexane solution was transferred to a 125-cc. Erlenmeyer flask and placed in a thermostat at 25° for several hours. For both the direct and indirect method of titration 50 cc. of 95% alcohol, cooled to −7 to −10°, was added to the hexane solution before titration to freeze the equilibrium.

In the direct method of titration this cold alcoholic solution was titrated immediately with an approximately 0.1 *N* solution of bromine in absolute, aldehyde-free alcohol to a faint yellow color that remained for ten seconds. Exactly the same amount of this bromine solution was run

---

(6) For example, Conant and Thompson[4] reported 10.3–12.9, 14–15, 14.3–14.5 and 9–11% enol for α-methyl-, α-ethyl-, α-*n*-propyl- and α-*n*-butylacetoacetic ester, respectively, in 0.1 *M* hexane solution.

(7) The α-isopropylacetoacetic ester and α-*s*-butylacetoacetic ester showed enol contents of 5.85–6.1 and 8.6–9.9%, respectively, in 0.1 *M* hexane (*cf.* values for the *n*-propyl and *n*-butyl compounds in footnote 6).

into a flask containing 50 cc. of water and 10 cc. of a 10% aqueous solution of potassium iodide. The liberated iodine then was titrated with 0.1 *N* sodium thiosulfate.

For the indirect method of titration an excess of the 0.1 *N* bromine solution in alcohol, which had been cooled to −7 to −10°, was added to the cold alcohol–hexane solution of the keto ester. The excess bromine was decolorized immediately by titration with a 10% solution of β-naphthol in absolute alcohol. To this point approximately fifteen seconds were required from the time the equilibrium was frozen by the cold alcohol. Then 15 cc. of a 10% solution of potassium iodide was added and the resulting solution warmed to 25–30° for five minutes, after which time the liberated iodine was titrated with 0.1 *N* sodium thiosulfate.

Summary

The enol contents of a number of alkyl acetoacetates and of some α,γ-dialkyl substituted ethyl acetoacetates are reported.

The Precipitation of Phenylmagnesium Bromide by Pyridine and by Dioxane

BY ARTHUR C. COPE

The accuracy of the Schlenk dioxane precipitation method[1] for determining the position of Grignard equilibria ($2RMgX \rightleftarrows R_2Mg + MgX_2$) is still open to question. The method depends upon precipitation of insoluble dioxanates of the RMgX and MgX_2 components, and this precipitation must be rapid compared to the rate of equilibration in order to avoid shifting the equilibrium in the direction of the less soluble dioxanate during precipitation. Recent work has shown that the compositions of the solution and the precipitate change if the two remain in contact,[2] presumably because of the reaction: $2RMgX \cdot$ dioxane (insoluble) $\rightleftarrows R_2Mg$ (soluble) $+ MgX_2 \cdot$ dioxane (insoluble). If the precipitation is used as an analytical method for determining the position of the original Grignard equilibrium, the latter reaction must be minimized by rapid removal of the precipitate.

In this investigation a number of ethers, sulfides and tertiary amines were added to ether solutions of phenylmagnesium bromide in an effort to find other precipitants for the halomagnesium components, thus making it possible to compare analyses obtained with two or more precipitants. Phenylmagnesium bromide was chosen because in this Laboratory arylmagnesium halides have given consistent analyses by dioxane precipitation.

Pyridine produces a precipitate with phenylmagnesium bromide which is grossly similar to the one obtained with dioxane. The precipitate can be separated by centrifuging, and the solution analyzed for basic magnesium and halogen. Typical data are plotted in Fig. 1, which shows the percentage of basic magnesium and bromide ion left in solution after the addition of a definite number of equivalents of pyridine, together with similar data for dioxane. The behavior of the two precipitants is very different in several respects. Dioxane precipitates the halomagnesium components more completely than does pyridine. Diphenylmagnesium is not precipitated by dioxane even when the latter is in large excess and high concentration. Pyridine precipitates only

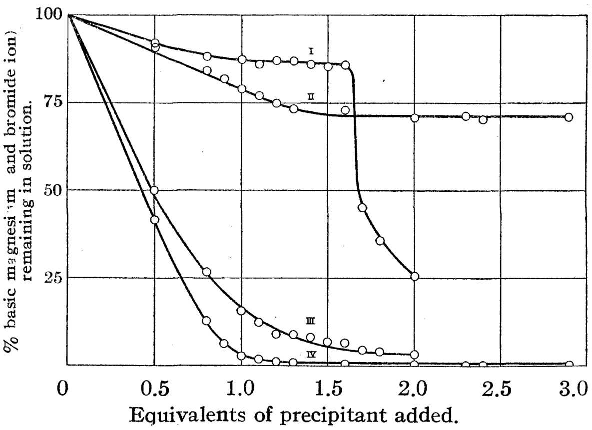

Fig. 1.—Precipitation of a phenylmagnesium bromide solution 0.2325 *N* in basic magnesium and 0.2402 *N* in bromide ion. The equivalents of precipitants are based on the normality in bromide ion. Curve I, % basic magnesium remaining in solution after precipitation with pyridine; II, % basic magnesium in solution after dioxane precipitation; III, % bromide in solution after pyridine precipitation; IV, % bromide in solution after dioxane precipitation.

---

[1] Schlenk and Schlenk, *Ber.*, **62**, 920 (1929); Schlenk, *ibid.*, **64**, 734 (1931).

[2] (a) Noller and White, THIS JOURNAL, **59**, 1354 (1937); (b) Cope, *ibid.*, **57**, 2238 (1935).

phenylmagnesium bromide and magnesium bromide up to a molar ratio of pyridine to bromide ion of 1.6, with the concentrations employed; with ratios higher than 1.6 diphenylmagnesium is also precipitated, and in large amount (note the point of inflection in Curve I).

A comparison of the dioxane and pyridine precipitation data (Table I) gives two independent evaluations of the extent of disproportionation of phenylmagnesium bromide. The most accurate analyses should be those in which there is least bromide ion left in solution, or those with 1.2 to 20.0 equivalents of dioxane and 1.2 to 1.6 equivalents of pyridine. These dioxane and pyridine values show 70–74% and 78–79% disproportionation,[3] respectively. The results do not indicate a high degree of accuracy for the dioxane precipitation method, but the approximate checks obtained with the two precipitants suggest that in this case the order of magnitude at least is correct.

TABLE I

DISPROPORTIONATION OF PHENYLMAGNESIUM BROMIDE

	% disproportionation[a]			
	from dioxane precipitation		from pyridine precipitation	
Molar ratio precipitant/Br^-	A	B	A	B
1.0	76.2	78.9	71.7	87.3
1.1	75.2	77.0	73.6	86.0
1.2	73.8	74.9	78.1	87.1
1.3	72.5	73.3	77.9	86.8
1.4	..	..	77.8	85.9
1.5	..	..	78.5	85.3
1.6	72.4	72.9	79.3	85.8
2.0 to 20.0	70–72	70–72	..	..

[a] In this calculation it is necessary to make some assumption concerning the bromide ion left in solution, which is an appreciable quantity in all cases with pyridine, and with dioxane if less than 1.2 equivalents is used. The values recorded are calculated from the data of Fig. 1. The values in the columns headed A are calculated assuming that all the remaining bromide ion is present as phenylmagnesium bromide, and those headed B assuming that it is all magnesium bromide. The A values are more nearly correct, since magnesium bromide dioxanate appears to be less soluble than phenylmagnesium bromide dioxanate, but the true values are probably somewhere between the two extremes.

Pyridine cannot be recommended as a precipitant for preparing dialkylmagnesium solutions from Grignard reagents for synthetic purposes, because it does not remove bromide ion as completely as does dioxane, nor is it as convenient a reagent for use in analyses. If its behavior with phenylmagnesium bromide is typical of Grignard reagents in general, it may serve a useful purpose in checking analyses made by the Schlenk method.

Oddo[4] has reported that the addition of two moles of pyridine to an ether solution of phenylmagnesium bromide causes precipitation of the definite compound, $C_6H_5MgBr\cdot(C_2H_5)_2O\cdot2C_5H_5N$. This and most of the other work on addition compounds of tertiary amines and other "donor" molecules with Grignard reagents[5] was done prior to Schlenk's demonstration of the existence of the Grignard equilibrium, and the addition compounds were usually analyzed after some purification, with no thought of a possible separation of the supposedly homogeneous reagent during precipitation. It is possible that in other cases like the above, where definite compounds are reported, analysis of the original precipitate or the residual solution after precipitation would disclose a differential precipitation of the components of the equilibrium.

Experimental Part[6]

The phenylmagnesium bromide solutions were prepared in the usual manner under dry nitrogen in a flask fitted with a filter tube,[2b] and filtered with nitrogen pressure directly into the reservoir of a specially designed buret (Fig. 2). During filtration the reagent was protected by a counter current of nitrogen introduced through the tip of the buret, the top half of the ground glass seal being removed and tube A stoppered temporarily. The solutions were standardized by acidimetric[7] and Volhard titrations.

Among the substances investigated which gave no precipitate with phenylmagnesium bromide in ether solution were the following: dimethyldioxane,[8] *p*-thioxane, *p*-dithiane, diphenylpiperazine, dimethylaniline, diethylaniline, N-phenylmorpholine and nicotine. Quinoline, α-picoline, N-methylmorpholine and diphenyl sulfoxide gave varying amounts of oily or gelatinous precipitates which could not be handled quantitatively.

The pyridine and dioxane analyses were made in the following manner. Twenty cubic centimeters of the Grignard solution (at 20°) was measured from the buret into a dry, nitrogen-filled centrifuge tube of 50-cc. capacity, made with a constricted neck. The access of air during transfer was prevented by a nitrogen mantle (shown in Fig. 2), and the tube was tightly stoppered as soon as it was removed from the mantle. Solutions of pyridine or dioxane were made up to contain the desired number of equivalents of precipitant in 10 cc. of dry ether solution, and this volume was added to the 20-cc. samples as rapidly as possible from a buret with a wide orifice, the sample

---

(3) According to assumption A above. With assumption B the values are 70–75% and 85–87%.

again being protected from the air with a nitrogen mantle. The tubes were stoppered immediately, shaken vigorously and centrifuged at 2800 r. p. m. for ten minutes. The clear supernatant liquid was decanted into a flask containing 75 cc. of water. A 20-cc. portion of dry ether was added to the solid residue remaining in the centrifuge tube, which was again shaken, centrifuged for five minutes and decanted into the flask containing water. Further washing of the precipitate with ether failed to remove significant quantities of basic magnesium or halogen, showing that there was little if any occlusion, except in analyses using pyridine in quantities sufficient to precipitate diphenylmagnesium. In the latter case the amount of basic magnesium taken into solution increased with each washing of the precipitate, so that the analyses with more than 1.6 equivalents of pyridine have no exact quantitative significance.

In the pyridine analyses, the ether was first boiled off, after which the aqueous mixture was boiled for thirty minutes to remove the pyridine, acidified with an excess of standard sulfuric acid, again boiled for five minutes and back titrated with standard alkali. Bromide analyses were made on the same samples, after cooling, by Volhard titration. The method was proved to be accurate by analysis of a Grignard reagent of known normality after the addition of pyridine. The end-points in the acidimetric titration were not as sharp as in the dioxane analyses. Solutions precipitated with dioxane were acidified initially with an excess of standard sulfuric acid and boiled long enough to expel completely the ether before back titrating with standard alkali.

Precipitations with Isoquinoline.—Isoquinoline gives a bulky solid precipitate with phenylmagnesium bromide in ether solution. The precipitate may be separated by centrifuging, and the solutions analyzed as in the pyridine procedure if they are boiled for one hour before acidification, although the end-points are obscure in the acidimetric titration. Interpretation of the analyses is difficult, because a relatively large proportion of the bromide ion remains in solution. The following data are representative. A solution of phenylmagnesium bromide 0.2060 *N* in basic magnesium and 0.2138 *N* in bromide ion was precipitated as described above with 1.0 and 1.1 equivalents of isoquinoline. The solutions after centrifuging contained: (1 equivalent of isoquinoline) basic magnesium 0.1720 *N* (with respect to the volume of the original sample); bromide ion 0.0522 *N;* (1.1 equivalents of isoquinoline) basic magnesium 0.1690 *N;* bromide ion 0.0443 *N.*

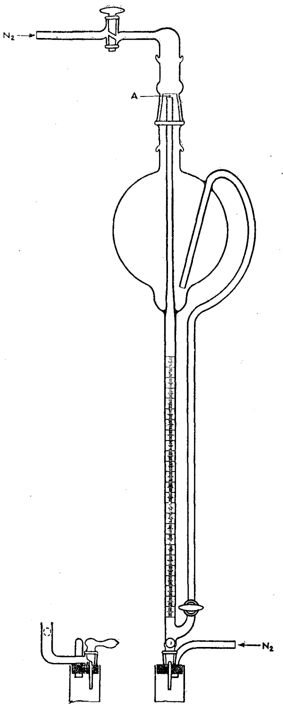

Fig. 2.—Apparatus.

Summary

Pyridine behaves like dioxane in precipitating the halomagnesium components of the equilibrium, $2C_6H_5MgBr \rightleftarrows (C_6H_5)_2Mg + MgBr_2$. The two precipitants indicate 78–79% and 70–74% disproportionation in the above equilibrium, respectively. This rough check with two different precipitants indicates that the Schlenk dioxane precipitation method, for this Grignard reagent at least, gives approximately correct results.

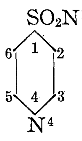
Sulfanilamide Derivatives. I. Aminoarylsulfonamidoarylsulfonic Acids and Aminoarylsulfonamidoarylcarboxylic Acids*

BY M. L. CROSSLEY, E. H. NORTHEY AND MARTIN E. HULTQUIST

Nomenclature of Sulfanilamide Derivatives.—Chemical and medical literature on sulfanilamide derivatives suffers from a confusion of names and naming systems which is bewildering to the medical reader and often misleading to chemists. The name "sulfanilamide" has been adopted officially by the American Medical Association and is now generally used. It would seem desirable, therefore, to continue with this and relate the names of new derivatives, where possible, to the parent sulfanilamide. In the interest of setting up such a system, we have corresponded with Austin M. Patterson, who has given valuable suggestions on the following:

a. Naming as substituted sulfanilamides



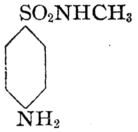
In sulfanilamide the sulfonamide group, being the principal functional group, occupies the 1-posi-

---

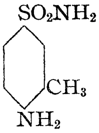
(*) Presented in part before the Division of Medicinal Chemistry, A. C. S., April 20, 1938.

tion in the ring. The nitrogens are differentiated by superscripts: N^1 referring to substituents on the amide nitrogen and N^4 to substituents on the amino nitrogen.

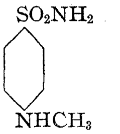
The following examples illustrate the method



N^1-Methylsulfanilamide

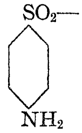


3-Methylsulfanilamide

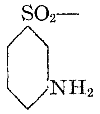


N^4-Methylsulfanilamide

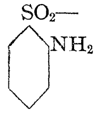
b. Radical names.—For simple derivatives the above method should be used, but it becomes unwieldy in naming compounds with complex substituents. In such cases radical names are useful. The following radicals are suggested



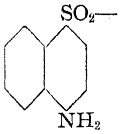
Sulfanilyl-



Metanilyl-



Orthanilyl-

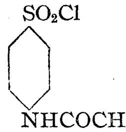


Naphthionyl-

These names follow directly from the corresponding amino acids.

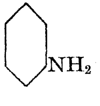
An example of their usefulness is shown by the compound

which we name N,N′-disulfanilylbenzidine-2,2′-disulfonic acid. This seems preferable to the name, N,N′-*bis*-(4-aminobenzenesulfonyl)-4,4′-di-aminobiphenyl-2,2′-disulfonic acid. A simpler case is

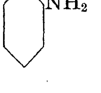


an important intermediate, which we call N-acetylsulfanilyl chloride instead of *p*-acetamidobenzenesulfonyl chloride. Other useful radicals are

Sulfanilamido-

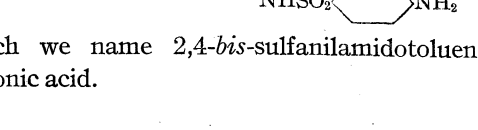


Metanilamido-



Orthanilamido-

An example is



which we name 2,4-*bis*-sulfanilamidotoluene-5-sulfonic acid.

An example of the use of all three types of names is the following

N^1,N^1-*bis*[2-(N^4-Sulfanilylsulfanilamido)-ethyl]-N^4-sulfanilylsulfanilamide

New Derivatives.—In spite of the fact that the literature on sulfanilamide and its derivatives now numbers over 300 references, a relatively few outstanding publications summarize most of the published work on new derivatives.[1–5]

The published work has indicated the following generalities on the relationship of structure and antistreptococcal activity. (1) Little or no activity was found in mononuclear compounds in which either the amino or sulfonamide groups of sulfanilamide were replaced. (The highly active diamino- and dinitrodiphenylsulfones, sulfoxides and sulfides have two rings joined through a sulfur linkage.) (2) Shifting the amino group to the meta or ortho position resulted in marked loss of activity. (3) A third group on the ring lowered the activity. (4) Substitution of the amino group with alkyl, aralkyl, substituted alkyl or aryl, acyl and alkylidene groups had less effect, but in general lowered the activity. (5) Substitution of the amide nitrogen had a variable effect. Methyl and ethyl groups did not change the activity while higher alkyl groups decreased the activity. *p*-Amino- and *p*-nitrophenyl groups increased the activity.

The low solubility of sulfanilamide and its toxicity at effective dosage levels led us to attempt new derivatives of increased solubility which might also have a higher therapeutic index. Our first attempts were to combine N-acetylsulfanilyl chloride with various aminobenzenesulfonic acids and aminobenzenecarboxylic acids in aqueous solution at *p*H 8–10. The reaction went smoothly and after hydrolysis of the acetyl group with acid or base gave us the desired sulfanilyl derivative.

Orthanilyl and metanilyl derivatives were made by treating the corresponding nitrobenzenesulfonyl chlorides with the desired amino acid, followed by reduction of the nitroamide with ammonium polysulfide or in some cases iron in neutral solution.

In the form of the neutral salts of the sulfonic or carboxylic acids, these derivatives had high water solubility, while the free acids were, in general, only slightly soluble.

The table shows the derivatives and the results of preliminary tests in mice infected with β-hemolytic streptococci. The signs and their meaning are: +++ indicates compounds superior to sulfanilamide, ++ equal to, + somewhat inferior to sulfanilamide; while ± designates compounds with very slight activity, 0 no activity, and − identifies compounds which killed the animals faster than the controls died.[6,7]

The compounds are named as substituted sulfonic or carboxylic acids. The acid function, therefore, occupies the 1-position in the ring.

Sodium N-sulfanilylsulfanilate is extremely water soluble—so much so that a solution of it may be evaporated to a very thick sirup. The addition of benzene to a moderately concentrated aqueous solution caused precipitation of a white crystalline compound containing benzene of crystallization. This was stable to drying at 60°, but was decomposed on dissolving in boiling water, when the benzene was evolved with effervescence, like a carbonate dissolving in acid.

While sodium N-sulfanilylsulfanilate was synthesized primarily for trial in bacterial diseases, this unusual property gave us the idea that it might be effective against viruses, for if it had the power of coördinating with an inert substance such as benzene, might it not coördinate with, or inactivate, the infinitely more complex molecules of a virus?

We suggested, therefore, to Dr. Dochez that he try it against the common cold and influenza viruses. The latter being capable of investigation in experimental animals was tried first and the compound found ineffective. The thing might have died a natural death at this point but, fortunately, Dr. Dochez tried it against dog distemper virus, with striking results.[8]

We have tested other of the above compounds in other virus diseases with promising results. Our most interesting compound in this respect is 2,5-*bis*-sulfanilamidobenzenesulfonic acid, which not only appears to be more efficient than sulfanilamide in antistreptococcal effect, but which shows definite activity against the Francis strain of influenza virus in mice.

Attempts to correlate antistreptococcal activity with structure, based on the above series, indicate that in the parent aminobenzenesulfonamide the para position gives the greater therapeutic effect with the meta position next and the ortho position least. In the second ring, however, this is reversed completely and the more effective compounds are obtained when a carboxyl or sulfonic group is ortho to the amido group. These compounds, in fact, seem to be more effective than sulfanilamide.

Addition of a methyl, chlorine, OH or OR to these derivatives gives less active compounds.

Addition of NH_2 also gives an inactive derivative. However, a very active derivative is obtained by placing an additional sulfonamido group on this ring as in 2,4-*bis*-sulfanilamidobenzenesulfonic acid. Addition of a fourth group, CH_3, to this ring again completely destroys the activity.

Further interesting evidence on the relation of structure to therapeutic effect in these compounds is furnished by 1,3-*bis*-sulfanilamidobenzene which rates only ± while its sulfonic acid is +++; 1,4-*bis*-sulfanilamidobenzene rates ++, while its sulfonic acid as stated above has a superior antistreptococcal effect coupled with viruscidal activity.

In the naphthalene series position isomerism also has a pronounced effect on the therapeutic activity. The 1,4-position was much superior to the 1,5-, while the 2,6-derivative was toxic. An attempt to prepare N-sulfanilyl-2-naphthylamine-1-sulfonic acid failed when the sulfonic group was lost during hydrolysis of the acetyl derivative. This compound would have been of interest in view of our results in the benzene series.

Experimental

Preparation of Sulfanilyl Derivatives.—The general method of preparing sulfanilyl derivatives of aminoarylsulfonic acids and aminoarylcarboxylic acids is illustrated below for the synthesis of sodium N-sulfanilylsulfanilate.

Sodium N-Sulfanilylsulfanilate.—One hundred seventy-three grams (1 mole) of sulfanilic acid, 40 g. (1 mole) sodium hydroxide and 20 g. sodium carbonate were dissolved in 800 cc. of water. The solution was cooled to 40° and 1 mole of N-acetylsulfanilyl chloride in the form of a freshly prepared and analyzed paste was added over one hour, with vigorous agitation. The temperature was held at 40–45° by addition of ice, and the *p*H maintained between 8 and 11 by addition of 50% sodium hydroxide solution as required.

---

(6) The pharmacological study was carried out by D. R. Climenko and will be reported elsewhere.

(7) Micro-analyses were made under the direction of G. L. Royer.

(8) Dochez and Slanetz, *Science*, **87**, 142 (1938).

After stirring for fifteen minutes a 2-cc. sample of the reaction mixture was diluted to 50 cc., acidified and titrated with 0.1 *N* sodium nitrite at about 20°. This gave an estimation of unreacted amino nitrogen. If the value corresponded to more than 5% of the starting amount, more N-acetylsulfanilyl chloride was added until the nitrite titration reached a minimum, or until 25% excess had been added.

Isolation of N-acetylsulfanilylsulfanilic acid at this point offered no advantage in purity of the final compound. Hydrolysis was therefore made by adding 100 g. (2.5 moles) of sodium hydroxide and boiling the solution for one and one-half hours, or until there was no further increase in diazotizable amine.

N-Sulfanilylsulfanilic acid was isolated from the hydrolysate by acidifying to about *p*H 1 with hydrochloric acid, filtering the precipitate and washing five or six times with 100-cc. portions of water at 80–90° to remove sulfanilic acid.

The crude N-sulfanilylsulfanilic acid was dissolved as the sodium salt at *p*H 5–6, treated with decolorizing carbon and reprecipitated twice. The resulting filter cake was dissolved with solid sodium hydroxide to give a 2.2 *N* solution having a *p*H of 6.5. An equal volume of 95% ethyl alcohol was added to the warm solution. On cooling, crystallizing, filtering, washing with alcohol and drying finally at 100°, 110 g. of anhydrous sodium-N-sulfanilylsulfanilate resulted. Approximately an equal amount was recovered from the mother liquor, giving a yield over all of 60%.

Notes on General Procedure. **1.**—This type procedure was followed with the other sulfanilyl derivatives listed, substituting an equivalent amount of the corresponding amino or diaminosulfonic acid. Some variation was necessary in concentration because of the difference in solubility of intermediates and final compounds. Thus, in the case of N-sulfanilylorthanilic acid, N-sulfanilylmetanilic acid and 6-ethoxy-N-sulfanilylmetanilic acid, the free acids were moderately soluble and were therefore recrystallized from water without passing through the sodium salt. Sodium salts listed, with the exception of sodium-N-sulfanilylsulfanilate, were crystallized from concentrated aqueous solutions without use of alcohol.

2.—Yields averaging 60–70% were obtained in most cases but were of no special significance since recoveries from the numerous mother liquors were not made unless these contained more than 10% of the yield as determined by nitrite titration. Yields of derivatives where a sulfonic acid or other large group was in the ortho position to the sulfanilamido group were generally poor, probably because of steric hindrance.

3.—In making sulfanilyl derivatives of aminonaphthalenesulfonic acids, and diaminosulfonic acids, care was taken to prepare or purify these immediately before use, since highly colored impurities were difficult to remove later. Use of small amounts of sodium hydrosulfite following treatment with decolorizing carbon was helpful in removing color and preventing further oxidation, both on intermediates and final compounds.

4.—Usage of sodium hydroxide in hydrolysis was based on one mole for each acetyl group, plus one mole for each —SO_2NH— (or other acidic group not neutralized), plus one-half mole excess. This excess was sufficient to promote complete hydrolysis of the acetyl groups in about one hour at 102–103°, for the concentrations used.

5.—Hydrolysis of acetyl groups was also effected by boiling in 15% hydrochloric acid, but this was generally less satisfactory since many of the products were only slightly soluble in acid. The resulting thick slurry bumped on boiling and was otherwise difficult to handle. Hydrolysis did not proceed to completion in some cases because the particles of intermediate were protected by a coating of the product.

2-Sulfanilamidosulfanilic Acid.—This was prepared by the type procedure starting with 1 mole of 2-amino-4-acetylaminobenzenesulfonic acid per mole of N-acetylsulfanilyl chloride; 3.5 moles of sodium hydroxide was used for hydrolysis of the acetyl groups.

Orthanilyl and Metanilyl Derivatives.—These derivatives were made following the general procedure outlined above but with substitution of *o*-nitrobenzenesulfonyl chloride or *m*-nitrobenzenesulfonyl chloride in equivalent amount for N-acetylsulfanilyl chloride. Since these acid chlorides were somewhat more resistant to hydrolysis, the reaction temperature was raised to 45–50°. The resulting nitrosulfonamide was isolated by acidification of the reaction mixture and reduced to the amino derivative by the method illustrated below.

2-Metanilamidobenzoic Acid.—The 2-(*m*-nitrobenzenesulfonamido)-benzoic acid resulting from one mole of anthranilic acid was dissolved in 500 cc. of 28% ammonia. A stream of hydrogen sulfide was passed in with vigorous agitation and cooling. When the initial reaction had moderated, the flask contents were heated to a gentle boil under a reflux condenser with a continued slow stream of hydrogen sulfide, for an hour and a half. Boiling was then maintained while a rapid stream of air was passed through the solution until sulfides had been oxidized to sulfur and most of the excess ammonia removed. Sulfur was removed by filtration. The filtrate was acidified slowly with hydrochloric acid and the crude product filtered off. This was twice recrystallized by dissolving as the sodium salt, treating with activated charcoal and reprecipitating. A yellow color still persisted. The material was dissolved as the sodium salt, made slightly acid with acetic acid and boiled with about 1 g. of zinc dust. This decolorized the solution. The product was isolated as the acid and recrystallized twice from 1 liter of alcohol using activated charcoal.

Attempts to reduce the nitro compound with iron failed because of the formation of an insoluble iron salt.

Summary

A naming system for sulfanilamide derivatives is proposed which relates the names where possible to the parent sulfanilamide. For more complex derivatives, the radicals "sulfanilyl,"  and "sulfanilamido,"  are used.

Highly soluble salts of sulfanilamidobenzenesulfonic acids and sulfanilamidobenzenecarboxylic acids are described. Preliminary tests in mice indicate that while in the parent ring highest antistreptococcal activity is found in the para derivative, this is reversed completely in the second ring, where compounds in which the acid function is ortho to the nitrogen have the highest activity.

Addition of —CH_3, —OH, —OR or —Cl to the second ring greatly lowers or destroys the activity.

Sodium 2,4-*bis*-sulfanilamidobenzenesulfonate and 2,5-*bis*-sulfanilamidobenzenesulfonic acid appear to have activity against influenza virus in mice, as well as to have high antistreptococcal powers.

Sulfanilamide Derivatives. II. Disulfanilamides and Related Compounds[1]

BY M. L. CROSSLEY, E. H. NORTHEY AND MARTIN E. HULTQUIST

The compound called by Rosenthal[2] "Disulfanilamide"

is incorrectly named. We suggest that it be called N⁴-sulfanilylsulfanilamide.

We have synthesized true disulfanilamide

and have prepared a number of derivatives having the disulfonamide linkage, —SO_2NHSO_2—. These compounds as a class behave as strong acids, forming neutral sodium salts of the type —SO_2NNaSO_2—. The salts have high water solubility and are very stable to heat, decomposing at temperatures above 300°. However, if the hydrogen of the disulfonamide is replaced by alkyl, the compound becomes water and alkali insoluble and is broken down more readily by strong acids or bases.

Disulfanilamide was synthesized by treating more than two moles of N-acetylsulfanilyl chloride with one mole of ammonia, keeping the *p*H at 10–11 by addition of sodium hydroxide solution and holding the temperature below 45°. It was also made starting with N-acetylsulfanilyl chloride and N^4-acetylsulfanilamide. The resulting N^1-sodium-N^4,$N^{4'}$-diacetyldisulfanilamide was hydrolyzed by boiling with sodium hydroxide and was purified by recrystallization as the sodium salt.

Alkylation was accomplished by boiling the N^1-sodium-N^4,$N^{4'}$-diacetyldisulfanilamide with excess dimethyl sulfate in xylene. The resulting N^1-methyl-N^4,$N^{4'}$-diacetyldisulfanilamide was hydrolyzed to N^1-methyldisulfanilamide by adding the theoretical amount of 36% hydrochloric acid, dropwise, to a boiling alcoholic solution so that the acidity at no time was sufficient to give a green spot on methyl violet paper. Boiling aqueous 20% hydrochloric acid caused rapid breakdown at the amide linkage giving sulfanilic acid and N^1-methylsulfanilamide. The same type of decomposition occurred during hydrolysis with sodium hydroxide but at a much slower rate.

Dimetanilamide was made by treating an excess of *m*-nitrobenzenesulfonyl chloride with *m*-nitrobenzenesulfonamide at 50–60° in aqueous solution and at *p*H 10–11. The *p*H was maintained by addition of sodium hydroxide as necessary. The resulting 3,3′-di-*m*-nitrodibenzenesulfonamide was reduced to dimetanilamide with ammonia and hydrogen sulfide.

The compounds synthesized and their relative effectiveness as indicated by preliminary studies on β-hemolytic streptococcal infections in mice are shown in the table, where sulfanilamide = ++.[3,4]

The inferences drawn from the results are:

1. Acetylation of the amino groups lowered the therapeutic effect. This was in agreement with all other work on sulfanilamide derivatives.

2. Alkylation of the amide nitrogen had no apparent effect on the therapeutic efficiency although the compound had lost its water solubility almost completely.

3. Metanilyl derivatives had a lower effectiveness than the corresponding sulfanilyl derivatives. However, dimetanilamide had about the same activity as sulfanilamide.

In addition to the sodium and magnesium salts

[a] In cold solution was precipitated as bronze scales which spontaneously changed to the above. [b] Apparently light stable.

of disulfanilamide we have prepared (but have not analyzed) the other salts shown in Table II. The method of preparation for sparingly soluble salts was double decomposition between N^1-sodium disulfanilamide (sod. DSA) and a soluble salt of the metal. For soluble salts disulfanilamide (DSA) was neutralized with the corresponding hydroxide or carbonate of the metal.

The cupric salt is of interest since in the cold it was precipitated first as bronze scales which spontaneously changed over to light green needles. There was no evidence of the deep blue copper–ammonium coördination complex which might have been expected. The silver salt was white and apparently light stable. The monoamylammonium salt was peculiar in that it crystallized in unusual forms, one of which appeared to consist of spherical segments like the sections of an orange. The monoamylamine was obtained from the Sharples Solvent Corp. and was a mixture of isomers.

Of this series, N^1-sodium disulfanilamide and N^1-methyldisulfanilamide appeared very interesting and their pharmacology is being studied extensively. We have tested disulfanilamides of this type, successfully, in certain of the virus diseases. N^1-Methyl- and N^1-ethyldisulfanilamide are most outstanding, since they have shown promising results on infections caused by the Francis strain of influenza in mice.

Experimental

N^1-Sodium-N^4,$N^{4'}$-diacetyldisulfanilamide.—To one mole of ammonia dissolved in 150 cc. of water at 10° there was added over one hour with vigorous agitation, 2.5 moles of freshly prepared and analyzed N-acetylsulfanilyl chloride. Sufficient 50% sodium hydroxide solution was added to maintain the *p*H between 10 and 12. Ice was added to hold the temperature at 35–40°. After all of the N-acetylsulfanilyl chloride was added, stirring was continued for about an hour. The mixture was cooled to 10° and filtered. The crude product was recrystallized twice from concentrated aqueous solutions with use of activated charcoal, after adjusting the *p*H to 6–7. Under these conditions, N^4-acetylsulfanilamide was very slightly soluble while N^1-sodium-N^4,N$^{4'}$-diacetyldisulfanilamide was very soluble, so that a separation was obtained readily. N^4,N$^{4'}$-Diacetyldisulfanilamide was recovered from the mother liquors by acidifying to *p*H 1–2. It was sparingly soluble in cold water. Anhydrous N^1-sodium-N^4,N$^{4'}$-diacetyldisulfanilamide was obtained by drying the hydrated salt at 130° *in vacuo*.

The same product was obtained starting with 1 mole of N^4-acetylsulfanilamide and 1 mole of N-acetylsulfanilyl chloride under similar conditions.

N^1-Sodium Disulfanilamide.—The filter cake of crude N^1-sodium-N^4,N$^{4'}$-diacetyldisulfanilamide prepared as above was hydrolyzed by boiling with 200 g. of sodium hydroxide and 200 cc. of water until there was no further increase in diazotizable amine (one to two hours). The mixture was then cooled to 10° and crude N^1-sodium disulfanilamide filtered. This was purified by recrystallization from concentrated aqueous solutions at *p*H 6–7 with use of activated charcoal. Solubility of N^1-sodium disulfanilamide in water was 9.6 g. per 100 cc. at 10° and 20 g. per 100 cc. at 37°. The anhydrous salt was obtained by drying at 100°.

Crude disulfanilamide was recovered from the mother liquors by acidification to *p*H 2–3 where it had a minimum solubility. Additional hydrochloric acid formed the more soluble hydrochloride or dihydrochloride. Disulfanilamide was only moderately soluble in boiling water. Disulfanilamide dihydrochloride was readily tetrazotized and this reaction served as a means of analyzing both disulfanilamide and its salts.

Dimetanilamide.—One mole of *m*-nitrobenzenesulfonamide was dissolved in 1600 cc. of water containing 16 g. of anhydrous sodium carbonate and 30 g. of sodium hydroxide at 45°; 1.3 moles of *m*-nitrobenzenesulfonyl chloride was then added with vigorous agitation at 45–60° over one-half hour while maintaining a *p*H of 10–11 by addition of 50% sodium hydroxide solution as required. After stirring for an hour the reaction mixture was cooled to 10° and the crude product filtered. Sodium di-(*m*-nitrobenzenesulfon)-amide was obtained by recrystallization from water.

The nitro compound was reduced in two and one-half times its weight of 28% ammonia by passing a stream of hydrogen sulfide through the suspension while stirring vigorously. Cooling was necessary at first but after the reaction moderated, the mixture was held at a slow boil under a reflux condenser with constant passage of hydrogen sulfide for one hour. A rapid stream of air was then passed through the solution at the boil, to remove excess ammonia and oxidize sulfides to sulfur. The mixture was made alkaline to phenolphthalein with sodium hydroxide, and sulfur removed by filtration. The solution was acidified with hydrochloric acid to *p*H 4.5 to 5 and crude dimetanilamide obtained. This was purified by dissolving as the sodium salt, treating with activated charcoal and reprecipitating. Dimetanilamide melts to a characteristic blue-green liquid above 330°.

N^1-Methyl-N^4,N$^{4'}$-diacetyldisulfanilamide.—One mole of anhydrous N^1-diacetyldisulfanilamide was suspended in 2 liters of dry xylene containing two moles of dimethyl sulfate. The mixture was heated with constant agitation under a reflux condenser for two hours. The solid material was removed by filtration and the filtrate discarded. The solid was suspended in 3 liters of water and warmed with addition of sodium hydroxide solution until it remained alkaline to phenolphthalein. The insoluble material was filtered off and twice retreated with warm dilute sodium hydroxide. The final residue was the crude methylated product. It was purified by dissolving in glacial acetic acid, treating with activated charcoal and diluting with water. The yield of N^1-methyl-N^4,N$^{4'}$-diacetyldisulfanilamide was about 50%.

N^1-Methyldisulfanilamide.—One-half mole of N^1-methyl-N^4,N$^{4'}$-diacetyldisulfanilamide was suspended in 1200 cc. of 95% alcohol; 1.05 moles of 36% hydrochloric acid was added dropwise over one and one-half hours to the boiling, well agitated suspension. The liquid was spot tested on methyl violet paper frequently. Insufficient hydrochloric acid was present at any time to give a green spot. This was important since excess acid would have caused cleavage at the sulfonamide linkage. At the end a complete solution was obtained, which was exactly neutralized with 50% sodium hydroxide solution. After removal of salt the filtrate was evaporated to low volume and gradually diluted with water under agitation, so as to induce crystallization and avoid precipitation of the product as an amorphous mass. The crystals were suspended in 700 cc. of water at 35°, treated with excess sodium hydroxide and filtered, to remove any N^1-methylsulfanilamide. The crude product was then recrystallized several times from 80% alcohol (in which it was considerably more soluble than in 95%) using activated charcoal. N^1-Methyldisulfanilamide was water insoluble but readily dissolved in strong hydrochloric acid, in which it could be tetrazotized quantitatively. Yield in the hydrolysis was about 60%.

N^1-Ethyldisulfanilamide.—This was made by the same procedure using diethyl sulfate instead of dimethyl sulfate. Yields were somewhat lower.

Summary

The compound  has been misnamed "disulfanilamide." Synthesis of true disulfanilamide, , is reported, and it is suggested that the first compound be named N^4-sulfanilylsulfanilamide to avoid confusion.

Disulfanilamide reacts with many bases to form a series of neutral salts, most of which are highly water soluble.

N^1-Alkyl derivatives have been made which are water insoluble and which do not form salts with bases.

These compounds appear from preliminary experiments in mice to have high antistreptococcal activity, and in the case of the N^1-alkyl derivatives, viruscidal activity as well.

Sulfanilamide Derivatives. III. *strepto*-N-Polysulfanilylsulfanilamides and Related Compounds[1]

BY M. L. CROSSLEY, E. H. NORTHEY AND MARTIN E. HULTQUIST

Fourneau and his co-workers[2] describe the compound which we would name N^4-(N-acetylsulfanilyl)-sulfanilamide as having little therapeutic effect. Later Rosenthal[3] studied N^4-sulfanilylsulfanilamide and more recently[4] N^1-(2-hydroxyethyl)-N^4-sulfanilylsulfanilamide, and *strepto*-N^4-disulfanilylsulfanilamide.

In the meantime investigators at the I. G. had studied N^4-sulfanilylsulfanilamide and its N^4-mono- and dimethyl derivatives.[5]

Gray, Buttle and Stephenson[6] also made N^4-sulfanilylsulfanilamide, which they named *p*-aminobenzenesulfonyl - *p*′ - sulfonamidophenylamide. This is an example of what one encounters in trying to name such derivatives by conventional methods. The name is sufficiently formidable to make even chemists think twice, or reach for paper and pencil.

We have synthesized, independently of the others, not only the parent compound but a large number of derivatives using as starting materials many of the compounds described in the first two papers of this series.

The method of synthesis was to treat N-acetylsulfanilyl chloride with sulfanilamide or any of its N^1-derivatives at *p*H 8–10, followed by hydrolysis of the acetyl group with either acid or base depending on the character of the compound.

By increasing the chain of sulfanilyl groups the compounds become increasingly difficult to crystallize. Thus *strepto*[7]-N-trisulfanilylsulfanilic acid

forms an emulsion in water which is difficult to work with. However, its sodium salt is nearly impossible to handle, since it forms a pearly dispersion closely resembling a vanishing cream, which resists all attempts to filter.

In the synthesis of N^1-hydroxyalkyl-*strepto*-N-polysulfanilylsulfanilamides crystallization of the product is difficult not only because of the tendency of the desired compound to form tars or oils, but because the crude products are often contaminated by sulfanilic esters. However, after crystals once have been obtained subsequent crystallizations are easy. In general, these compounds were purified by dissolving in alcohol, treating with activated carbon, and slowly diluting with water so as to prevent immediate precipitation of the bulk of the material as an oil.

The derivatives made and their pharmacology are indicated in the following table, where sulfanilamide = ++, comparison being made on β-hemolytic streptococcic infections in mice.[8,9]

Inferences which can be drawn from a study of the present results and the results described in our first two papers are:

1. There is an apparent increase of activity by adding a sulfanilyl group to the amino group in sulfanilamide, N-sulfanilylsulfanilic acid, N^1-(2-hydroxyethyl)-sulfanilamide and N^1-(2-hydroxypropyl)-sulfanilamide.
2. Activity is decreased by adding a sulfanilyl group to 2-sulfanilamidobenzoic acid, N^1,N^1-*bis*-2-hydroxyethylsulfanilamide, and disulfanilamide.
3. Addition of a third sulfanilyl group decreases the activity in N^1-2-hydroxyethyl-N^4-sulfanilylsulfanilamide; increases it in *strepto*-N-disulfanilylsulfanilic acid.
4. The much better activity of N^3-sulfanilylmetanilamide as compared with N^4-metanilylsulfanilamide is significant and was predicted. The first compound is behaving as a sulfanilamide substituted on the amido nitrogen while the second is behaving as a sulfanilamide substituted on the amino nitrogen. All previous results, including our own, indicate that new *sulfanilamide* derivatives of greater activity will be substituted by groups on the amido nitrogen and probably not elsewhere.
5. Certain of these compounds have been found effective against virus diseases.

[b] Bauer and Rosenthal, ref. 4.

It should be pointed out that the therapeutic effectiveness of these various sulfanilamide compounds is described in terms of a series of preliminary pharmacological experiments carried out on large groups of mice experimentally infected with a very virulent strain of β-hemolytic streptococci, using massive infecting doses and single protective doses of the therapeutic agent. In all cases the control animals died in sixteen hours. Reported results are in terms of animals surviving at the end of seventy-two hours. Much further experimental evidence will be needed to establish the usefulness of these products in human medication, since acute toxicity studies in mice tell nothing of the complications of human administration, such as fever, cyanosis, dermatitis, acidosis and peripheral neuritis.

Experimental

General Method of Preparation.—The general method for making the present derivatives was the same as that described in the first paper of this series for the preparation of sodium N-sulfanilylsulfanilate.[10] Syntheses of compounds involving important variations of this method are given below.

N^4-Metanilylsulfanilamide.—Seven-tenths mole of sulfanilamide was dissolved in 500 cc. of water at about 95°; 0.5 mole of freshly prepared *m*-nitrobenzenesulfonyl chloride was added rapidly with vigorous agitation. When the mixture had crystallized (ten to fifteen minutes) sufficient sodium hydroxide was added to dissolve the solid. The solution was clarified and poured into 400 cc. of concentrated hydrochloric acid. N^4-*m*-Nitrobenzenesulfonylsulfanilamide precipitated while excess sulfanilamide remained dissolved. The precipitate was filtered and washed with hot water. It was reduced with ammonia and hydrogen sulfide by the general procedure for metanilyl derivatives.[11]

Attempts to prepare this compound by the usual procedure lead to N^1,N^4-di-(*m*-nitrobenzenesulfonyl)-sulfanilamide as the main product.

N^1-(2-Hydroxyethyl)-N^4-sulfanilylsulfanilamide and similar derivatives were made by the general method while maintaining a *p*H of 7–9 (when foaming occurred sufficient sodium hydroxide solution was added to give a faint pink spot test on phenolphthalein paper). It was thought that a somewhat lower *p*H led to formation of less of the sulfanilic esters which gave difficulty in purification of the final products. The crude hydrolyzed products were oils or sticky masses which were partially purified by dissolving as the sodium salts in water, treating with activated charcoal, and reprecipitating with acid. Initial crystallization was frequently very slow, extending in some cases to weeks. Most favorable conditions found for inducing initial crystallization were established by dissolving the material in about twice the amount of 60–80% alcohol, treating with decolorizing carbon, and diluting with water

(11) Crossley, Northey and Hultquist, THIS JOURNAL, **60**, 2220 (1938).

at room temperature until the solution remained slightly milky. It was then allowed to stand with occasional agitation and scratching of the walls until crystallization started. Once seed crystals were obtained subsequent recrystallizations were comparatively easy.

N^4-Sulfanilyldisulfanilamide.—One-half mole of sulfanilamide was dissolved in 500 cc. of water with sufficient sodium hydroxide to give a *p*H of 10–12; 1.2 moles of freshly prepared N-acetylsulfanilyl chloride was added over half an hour at 35–40° while maintaining the above *p*H by addition of 50% sodium hydroxide as necessary. Stirring was continued for one hour, then 100 g. of sodium hydroxide was added, and the mixture boiled for two hours. The hydrolysis mixture was neutralized with concentrated hydrochloric acid, cooled, crystals of crude N^1-sodium-N^4-sulfanilyldisulfanilamide filtered off, and recrystallized several times from water, using activated charcoal. The free amide was made by acidification of a solution of the sodium salt. The initial amorphous mass was crystallized by rubbing in alcohol.

$N^1,N^4,N^{4'}$-Trisodium $N^4,N^{4'}$-disulfanilyldisulfanilamide.—This was made by the general procedure starting with an equivalent of N^1-sodium disulfanilamide. Attempts to prepare a crystalline monosodium salt or crystalline free amide failed. The trisodium salt (actually a mixture with some of the disodium salt) was crystallized from a concentrated aqueous solution at *p*H 9–10, by dilution with alcohol.

N^1-(2-Hydroxyethyl)-N^3-metanilylmetanilamide.—One-third mole of N^1-(2-hydroxyethyl)-metanilamide was dissolved in 300 cc. of water containing 30 g. of boric acid; $^1/_3$ mole of *m*-nitrobenzenesulfonyl chloride was added over an hour at 55–65° with vigorous agitation while maintaining a *p*H of 6–8 by addition of 50% sodium hydroxide solution as required. The nitro compound which separated on cooling was reduced with 150 g. of fine iron, 500 cc. of water, and 1 cc. of glacial acetic acid at 95–100°. After complete reduction excess sodium hydroxide was added to dissolve completely the product, the mixture was filtered, and the filtrate neutralized. A sticky mass separated which crystallized on standing overnight. This crude product was recrystallized by dissolving in hot alcohol, treating with activated charcoal, then diluting gradually with water, cooling and seeding. After several recrystallizations, colorless crystals were obtained.

Boric acid was used in the hope that by forming a complex with the hydroxyl groups, it would aid in preventing formation of sulfonic esters. Success in obtaining a crystalline product through its use, where previously there had been failure, leads us to believe that it was of value.

Summary

A series of *strepto*-N-polysulfanilyl derivatives of aminobenzenesulfonic acids and carboxylic acids, hydroxyalkylamines, sulfonamides, and disulfonamides are described, together with preliminary results of the pharmacological study of their effect in mice infected with β-hemolytic streptococci.

No general conclusions can be drawn concerning the effect of increasing the number of sulfanilyl groups.

Better activity was shown by N^3-sulfanilylmetanilamide than by N^4-metanilylsulfanilamide. This was predicted from previous results.

Certain of these compounds appear effective in virus diseases, but caution is expressed against assuming that the results of these preliminary studies in mice are translatable to human therapy.

Ethylenediamine and Propylenediamine Vanadates

BY EUGENE H. HUFFMAN

In the course of an investigation, some diamine vanadates were desired. A search of the literature did not reveal the previous preparation of these, though some alkyl amine vanadates[1] and a pyridinium vanadate[2] have been described. This paper describes the preparation and some properties of hydrated hexavanadates of ethylenediamine and propylenediamine and the metavanadate of ethylenediamine.

Preparation

Ethylenediamine and Propylenediamine Hexavanadates.—Ten grams of vanadium pentoxide (either C. P. grade or prepared by gently heating ammonium metavanadate) is added to a solution of 5 cc. of 69.8% ethylenediamine and 15 cc. of water, or 8 g. of vanadium pentoxide to 5 cc. of 70–75% propylenediamine and 15 cc. of water. Then 15 cc. of 30% hydrogen peroxide is added slowly, with stirring, over a period of half an hour, while keeping the temperature below 60°. The mixture is filtered, washed with 25 cc. of water, to which is added 3 cc. of 30% hydrogen peroxide, and the filtrate and washings diluted to 150 cc. After just neutralizing the solution to

(2) Katzoff and Roseman, THIS JOURNAL, **58**, 1785 (1936).

litmus with the corresponding diamine, crystallization usually begins in thirty minutes. It can be hastened by the addition of a small amount of the diamine dihydrochloride. The bright brownish-yellow product is filtered off, washed with water, and air-dried at room temperature.

Ethylenediamine Metavanadate.—This compound may be prepared by the following three methods. (1) Solid ethylenediamine dihydrochloride is added slowly to a saturated solution of ammonium metavanadate (prepared by heating to boiling, cooling, and filtering) until precipitation is complete. About 3 g. of the hydrochloride is required for every 100 cc. of saturated metavanadate solution. The golden-yellow product is washed on a filter with water until free from chloride and dried over calcium chloride.

(2) Three grams of vanadium pentoxide is added to a mixture of 5 cc. of ethylenediamine (69.8%) and 10 cc. of water. The mixture is heated to 90° for five minutes, filtered, and cooled to 20°. The brown turbid appearance is discharged by adding 2 drops of 30% hydrogen peroxide and allowing to stand for ten minutes. The vanadate is precipitated either by diluting to 200 cc. and passing carbon dioxide into the solution or by diluting to 40 cc. and slowly adding, with stirring, 150 cc. of 95% ethyl alcohol. The white product is washed first with four 10-cc. portions of alcohol to remove excess amine, and then with water to remove carbonate. If it is washed with water before the amine is removed, the precipitate redissolves.

(3) Two grams of the hexavanadate is dissolved in 6 cc. of ethylenediamine (69.8%) and 30 cc. of water. The orange color of the solution changes to colorless in forty minutes. The solution is diluted to 50 cc. and 100 cc. of 95% ethyl alcohol added, with stirring, to precipitate the white metavanadate. The product is filtered, washed with four 10-cc. portions of alcohol and then with water.

Similar attempts to prepare propylenediamine metavanadate gave discordant results which approached the hexavanadate in composition.

Analysis

The compounds were analyzed for vanadium and diamine. (1) Vanadium is determined readily by direct ignition to vanadium pentoxide in a platinum crucible. The fluid vanadium pentoxide should be allowed to run off the un-oxidized part to ensure complete oxidation.

(2) The diamine can be determined by a modified Kjeldahl method. A sample (0.4 to 0.6 g.) is digested with sulfuric acid and potassium sulfate, but without the addition of any other oxidation catalyst. The vanadium pentoxide brings about complete oxidation in one and a quarter hours. The ammonia is then distilled and titrated in the usual manner. The results[3] allow the ratio between vanadium and diamine to be determined quite accurately.

The water content was based upon the vanadium and diamine determinations. The results were: (1) ethylenediamine metavanadate, 38.99, 38.99, 39.08, and 39.13% vanadium and 23.24, 23.02, 23.73, and 22.90% ethylenediamine; calculated for $C_2H_4(NH_2)_2 \cdot 2HVO_3$, 39.19% vanadium and 23.11% ethylenediamine; (2) ethylenediamine hexavanadate, 39.46 and 39.50% vanadium and 15.31 and 15.25% ethylenediamine; calculated for $2C_2H_4(NH_2)_2 \cdot H_4V_6O_{17} \cdot 4H_2O$, 39.50% vanadium and 15.53% propylenediamine; (3) propylenediamine hexavanadate, 39.75, 39.99, and 40.10% vanadium and 19.56 and 19.20% propylenediamine; calculated for $2C_3H_6(NH_2)_2 \cdot H_4V_6O_{17} \cdot 2H_2O$, 39.91% vanadium and 19.35% propylenediamine.

Properties

Ethylenediamine metavanadate is golden-yellow in color when prepared by precipitation from an ammonium metavanadate solution or white when precipitated from an ethylenediamine solution. Both hexavanadates are brownish-yellow. All three compounds are insoluble in alcohol, ether, acetone, dioxane, and benzene, and are not appreciably soluble in water. All are soluble in aqueous solutions of ammonia, ethylenediamine, propylenediamine, and 30% hydrogen peroxide.

The compounds undergo no detectable change in composition on standing in diffused light for one month, but turn dark when exposed to direct sunlight. The hexavanadate and yellow metavanadate of ethylenediamine change to the white metavanadate when allowed to remain in a solution of ethylenediamine until just colorless.

Summary

The preparation and some properties of ethylenediamine hexavanadate, propylenediamine hexavanadate, and ethylenediamine metavanadate have been described. Attempts to prepare propylenediamine metavanadate gave discordant results.

[3] The method was checked by determining the diamine content of ethylenediamine dihydrochloride, carefully purified by recrystallization and dried over calcium chloride. For this purpose about 0.2 g. of vanadium pentoxide was used as a catalyst in the digestion. The variation amounts to 0.5 to 0.8% of the diamine content.

The Elimination of Liquid Junction Potentials. I. The Solubility Product of Silver Chloride from 5 to 45°

BY BENTON BROOKS OWEN

There are two types of liquid junctions commonly encountered in electrochemical studies: homoionic junctions formed by juxtaposition of solutions differing only in ionic concentrations, and heterionic junctions involving differences in ionic species. The potentials of heterionic junctions are not subject to simple thermodynamic definition,[1] which accounts for the necessity of their "elimination" when such junctions occur in cells used for thermodynamic purposes. This elimination has been attempted by both mathematical and physical means, but it always involves some extra-thermodynamic hypothesis which remains to be justified on empirical grounds. In the method described in this communication, the essential hypothesis is so simple in principle, and direct in operation, that the possibility of its adequate experimental verification is unusually high. A variety of data may be used in this connection, and will be presented in this paper, and elsewhere.[2]

Outline of the Method

The method involves the study of series of cells containing solutions of varying concentrations of the dissimilar ions giving rise to the junction potentials, but maintained at constant total ionic strength by the presence of an additional electrolyte which takes no part in the electrode reactions. Extrapolation to zero concentration of the dissimilar ions eliminates the junction potentials. The effect of the inert electrolyte can be eliminated by subsequent extrapolation to zero ionic strength. Somewhat similar schemes have been used, or implied, in the work of previous investigators,[3] but the simplicity of linear extrapolations was not obtained. This practical advantage of the present method is probably a consequence of the simple behavior of electrolytes in mixtures at constant ionic strength,[4] and the attainment of maximum symmetry in the electrode–electrolyte systems.

The determination of the solubility product of silver chloride was selected to illustrate the method because the results may be used as an independent check on the standard potential of the silver electrode.[2] The cells can be represented as follows

$$\text{Ag, AgCl}\left|\begin{matrix}\text{KCl}(x)m\\ \text{KNO}_3(1-x)m\end{matrix}\right|\ \text{KNO}_3(m)\ \left|\begin{matrix}\text{AgNO}_3(x)m\\ \text{KNO}_3(1-x)m\end{matrix}\right|\text{AgCl, Ag}^+$$

The total ionic concentration in each solution is m, but a fraction, x, of this is composed of chloride ion in the left-hand compartment, and silver ion in the right. The e. m. f. of such a cell is given by

$$E = k \log a'_{\text{Ag}}/a_{\text{Ag}} \pm E_{\text{j}} \qquad (1)$$

E_{j} is the sum of the unknown liquid junction potentials, $k = 0.00019844T$, and a'_{Ag} and a_{Ag} represent the activities of the silver ion in the right-hand and left-hand solutions, respectively. The solubility product

$$K = a_{\text{Ag}}a_{\text{Cl}} \qquad (2)$$

can be used to eliminate a_{Ag} in the left-hand solution, and equation (1) becomes

$$E - k \log a'_{\text{Ag}}a_{\text{Cl}} = -k \log K \pm E_{\text{j}} \qquad (3)$$

The introduction of the concentrations, xm, and the individual ionic activity coefficients leads to

$$E - 2k \log xm = -k \log K + k \log \gamma_{\text{Cl}}\gamma'_{\text{Ag}} \pm E_{\text{j}} \qquad (4)$$

The last two terms of this equation are not *independently* defined by thermodynamics alone, and this fact constitutes the essential limitation on the use of cells with heterionic liquid junctions.

Inspection of equation (4), and consideration of the symmetry of the electrochemical system it represents, shows that if m is held constant while x is varied, extrapolation to $x = 0$ must yield

$$[E - 2k \log (xm)]_{x=0} = -k \log K + [k \log \gamma_{\text{Cl}}\gamma'_{\text{Ag}}]_{x=0} \qquad (5)$$

because E_{j} becomes zero under this condition. Since it is no longer necessary to retain the prime on γ'_{Ag} when $x = 0$, the last term is amenable to thermodynamic treatment, and can be expressed as a function of m similar to that for any uni-univalent strong electrolyte.

To allow compact graphical representation of the experimental results, the term $2k\alpha\sqrt{m}$ will be added to both sides of equation (5) (α = Debye–Hückel limiting slope). Since this term is not a function of x, the extrapolation function may be rewritten as follows

$$[E - 2k \log (xm) + 2k\alpha\sqrt{m}]_{x=0} = -k \log K + [k \log \gamma_{Cl}\, \gamma_{Ag} + 2k\alpha\sqrt{m}]_{x=0} \quad (6)$$

The determination of $[E - 2k \log (xm) + 2k\alpha\sqrt{m}]_{x=0}$ by extrapolation at various values of m is shown in Fig. 2. The determination of $-k \log K$ by subsequent extrapolation of these intercepts to $m = 0$ is given in Fig. 3. This final step is equivalent to the familiar Hitchcock[5] extrapolation.

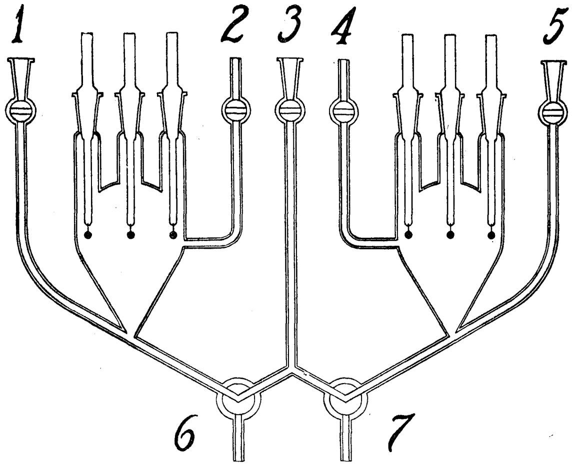

Fig. 1.—Cell assembly.

Materials and Technique

Water from an electrically heated Barnstead still was used in the purification of chemicals, and the preparation of stock solutions. "Jena" sintered glass mats were used in all filtrations. Concentrations of stock solutions were based upon weights of water and dry salts. Vacuum corrections were applied throughout.

The silver nitrate was Merck "Reagent" grade, recrystallized once, and air dried at 85 to 95° for twenty-four hours. Just before use, it was heated for five hours to 100° under reduced pressure (<1 mm.). The 0.05 molal stock solution was shielded carefully from light, and protected from contact with reducing substances and laboratory fumes.

The potassium chloride was Baker "Analyzed" grade, recrystallized twice. It was dried for two days at 95° followed by three days at 115°. The potassium nitrate was from the same source as the chloride, and received the same treatment.

The electrodes were prepared by decomposition of well-washed silver oxide at 450°, followed by electrolysis (series) in 0.5 m hydrochloric acid solutions at 3 m. a. for two or three hours. They were shielded from strong light at all times. An effort was made to have them very similar to those used by Harned and Ehlers,[6] because the standard potentials reported by them are to be combined with the present results to obtain the standard potential of the silver electrode.

The cell construction is illustrated in Fig. 1. The inlets numbered 1 and 5 are connected to flasks containing the air-free chloride and silver solutions, and number 3 is connected to the pure potassium nitrate junction solution. All connections which come in contact with cell solutions are ground glass joints, lightly greased with vaseline which had been boiled with silver nitrate solution, and subjected to numerous rinsings with hot water. The cells are evacuated through the lower outlets to stopcocks 6 and 7. Then nitrogen, freed of oxygen by copper turnings at 700°, is introduced through 2 and 4. By successive evacuation and admission of nitrogen, the air is completely displaced from the cells and connections to solution flasks. After a final evacuation, cell solutions are admitted, under slight pressure, through 1 and 5 until the pressure inside exceeds the atmospheric. The electrodes are lifted slightly, one at a time, to allow the ground glass joints to be rinsed by overflowing cell solutions. After half an hour the cells are emptied through 6 and 7, and fresh solutions admitted. About twelve hours later, this rinsing process is twice repeated before e. m. f. readings are begun at 5°. Since equilibrium is slowly attained at this temperature, the readings usually extended over two or three hours. At higher temperatures one hour is quite sufficient. The temperature of the water-bath varied by ± 0.02° at 5 and 15°, but was controlled within 0.01° at the higher temperatures.

After each reading, the junctions (3-mm. bore of stopcocks) were flushed through the outlets of 6 and 7, but as an additional precaution against contamination by diffusion, or otherwise, the cells and ground glass joints were rinsed several times with fresh solutions during the course of the measurements, usually at 25 and 45°.

Experimental Results and Discussion

The experimental data are collected in Table I. The results of all measurements are included except two early ones in which the product xm was 0.002, or less. Erratic results were obtained with silver ion concentrations of this order unless the electrodes were rinsed thoroughly with the solution, and extra time allowed for equilibrium at the lower temperatures. The recorded values of E are the means of pair-wise combinations of the six electrodes. These were ordinarily concordant well within 0.1 mv. The over-all reproducibility of a cell was also of this order at the higher concentrations, but irregularities as high as 0.1 and 0.15 mv. were sometimes observed at m = 0.02 and m = 0.01, respectively. The effects of these irregularities can be seen in Fig. 2, where the radii of the plotted circles are 0.1 mv.

(5) Hitchcock, This Journal, **50**, 2076 (1928).

(6) Harned and Ehlers, *ibid.*, **55**, 2179 (1933).

The plots for all values of m and T show that a linear extrapolation is indicated on purely empirical grounds. Because of experimental difficulties when $xm < 0.002$, a rather long extrapolation is required at low values of m, but when $m = 0.05$ the linearity of the extrapolation function seems definitely established down to $x = 0.05$. These observations are corroborated by analogous plots from a study of buffer solutions.[2] This is an important point because *the possibility of this extrapolation, and its linearity* (or form ultimately arrived at by further study) *constitute the extrathermodynamic hypothesis upon which this method of eliminating liquid junction potentials is based.*

The intercepts obtained from the extrapolations in Fig. 2 are recorded in Table I to the nearest 0.05 mv.

Figure 3 shows the plots of these intercepts against m, which according to equation (6) permits the evaluation of $-k \log K$ by extrapolation to $m = 0$. These extrapolations are also linear within the estimated uncertainty of ± 0.1 mv. for the plotted points, which are drawn with 0.1-mv. radii. It will be noted that the straight lines intersect all the points except two at 5° where experimental difficulties were high, and the accuracy correspondingly low. It appears from the plots that the purely extrapolative uncertainty in $-k \log K$ might exceed 0.2 mv. at 5°, but not at the other temperatures.

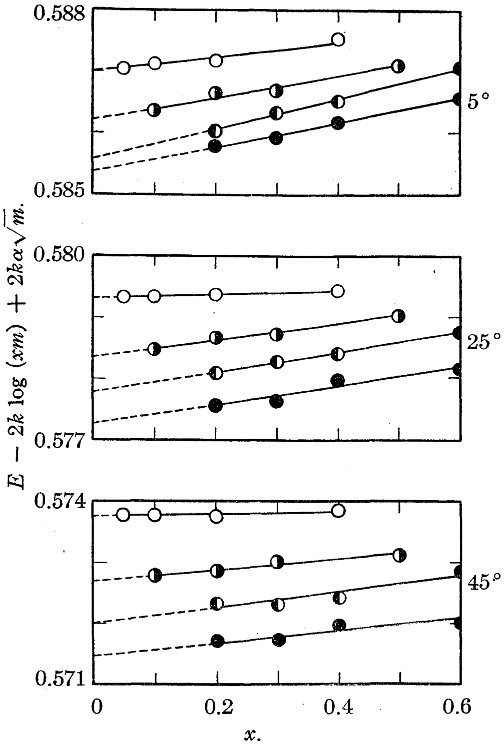

Fig. 2.—Elimination of E_j by extrapolation; ○, $m = 0.05$; ◑, $m = 0.03$; ◐, $m = 0.02$; ●, $m = 0.01$.

The intercepts, $-k \log K$, from the extrapolations in Fig. 3 are recorded in the second column of Table II to the nearest 0.1 mv. Their variation with temperature is satisfactorily expressed by

$$k \log K = -0.5768 + 345\,(t - 25)\,10^{-6} - 25\,(t - 25)^2 10^{-7} \quad (7)$$

or

$$\log K = 9.2496 - 4544.4/T - 0.012598T \quad (8)$$

Values calculated by these equations are given in the third and fourth columns, respectively. The solubility of silver chloride in pure water was calculated by the equation

$$\log m_0 = {}^1/_2 \log K + \alpha\sqrt{c_0} \quad (9)$$

which assumes the applicability of the Debye–Hückel limiting law at such high dilutions. The solubility, m_0, is in moles per kilogram of water, and c_0 is the corresponding value in moles per liter of solution.

The absolute accuracy of the results depends mainly upon three factors. These are the accuracy with which the concentrations are known,

the physical state (and purity) of the silver chloride, and the validity of the extension of the plots in Fig. 2. The uncertainties in the concentrations could hardly cause an error greater than 0.1 mv.

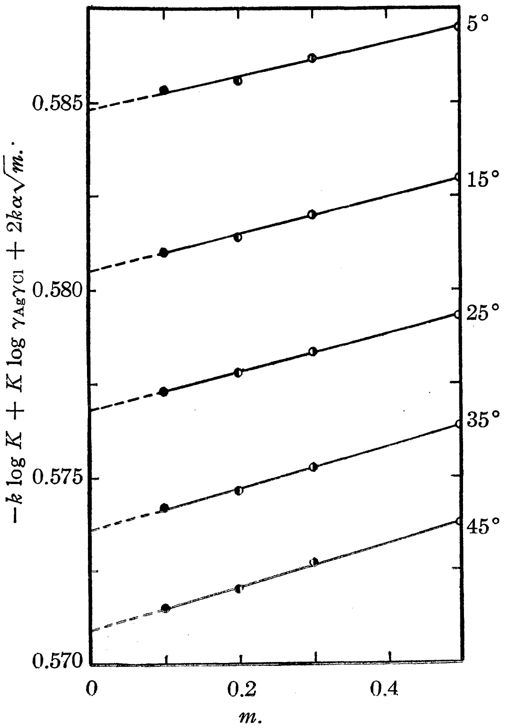

Fig. 3.—Evaluation of $-k \log K$ by extrapolation to infinite dilution.

The preparation of the electrolytic silver chloride has been described in the foregoing section. A review[7] of the determinations of the standard potential of the electrolytic silver–silver chloride electrodes shows that the results of the several independent investigators agree within 0.1 to 0.4 mv. This may be taken as indicative of high thermodynamic reproducibility of electrolytic silver chloride, because this agreement must also include uncertainties in analysis and extrapolation, and possible differences in the physical state and purity of the metallic silver. In the present solubility product determination the thermodynamic properties of the metallic silver cancel in the operation of the cell, so long as they are the same in all of the electrodes. It was to ensure this identity that all six of the electrodes used in any cell were electrolyzed in series, without distinction as to which were to be used in the silver and which in the chloride solutions. It is therefore probable that the absolute accuracy of the final results is of the same order as that of the two extrapolations. This seems to be better than ±0.2 mv. on the basis of the plots as drawn, but if linearity is not strictly maintained, then, in the absence of further data at high dilutions, the uncertainty might easily be twice as great.

Although comparison with values previously recorded in the literature constitutes a satisfactory check upon the essential correctness of the results, it does not furnish a dependable criterion of their absolute accuracy, because the discordance among such values appears to be much greater than the combined experimental errors of the various measurements. Variability in the physical condition of precipitated silver chloride is responsible for most of the difficulty. There are several papers which review[8,9] the literature, and discuss possible explanations of the discrepancies, so this matter need not be elaborated. Three previous investigations cover a considerable temperature range. Kohlrausch[10] determined the solubility of well-aged, precipitated silver chloride conductometrically from 1.55 to 34.12°. His values are about 3% lower than the present results. The results of the electrometric titrations of Hahn and Klockmann[11] (15 to 40°) are in good agreement, while the nephelometric values (0 to 50°) of Dave and Krishnaswami[9] are 3 to 4% higher. This is representative of the agreement to be expected when precipitated silver chloride is involved. Accordingly the score of determinations at single temperatures will not be discussed further than to consider one particular experiment in which electrolytic silver chloride was employed.

Brown and MacInnes[12] found that the solubility of silver chloride is 1.570×10^{-5} mole per liter in a 0.0286 normal solution of potassium nitrate at 25°. Although precipitated silver chlo-

ride was formed during the course of their electrometric titrations, the electrodes were coated with the electrolytic variety. If the concentration of silver chloride in the immediate neighborhood of the electrodes was successfully controlled by the electrolytic variety, the results should be comparable with those of the present research. Interpolation based on Fig. 3 leads to 1.577×10^{-5}, in excellent agreement with the above, but the value for the solubility in pure water reported by Brown and MacInnes is 1.314×10^{-5}, which is 1.5% lower than that given in Table III. The discrepancy is caused by the difference between the activity coefficients used by Brown and MacInnes[13] and those which may be obtained from consideration of equation (6) and Fig. 3. The slope of the 25° plot in Fig. 3 is 0.051, which leads to the expression

$$\log \gamma = -0.506 \sqrt{\mu} + 0.43\mu \qquad (10)$$

for the activity coefficient of silver chloride. On the basis of this equation, the result of Brown and MacInnes would be increased to 1.332×10^{-5}.

Although this concordance leaves little to be desired, it should be borne in mind that two electrometric determinations of the solubility of identical samples would not be strictly comparable unless the extra-thermodynamic hypotheses used to eliminate liquid junction potentials could be verified experimentally, or shown to be equivalent. It therefore seems necessary to reserve final judgment upon the absolute accuracy of the results reported in this paper until the reliability of the hypothesis represented by Fig. 2 has been established, or discredited, by further experimental work. Some familiar indirect checks upon the accuracy of solubilities and their temperature coefficients will be considered in a later communication.[2]

Summary

A method is proposed by which heterionic liquid junction potentials may be eliminated by extrapolation. Experimental data are presented which indicate that the junction extrapolation is linear as a first approximation.

The method is applied to the determination of the solubility product of electrolytic silver chloride in water at 5, 15, 25, 35, and 45°.

The Elimination of Liquid Junction Potentials. II. The Standard Electrode Potential of Silver from 5 to 45°, and Related Thermodynamic Quantities

BY BENTON BROOKS OWEN AND STUART R. BRINKLEY, JR.[1]

In the first paper of this series,[2] an extrapolation method for eliminating heterionic liquid junction potentials was described, and employed in a determination of the solubility product of silver chloride. It was considered desirable to test the validity and generality of the method by applying it to a comparison of the silver and hydrogen electrodes in buffer solutions. The results of these two investigations are interrelated through the potential of the silver–silver chloride electrode, and can be used to check one another. By the use of identical measuring equipment and technique, and consistent supplementary data, the concordance of these results becomes a necessary, but not a sufficient, condition to the validity of the extra-thermodynamic extrapolation upon which the method is based. Complete demonstration of its validity is contingent upon further direct investigation of the extrapolation, and comparison of its consequences with thermodynamic data obtained without recourse to liquid junctions. Several such comparisons can be made with the data at hand, and others will be available in the future.

Buffer solutions were used to depress and stabilize the hydrogen ion concentration, so that transfer of electricity across the liquid junction would be accomplished, for the most part, by ions other than hydrogen. The cell may be represented as follows

$$H_2 \mid HAc_{(m)}, NaAc_{(m)} \mid HAc_{(m)}, NaAc_{(m-mx)}, AgAc_{(mx)} \mid Ag^+$$

The ionic strength, $\mu \simeq m$, is practically identical

---

[1] This communication embodies part of the experimental material to be presented by Stuart R. Brinkley, Jr., to the Graduate School of Yale University in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Owen, THIS JOURNAL, **60**, 2229 (1938).

on both sides of the junction, but a small fraction, x, of the total salt in the right-hand solution is silver acetate. The electromotive force of this cell is given by

$$E = -E^0_{Ag} - k \log a_H/a'_{Ag} \pm E_j \qquad (1)$$

where $k = 0.00019844T$, and a_H and a'_{Ag} denote the activities of the hydrogen and silver ion in the left and right-hand solutions, respectively. The ionization of acetic acid requires that

$$a_H = Ka_{HAc}/a_{Ac} \qquad (2)$$

and by substitution, equation (1) becomes

$$E = -E^0_{Ag} + k \log a'_{Ag}a_{Ac}/a_{HAc} - k \log K \pm E_j \quad (3)$$

With a buffer ratio unity, it is permissible to write $m_H = K$ throughout the concentration range investigated. Accordingly equation (3) becomes

$$E - k \log mx(m + K)/(m - K) + k \log K = -E^0_{Ag} + k \log \gamma'_{Ag}\gamma_{Ac}/\gamma_{HAc} \pm E_j \quad (4)$$

by rearrangement, and introduction of concentrations and the corresponding ionic activity coefficients.

It is evident that when $x = 0$ the solutions are identical, and E_j vanishes. At constant m, a plot of the left-hand member against some convenient function of x yields the intercept

$$[E - k \log mx(m + K)/(m - K) + k \log K]_{x \doteq 0} = -E^0_{Ag} + k \log \gamma_{Ag}\gamma_{Ac}/\gamma_{HAc} \quad (5)$$

Since the two solutions are identical, it is no longer necessary to retain the prime on the activity coefficient term. At high dilutions, this term becomes equal to $-2k\alpha\sqrt{m}$, where α is the Debye–Hückel limiting slope. Therefore we may add $2k\alpha\sqrt{m}$ to the values of the bracketed term of equation (5), and extrapolate[3] the resulting quantities to zero ionic strength. The intercept is $-E^0_{Ag}$.

Materials and Technique

Baker C. P. glacial acetic acid was purified further by one partial freezing, and two distillations from chromic oxide in an all-glass still. The acid was diluted with conductivity water to form a stock solution approximately 0.2 molal. It was standardized by comparison with Bureau of Standards potassium acid phthalate and an independently standardized hydrochloric acid solution. The titer was known to ±0.04%. The solution was stored under hydrogen. Eimer and Amend C. P. silver acetate was analyzed gravimetrically, as silver bromide, and found to be 99.45 ± 0.03% silver acetate. It was used on this basis without further purification. Baker and Adamson sodium bicarbonate was recrystallized once from distilled water saturated with carbon dioxide, and dried in an atmosphere of carbon dioxide. Commercial nitrogen and hydrogen were freed from oxygen by passing them over copper turnings at 700°. Sodium carbonate was prepared fresh for each cell solution by heating the bicarbonate, in a platinum dish, in an electric furnace at 290 ± 10° for at least ten hours.

The calculated amounts of sodium carbonate, silver acetate, acetic acid stock solution and water were weighed into the solution flasks to obtain solutions with the desired values of x, m and a buffer ratio of unity. Conductivity water was used, and vacuum corrections applied. The solutions for the hydrogen half-cell were swept with hydrogen which had passed through a saturator of large volume, and they were then kept under hydrogen. The silver half-cell solutions were swept with nitrogen, and stored under this gas. The silver solutions were protected from light.

The essential features of the cell have been described by Owen.[2] No intermediate solution was required, and our cell differs from his only in the elimination of one of the junction stopcocks, and the necessary modifications for the electrodes employed. The silver electrodes were prepared by the thermal decomposition of silver oxide at 450°. The sample of silver oxide which was used was the same as for the previous investigation.[2] The hydrogen electrodes were of the usual type employed in work from this Laboratory. The measuring equipment was the same as that of the previous investigation, and the technique was practically identical. The cells were filled twelve hours before the first measurement, the usual vacuum technique being employed. Measurements were made from 5 to 45° at 10° intervals, and the cells were refilled frequently during the course of the measurements.

Discussion of the Results

The observed electromotive forces of the cells were corrected to a partial pressure of hydrogen of one atmosphere, and to round temperatures. They are recorded in Table I. The reported values are the mean of two cells (of four cells, in a few cases) differing by no more than 0.03 mv. In one case ($m = 0.05$, $x = 0.089$), the value represents two independent runs. The first group of cells were taken from 5 to 45° in one day. The second were taken from 5 to 25°, maintained at 25° for three days, returned to 5° and then taken to 45°. All values for the two runs agree within the deviation noted above. The cells therefore appear to be very stable once equilibrium is attained. Reproducible results were not obtained for silver concentrations below 0.002 molal, and these results have been discarded.

The values for the dissociation constant of acetic acid were taken from a paper by Harned and Ehlers.[4] The left-hand member of equation (4) is plotted against x in Fig. 1 at the five temperatures investigated. The results at 25° are similarly plotted on a larger scale in Fig. 2 to illustrate

the accuracy of the extrapolation. In Fig. 2, the radius of the experimental points represents an uncertainty of 0.1 mv. With the exception of a single point at 5° (m = 0.05, x = 0.047), the deviations from linearity are in no cases greater than 0.10 mv. This result for cells with buffer solutions corroborates the linearity previously observed[2] without buffer solutions. In that investigation, the slope of the extrapolation function increases with increase in ionic strength; in this investigation, the slope has the opposite sign, and shows an algebraic decrease with increasing ionic strength that is more rapid than in the former case. By reason of its steeper slope, the extrapolation at m = 0.05 is probably of no greater accuracy than that at m = 0.02, although in the former case it was possible to extend the measurements to a lower value of x. It should be noted that a plot of the electromotive forces of these cells against x does not form a basis for the estimation of the magnitude of the liquid junction potential, or of its variation with total ionic strength or temperature, since these plots also contain the variation of the unknown activity coefficient term, $\log \gamma'_{Ag^+}\gamma_{Ac^-}/\gamma_{HAc}$. The linearity of the extrapolation *function* seems established within the experimental error for the concentration range which has been investigated with both types of cells.

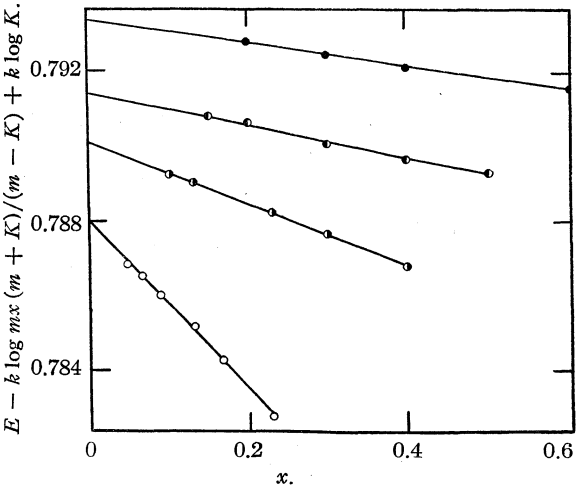

Fig. 2.—Extrapolation to eliminate liquid junction potentials at 25°. Radius of circles is 0.1 mv.: ○, m = 0.05; ◐, m = 0.03; ◑, m = 0.02; ●, m = 0.01.

The intercepts from the extrapolation in Fig. 1 are recorded in Table I to the nearest 0.05 mv. The term $2k\alpha\sqrt{m}$ is added to these intercepts as explained above, and the resulting quantities ex-

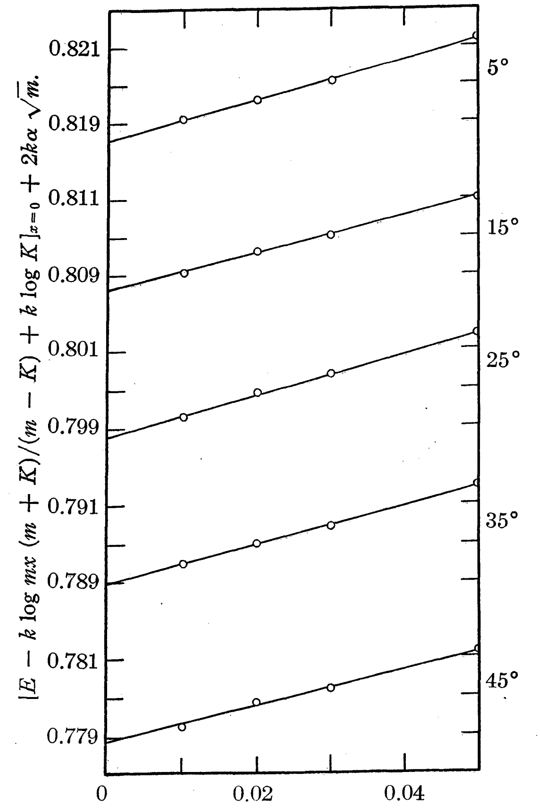

Fig. 3.—Extrapolation to eliminate activity coefficients.

trapolated to infinite dilution in Fig. 3. The values of E^0_{Ag} thus obtained are recorded in Table II. Uncertainties in concentrations, temperature and the measurement of the electromotive force are not likely to cause an error as great as 0.1 mv. and hence the uncertainties in E^0_{Ag} may be assigned to that of the two extrapolations, which we estimate to be less than ±0.2 mv.

TABLE II

STANDARD ELECTRODE POTENTIAL OF SILVER, AND DERIVED THERMODYNAMIC QUANTITIES FOR THE ELECTRODE REACTION

35	.7891	.7892	$.7891_5$	23.10	25,319	9.95
45	.7788	$.7791_5$	$.7790_6$	...	....	..

In the previous paper,[2] values of the logarithm of the solubility product of silver chloride have been tabulated. E^0_{Ag} can be calculated from the relation

$$E^0_{\mathrm{Ag}} = k \log K + E^0_{\mathrm{AgCl}} \qquad (6)$$

We have employed Harned and Ehlers' values[5] of E^0_{AgCl} because their investigation led to the values of the dissociation constant of acetic acid[4] which we have used above. The result of this calculation is given in column three of Table II. The two sets of data constitute a satisfactory check on the precision of the measurements. The difference between the two sets of values is well within the combined experimental uncertainties of the two determinations. Accordingly, we consider the best values of E^0_{Ag} to be the mean of the two determinations. This can be expressed satisfactorily by the equation

$$E^0_{\mathrm{Ag}} = -0.7991 + 0.000988(t - 25) + 7 \times 10^{-7}(t - 25)^2 \qquad (7)$$

Values calculated from this equation are given in Table II, column 4. The maximum deviation of observed from calculated values is 0.26 mv., and the average deviation is 0.11 mv. for both series of results. Since the temperature coefficient of E^0_{Ag} is of particular interest, it should be remarked that by a change in the constant term this equation will reproduce either set of values with a maximum deviation of 0.1 mv., and an average deviation of 0.05 mv. The values from the equation are used in all subsequent calculations.

Lewis[6] and Noyes and Brann[7] have compared the silver electrode in a 0.1 normal silver nitrate solution with the 0.1 normal calomel electrode. On the basis of various values for the reference electrode potential, and of various assumptions regarding the liquid junction potential and ionic activities, different authors have obtained the values −0.7995[6-8] and −0.7978[9] for E^0_{Ag} at 25° from these data. Chloupek and Daneš[10] have compared the silver electrode in a silver sulfate solution with the decinormal calomel electrode, using various bridge solutions. They obtain −0.7996 for E^0_{Ag} at 25°. Considering the diversity of the methods used to eliminate liquid junction potentials, the agreement of these values with ours seems satisfactory.

Differentiation of equation (7) yields

$$\mathrm{d}E^0_{\mathrm{Ag}}/\mathrm{d}T = 0.000988 + 1.4 \times 10^{-6}(t - 25) \qquad (8)$$

Skotnický[11] has measured the temperature coefficient of various half-cells against reference electrodes maintained at constant temperature. His method involves a thermal e. m. f. in the bridge solution, and a correction for the change in activity of the electrolyte with temperature, which is estimated from conductance measurements. He obtained the value 0.978 mv./deg. for dE^0_{Ag}/dT at 25°. Lingane and Larson[12] have measured the temperature coefficient of the cell

$$\text{Quinhydrone} \mid \text{HClO}_4c_1 \mid \text{HClO}_4c_1,\ \text{AgNO}_3c_2 \mid \text{Ag}$$

They obtain the value 0.967 mv./deg. for dE^0_{Ag}/dT at 25°. Their lowest concentration is 0.04 molar, and they made no extrapolation to infinite dilution. Their silver ion concentrations are lower than those with which we could obtain reproducible results, and no account was taken of liquid junction potentials. In view of the nature of the calculations employed by Skotnický, and by Lingane and Larson, we regard our value, 0.000988, as the most reliable figure.

Derived Thermodynamic Quantities

By application of familiar thermodynamic relations to equations (7) and (8), ΔS^0, ΔH^0 and ΔC^0_p are computed readily for the electrode reaction

$$\text{Ag} + \text{H}^+ \longrightarrow {}^1/_2\text{H}_2 + \text{Ag}^+$$

The values of these quantities are given in Table II for 15, 25 and 35°, the three temperatures at which equation (7) best reproduces the experimental results.

The solubility products of the silver halides may be computed from the relation

$$k \log K_{AgX} = E^0_{Ag} - E^0_{AgX} \qquad (6a)$$

By substitution of equation (7) from this paper, and the equations for the temperature variation of the standard silver halide electrode potentials[5,13,14] into equation (6a), the following expressions for the logarithm of the solubility product are obtained

$$k \log K_{AgCl} = -0.57671 + 0.00034248(t-25) - 2.584 \times 10^{-6}(t-25)^2 + 9.948 \times 10^{-9}(t-25)^3$$
$$k \log K_{AgBr} = -0.72776 + 0.000490(t-25) - 2.9 \times 10^{-6}(t-25)^2 \qquad (9)$$
$$k \log K_{AgI} = -0.95129 + 0.000660(t-25) - 2.9 \times 10^{-6}(t-25)^2$$

or

$$-\log K_{AgCl} = 5905.8/T - 22.8538 + 0.057854T - 5.0131 \times 10^{-5}T^2$$
$$-\log K_{AgBr} = 5702.2/T - 11.1822 + 0.014610T \qquad (10)$$
$$-\log K_{AgI} = 7084.0/T - 12.0389 + 0.014610T$$

Values of the logarithms of the solubility products and the corresponding solubilities are given in Table III. The solubilities have been converted into moles per liter of solution in order to facilitate comparison with the literature. Activity coefficients were calculated by the Debye–Hückel limiting law.

TABLE III

SOLUBILITY PRODUCTS AND SOLUBILITIES OF THE SILVER HALIDES

t, °C.	AgCl		AgBr		AgI	
	$-\log K$	$c \times 10^5$	$-\log K$	$c \times 10^6$	$-\log K$	$c \times 10^8$
5	10.5945	0.506	13.3860	0.203	17.4980	0.178
15	10.1520	0.842	12.8201	.380	16.7598	.417
25	9.7492	1.337	12.3026	.704	16.0813	.908
35	9.3809	2.038	11.8280	1.213	15.4562	1.859
45	9.0425	3.002	11.3920	1.997	14.8792	3.599

The discordance between the values in the literature for the solubility of silver chloride has been discussed in the previous paper.[2] The same considerations apply to the bromide and iodide. Comparison with previously recorded results does not, therefore, constitute a criterion of the absolute accuracy of the results in Table III. Our values do constitute a self-consistent set of solubilities which have been derived from e. m. f. methods alone. It is important to note in this connection that identical values of the standard potential of the silver–silver chloride electrode[5] were used in all of the supplementary data[13,14] involved in the construction of Table III. The solubilities in Table III are 0.25% higher than those recorded by the first paper[2] due to the combination of those data with ours in equation (7). The values in the literature for the solubility of silver bromide and silver iodide consist of determinations at a single temperature. The mention of a few of these will be sufficient. The determination of the solubility of silver bromide at 21.1° by Kohlrausch and Dolezalek[15] is 5% lower than our interpolated value. That of Bodländer and Fittig[16] at 25° is 2% higher than ours. The discordance with other values is considerably greater. The disagreement with the few recorded values of the solubility of silver iodide is even greater. The value of Goodwin[17] at 25° is 5% higher than ours, and that of Thiel[18] at the same temperature is 15% higher than ours.

RELATIVE IONIC ENTROPIES AND HEAT CAPACITIES

t, °C.	$S^0_{Ag^+}$	$S^0_{Cl^-}$	$S^0_{Br^-}$	$S^0_{I^-}$	$C^0_{pAg^+}$	$C^0_{pCl^-}$	$C^0_{pBr^-}$	$C^0_{pI^-}$
15	16.96	14.82	20.84	26.26	12.0	−34.6	−38.1	−37.6
25	17.38	13.52	19.52	24.94	12.3	−35.7	−39.6	−39.2
35	17.87	12.30	18.12	23.54	12.6	−36.7	−41.2	−40.7

By application of the usual thermodynamic relations to equations (9) or (10), it is possible to compute ΔS°, ΔH° and ΔC_p^0 for the reaction, $AgX \longrightarrow Ag^+ + X^-$. The values of these quantities for the silver halides are given in Table IV for 15, 25 and 35°. Pitzer and Smith[19] have calculated the heat of solution at 25° of silver chloride from the heat of precipitation data of Lange and Fuoss.[20] They obtain the value $\Delta H^0 =$ 15,740 cal. Latimer, Schutz and Hicks[21] report 26,710 cal. for the heat of solution of silver iodide, at 25° using the data of Lange and Shibata.[22]

The supplementary thermodynamic data necessary for the computation of relative ionic entropies and heat capacities are summarized in Table V.[23] Using the convention that the entropy of the hydrogen ion is zero at all temperatures, the relative ionic entropies and heat capacities of the silver and halide ions have been calculated from the values in Tables II, IV and V. These quantities are summarized in Table VI at 15, 25 and 35°.

Skotnický's[11] value of dE^0_{Ag}/dT leads to 17.0 cal./deg. mole for $S^0_{Ag^+}$ at 25°. Lingane and Larson[12] obtain 16.7 cal./deg. mole for the same quantity. A more reliable value from calorimetric methods is from the recent heat capacity data for silver oxide of Pitzer and Smith.[19] They obtained 17.46 ± 0.2 cal./deg. mole for $S^0_{Ag^+}$ at 25°. They have also recalculated the value given by Latimer, Schutz and Hicks,[21] based upon the heat of precipitation data of Lange and Fuoss,[20] and obtained 17.62 ± 0.2. They proposed the mean of these two figures as the best value, but in view of the approximate heats of dilution used to correct the data of Lange and Fuoss, and the close agreement with our value, we suggest the adoption of 17.4 ± 0.2 cal./deg. mole as the most probable value of $S^0_{Ag^+}$ at 25°.

From a number of sources, Latimer, Schutz and Hicks[21] have selected 13.5 ± 0.1, 19.4 ± 0.4 and 25.7 ± 0.7 cal./deg. mole for the best values[24] of $S^0_{Cl^-}$, $S^0_{Br^-}$ and $S^0_{I^-}$, respectively, at 25°. The agreement with the values in Table VI is well within the estimated uncertainties for the chloride and bromide ions, and is probably also satisfactory in the case of the iodide ion.

Summary

A method for the elimination of heterionic liq-

---

(23) The entropy and heat capacity data at 25°, except for hydrogen, are from the review of Kelley, *Bur. Mines*, Bull., 394, 35 (1935). The heat capacity of hydrogen [*cf.* Murphey, *J. Chem. Phys.*, **5**, 637 (1937)] and the temperature coefficients of all heat capacities are from the review of Kelley, *ibid.*, Bull. 371 (1934), being described by the equation, $C_p^0 = a + bT$. "a" was recalculated from "b" and C_p^0 at 298.1°K. (given in Bull. 394). The entropy at temperatures other than 298.1°K. is then given by $S^0 = S^0_{298.1} + a(2.303 \log T/298.1) + b(T - 298.1)$.

(24) While this paper was in press, Latimer, Pitzer and Smith [THIS JOURNAL, **60**, 1829 (1938)] have published another review of the subject. Their revised "best" values are 13.5 ± 0.1, 19.7 ± 0.2 and 25.3 ± 0.5 for the entropies of the halide ions, and 17.54 ± 0.15 for the silver ion.

uid junction potentials by extrapolation has been tested in cells with buffer solutions. Experimental data are presented which indicate that the junction extrapolation is linear as a first approximation.

The method is applied to the determination of the standard potential of the silver electrode at 5, 15, 25, 35 and 45°. Values of ΔS^0, ΔH^0 and ΔC_p^0 have been calculated for the electrode reaction at 15, 25 and 35°.

By combination of the normal potentials of the silver and silver–silver halide electrodes, the solubility products and solubilities of (electrolytic) silver chloride, bromide and iodide have been computed from 5 to 45°. Values of ΔS^0, ΔH^0 and ΔC_p^0 for the reaction $AgX = Ag^+ + X^-$ have been recorded at 15, 25 and 35°.

A self-consistent table of relative ionic entropies and heat capacities from electromotive force data has been made for the silver ion, chloride ion, bromide ion and iodide ion at 15, 25 and 35°.

Infrared Absorption Studies. V. Association in the Carboxylic Acids

BY A. M. BUSWELL, W. H. RODEBUSH AND M. F. ROY

The electron conception of valence proposed some twenty years ago led to the prediction in 1920 of two types of associated liquids.[1] In one of these the molecules should be combined with the formation of definite polymers (dimers in the case of acetic acid) while in the other type polymers of indefinite molecular weight and structure were anticipated. Radically different behavior, especially in the case of solvent properties, was predicted in the two cases. The liquids composed of polymers of indefinite molecular weight comprised the typically polar solvents such as water or alcohol, while in those having definite polymer molecules non-polar properties were to be expected.

Since then a great deal of additional evidence has been accumulated to emphasize this difference. For example, acetic acid shows no dipole moment in benzene solution whereas alcohols show an increasing polarization with increasing concentration. Alcohols also form glasses at low temperatures, which have been shown by Zachariasen[2] to involve polymerization with hydrogen bond formation. It is not possible, of course, to anticipate or predict in every case the type of polymer to be expected and that problem is one which still holds the greatest interest. The data from which conclusions could be drawn have been available for a long time; witness the excellent review by Lassettre[3] based entirely upon the ordinary data of physical chemistry. More recently a study of simple solubility by Zellhoefer, Copley and Marvel[4] has yielded a surprising amount of additional confirmatory data along these lines.

The existence of these two types of association has perhaps contributed to the confusion which for many years characterized the attempts of physical chemists to discuss the behavior of the so-called "normal" and "associated" liquids. This confusion was all the more inevitable because it is now obvious that the normal or unassociated liquid lies intermediate in its properties between the two types of associated liquids.

It should be mentioned at this point that a third type of association through hydrogen, namely, intramolecular association or chelation, may occur, which has the result of producing a "normal" behavior in a molecule which would otherwise show abnormal behavior as a liquid and solvent. This type of association has been much studied by Sidgwick[5] and his collaborators. The conditions under which it occurs are well defined, and one of the important ones is apparently the possibility of two configurations of the molecule with respect to the hydrogen, thus giving an opportunity for resonance.

All of the types of association of interest in the liquid state appear to involve hydrogen bonding. The formation of polymers depends upon potential cross linkages or additional valences between

(5) N. V. Sidgwick, "The Electronic Theory of Valency," Oxford University Press, 1929.

molecules. In the typical organic polymers these cross linkages are strong and irreversible and lead to the formation of inert solids. Because of the low energies of activation and dissociation of the hydrogen bond, the polymers formed may be liquid or if the unit molecules are large, substances capable of colloidal dispersion as in the case of the proteins may be formed.

While it is possible to determine from a study of the physical data the type of association present, it is not possible to explain or predict such association without more direct information as to the molecular structure. The first important advance in this type of study was made by Pauling and Brockway[6] when they confirmed the prediction of Latimer and Rodebush, showing by means of electron diffraction that the dimer of formic acid has a symmetrical ring structure involving both carboxyls. The methods of electron diffraction do not, of course, lend themselves to the study of solutions and a further great advance was made when Wulf[7] and his collaborators began the study of the infrared absorption of organic substances in an inert solvent. They noted the absence of the second harmonic in the case where hydrogen bonding, particularly of the chelated type, was to be anticipated.

After the work of Wulf and his collaborators came to our attention, experiments were begun in this Laboratory[8] upon the infrared absorption of certain types of compounds in which hydrogen bonding was present. We investigated a large number of compounds in the region where the fundamental of hydroxyl was to be expected and found the very important generalization that the formation of a hydrogen bond is accompanied by a very considerable increase in the absorption and a marked change in frequency, the shift being in the direction of longer wave lengths. This work has been amply confirmed by other investigators working independently,[9] at least in the case of polymerization. So far as we know, we were the first to call attention to the shift in absorption accompanying the formation of an intramolecular hydrogen bond. In previous publications we have reported the investigation of the shifts in the fundamental frequency of a considerable variety of compounds, following more or less the lines laid down by Wulf and his collaborators in their investigation of the harmonic absorption. In the present paper we wish to report results which have to do mainly with association and which include the formation of hydrogen bonds where the hydrogen is linked to atoms other than oxygen and, in particular, the formation of hydrogen bonds between different types of molecules, a subject which is of the greatest interest and which has not been studied to any considerable extent.

Hydrogen bonds are known to be formed readily when hydrogen is attached to nitrogen, oxygen and fluorine. Certain types of compounds such as ether hydrochloride and chloroform–ether suggest that carbon and the other halogens should be included in the list. It is certain that for bond formation the hydrogen must be active to some degree, which means, of course, ionizable in the proper solvents. Hydrogen attached to carbon in an ordinary hydrocarbon is incapable of forming a bond; likewise apparently there is little tendency for the hydrogen of ammonia of the amines to form bonds. All the physical properties of the amines indicate[10] the lack of association and our infrared studies do not indicate any bonding in the case of aniline for example. On the other hand, the hydrogen of chloroform shows a strong tendency toward bonding, even with the oxygen of ether. The question as to whether the hydrogen of chloroform is more "active" than the hydrogen of an amine, such as aniline, is one to which it is difficult to make an answer. Data upon the ionization constants must be applied in non-polar solvents with a good deal of caution. Certainly our conclusions show that the hydrogen of chloroform and all the hydrogens which are more active will form hydrogen bonds either with another molecule of the same kind or with one which is perhaps more basic. There seems to be no evidence, for example, that hydrogen chloride is associated but the ether hydrochloride complex is a clear case of hydrogen bonding. On the other hand, moderately acidic substances such as the amides or carboxylic acids show a very strong tendency toward association.

One important generalization that has been suggested by Venkateswaran[11] from a study of the Raman and infrared spectra appears to be con-

firmed here. When a bond is formed, the more acidic the hydrogen, the greater the shift in frequency toward the longer wave length and the broader the resulting absorption band. The foregoing statement applies to the stretching frequency. Our evidence on the bending frequency is limited to the case of chloroform, and since there is possibly some uncertainty concerning it, we will discuss the behavior of the bending frequency in connection with the experimental work on chloroform compounds in a subsequent paper.

The question as to the strength of the bond formed between various types of molecules is one upon which we have only qualitative evidence. Qualitatively, the bond strengths appear to be all of the same order of magnitude. This can scarcely be true, but a study of the heats of mixing under various conditions would be very desirable.

In the foregoing discussion we have tacitly assumed that such a thing as hydrogen "bond" exists and have ignored the fact that some believe it to be nothing more than an attraction due to dipole interaction. One might evade the argument by simply stating that the association takes place through hydrogen without further implication as to the nature of the interaction. We believe, however, that the evidence warrants a much more detailed picture. The characteristic effect of hydrogen bonding on the fundamental in infrared absorption is the increase in absorption coefficient and the shift of frequency to longer wave length. The increase in absorption coefficient is presumably due to an increase in dipole moment. All of these effects would be accounted for by an increase in the internuclear distance of the hydrogen from its original partner accompanied by a transformation toward the ionic type of bonding. In the case where the hydrogen is not active as in chloroform this transformation is small but in the case of the carboxylic acids the result is the formation of a symmetrical eight-membered ring which can hardly be considered as anything short of a chemical reaction. One may say therefore that all degrees of interaction are to be found but that in general the interaction is more than could be predicted from a simple dipole theory. It must be remembered that the hydrogen bond is formed in non-polar solvents and in the vapor state so that no question of ionization is involved.[12]

One may say, therefore, that the formation of a hydrogen bond involves a definite alteration in molecular structure which is scarcely envisaged in the term dipole interaction; this structure is sufficiently rigid to justify the use of the term bond. The fact that the bond is easily broken does not invalidate the use of the term.

The colligative and other physical properties of the molecule still furnish the best evidence as to the type of association. For example, when dimers are formed the dipole moments tend toward zero while in the case of polymers the polarization is increased. Thus alcohol has a much higher dielectric constant than acetic acid. One may hope, however, that when sufficient data have been obtained on the infrared absorption, vibrational analysis will give a definite picture of the structure in all types of association.

In this paper we shall report the results obtained on the carboxylic acids. Hydrogen bonding between other types of molecules will be discussed in subsequent papers.

Experimental

The infrared spectrograph and other equipment has been described briefly in a previous paper.[8] In the spectrograph a 75-mm. rock salt prism is used with a Littrow mounting. The source of radiation is a 220-volt Nernst glower, and the deflections are read directly from a high sensitivity galvanometer. The resolving power and accuracy of calibration are such as to make all details shown in the accompanying absorption curves significant and reproducible.

In the region in which these results were obtained thin glass proved satisfactory for all windows. The results reported here are mainly for solutions, carbon tetrachloride being the solvent. For absorption in solution the molal absorption coefficient K is calculated, as defined arbitrarily by the expression

$$K = \frac{1}{cd} \log \frac{I_0}{I}$$

Here I is the intensity (as measured by galvanometer deflection) through the solution and I_0 the intensity through an equal thickness of pure solvent; c is the concentration expressed as moles per liter of solution and d is the cell length. Because of insufficient resolving power and other factors

---

[12] Scatchard and Raymond [THIS JOURNAL, **60**, 1278 (1938)] recently have discussed negative evidence for hydrogen bond formation in chloroform–alcohol solutions. The evidence here is unquestionably that the association of the alcohol is so strong that there is no tendency toward the formation of an intermolecular compound with chloroform. This is because the hydrogen of the alcohol is more active than the hydrogen of the chloroform; *cf.* the article by Zellhoefer, Copley and Marvel referred to above.

K is not independent of the product $c \times d$. In order to make comparisons at different concentrations it is necessary therefore to maintain the product $c \times d$ constant; this was accomplished by using cells of various lengths. When $c \times d$ is maintained constant, the value of K for a static group such as C–H was found to be quite independent of concentration.

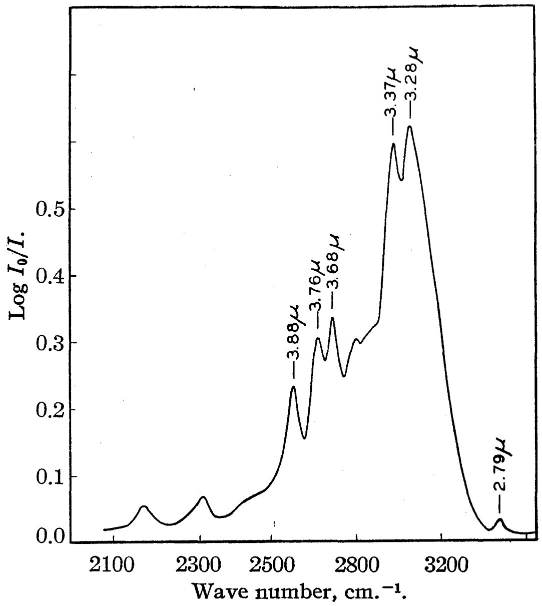

Fig. 1.—Acetic acid vapor: air saturated with acetic acid at 21° in 10.18 cm. cell.

The utmost care was exercised in the preparation and purification of materials, including the solvent material. Benzoic acid was purified by recrystallization from alcohol–water solutions. Acetic acid, benzoyl chloride and trichloroacetic acid were purified by distillation at low pressures.

The deuterobenzoic acid was prepared by heating benzoyl chloride with a fivefold excess of 99.6% deuterium oxide in a sealed tube at 100° for two hours. The deuterium chloride and excess deuterium oxide were removed by distillation at low pressures. The carbon tetrachloride used as solvent was dried over phosphorus pentoxide. After the absorption curve of the deuterated acid was obtained the acid was reconverted to ordinary benzoic acid by exposure to moist air. The absorption curve was identical with ordinary benzoic acid.

The association of acetic acid in the vapor has been recognized for a very long time and many references could be cited to the effect that a dimer is formed. The first direct experimental evidence as to the structure of this dimer was obtained by Pauling and Brockway, as cited above. Electron diffraction does not, however, give information about the hydrogen atoms. Studies have also been made of the Raman spectrum but the method *par excellence* for the observation of the behavior of hydrogen in molecules is infrared spectroscopy.

The infrared absorption spectra of the carboxylic acids have been investigated by a number of workers in recent years, particularly in the vapor. We shall refer here only to work dealing with the absorption due to hydrogen.

Gillette and Daniels[13] observed a complicated spectrum in the region of 3.0 μ which they attributed to C–H and to overtone and combination frequencies. Badger and Bauer[14] have studied the infrared spectrum of acetic acid by photographic methods and have observed what they believe to be shifts in the second overtone frequency which they believe to be due to hydrogen bonding. Davies and Sutherland[15] have studied the effect of temperature on the infrared absorption of solutions of the carboxylic acids. They find that increasing temperature increases the monomeric O–H frequency and report a broad "association" band in trichloroacetic acid at 3.3 μ. Herman and Hofstadter[16] have published a curve showing the infrared absorption of deuteroacetic acid, CH_3COOD, and have suggested that the absorption band at 4.3 μ is due to deuterium bonding. Only a very weak C–H absorption was observed.

In the accompanying curves are shown the infrared absorption in the region of the C–H and O–H fundamental for acetic acid, trichloroacetic acid, benzoic acid and deuterobenzoic acid. One curve is shown for acetic acid vapor. Comparison with the curve for acetic acid in carbon tetrachloride solution shows that the absorption is the same in solution except that there is a shift of 0.01–0.02 μ toward longer wave lengths in solution. We may therefore assume that any conclusions drawn from our observations in solution apply to the vapor of acetic acid.

An examination of the curves in Fig. 2 shows that acetic acid is slightly dissociated into single

molecules at 0.0005 *M* solution; much less so in 0.008 *M* solution. The unbounded hydroxyl band is at 2.82 μ; the slight absorption at 2.67 μ being due to water. A study of Figs. 3 and 4 shows that the absorption due to C–H must be very slight. This is a point about which Daniels and Gillette were uncertain but it is clear that both benzoyl chloride and deuterobenzoic acid have very little absorption in this region and some of the absorption in the case of the deuterobenzoic acid is undoubtedly due to the presence of a small amount ($\sim$1%) of ordinary benzoic acid. It will be further noted that the absorption of trichloroacetic is very similar to that for acetic and benzoic acids.

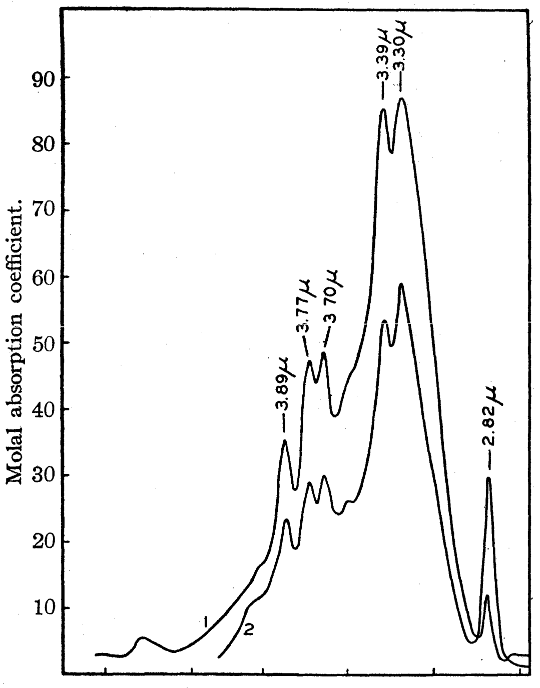

Fig. 2.—Acetic acid: (1) 0.008 *M* in 0.640 cm. cell; (2) 0.0005 *M* in 10.18 cm. cell.

One may therefore conclude that the strong absorption in the neighborhood of 3.3 μ is due mainly to the hydrogen bonding as Herman and Hofstadter suggest. In deuterobenzoic acid the absorption band is narrower and apparently simpler in structure, although the shift in the principal peak is just what one would calculate for deuterium substitution.

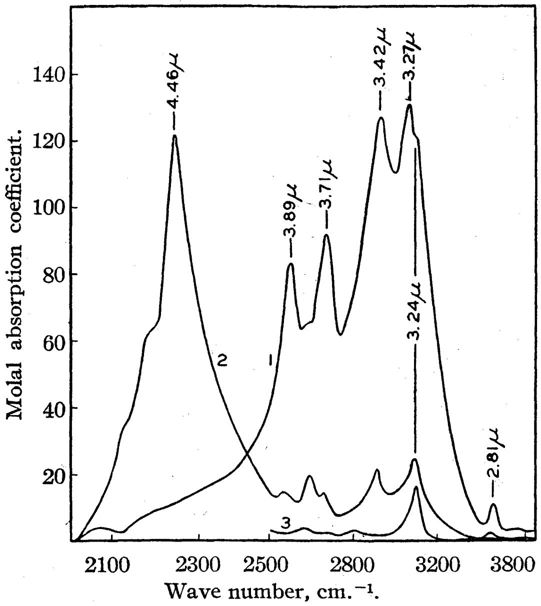

Fig. 3.—(1) Benzoic acid, 0.008 M solution in 0.640 cm. cell; (2) deuterobenzoic acid, 0.008 *M* solution in 0.640 cm. cell; (3) benzoyl chloride, 0.008 *M* solution in 0.640 cm. cell.

It is evident that the absorption band for the acids contains two or more pairs of doublets. The exact identification of these doublets must await the vibrational analysis of the carboxylic dimer. This has been undertaken by Dr. F. T. Wall of this Laboratory. Meanwhile one may speculate as to the probable cause of the doublet

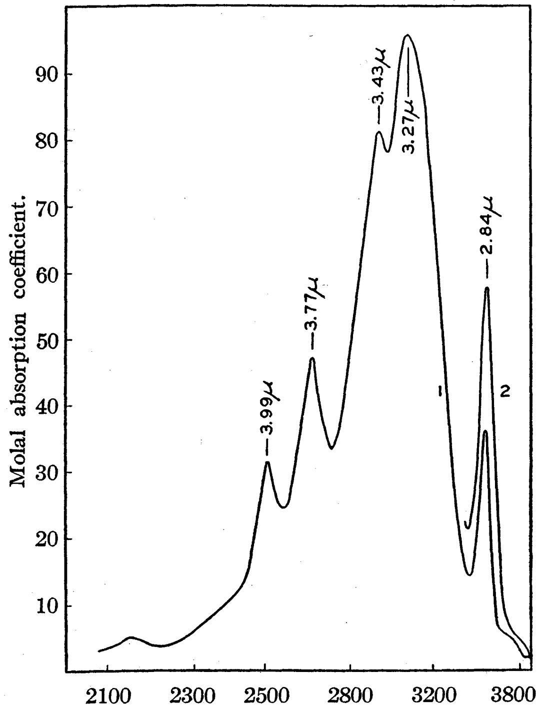

Fig. 4.—Trichloroacetic acid: (1) 0.008 *M* in 0.640 cm. cell; (2) 0.0005 *M* in 10.18 cm. cell.

structure observed. If we assume that the hydrogen atoms are placed unsymmetrically in the eight-membered ring formed by the two carboxyl groups, *i. e.*, each hydrogen being nearer to the oxygen to which it was originally attached, then there are two modes of vibration involving the stretching of the hydrogen bonds which are active in infrared absorption. Each vibration is antisymmetric with respect to a center of symmetry but they differ in the relative motions of the oxygen atoms on either side of the hydrogen atoms. These two frequencies might be guessed to differ by the separation of the two pairs of doublets, *viz.*, 50 cm.$^{-1}$. Because of the fact that there are alternative positions for each hydrogen and consequently, a double minimum in the potential energy curve, the doublets themselves might be expected. Their separation varies from 10 to 20 cm.$^{-1}$. This is, of course, to say nothing of the possibility of resonance between the O–H and C–H vibrations which have nearly the same frequency. Since the C–H absorption is small this effect is probably unimportant although the C–H absorption might be considerably increased by the resonance itself.[17]

Some plausibility is lent to the foregoing explanations by the much simpler structure observed in the absorption peak for deuterobenzoic acid. Here the last effect is absent and because of the greater mass of the deuterium atom the doublet separation would be too small for resolution. There would remain only the two modes of vibration differing markedly in absorption coefficients and these appear to be present.

It has been noted by various authors that formic acid in the liquid state has a dielectric constant some ten times that of liquid acetic acid. Because of the difficulty of purification no studies have been made upon formic acid but there can be little doubt that in the liquid state the dimers are transformed into higher polymers perhaps through the hydrogen attached to the carbon. In a subsequent paper this possibility will be discussed again in connection with formamide. The high dielectric constant which results from polymerization such as occurs in formamide probably offers a clue to the explanation of the greatly reduced solubility of chloroform in this solvent.

The authors wish to acknowledge their indebtedness to the Rockefeller Foundation for funds which enabled them to conduct this research.

Summary

The general character of the infrared absorption spectra indicative of hydrogen bonding is discussed. Curves are shown for the absorption of the active or bonding hydrogen in acetic, benzoic and deuterobenzoic acids under various conditions. The generalization of Venkateswaran in regard to the shift of the hydroxyl frequency is confirmed and some suggestions are made to explain the complex absorption characteristic of association in the carboxylic acids.

URBANA, ILLINOIS RECEIVED JUNE 30, 1938

---

[17] In a previous note [THIS JOURNAL, **59**, 176 (1937)] the authors reported on the lack of evidence for the enolization of dibenzoylmethane. This molecule shows absorption resembling that of the carboxylic acids and it is possible to write a hydrogen bonded structure for the enolic form that resembles one-half of the dimeric ring of the acids. The matter therefore requires further investigation.

The Negative Temperature Coefficient in the Rate of Propane Oxidation

BY ROBERT N. PEASE

In the early work[1] on the slow combustion of propane and the butanes, it was noted that under certain conditions the rate of oxidation decreased markedly with increasing temperature, although eventually (at a higher temperature) explosion occurred. Similar observations have since been made by Beatty and Edgar[2] on heptane–air mixtures, by Aivazov and Neumann[3] on pentane–oxygen mixtures, and by Newitt[4] on propane–oxygen mixtures.

The beginnings of an explanation of this anomalous behavior follow from the latter investigation. It had been found by Townend[5] that mixtures of air with vapors of hydrocarbons, alcohols, or aldehydes show, in addition to a "true ignition" region (higher pressures and temperatures), a region of limited explosibility giving rise to so-

---

[4] Newitt, *et al.*, *J. Chem. Soc.*, 1656, 1665, 1669 (1937).

[5] Townend, *Chem. Rev.*, **21**, 259 (1937).

called "cool-flames." In a pressure–temperature plot, the latter region appears as a tongue or peninsula pointed toward lower pressures over a limited temperature range in the neighborhood of 300°.

Now it so happens that much of the work which has been done on the oxidation of hydrocarbons apparently has fallen in or near the region of cool flames. Hence the anomalies which have appeared in such work (including the negative temperature coefficient) are in effect incidental to the anomaly of the limited cool-flame region itself.

With the above in mind, Newitt investigated in some detail the characteristics of the cool-flame region for propane–oxygen mixtures. He found among other effects that at temperatures immediately above the cool-flame limit (∽350°), the rate of reaction dropped abruptly to a fairly flat minimum (∽425°) and then rose abruptly to the ignition point (∽450°). The negative temperature coefficient was thus identified with the crossing of the cool-flame limit on the high temperature side.

The region of negative temperature coefficient is more accurately described as a region of minimum rate, bounded at lower and higher temperatures by explosion limits. It would thus appear to be a region of transition from one to another mechanism of oxidation. One should then expect a corresponding change in the kinetics of the process, and this can in fact be observed.

The author[6] has reported measurements of the rate of propane oxidation at a temperature (270°) well below the lower cool-flame limit. With an uncoated[7] Pyrex bulb, it was found that the maximum rate was nearly independent of the oxygen concentration but varied with a power of the propane concentration between one and two, as shown in Table I.

TABLE I

RATE OF PROPANE OXIDATION AT 270° (5 MM. CH_3CHO ADDED)

Initial pressure, mm. C_3H_8	O_2	N_2	Total pressure change, mm.	$[dP/dt]_{(max.)}$ mm./min.
199	202	.	61	9.93
212	197	202	61	11.03
205	384	.	119	10.62
300	301	.	92	23.5
408	202	.	65	34.8

On the other hand, Newitt found that above the cool-flame limit (but below the ignition point), the equimolecular mixture is the most reactive (total pressure constant at 360 mm.; temp. 408°) *i. e.*, the rate is roughly proportional to the product of propane and oxygen concentrations.

In order to make sure that this difference is real, the author has repeated Newitt's experiments under somewhat different conditions as follows.

A reaction bulb like that used for the low temperature experiments was prepared, and washed out with nitric acid and then with distilled water. This was mounted in an electric heater and connected with sources of tank gases, with a manometer, and with vacuum pumps. A series of runs was then carried out at 400° with results as shown in Table II.

It is clear from these results that the rate now depends on *both* propane and oxygen concentrations, the powers being rather higher than the first. There is thus excellent evidence from the kinetics of the reaction that there are two mechanisms of oxidation, one predominating at low temperatures (and leading to cool-flames under optimum conditions), and the other predominating above the cool-flame region and leading to true ignition.

TABLE II

RATE OF PROPANE OXIDATION AT 400°

Initial pressure, mm. C_3H_8	O_2	N_2	Total pressure change, mm.	$[dP/dt]_{max.}$ mm./min.
105	103	.	59	15.9
101	103	104	60	15.6
207	101	.	67	42.
102	203	.	115	51.
102	103	.	59	14.2

In order the better to visualize these two alternative reactions, a series of runs was made at 10° intervals between 300 and 430° (Fig. 1). These runs were made with 100 mm. each of propane and oxygen. With such a mixture, one would (according to Newitt's results) just cut the tip of the cool-flame peninsula at about 290–320°. As, however, Newitt worked with a reaction vessel 5.5. cm. in diameter, whereas the one here used was 2.0 cm. in diameter, it is probable that the experiments were outside the cool-flame region entirely. Certainly there was nothing in the pressure records to indicate the occurrence of cool-flames.

The procedure was to measure rates at 20° intervals from 300 to 420°, then to return to 310° and again proceed upward (to 430°) by 20° intervals. The second set of measurements are lower

---

[6] Pease, *Chem. Rev.*, **21**, 279 (1937).

[7] That is, *not* treated with potassium chloride solution.

than the first but the general form of the curve is evident (Fig. 1.).

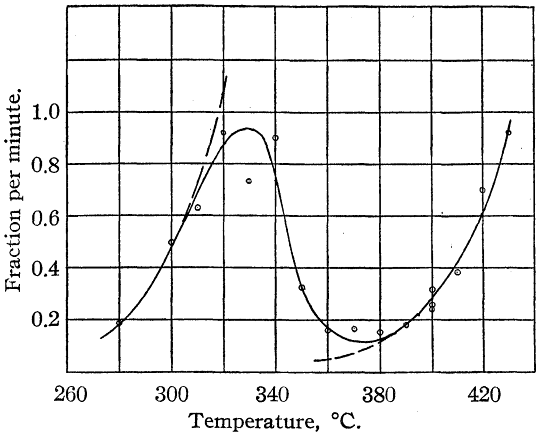

Fig. 1.—Variation of rate of oxidation of propane with temperature for 1:1 mixture at 200 mm. The rates are maximum rates corresponding to the inflection points of the pressure–time curves.

Individual rate curves were of the familiar S-shaped type, with an induction period which decreased regularly with increasing temperature. The values of the rate given are the maximum rates as read from the curves.

This maximum rate rises to an upper level at about 340°, and then drops to a fairly flat minimum. Subsequently, it rises again, and would terminate in true ignition.

Two curves have been sketched in Fig. 1 to emphasize the existence of two mechanisms of oxidation. These curves were drawn on the basis of points read from a log rate–reciprocal temperature plot. The one for lower temperatures corresponds to an activation energy of 29,000 cal.; that for the higher temperature range corresponds to an activation energy of 38,000 cal.

Between these two curves lies the transition region within which the rate passes through a minimum as the temperature increases. If we assume with von Elbe and Lewis[8] that the low-temperature reaction at least is of the branched-chain type, the rather sharp suppression of reaction as temperature rises may be attributed to suppression of branching. The subsequent development of reaction at higher temperatures would then represent the same or a new reaction proceeding by an unbranched chain. In bare outline, one might write

$$\text{Intermediate} \begin{cases} \nearrow \text{Branched chain} \\ \searrow \text{Unbranched chain} \end{cases}$$

the balance between the two alternatives being determined by the temperature, other things being equal. The experimental work here reported appears to be in general accord with the speculations of von Elbe and Lewis.

Summary

A further study of the negative temperature coefficient in the rate of oxidation of propane has been carried out. It is shown that the rate passes through a minimum at 360–380° (100 mm. of each gas). At low temperatures, the steady-state rate is independent of oxygen concentration (uncoated reaction bulb), whereas at higher temperatures it depends upon the concentrations of both gases, the powers being between one and two.

It is suggested that a low-temperature branched-chain reaction is suppressed in the transition region and gives place to an unbranched chain.

The Structure of the Insulin Molecule

BY D. M. WRINCH AND IRVING LANGMUIR

The cyclol hypothesis has yielded a cage structure C_2 for the insulin molecule.[1,2,3] This structure has a skeleton framework lying on the surface of a truncated tetrahedron (hereafter called the C_2 polyhedron) whose faces are parallel to those of a regular octahedron having 6 corners S, as shown in Fig. 1a. The arrangement of the carbon and nitrogen atoms in the skeleton (cyclol fabric) which forms two of the faces of the C_2 polyhedron is shown in Fig. 1b.

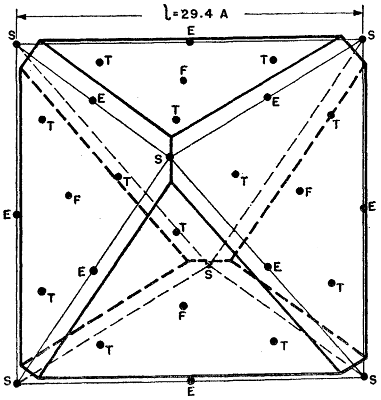

Fig. 1a.—The C_2 truncated tetrahedron (heavy lines) and the C_2 octahedron (light lines), showing on the front half the centers of lacunae at the midpoints of edges E, the centers of faces F and at points T midway between F and S.

The dimensions are determined by a, the only metrical parameter of the cyclol structure, which, being a mean between the C–C and the C–N bond lengths, was taken as $a = 1.50$ Å. The shortest distance between the centers of lacunae in the cyclol fabric is $4\sqrt{2a} = 8.48$ Å.; the length of the sides of the triangular faces of the C_2 polyhedron is $7\sqrt{6a} = 25.7$ Å.; the length of the slits which form the 3 short sides of the hexagonal faces is $\sqrt{6a} = 3.68$ Å., and the distance between the parallel opposite faces of the polyhedron is $16a = 24.0$ Å.

For many calculations we shall find it convenient to replace the C_2 polyhedron by an equivalent regular octahedron which we shall call the C_2 octahedron whose side length is $l = 8\sqrt{6a} = 29.4$ Å. This size is so chosen that the distance between the opposite faces is the same ($16a = 24.0$ Å.) as the corresponding distance in the C_2 polyhedron.

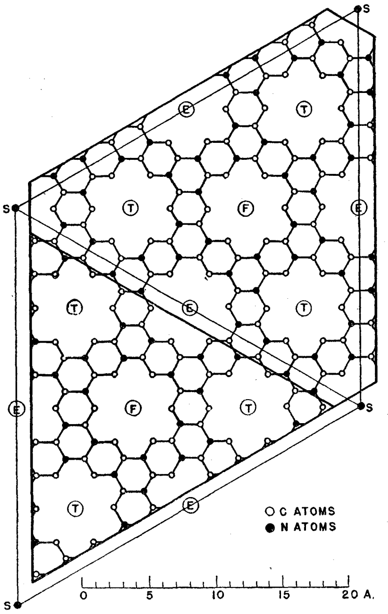

Fig. 1b.—The C, N skeleton of the cyclol fabric on two faces of the C_2 polyhedron, whose boundaries are given by heavy lines. The light lines are the projections of the boundaries of the faces of the C_2 octahedron which, after folding, lie 1 Å. above or below the faces of the C_2 polyhedron.

The faces and corners of the C_2 octahedron are shown in Figs. 1a and 1b. The distance SE between a corner S of a triangular face and E the center of an opposite side of the same triangle is $12\sqrt{2a} = 25.5$ Å., which is three times the shortest distance between lacunae. Thus there are lacunae at E, the midpoints of edges; at F, the centers of faces; and at T, the midpoints between F and S.

The faces of the C_2 polyhedron and the corresponding faces of the C_2 octahedron are parallel and are separated by the distance $(2/3)a = 1.0$ Å.; four of the faces of the polyhedron lie within and the other four lie outside the octahedron. The surface area and volume of the C_2 polyhedron are,

respectively, $762\sqrt{3}a^2 = 2970$ Å.^{2} and $2003\sqrt{3}a^3 = 11{,}710$ Å.^{3}, which differ very little from the corresponding values for the C_2 octahedron $768\sqrt{3}a^2 = 2993$ Å.^{2} and $2048\sqrt{3}a^3 = 11{,}970$ Å.^{3}, respectively.

The final test for the correctness of a structure of molecules which form a crystal lattice is that it should be in agreement with deductions properly made from X-ray data. It was found[3] that the C_2 molecules, each having a trigonal axis parallel to the trigonal axis of the insulin lattice, fit the rhombohedral cell of the insulin lattice given by an X-ray analysis.[4] They can be arranged with any orientation δ in the corresponding hexagonal cell, and this single parameter was necessarily left undetermined until further information should be obtained from X-ray studies.

The necessary data are now available through Crowfoot's recent measurements[5] of insulin crystals (59 terms). Her data were summarized in five Patterson–Harker diagrams, which are reproduced herewith[6] in Figs. 1c to 5.

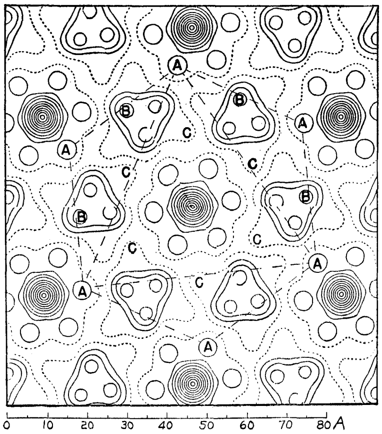

Fig. 1c.—P(xyo) projection of Patterson–Harker map for insulin. Origin in center.

Diagrams of this kind must be sharply distinguished from electron density maps which have played so large a part in establishing the structures of molecules containing relatively few atoms. The Patterson–Harker maps represent not distributions of matter in space but of vectors erected at a common point or origin, each vector giving in magnitude and direction the distance between two atoms in the original stucture. The Patterson–Harker diagrams obtained from the X-ray data are essentially sections or projections of a three-dimensional map showing the distribution of these vectors in space. They constitute an intermediate step between the X-ray photograph and the determination of the molecular structure. Whereas the electron density maps make it possible to confirm a structure directly, the Patterson–Harker diagrams need to be interpreted before they become of use.

In the case of the insulin lattice, Crowfoot has performed the transition from the X-ray pictures to the Patterson–Harker diagrams but has not accomplished their interpretation.

In a recent preliminary investigation,[7] however, it has been found that all the 18 peaks per molecule on Crowfoot's xy-plane projection (A, B, and C in Fig. 1c) lie in the positions to be expected if the insulin molecule is characterized by regions of high electron density at the 6 corners (S) of the C_2 octahedron shown in Fig. 1a.

Thus, taking in turn each of the 6 corners of the C_2 octahedron of side l, and drawing lines to the other 5 corners, we obtain 30 vectors. Erecting these from a common origin, we find that 6 give points at the corners of a similarly oriented octahedron of side $2l = 58.8$ Å. and the other 24 give two points at each of the midpoints of the 12 edges of the same octahedron. These points thus constitute the Patterson–Harker diagram of the S points of the C_2 octahedron.

If we project these 30 points upon a plane parallel to any face of the octahedron (the xy-plane), we find that 6 lie at the corners of a regular hexagon of side length $16\sqrt{2}\,a = 33.9$ Å., 2 at each midpoint of a side (lines connecting *adjacent* corners) and 2 at each midpoint of lines connecting *alternate* corners. A hexagon of this size has been drawn in Fig. 1c having its center at the origin with its axes turned through 6° corresponding to the previously undetermined[3] angle δ. The points, designated A, B, and C by Crowfoot, in Fig. 1c lie in positions which correspond to the projections of the Patterson–Harker diagram of the slits S of the C_2 molecule.

The Patterson–Harker diagram given by points

---

(4) D. Crowfoot, *Nature*, **135**, 591 (1935).

(5) D. Crowfoot, *Proc. Roy. Soc.* (London), **164A**, 580 (1938).

(6) The figures given by Crowfoot map the contours within a single rhombohedral cell. Since we wish to consider the molecular rather than the crystal structure, we have fitted together four photographic enlargements of each of Crowfoot's figures and have so obtained maps of the whole neighborhood around the central molecule. The lettering, the scales, and the polygons corresponding to the projections of the Patterson–Harker octahedron, of side $2l$, were drawn in on these composite enlargements and they were rephotographed for the figures of this paper.

(7) D. M. Wrinch, THIS JOURNAL, **60**, 2005 (1938); *Science*, **88**, 148 (1938).

which lie on or within the C_2 octahedron of side l thus consists of points on or within a similarly oriented octahedron (the PH octahedron) of side $2\,l$. In Fig. 2 the cross section of the PH octahedron, through its center and parallel to the xy-plane, has been drawn about the origin. This hexagon is obtained by joining the midpoints of adjacent sides of the hexagon in Fig. 1c. In Figs. 4 and 5 the projections of the edges of the PH octahedron on to the plane of the section are shown, neglecting the effect of the slight rotation of the PH octahedron through $\delta = 6°$.

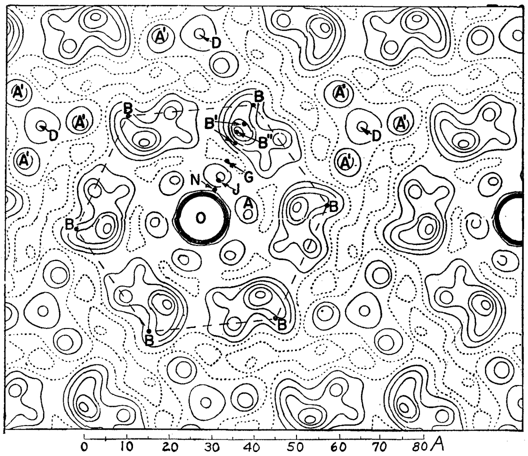

Fig. 2.—P(xyo) section of Patterson–Harker map for insulin.

Crowfoot used rectangular coördinates x, y, z to describe the position of peaks, and we shall describe the sections cut through the Patterson–Harker maps in this way; but, because of the trigonal symmetry of the lattice and molecule, we prefer for other purposes to use polar coördinates z, θ, ρ where θ is $\tan^{-1} y/x$ and ρ is the distance from the z-axis.

We shall use M to designate molecular centers: M_0 for that at the origin, M' for the next one along the z-axis at $z = c = 30.9$ Å., and M_1, M_2, . . . M_6 for the 6 nearest neighbors near the x, y plane in the positions indicated in Fig. 3. Thus M_1 and M_6 are located, respectively, at $z = \pm 10.3$ Å., $\theta = \pm 30°$, $\rho = 43.2$ Å., while the positions of the others are obtained by successive rotations through 120°. The distance M_1 to M_3 is 74.8 Å.

The agreement we have noted between the projection of Fig. 1c and the projection of the PH octahedron suggests that the A, B, and C peaks represent the S points of the C_2 octahedron. However, the points on the PH octahedron are not all in one plane. The A and C points lie at $z = \pm 24$ and the B points at $z = 0$. The calculated coördinates are given in Table II.

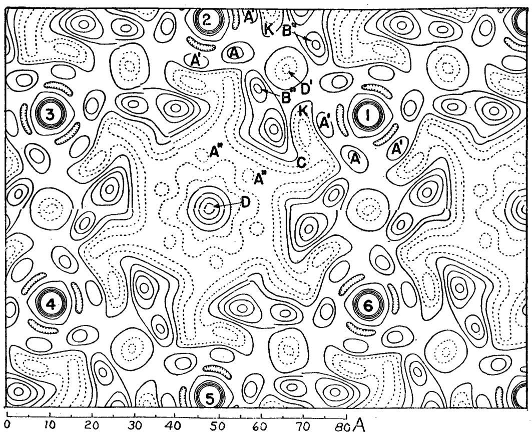

Fig. 3.—P($xy^1/_2c$) section of Patterson–Harker map.

It is thus important to examine the sections of Figs. 2–5 to see if the maxima whose projections give the A, B, and C points in Fig. 1c really lie at the proper values of z.

We are handicapped in this study by the fact that the sections of Figs. 4 and 5 are taken at $\theta = 0$ and 90°, while the maxima are to be expected at 6 and 96°. Figure 2 is a section which, for different molecules, corresponds to values of $z = 0$, and ± 10.3. Similarly, Fig. 3 gives $z = \pm 5.2$, and 15.5. None of these sections comes at $z = 24$, where the A or C peaks lie. However, the section at $z = 25.8$ is close enough to locate the peaks reasonably well.

Referring to Fig. 5, we see in fact that the A peak for M_0 lies close to the upper M_2 molecule at $z = +24$ and at a value of ρ only a few per cent. less than $\rho = 33.9$ which corresponds to the calculated PH octahedron (see Table II).

In Fig. 4 at $z = +3$ Å., $\theta = 0°$, $\rho = 10$ Å., there is a well-defined peak which we identify as the A peak belonging to M_1 (which lies at $z = -20.6$). With respect to M_1 this peak lies at $z = +23.6$. From Figs. 1c and 2 we see that its position with respect to M_1 corresponds to $\theta = 216°$, for which z should be $+24$.

The A peaks appear in their proper positions in Figs. 1c, 2, 3, 4 and 5, and these sections all show that the A peaks are comparatively isolated. Figure 4 shows, however, that in one direction, parallel to the z-axis, the A maximum is connected through a point J to another maximum A′, which, although really a separate peak, contributes to the

A peak seen in the projection of Fig. 1c. We shall discuss the origin of J and A′ later.

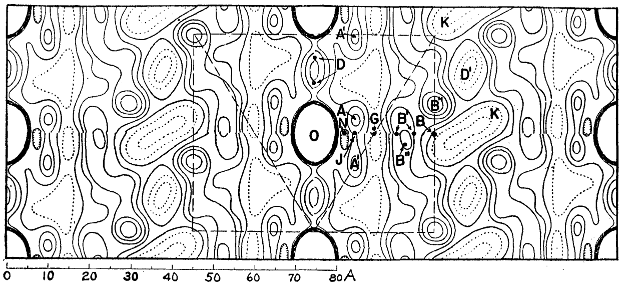

Fig. 4.—P(xoz) section of Patterson–Harker map. $\theta = 0°$.

The data prove that the A peaks lie alternately above and below the x, y plane at distances ± 24 Å., which is the distance between opposite parallel faces of the C_2 octahedron. We note from the section $\theta = 90°$ (Fig. 5) that the *molecule* at the origin must have one of its slits S at $\theta = 96°$, $z = +12$ Å., but there is no slit at -12 Å. for this value of θ. Since there is only one molecule in each rhombohedral cell, we conclude that all the molecules in the crystal lattice given by these diagrams are so oriented that an apex of the triangle forming the upper face of the C_2 octahedron is located at $\theta = 96$ but none at 276°.

The points in the PH octahedron which correspond to the B peaks lie at $z = 0$ on the corners of the hexagon shown in Fig. 2. There is, in fact, a prominent extension of the contours toward this point B, but the presence of other maxima B′ and B″ prevents us from estimating the exact contribution of B. We shall discuss the factors that cause these complications in this region.

The calculated coördinates for the C points in Table II give values of θ which are the same as for A, but the values of ρ are half as great, and z is of opposite sign although it has the same magnitude (24 Å.). Examination of Fig. 5 shows a maximum at $z = -27$, $\theta = 90°$, $\rho = 20$, not far from the calculated position of C at $z = -24$, $\theta = 96°$, $\rho = 17$. The agreement might be much better if the section had been taken at $\theta = 96°$.

Although the A, B, and C peaks in all the sections agree satisfactorily with the positions calculated from the slits of the C_2 octahedron, it will be recognized that the 6 slits provide a very incomplete description of the C_2 structure. It is reasonable to hope that the 62 additional maxima and minima per molecule listed in Table II, which are seen only in the sections of Figs. 2–5, correspond to other characteristic features of the C_2 molecule, such as the polyhedral nature of the skeleton. We may also expect to detect effects due to the 44 hexagonal lacunae in the positions shown in Figs. 1a and 1b by F, T, and E.

Density Deviations in Insulin.—Each molecule in the insulin crystal contains several thousand atoms of an average atomic weight of about 7. The heaviest atoms are 3 zinc atoms per molecule, and there are about 36 sulfur atoms. With the exception of these heavy atoms and a few groups of atoms having slightly higher or lower density than the average, we may look upon the volume distribution of electrons as being substantially uniform or at least as varying continuously in such a way as to show no fine structure. A slowly varying electron distribution would contribute to the general scattered X-ray radiation, but its effects would be eliminated automatically when the Patterson–Harker analysis is made by taking only photographic lines whose intensity is estimated visually. The finer structure given by the lines, which is the basis of the Patterson–Harker diagrams, can thus be regarded as representing positive and negative deviations from this assumed smooth volume distribution of electrons.

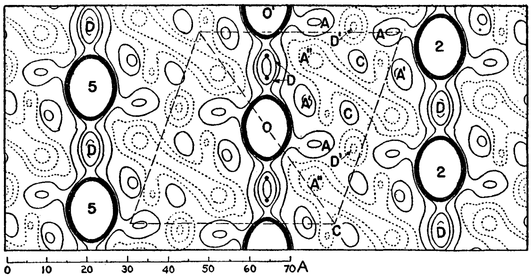

Fig. 5.—P(oyz) section of Patterson–Harker map. $\theta = 90°$.

In the protein molecule we may roughly assume 0.50 electron per unit of molecular weight, whereas in a water molecule we have 0.56 electron per unit. Considering that the density of the insulin crystal as a whole is about 1.32 and that of water is 1.0, it appears that water has an electron density about 16% lower than that of the average of the protein molecule. Thus low density may be expected in regions where the water content is high or where there are actual voids. Similarly, side chains comprising aliphatic or aromatic hydrocarbons would also correspond to minima, while the groups containing many oxygen or

TABLE I

DENSITY DEVIATIONS IN THE INSULIN LATTICE

especially sulfur atoms correspond to maxima.

In Table I we have listed the points associated with the C_2 molecule where density deviations are to be expected. Thus, the center O of the molecule is probably a region of negative density deviation $-o$, since the side chains within the cage are not long enough to reach the center, a distance of 12 Å. from the surface of the C_2 octahedron. To the slits S we assign an intensity $+s$, since even apart from side chains the atoms forming the skeleton are crowded at these points. To the lacunae F, T, and E, presumably regions of negative deviations, intensities $-f$, $-t$, and $-e$ are assigned. Furthermore, we note from symmetry considerations, and for reasons already given,[3] that the zinc atoms are located near the midpoints along lines connecting the centers of adjacent molecules (except along the z-axis). These zinc atoms and the polar oxygen or sulfur atoms probably associated with them we designate by Z (intensity $+z$). We shall find later that there are two regions U and V having deviations $+u$ and $-v$, respectively, probably associated with side chains contributed by neighboring molecules which bind the zinc.

If the lacunae are regions of low density, the spaces between them must be of comparatively higher density. We therefore may consider that the midpoints Q between the centers of lacunae are regions having a positive density deviation $+q$.

The foregoing assumptions regarding density distribution are designed as a description of the characteristic features of the C_2 structure. The effects of individual side chains (except U and V) have been neglected. The C_2 structure is not actually an octahedron and has at least 2 kinds of trigonal faces (Fig. 1a). The trigonal symmetry characteristic of insulin could be preserved even if the C_2 molecule had faces of four kinds,[3] *i. e.*, with 4 different distributions of side chains. It may be hoped that the effects of these features may also ultimately be taken into account in analyzing the X-ray data.

Construction of Patterson–Harker Diagrams.—To consider the Patterson–Harker diagrams given by any distribution of atoms in space, we take first two points a and b of intensities α and β, respectively. The diagram associated with these two points comprises the vectors of a on a, of b on b, of a on b, and of b on a. Each has associated with it the product of the intensities of its two constituents. We therefore write

$$V([\alpha a + \beta b]^2) = \alpha^2 V(a^2) + \beta^2 V(b^2) + \alpha\beta V(ab) + \alpha\beta V(ba)$$

The terms $V(a^2)$ and $V(b^2)$ correspond to locations at the origin. It will be noticed that the cross terms $V(ab)$ and $V(ba)$ will be positive if α and β have the same sign, negative if they have different signs. Thus a positive cross term will result both when two points of positive intensity are concerned and when two points of negative intensity are concerned. On the other hand, the cross terms will be negative only when a point with positive intensity is associated with a point of negative intensity. These are located at positions ab and ba with respect to the origin.

The A, B, and C peaks that we have previously considered have the intensities s^2, $2s^2 - e^2$, and $2s^2 - e$ as given in Table II. It hardly seems possible at present to compare the relative intensities of the A, B, and C peaks to get the actual ratio in the coefficients.

Let us now consider the peak A′. This point

TABLE II

MAXIMA AND MINIMA IN THE PATTERSON–HARKER MAPS FOR INSULIN

The coördinates give the positions with reference to the center of the molecule to which they are associated.

Symbol	Character[a]	Vector	Symmetry	Coördinates			Intensities

[a] In the second column of Table II, maxima or minima shown in the diagrams are classed as follows: I, well-defined isolated maxima or minima; II, maxima or minima whose effects are observable although partly masked by neighboring maxima or minima; and III maxima or minima which contribute to but are individually masked by neighboring terms.

(Fig. 5) lies close to the z-plane about one-third of the way from the origin to A (vector $^1/_3$ OA). We note that in the C_2 octahedron of Fig. 1a the lines connecting F points in adjacent faces lie parallel to the lines S–S between opposite corners and are of one-third the length of S–S. There are four such vectors, corresponding to each of the diagonals between opposite points, so that the intensity of A′ corresponds to $4f^2$. This is necessarily positive and produces a maximum. The point A′ in Fig. 5 at $z = +8$, $\rho = 11.3$ Å. is, in fact, a maximum and happens to come almost directly above one of the A points, at $z = -4$, although it is unrelated since A′ belongs to M_0, while A belongs to M_2.

At point D′ there is a well-defined and very symmetrical minimum, shown in Figs. 3, 4, and 5. Since it lies at the midpoint along the line connecting adjacent molecules, it must receive equal contributions from these. This appears to result from the interaction between O and Z, giving a minimum of intensity $-2oz$ at D′. Since the two molecular faces adjacent to the zinc are not of identical structure, it is possible that the zinc atom is not exactly at the midpoint between the two molecules. However, the contours around the point D′ (Fig. 5) are not elongated along the line connecting the atoms, so that the zinc atom is probably not far from this midpoint. The observed spheroidal nature of the D′ minimum may be an effect of neighboring A maxima.

The maximum D seen in Figs. 3, 4, and 5 lies approximately halfway between centers of adjacent molecules along the z axis from which it must receive equal contributions. The interaction between O and F lacunae in the upper and lower faces gives a maximum of intensity $+fo$ at $z = \pm 12$ Å. Thus we recognize that the maximum D represents the overlapping of two peaks at $z = \pm 12$ Å., the elongation in the vertical direction being due to the composite nature of this maximum. The size of the maximum gives a rough estimate of the maximum dimensions of the low density region O. The D′ minimum is of about the same size as the D minimum, both being dependent on the dimensions of O.

The well-defined minimum at A″ (Figs. 3 and 5) corresponds to the vector $^1/_2$ OC, and appears to be due principally to the interaction of E and S points along the edges between adjacent lateral faces of the C_2 octahedron. This gives an intensity $-4es$. However, we find that there are other terms which contributed to the intensity at this point: four vectors EE, four TT, and two DE, so that the total intensity is $-4es + 4e^2 + 4t^2 + 2eo$. The fact that we have here a minimum indicates that the $4es$ term must predominate.

This, and similar observations, enable us to make the rough estimates of the relative intensities of the various points given in the last column of Table I which seem consistent with all the observed maxima and minima of Table II. Accurate values of these intensities must probably await knowledge of the distribution of the side chains on the surface of the C_2 molecule.

The minimum G in Figs. 2 and 4 corresponds to the vector $^1/_2$ OB and contains exactly the same terms as the A″ minimum and should thus have the same relative intensity.

Figs. 1c, 2, 3, and 4 show high vector concentrations in 6 regions symmetrically arranged about the z-axis. This "B complex" lies between $\rho = 19$ and $\rho = 31$ Å., covers the range of angles θ from $-20°$ to $+20°$, and extends over all values of z. Figure 5, which corresponds to $\theta = 30°$, $90°$, etc., shows that in these planes the B complex is wholly absent. We recognize several definite maxima within the B complex. The principal one, B″, seen best in Fig. 4, appears to be due to the interaction of the low density regions O and V. Since O is at the origin, the OV term is located at V (see Tables I and II). The very strong maximum B″ at $z = +7$, $\theta = 0°$, $\rho = 29$ belongs to M_1, which lies at $z = 10.3$ Å. Another of the B″ points, the one belonging to M_0, thus lies at $z = -3$ Å., $\theta = 8°$, and $\rho = 22$ Å. The point marked B″ in approximately this position in Fig. 4 is really 3 Å. in front of the true B″ maximum, and this fact accounts for its lower intensity as compared to the B″ point located at $z = +7$, $\rho = 29$.

This maximum corresponds to a strong negative density deviation near the zinc atom Z. Perhaps it is associated with the phenyl group of one or two tyrosine side chains which bind the zinc atom.

In Table II we have listed two other maxima (B′) which correspond to the vectors $^2/_3$ OB and $^5/_6$ OB and result from FF and TT terms. They contribute to the B complex at $z = 0$ and ± 10.3.

The rest of the B complex, extending as it does over all values of z, is most readily interpreted as due to the interactions of T lacunae with other rather distant T, F, or E lacunae. With a total of 44 E, F, and T lacunae, there would be over 1900 vectors connecting them. We have attempted in Table II to consider particularly the single terms which are of greatest intensity because they contain the more important factors S, F, O, or U or because they involve a large number of contributing vectors as a result of symmetry. The terms of most significance have been those between extreme points in the molecules, such as the S points, for the Patterson–Harker map of these points has a simple structure with widely separated points.

We have naturally not attempted to analyze in detail all the terms involving T, E, and F. It does appear, however, from numerous trials that a particularly large fraction of the vectors which involve the more distant lacunae give terms that lie within the B complex, well distributed over various values of z. The terms are individually of small intensity but add up to substantial values because of their large number.[8]

We have now considered in Table II 80 well-defined points shown in the Crowfoot diagrams. These include nearly all points which might be expected to have high intensities. The total number of points per molecule for which we have assumed characteristic density deviations (neglecting the Q points), as shown in Table I, is 60 to 66 which corresponds to a total of about 3600 vectors. Many of these, however, coincide. We have not attempted to consider all the maxima and minima which would result from these vectors. We have considered a large number not given in Table II and in no case have we found that they conflict seriously with the Crowfoot diagrams. Some of the points come in positions where they are masked by neighboring maxima or minima, but many fall in positions where their effect is to modify the contour lines in a manner which improves the agreement with the Crowfoot diagrams.

It should be noted that the sections of the Patterson–Harker diagrams given by Crowfoot are chosen with reference to axes of the crystal lattice. The x, y projection and the sections in this plane show that the trigonal axis of crystal and molecule coincide, but that the hexagonal axes of the molecule do not coincide with those of the crystal but are turned through an angle about the z-axis of $\delta = +6°$.

The Patterson–Harker sections chosen with reference to the crystal lattice are, of course, useful in determining the symmetry of the crystal as a whole. For example, Crowfoot showed that the insulin crystal has symmetry corresponding to the R3 space group. She was not able, however, to determine the symmetry or orientation of the molecule itself.

These sections through the crystal lattice are also useful in determining the positions and the

---

[8] (Note added by I. Langmuir, August 14, 1938.) An alternative and perhaps preferable although nearly equivalent interpretation of the B complex is to regard it as being the result of the interaction of the slits S with a uniform positive density deviation over the faces of the C_2 octahedron. This gives a PH distribution very closely like that of the B complex. Upon this uniform positive surface distribution over the faces there is then to be superposed the negative deviations corresponding to the lacunae which have already been considered. This suggests that in Table I q should be taken larger than 0.1 so as to give a positive value for the average density deviation over the whole surface.

structure in the neighborhood of all atoms which lie midway between the adjacent molecules in the crystal. Thus Figs. 3, 4, and 5 give various sections through the maximum at D which is due to the overlapping of the EO vectors contributed by neighboring molecules along the z-axis. Furthermore, the maximum D′ is located approximately midway between other pairs of adjacent molecules and so furnishes direct information regarding the location of the zinc atoms and the groups which bind them to adjacent molecules. In other words, the crystal lattice sections give the location of the molecules and intermolecular structure.

To determine the intramolecular structure, however, sections should be chosen with reference to the axes of the C_2 octahedra. The projection of the x, y plane, in Fig. 1c, gives directly the value of δ. If sections parallel to the z-axis had then been taken at $\theta = 6°, 21°, 36°$, etc., simply related to the axes of the C_2 octahedron, the diagrams would have shown the intramolecular structure in far greater detail. For this purpose it would also be desirable to have x, y sections at the height $z = h = +24$ Å. and at halves, thirds, and sixths of this distance. To obtain these sections needed to bring out the molecular structure, it will not be necessary to obtain new X-ray data. These Patterson–Harker sections can be calculated directly from Crowfoot's data on the intensities of the X-ray reflections.

It has been shown[3] that the distance between faces of adjacent C_2 structures (not along the c-axis) varies from 7 to 13 Å. as δ varies. Since the zinc atoms and their attached groups lie between these faces, it appears that the angle δ is determined by the zinc atom. If we should substitute cadmium or if possible mercury for the zinc, we should expect to obtain different values of δ. This would change in marked degree the Patterson–Harker sections chosen with reference to the crystal lattice but would leave unchanged many of the intramolecular features characteristic of the sections which have been chosen with reference to the molecular orientation.

Attention should be called to the particular features of the Patterson–Harker diagrams near D′, the midpoint between neighboring molecules. The cross terms between the zinc atom and all the other points in the C_2 molecules reproduce about D′ as a center, an image of the whole of the C_2 structure of unaltered size and of intensity proportional to z. The minimum at D′ is merely the image of the hollow at the center of the C_2 molecule transposed to the point D′. If we could substitute a much heavier atom than zinc and so increase the factor z, this image should become more distinct and show more clearly all the features of the molecular structure.

We have examined the diagrams in the neighborhood of D′ to see if the 6 S points in this transposed image of the C_2 molecule are observable as maxima of intensity $+ sz$ in planes given by $z = \pm 5 \pm 12$ Å. We find that points in 3 locations are obtained: 2 of these fall at the edges of the B complex at $z = \pm 7$ and are masked by it. The third set of maxima lie with hexagonal symmetry at $\theta = 10°$ and $\rho = 5$ Å. and so appear to account exactly for the hexagonal form of the outermost of the closed curves that surround the molecular centers in Fig. 1c.

Just as we have seen that a high density point half way between molecular centers gives about that point an undistorted image of the whole molecule, so we must conclude that the vectors between a low density point O at the center of each molecule and all the other points in the molecule will produce another undistorted molecular image about O as a center but of intensity proportional to $-o$. The central part is, of course, lost because of the high central density, but the terms of intensity $-os$ resulting from the interaction of O and S should be present as minima in the diagrams. These 6 points occur at $^1/_2$ OA and in Fig. 5 all lie in the deep trough connecting the A″ points. The OE interactions we have already taken into account in points A″ and G.

The molecular image produced by the zinc around D′ could be greatly enhanced if a very heavy atom such as mercury could replace the zinc. It is conceivable that in this way simple structural analyses may be made of very complicated molecules.

The foregoing analysis shows that all the prominent features of the Crowfoot diagram are deducible from the C_2 structure whose octahedron has a side 29.4 Å. if $a = 1.50$ Å. During the development of this analysis we repeatedly found that as we introduced one by one the more delicate features of the C_2 molecule the more perfect became the concordance between the Patterson–Harker diagrams and the Crowfoot pictures. We feel therefore that these X-ray data, in giving so perfect a picture of the C_2 structure, provide the experimental basis for the cyclol theory.

Summary

Crowfoot's data on X-ray reflections from insulin crystals, as summarized in a set of Patterson–Harker vector maps, are found to correspond in great detail to the C_2 polyhedral structure predicted for the insulin molecule on the basis of the cyclol theory. The features of the insulin molecule confirmed by the X-ray data include: (1) six high density points at the corners of an octahedron of side 29.4 Å., which is the size given by the cyclol theory; (2) low density regions near the centers of the 44 lacunae in the cyclol fabric that are located in definite positions in the edges and faces of the polyhedron; (3) a comparative hollow at the molecular center, *i. e*, a cage structure; (4) three zinc atoms per molecule on lines connecting molecular centers (except along the *z*-axis) and low and high density groups attached to these zinc atoms outside the C_2 structure.

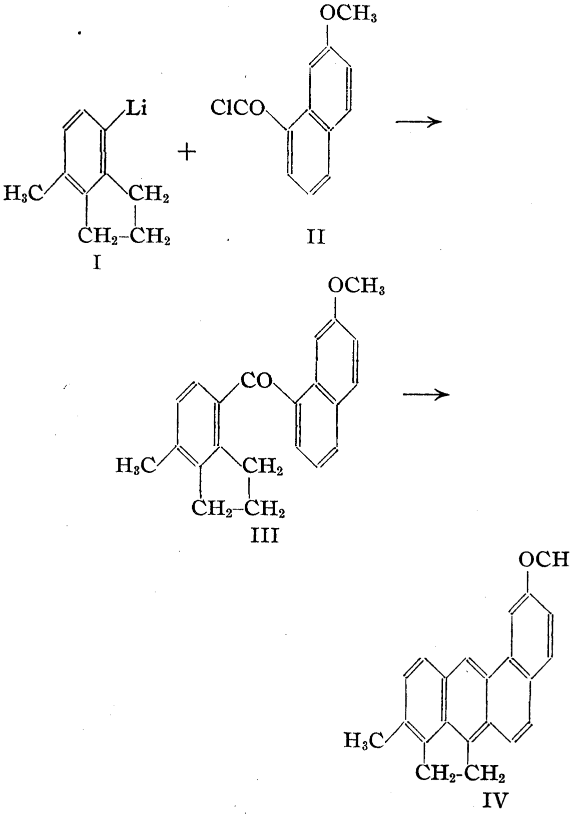
The Synthesis of 2- and 6-Substituted Derivatives of 20-Methylcholanthrene[1]

BY LOUIS F. FIESER AND VICTOR DESREUX[2]

Derivatives of carcinogenic hydrocarbons having active functional groups are of interest to the general problem of attempting to correlate structure and biological activity, and if, among such compounds, derivatives can be found which possess marked carcinogenic activity they may be of value in providing a route to the preparation of interesting glycosides or conjugated proteins.

The only functional derivatives of methylcholanthrene previously known are 3-hydroxy-20-methylcholanthrene,[3,4] and its ether and acetate, 3-chloro-,[4] and 3-cyano-20-methylcholanthrene.[4] These were all made available by application of the Fieser–Seligman methylcholanthrene synthesis[5] to suitable methoxy- and chloro-substituted ketones, and the successful outcome of the syntheses shows that these substituent groups are capable of withstanding the pyrolytic conditions of the Elbs reaction when located in a position corresponding to the 3-position of methylcholanthrene. This is a β-position and is located in the terminal angular nucleus at a point rather remote from the site of ring closure, and it seemed likely that the other β-position 2 in this ring also would offer an environment favorable for the retention of an active functional group. Consequently, as a next step in the search for compounds of the type desired we synthesized the ketone III and investigated its behavior on pyrolysis. For the preparation of the ketone the lithium derivative



I from 4-methyl-7-chlorohydrindene[5,6] was condensed with the chloride of 7-methoxy-1-naph-

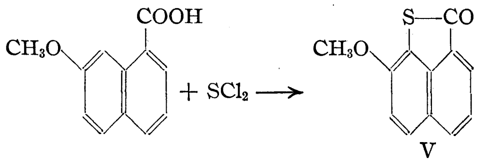
[6] If the condensation of such a lithium derivative with a suitable nitrile constitutes a "modification of the original method of Fieser and Seligman," as stated by Cook and de Worms,[3] it may be noted that the modification was introduced not by these workers but by Fieser and Hershberg, *ibid.*, **59**, 394 (1937).

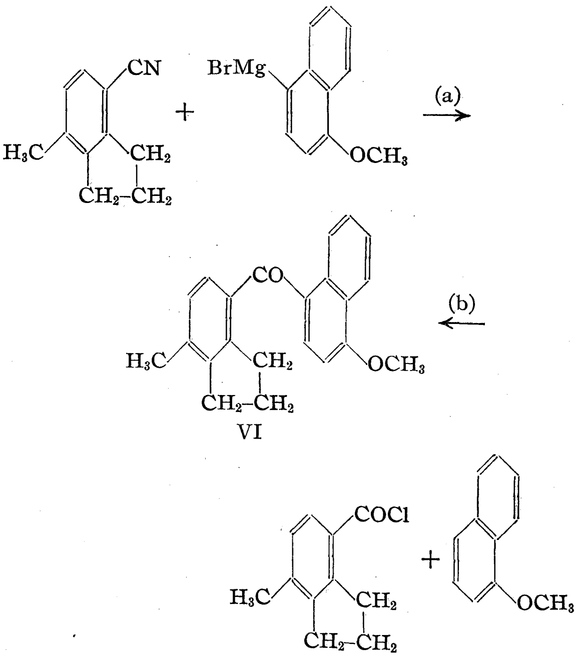
thoic acid, prepared by the synthesis described by Fieser and Holmes.[7] The 7-methoxy-1-naphthoyl chloride was prepared satisfactorily with the use of phosphorus pentachloride, but an unexpected difficulty was encountered on employing a commercial lot of thionyl chloride which, being colorless, had not been further purified. The acid chloride in this case was contaminated with a persistent yellow impurity, and when this was isolated it was found to contain sulfur and to have the properties of a lactone (insoluble in cold alkali, slowly dissolved by alcoholic alkali). From the analyses and properties it is probable that the yellow substance has the structure V and that it arises from the condensation of sulfur dichloride, present in the commercial thionyl chloride, into the activated 8(α)-position of the acid or acid chloride, with subsequent ring closure.



V

The pyrolysis of the ketone III proceeded satisfactorily and pure 2-methoxy-02-methylcholanthrene (IV) was obtained in 40% yield, which is practically the same as that obtained in this Laboratory[4] in the preparation of the isomeric 3-methoxy compound. The hydrolysis, however, presented special difficulties, for the 2-ether is unusually resistant to acid cleavage and the free hydroxy compound is very sensitive and decomposes extensively under the influence of acids or bases, or when heated in the presence of oxygen. The hydrolysis consequently could not be carried to completion without destruction of all of the product formed and it was necessary to work with mixtures. It was found, however, that after acetylation of the crude mixture the more stable acetate can be separated from the ether and purified satisfactorily, and careful saponification of the pure acetate afforded the hydroxy compound in such a condition that it could be purified.

The synthesis of the 2- and 3-methoxy compounds having been accomplished successfully by the Elbs reaction, we investigated the possibility of preparing 6-methoxy-20-methylcholanthrene by the pyrolysis of the ketone VI. As indicated in the formulas, this was synthesized by two different methods, the first of which fully establishes the structure of the ketone. The 4-bromo-1-naphthol required for this synthesis (a) was prepared by the bromination of α-naphthol with iodine bromide according to Militzer,[8] but the purification was very tedious and the yield of satisfactory material was only 23%. The Friedel and Crafts synthesis (b) was therefore investigated and found to give the identical ketone in excellent yield. The 4-methylhydrindene-7-carboxylic acid required was prepared conveniently by heating the corresponding 7-chloro compound with cuprous cyanide, pyridine, and water at 210°; this gave some acid and some amide, and the latter was easily converted into acid by alkaline hydrolysis.



Since the methoxyl group of the ketone VI is in an α-position of a ring involved in the cyclization, there is more opportunity here than with the previously investigated compounds for disturbance of the substituent in the course of the Elbs reaction conducted at a temperature above 400°. Such disturbance evidently occurred, for in several experiments the only product that could be isolated was methylcholanthrene, and when the total crude product was submitted to acid hydrolysis no trace of a phenolic substance was obtained. We are not prepared to say that conditions cannot be found permitting retention of the methoxyl group, but record merely that under the conditions found most satisfactory for the pyroly-

---

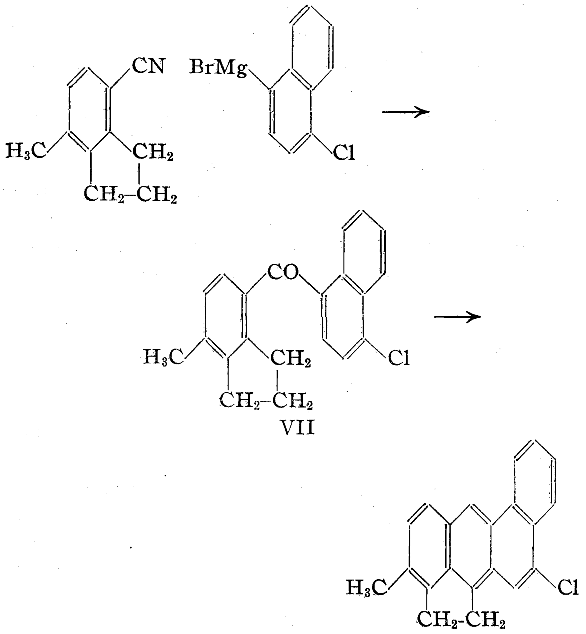
[8] Militzer, *ibid.*, **60**, 256 (1938).

sis of related ketones the methoxy group in this position is easily eliminated.

It was of interest to learn whether a chlorine atom in the same position would suffer a similar fate, and for this purpose we required 5-methyl-7-(4′-chloro-1′-naphthoyl)-hydrindene (VII). The synthesis was accomplished by the Grignard reaction indicated in the chart, the 1-bromo-4-chloronaphthalene being prepared conveniently in a very pure form from the known[9] acetyl-4-bromo-1-naphthylamine.



VII

VIII

The direct bromination of α-chloronaphthalene was also tried but gave a mixture from which the desired isomer was isolated in only very poor yield. When the chloro ketone VII is heated no change occurs until a critical temperature of about 410° is reached and at that point a vigorous reaction sets in with loss of water and evolution of hydrogen chloride. The reaction is exothermic, and if the external temperature is not decreased the product is largely destroyed. By quickly lowering the bath temperature as soon as the reaction had started, it was possible to conduct the pyrolysis with sufficient success to permit the isolation of 6-chloro-20-methylcholanthrene (VIII) in a pure condition, if in only 1.2% yield. The reaction mixture contained in addition a considerable quantity of methylcholanthrene, but the sparing solubility of the chloro compound made possible its isolation in a condition believed to be free from contamination with the carcinogenic hydrocarbon. The chloro compound is rather sensitive and decomposes when heated at the melting point in the presence of air, but it is nevertheless transformed very smoothly into the nitrile when heated with cuprous cyanide in pyridine. The nitrile is very resistant to hydrolysis, and in a few trial experiments we did not succeed in preparing the corresponding acid. 6-Chloro- and 6-cyano-10-methylcholanthrene are of particular interest because the position of substitution corresponds to that of 3-substituted 1,2-benzanthracenes, some of which have been found to possess carcinogenic activity.[10]

An interesting observation was made in the course of a preliminary attempt to prepare the chloro ketone VII by the Friedel and Crafts reaction between 4-methylhydrindene-7-carboxylic acid chloride and α-chloronaphthalene. Little reaction took place at −10°, but at room temperature in tetrachloroethane solution there was produced a yellow substance having two hydrogen atoms less than the expected ketone VII. After the latter compound had been made available by the Grignard synthesis it was found that the same yellow condensation product can be obtained by the action of aluminum chloride on the ketone in tetrachloroethane solution at 25°. From the composition of the condensation product and the structure of the intermediate from which it can be obtained, it would seem that the substance is probably either a benzanthrone derivative IX or the cholanthrone X.

[10] Fieser, Hershberg, Long, Jr., and Newman, This Journal, **59**, 475 (1937).

be given, the following observations appear to be significant. If the substance were a cholanthrone, it would be expected to yield a cholanthranol acetate on treatment with acetic anhydride in pyridine, but the yellow compound failed to react under these conditions and was recovered unchanged. The alternate structure IX, on the other hand, is consistent with the behavior of the substance in a qualitative test with zinc dust, sodium acetate and acetic anhydride. It has been observed recently in this Laboratory that benzanthrones can be converted by this method of reductive acetylation into easily hydrolyzed dihydrobenzanthrone-enol acetates,[11] and the compound in question gave evidence of reacting in this manner, although the product proved to be quite unstable and was not isolated in a pure condition. The structure therefore is probably that of formula IX, and the observations suggest that the α-benzoylnaphthalene derivative VII undergoes the Scholl peri-condensation under the influence of aluminum chloride in tetrachloroethane solution at a temperature lower than is required to produce benzanthrones by the usual process using aluminum chloride alone or sodium aluminum chloride.

In connection with the attempt to synthesize the ketone VII by the Friedel and Crafts reaction, we investigated the action of aluminum chloride on α-chloronaphthalene in tetrachloroethane at room temperature and found that a part of the material was isomerized to β-chloronaphthalene. This isomerization was observed some time ago by Roux,[12] but at a considerably higher temperature. There was also a higher boiling fraction probably similar to that obtained by Weitzenböck and Seer[13] at a higher temperature and found to contain perylene and dinaphthyl derivatives.

Experimental Part[14]

2-Hydroxymethylcholanthrene

Preparation of Starting Materials.—In the preparation of **β-(4-methoxybenzoyl)-propionic acid** by the procedure of Fieser and Hershberg[15] it was found unnecessary to keep the mixture at 0–5° after adding the aluminum chloride; we allowed the mixture to stand at room temperature for three days and obtained purified acid, m. p. 146.5–147°, in 90% yield. Reduction (Martin[16]) gave **γ-(4-methoxyphenyl)-butyric acid,** m. p. 60.5°, in 90% yield, and the ethyl ester (96% yield) boiled at 176.5–177° (15 mm.). **α-Keto-δ-(4-methoxyphenyl)-valeric acid** was prepared by condensing the ester and ethyl oxalate with the use of sodium ethylate following the procedure of Fieser and Holmes,[7] but our observations indicated that the time specified for the condensation is insufficient for complete conversion. Probably a longer period should be allowed also for effecting decarboxylation. The following method of purification gave a better product than that previously described and made possible the recovery of starting material. After decarboxylation, the crude keto acid was treated with dimethyl sulfate in warm alkali and after clarifying the solution with Norite the sodium salt of the keto acid was allowed to crystallize. After this purification through the crystalline salt, the liberated acid was obtained directly in a very pure condition and melted sharply at 76–77°. The material failing to crystallize as the sodium salt was refluxed again with 15% sulfuric acid (five hours) and put through the above process, but as the product seemed to be a mixture it was esterified and distilled. The main fraction (b. p. about 160° at 2 mm.) after saponification was found to consist chiefly of γ-(4-methoxyphenyl)-butyric acid, while the fraction boiling at 190–200° (2 mm.) was a mixture of the ester of this acid and the keto ester. A separation was accomplished easily by taking advantage of the greater ease of saponification of the keto ester, and by purifying the keto acid as sodium salt. In all 444 g. of ethyl γ-(4-methoxyphenyl)-butyrate gave 223 g. (50%) of very pure keto acid and 110 g. (25%) of recovered starting material.

7-Methoxy-Δ'-dihydro-1-naphthoic acid was prepared as described[7] except that the acid was used for cyclization rather than the ester. The crude material was remethylated in alkali and the solution was clarified and acidified. Acetone proved unsatisfactory as a solvent for crystallization and this was done from water, giving pure acid, m. p. 117.5°, in 65% yield. **7-Methoxy-1-naphthoic acid** was prepared as described[7] and purified by remethylation of the sodium salt; m. p. 169–170°, yield 87%.

In preparing **4-methyl-7-chlorohydrindene**[5b] it was found convenient, after cyclizing the β-chloropropionyl derivatives, to take up the ketone mixture in benzene and wash the solution with saturated sodium chloride solution at 50–60°. Decantation was then easily accomplished and after removing the solvent the product was distilled quickly; yield 60%. No other changes were made in the procedure and the yields agreed closely with those reported.

Action of Thionyl Chloride on 7-Methoxy-1-naphthoic Acid.—The acid was treated with 3–4 equivalents of commercial thionyl chloride (Fraenkel and Landau, colorless), and after it had dissolved the solution was warmed for about one-half hour longer. The excess reagent was removed in vacuum and the product was distilled at 2 mm. (liberation of hydrogen chloride noted). The distillate was a yellow, unhomogeneous solid, m. p. 75–85°, and as trial crystallizations were not promising the material was saponified with a hot sodium hydroxide–acetone mixture. Distillation of the acidic material gave a yellow solid, m. p. 158–168°, and on crystallization from dilute acetone this yielded a product melting at 167° and giving no de-

pression when mixed with methoxynaphthoic acid. The material was still yellow, however, and it was noted that it dissolved with difficulty in alkali, and only on warming, and that it contained sulfur. Six crystallizations from benzene served to remove the impurity and gave pure white methoxynaphthoic acid, m. p. 170° (neut. equiv. 200; calcd. 202). The yellow benzene mother liquors were extracted three times with 10% alkali to remove the remaining acid, and on concentrating the benzene solution the by-product was obtained in a nicely crystalline condition. Purified further for analysis, the **sulfur compound (V?)** formed bright yellow needles melting constantly at 143.5–144°. The substance is attacked only very slowly by boiling aqueous alkali; it dissolves in hot alcoholic alkali with almost complete loss of color and precipitates in the original condition on acidification of the diluted solution.

Anal. Calcd. for $C_{12}H_8O_2S$: C, 66.63; H, 3.73; S, 14.83; mol. wt., 216. Found: C, 66.87; H, 3.82; S, 14.76; mol. wt. (micro Rast), 221, 231.

7-Methoxy-1-naphthoyl Chloride.—A mixture of 10 g. of the acid and 12 g. of phosphorus pentachloride was warmed at 50° until solution was complete and the phosphorus oxychloride was removed in vacuum at 50°. As the clear mixture was found to darken rapidly even at this temperature it seemed inadvisable to attempt to distil the acid chloride, and the mixture therefore was cooled and extracted with 150 cc. of dry petroleum ether (b. p. 30–60°). Evaporation gave 8 g. (73%) of pale yellow crystalline product, m. p. 65–75°, and titration with alkali indicated the presence of 90% of the desired acid chloride. When prepared immediately before use, this material was satisfactory for the Grignard reaction, but it is subject to ready hydrolysis and does not keep well. It dissolves readily in warm alkali, but not in the cold. A recrystallized sample melted at 78.5°.

4-Methyl-7-(7′-methoxy-1′-naphthoyl)-hydrindene (III).—A three-necked flask provided with a stirrer, condenser and funnel was charged under nitrogen with 1 g. of lithium (cut under dry ether into small pieces), 10 cc. of ether and 1 g. of 4-methyl-7-chlorohydrindene. The reaction started after warming and stirring for about ten minutes, and in the course of three hours 7 g. more of the chloro compound in 90 cc. of ether was introduced, adding benzene as required to keep the lithium compound in solution. After twenty hours the reaction was complete; the solution was then forced under nitrogen pressure into a stirred benzene solution of 9 g. of 7-methoxy-1-naphthoyl chloride, while cooling to 0°. The mixture was eventually brought to boiling, the ether was allowed to distil and refluxing was continued for two hours. After the careful addition of dilute acid, the mixture was neutralized and steam distilled in the presence of soda. The solid residue, after being dried in ether, distilled at 260–270° (3 mm.), but in order to remove traces of acid or acid chloride the distillate was taken into an acetone-alkali mixture and boiled for two hours. A second distillation, followed by crystallization from ether–petroleum ether, gave colorless prisms melting at 91.4–91.6°; yield 7 g. (48%).

Anal. Calcd. for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37. Found: C, 83.60; H, 6.27.

2-Methoxy-20-methylcholanthrene (IV).—One gram of the above ketone was heated in a bath kept at 405° for fifteen minutes and the temperature was then rapidly raised to 420°. Once this temperature had been reached the mixture was cooled and distilled at 3 mm. The distillate was taken into benzene and the solution filtered through a tower of activated alumina and concentrated. Satisfactory crystalline material was in this way obtained without difficulty in total yield of 40%. When the ketone (2 g.) was heated in the presence of zinc dust (0.5 g.) loss of water occurred at exactly the same temperature as above and the total yield was 36%.

The methoxy compound on recrystallization from benzene–ether formed yellow prisms melting constantly at 163–163.4°. Like the 3-methoxy isomer,[4] the substance exists in two crystalline forms, for on standing in contact with the mother liquor the prisms are slowly transformed into needles; both forms have the same melting point.

2-Acetoxy-20-methylcholanthrene.—Because of the great resistance of the methoxy derivative to hydrolysis and the sensitivity of the hydroxy compound to acid, alkali, and oxidation, the isolation of the hydrolysis product could only be accomplished by way of the acetate. In the first successful method found the conditions were similar to those employed by Cook and de Worms[3] for the 3-isomer, but somewhat more drastic. A suspension of 95 mg. of the ether in 3 cc. of glacial acetic acid and 0.5 cc. of constant boiling hydrobromic acid was sealed in a tube in an atmosphere of nitrogen and heated at 140° for three hours. The product was precipitated with water, collected and dried, and treated directly with acetic anhydride and sodium acetate under nitrogen. Dried in ether and fractionally crystallized from ethyl acetate, the product yielded in all 26 mg. (25%) of pure acetate. Some unchanged methoxy compound was still present but the acetate can be separated from this without difficulty by fractional crystallization. The pure acetate forms yellow micro prisms melting, when sealed into an evacuated capillary tube and introduced at a bath temperature of 210°, at 218–219°. When heated in the presence of air the sample turns black at about 210°.

Anal. Calcd. for $C_{23}H_{18}O_2$: C, 84.63; H, 5.56. Found: C, 84.59; H, 5.72.

In an attempt to increase the yield the methoxy compound (500 mg.) was warmed in a sealed tube on the steam-bath with 13 cc. of glacial acetic acid and 5 cc. of hydrobromic acid solution under nitrogen for fifteen hours. The solution became highly colored, but unchanged ether was still present. After acetylating the crude product, purification by fractional crystallization and sublimation in high vacuum at 210° gave 130 mg. (23.5%) of pure acetate.

In other trials it was found that demethylation does not occur at either 25 or 40° on shaking for several days. At higher temperatures decomposition to dark products invariably occurred and some ether always escaped hydrolysis. Attempts to isolate the hydroxy compound by chromatographic adsorption on alumina and elution of a pale blue fluorescent zone with benzene–alcohol gave no crystalline product, and separation with alkali led to extensive oxidation. Demethylation with aluminum chloride was tried without success.

2-Hydroxy-20-methylcholanthrene.—For hydrolysis a mixture of 200 mg. of the acetate, 35 cc. of alcohol and 2 cc. of 50% aqueous sodium hydroxide solution was sealed in a tube under nitrogen and heated at 40°. In about five minutes the acetate dissolved, and the deep orange-red solution was then diluted and acidified. The crude precipitated material was dried and sublimed in high vacuum, giving 120 mg. of crystalline yellow material, but this was still impure. A product of constant melting point was obtained by fractional crystallization from benzene, in which the hydroxy compound is sparingly soluble, but the yield of pure product was only 49 mg. (28%). The substance forms fine yellow needles which, when heated in an evacuated capillary in a bath preheated to 220°, melt at 225.5–226°. In concentrated sulfuric acid the substance gives an orange color turning blue on heating.

Anal. Calcd. for $C_{21}H_{16}O$: C, 88.70; H, 5.67. Found: C, 88.63; H, 5.55.

The picrate forms brown needles from benzene and melts, under the above conditions, at 204°.

Synthesis and Pyrolysis of 4-Methyl-7-(4′-methoxy-1′-naphthoyl)-hydrindene

Preparation of Starting Materials.—For the preparation of **4-bromo-1-naphthol** the procedure of Militzer[8] was modified in the following respects. The solution of bromine and iodine in acetic acid was added dropwise to a vigorously stirred solution of α-naphthol in an atmosphere of nitrogen at 10°, and at the end of the reaction the solution was added by drops to the sulfite solution under mechanical stirring, which avoids occlusion of iodine by the precipitate. After complete precipitation with sodium bicarbonate the washed and dried product was crystallized once from chloroform and several times from aqueous alcohol. The purification is very tedious and the yield of pure material, m. p. 120° (constant), was only 23%. **4-Bromo-1-methoxynaphthalene,** prepared with the use of excess dimethyl sulfate, was obtained in 60% yield as an oil, b. p. 182° (15 mm.).

4-Methyl-7-cyanohydrindene was prepared as described by Fieser and Seligman[5b] (E. B. H. procedure) except that a few cc. of acetonitrile was added to take up traces of water and the heating was conducted at 240–245°. It was found advisable to use very pure chloro compound. The yield in several experiments was close to 90%. **4-Methylhydrindene-7-carboxylic acid**[5b] was most conveniently prepared directly from the chloro compound. A mixture of 12.5 g. of 4-methyl-7-chlorohydrindene, 7 g. of anhydrous cuprous cyanide, 10 cc. of pyridine and 2 cc. of water was heated in a sealed tube at 200–210° for twenty hours (probably a longer period would be better). The mixture was treated with aqueous ammonia, the solid material was collected and extracted with benzene and the ammoniacal filtrate was extracted with the same solvent. The ammonia solution was evaporated until copper oxide precipitated, and on acidifying the filtered solution methylhydrindene-carboxylic acid precipitated (1.6 g.). The combined benzene extracts, after being washed with bicarbonate solution and dried, afforded 8 g. of the corresponding amide on concentration, and the amide was transformed into acid by refluxing with 20% sodium hydroxide solution, the total over-all yield of acid being 75%. The Rosenmund reaction[17] was tried without success, no acid being found on acidification. **4-Methylhydrindene-7-carboxylic acid chloride** was obtained without difficulty from the acid (4.5 g.) and phosphorus pentachloride (5.2 g.) at 40–50° (ten minutes), distilling the product (low melting solid) in vacuum; yield 4 g. (80%).

Grignard Synthesis.—The reaction between 4-bromo-1-methoxynaphthalene (12.5 g. in 60 cc. of ether) and magnesium (1.5 g.) started very easily and was complete in three hours, some benzene being added to keep the complex in solution. The Grignard solution was cooled in ice and 8.5 g. of 4-methyl-7-cyanohydrindene was added in benzene; after distilling the ether the mixture was refluxed for three hours and allowed to stand overnight. After adding water and acid the benzene was removed by distillation, and hydrolysis of the ketimine was accomplished by adding toluene, acetic acid and concentrated hydrochloric acid and refluxing for four hours. The toluene solution was dried and distilled, the ketone boiling at about 262° (2 mm.). Crystallized from ether, **4-methyl-7-(4′-methoxy-1′-naphthoyl)-hydrindene** formed colorless prisms, m. p. 121.5–122°; yield, 11 g. (66%).

Anal. Calcd. for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37. Found: C, 83.26; H, 6.30.

Friedel and Crafts Synthesis.—A mixture of 4 g. of the chloride of 4-methylhydrindene-7-carboxylic acid, 30 cc. of purified tetrachloroethane and 4 g. of 1-methoxynaphthalene was stirred at 0° and 6.5 g. of aluminum chloride was added in portions over six hours. After standing overnight at room temperature, the mixture was decomposed with acid, steam distilled, and the product distilled in vacuum. To remove traces of acid, the distillate was heated with acetone–alkali and the recovered material melted at 118.5°; yield, 5.2 g. (82%). Crystallized from ether, the substance melted at 121.5° and did not depress the melting point of the above sample.

Pyrolysis.—In a typical experiment 2 g. of the ketone was heated at 405° for fifteen minutes and the product then was distilled in vacuum. A solution of the distillate in benzene was filtered through a tower of alumina, and after many crystallizations there was obtained a crystalline yellow substance melting at 174.5° and giving no depression when mixed with a sample of methylcholanthrene, m. p. 175.5°. No other substance was encountered, and the following observation indicates that the desired methoxy compound was not present. The material (150 mg.) obtained from a pyrolysis similar to that described and purified by passage through an adsorption tower was boiled with 10 cc. of glacial acetic acid and 1 cc. of hydrobromic acid for two hours, the solution was diluted and extracted with benzene. On extraction with dilute alkali there was no coloration in the alkali layer and no precipitate on acidification.

---

(17) Rosenmund and Struck, *Ber.*, **52**, 1749 (1919).

Pyrolysis in the presence of zinc dust gave the same results.

6-Chloro-20-methylcholanthrene

1-Bromo-4-chloronaphthalene. (a) **By Direct Bromination.**—As no mention of this possible method was found in the literature, a trial was made in which 50 cc. of bromine was added in twenty-four hours to a stirred solution of 162 g. of carefully fractionated (1-meter column) α-chloronaphthalene in 1 liter of carbon tetrachloride at 50–60°. After refluxing overnight the solvent was removed with steam and the residue was treated with steam in the presence of alkali, fractionated at 3 mm. and crystallized from acetic acid. After six crystallizations the 1-bromo-4-chloro compound was obtained in a pure condition, m. p. 67° (compare 66.5–67°[18]), but the yield was only 6.5 g.

(b) **From Acetyl-α-naphthylamine.**—The acetyl compound (200 g.) was brominated in glacial acetic acid solution with vigorous stirring at about 10° according to Meldola,[9] and the crystallized product was hydrolyzed[19] by refluxing with 3 liters of alcohol and 300 cc. of concentrated hydrochloric acid for three hours. Most of the resulting amine hydrochloride crystallized on cooling in a very pure form, and a further crop was obtained on concentrating the solution. The total yield was 215 g. (overall yield, 77%). The amine liberated from the salt melted at 102.5° (compare[19] 102°).

For diazotization 35 g. of 4-bromo-1-naphthylamine hydrochloride in 650 cc. of water and 65 cc. of concentrated hydrochloric acid was stirred at 0° and treated with a cold aqueous solution of 20 g. of sodium nitrite. After one hour a cold aqueous solution of 10 g. of urea was added and after forty-five minutes the solution was added slowly to a stirred solution of 33 g. of cuprous chloride in 350 cc. of concentrated hydrochloric acid at 5–10°. The mixture was allowed to come to room temperature, with continued stirring, and at 15–20° there was a color change and decomposition of the complex occurred. After heating on the steam-bath until the reaction product melted, the mixture was cooled and extracted with benzene. On distillation the product boiled at 159–160° (3 mm.) and melted at 65–66°. One crystallization gave very pure 1-bromo-4-chloronaphthalene, m. p. 67.5°, and the yield was 82–84% in several experiments.

When copper powder was used as catalyst in the Sandmeyer reaction the yield was the same and the only difference noted was that there was a shorter induction period before evolution of nitrogen commenced, although the decomposition occurred at the same temperature.

4-Methyl-7-(4′-chloro-1′-naphthoyl)-hydrindene (VII).—The reaction of 1-bromo-4-chloronaphthalene (6.5 g.) in ether (60 cc.) and magnesium (0.7 g.) started very easily and was complete in two hours, some benzene being added to keep the complex dissolved. The solution was cooled in ice and 4.2 g. of 4-methyl-7-cyanohydrindene in benzene solution was added with stirring. After removing the ether and refluxing for three hours, the product was decomposed with dilute acid and the ketimine hydrolyzed by refluxing with toluene, acetic and hydrochloric acids, as above. The hydrolysis proceeded very slowly and sometimes refluxing had to be continued for fifteen hours. The toluene layer was washed with water and with bicarbonate solution and the aqueous layer was extracted with ether. The material from the toluene–ether solutions was distilled at 3 mm. and the product crystallized from benzene–ether. The yield of very satisfactory ketone was 6.2 g. (72%), and the purest sample formed prisms, m. p. 144.5–145°.

Anal. Calcd. for $C_{21}H_{17}OCl$: C, 78.62; H, 5.34. Found: C, 78.62; H, 5.47.

In one experiment the ketimine hydrochloride was collected before hydrolysis, and in this case the distilled ketone was directly pure (m. p. 144.5–145°) and required no crystallization; the yield, however, was slightly lower (65%).

6-Chloro-20-methylcholanthrene (VIII).—The Elbs reaction with the above ketone proceeds very poorly, and in order to obtain any of the desired chloro-hydrocarbon it is necessary to control the temperature very carefully. Otherwise the sole product that can be isolated is methylcholanthrene. A critical temperature must be reached before loss of water begins and at this temperature considerable hydrogen chloride is evolved and the reaction proceeds exothermally with extensive decomposition.

In the most successful experiment 80 g. of ketone was pyrolyzed in two lots as follows. The bath was heated to 410° and as soon as the reaction started the temperature was decreased to 360–370°. Evolution of water continued to occur at this temperature for about ten minutes, after which the bath was again heated to 410°. The very dark, tarry mixture was then distilled at 3 mm. pressure and a solution of the distillate was passed through an adsorption tower of alumina. Concentration of the solution afforded a clean, crystalline product, but this proved to be a mixture which was separated only by a tedious process of fractional crystallization. Chloromethylcholanthrene is but sparingly soluble in benzene and was obtained as the top fraction, the yield of thoroughly purified material, m. p. 233.5–233.8° (see below), being 940 mg. (1.2%). There was a second fraction of nearly pure material (140 mg.), m. p. 230°, and 450 mg. of a mixture of the chloro compound and the hydrocarbon. From the residue there were isolated 1.7 g. of nearly pure methylcholanthrene and 8 g. of very impure hydrocarbon picrate.

After very careful purification to remove traces of the hydrocarbon, 6-chloro-20-methylcholanthrene formed glistening, pale yellow needles, m. p. 233.5–233.8° (evacuated capillary, preheated bath).

Anal. Calcd. for $C_{21}H_{15}Cl$: C, 83.29; H, 4.99; Cl, 11.71. Found: C, 83.28; H, 5.18; Cl, 11.77.

A pure picrate could not be obtained from the chloro compound, possibly because of the low solubility of the substance in the usual solvents The separation of the pyrolysis mixture through the picrate was tried but found unsatisfactory.

We tried carrying out the Elbs reaction by distilling the ketone through a glass coil heated at 520° in a nitrate bath but little pyrolysis occurred under these conditions.

6-Chano-10-methylcholanthrene.—A mixture of 120 mg. of the pure chloro compound, 50 mg. of cuprous cyanide, 0.2 cc. of pyridine and a trace of acetonitrile was heated in a sealed tube at 230–240° for twenty hours. The

---

(19) Gomberg and Blicke, THIS JOURNAL, **45**, 1765 (1923).

cooled mixture, which was very clean and partly crystalline, was washed out with water and ammonia and the precipitated cyano compound was collected, washed with ammonia water and dried. It was crystallized from glacial acetic acid (sparingly soluble) and from pyridine-benzene and obtained in the form of long yellow needles m. p. 268–268.5° (evacuated capillary, preheated bath). The yield was 75 mg. (66%).

Anal. Calcd. for $C_{22}H_{15}N$: C, 90.07; H, 5.15. Found: C, 89.87; H, 5.29.

The nitrile is very resistant to hydrolysis and was recovered unchanged after being heated with concentrated hydrochloric acid in a tube at 118° for one day. On attempting to convert the chloro compound (140 mg.) directly into the acid with cuprous cyanide, pyridine and water at 230° (twenty hours), the chief product appeared to be the amide (insoluble in dilute ammonia, decomposes when heated above 300°) and only 10 mg. of an acidic product was obtained.

Condensation Product, Probably 2-Chloro-7-methyl-5,6-cyclopenteno-1,9-benzanthrone-10 (IX). **(a) By the Friedel and Crafts Reaction.**—In a first attempt to condense the chloride of 4-methylhydrindene-4-carboxylic acid with α-chloronaphthalene in the presence of aluminum chloride, the chloro compound was taken in excess and no other solvent was employed. No condensation was observed. In another experiment a mixture of 3.5 g. of the acid chloride, 30 cc. of α-chloronaphthalene and 10 cc. of tetrachloroethane was stirred in ice and 6 g. of aluminum chloride was added during six hours. After standing for several hours at room temperature the mixture was decomposed and the product distilled at 3 mm. By careful distillation it was possible to obtain a certain amount of a crystalline yellow product (b. p. 260°, m. p. 210°, dec.), although the substance is very sensitive to heat and much of the material present was destroyed. Crystallization from benzene (moderate solubility) gave 150 mg. of the pure substance. This forms yellow needles melting at 215° (evacuated capillary, preheated bath). It is insoluble in hot alkali and gives a positive test for chlorine. Decomposition occurred in an attempted molecular weight determination in camphor.

Anal. Calcd. for $C_{21}H_{15}OCl$: C, 79.11; H, 4.74. Found: C, 79.02; H, 4.84.

It may be noted that the Friedel and Crafts reaction is complicated by the sensitivity of α-chloronaphthalene to aluminum chloride. A solution of the substance (5 g.) in tetrachloroethane (40 cc.) was treated at 0° with aluminum chloride (7 g.), and after standing overnight at room temperature the product was recovered and distilled. From the first fraction there was isolated a solid product melting, after crystallization, at 56.5° and identified by mixed melting point determinations as β-chloronaphthalene. There was also considerable high boiling material present, but this appeared to be a mixture and pure components were not isolated.

(b) From the Ketone VII.—The action of aluminum chloride (4 g.) on the ketone (5 g.) in tetrachloroethane (40 cc.) was tried at −10°, but most of the ketone was recovered unchanged. In a second experiment (3.5 g. of ketone) the aluminum chloride was added at 5° and the solution was then allowed to stand overnight at room temperature. On working up the mixture and distilling the product as above, there was obtained 150 mg. of the yellow condensation product melting at 213° (as above, 215° when further purified) and giving no depression when mixed with the first sample. Another fraction (500 mg.) proved to be a mixture of the yellow substance and the original ketone.

On attempted acetylation by boiling the yellow product in pyridine with acetic anhydride for five minutes, the starting material was recovered quantitatively in an unchanged condition. On treatment of the yellow compound (80 mg.) with acetic anhydride, sodium acetate and zinc dust a reaction occurred even on moderate heating and a practically colorless solution was obtained. The addition of water precipitated an amorphous product which became more and more yellow as attempts were made to purify it by crystallization, and no satisfactory product could be obtained.

Summary

The general cholanthrene synthesis developed in this Laboratory has been extended to the preparation of 2-methoxy-20-methylcholanthrene. The Elbs reaction proceeded satisfactorily and the corresponding hydroxy compound was obtained, if with some difficulty, on hydrolysis. In an attempt to synthesize 6-methoxy-20-methylcholanthrene by the same method the methoxyl group was completely eliminated. A similar lability of the substituent was noted with the corresponding chloro ketone, but 6-chloro-20-methylcholanthrene was isolated in a pure condition if in poor yield. This was transformed in good yield into the 6-nitrile by reaction with cuprous cyanide in pyridine.

It was noted that 4-methyl-7-(4′-chloro-1′-naphthoyl)-hydrindene suffers dehydrogenation in the presence of aluminum chloride in solution at room temperature and is converted into a yellow substance which probably is a benzanthrone derivative.

Synthesis, Isolation and Identification of Cocarboxylase

BY JOHN WEIJLARD AND HENRY TAUBER

From the reaction mixture recently described[1] cocarboxylase may be isolated in pure state by a procedure to be described in the present communication. A series of experiments will be presented which show that the synthetic cocarboxylase as obtained from synthetic thiamin chloride is in every respect identical with the natural cocarboxylase isolated by Lohmann and Schuster[2] from bottom yeast.

Experimental

Synthesis.—One gram of sodium pyrophosphate was placed in a Pyrex test-tube and heated until all of the water of crystallization was removed. Two cc. of orthophosphoric acid (c. P. 85%) was placed in another large Pyrex tube and heated until a slight amount of solid deposit formed on the side of the tube. Then the pyrophosphate was added and the mixture gently heated until solution took place. After cooling 1 g. of thiamin was added. The tube was placed in an oil-bath of 155°, kept there for fifteen minutes and constantly stirred. Then the tube was removed and after cooling the solid mass was dissolved in 15 cc. of cold water. Cold saturated barium hydroxide solution was added until no more precipitate formed and the solution just commenced to turn yellow. The precipitate was centrifuged out and the supernatant fluid was decanted. The precipitate was extracted four times with 80 cc. of cold water. The supernatant fluids (five) were united and 3% sulfuric acid was added to slight blue reaction of congo red paper. The barium sulfate was centrifuged off and discarded. The barium-free solution was concentrated to 30 cc. in vacuum at 25°. It was cooled in ice water and 15 volumes of a mixture of one part of absolute alcohol and two parts of ether were added which precipitated the cocarboxylase in the form of microscopic needles. Sometimes a gummy mass formed which turned into long macroscopic needles on short standing in the cold. The yield was about 1 g. of crude cocarboxylase.

Isolation.—One and one-half grams of crude cocarboxylase was dissolved in 150 cc. of water, neutralized to congo red with ammonium hydroxide and treated with 3 cc. of *N* silver nitrate. This first precipitate was mainly silver chloride and, accordingly was discarded. The clear solution was made neutral to litmus with ammonium hydroxide and 15 cc. of *N* silver nitrate was added. A copious yellow precipitate appeared. It contained most of the active cocarboxylase in the form of the silver salt. This was centrifuged and washed with water, suspended in 150 cc. of water and decomposed with hydrogen sulfide. The precipitate was centrifuged and washed with 20 cc. of water. The liquids were united and the hydrogen sulfide removed by aëration. To the neutral, hydrogen sulfide-free solution 96 cc. of 2.5 *N* hydrochloric acid was added and the mixture was diluted to 300 cc. with water. A moderate excess of a 25% phosphotungstic acid solution was added and the mixture centrifuged. The supernatant liquid was discarded. The precipitate was treated with 150 cc. of acetone which dissolved the phosphotungstic acid whereas the cocarboxylase separated as an oil which tended to crystallize on scratching. The cocarboxylase was centrifuged off and the acetone fraction was discarded. The precipitate was extracted twice more with 50 cc. of acetone. The residue was then extracted with 20 cc. of 0.1 *N* hydrochloric acid and filtered. The insoluble part was treated with 75 cc. of acetone and the acetone discarded. The residue was extracted with 15 cc. of 0.1 *N* hydrochloric acid. To the total (35 cc.) 0.1 *N* hydrochloric acid solution, 350 cc. of acetone was added and the mixture placed in the refrigerator overnight. The supernatant fluid was discarded and the residue dissolved in 15 cc. of 0.1 *N* hydrochloric acid; 150 cc. of acetone was added and the mixture allowed to crystallize in the refrigerator for twenty-four hours. The crystalline precipitate was dissolved in 15 cc. of 0.1 *N* hydrochloric acid and 30 cc. of absolute alcohol and 120 cc. of acetone added. The mixture was allowed to crystallize in the refrigerator for twenty-four hours; yield 180 mg.

Analysis.—The synthetic, practically pure cocarboxylase dried in a vacuum over sulfuric acid had a slightly yellowish color similar to the natural product and melted at 240°. Its elementary composition agrees well with that found for the natural cocarboxylase by Lohmann and Schuster. Calcd.: C, 30.08; H, 4.42; N, 11.71; P, 12.96; Cl, 7.40. Found: C, 30.62; H, 4.20; N, 11.82; P, 12.37; Cl, 7.95.

One more crystallization (50 mg. in 1 cc. of 0.1 *N* hydrochloric acid with 3 cc. of alcohol) gave a cocarboxylase which may be considered to be 100% pure. Found: C, 30.36; H, 4.24; N, 11.30; P, 12.83.

Acid Hydrolysis.—3.206 mg. of synthetic cocarboxylase with 2 cc. of *N* hydrochloric acid was placed in a bath of boiling water for forty minutes. The solution was then evaporated to dryness in vacuum at room temperature, and the ionized phosphate determined: found, 12.978 mg. of ammonium phosphomolybdate (5.89% P) or 47.6% of the total phosphorus. The second phosphate radical is more firmly bound, as also found by Lohmann and Schuster for natural cocarboxylase. Twenty-five micrograms of cocarboxylase in 1 cc. of 0.1 *N* hydrochloric acid boiled for sixty minutes at 100° lost 50% of its coenzyme activity.

Enzymic Hydrolysis.—To 4 g. of minced kidney tissue, 50 micrograms of cocarboxylase in 4 cc. of water was added and incubated at 37°. In thirty minutes 58% of the cocarboxylase was hydrolyzed by the kidney phosphatase, as determined enzymatically, using alkaline washed, cocarboxylase-free dry brewers' yeast.

Thiamin Content and Thiochrome Formation.—It is well known that thiamin may be oxidized to thiochrome

---

[1] H. Tauber, THIS JOURNAL, **60**, 730 (1938).

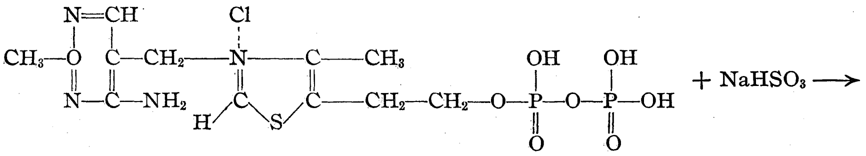
[2] K. Lohmann and P. Schuster, *Biochem. Z.*, **294**, 188 (1937).

by an alkaline potassium ferricyanide solution. Tauber[3] found that the ferrocyanide formed during the reaction may be converted quantitatively to Prussian blue and the color measured colorimetrically. The same is true for cocarboxylase. Its thiamin portion may be converted quantitatively to thiochrome. Cocarboxylase also forms thiochrome on the addition of alkali alone. The thiochrome compound, however, is inactive. It becomes enzymatically active again on acidification.

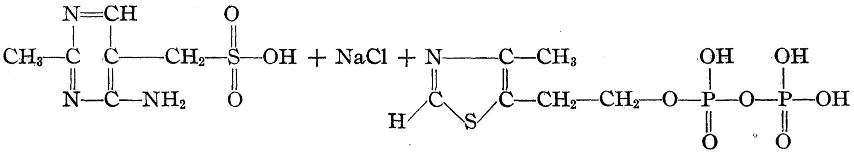
Formaldehyde–Azo Test.—The formaldehyde-azo test[4] gave an intense yellow color with cocarboxylase. Thiamin gave a red color.

Coenzyme Activity.—Synthetic cocarboxylase is as active as natural cocarboxylase (very kindly furnished by Professor Lohmann). Exact comparisons can only be made, however, if the same yeast preparation is employed as the source of carboxylase. The carboxylase content of various yeasts differs considerably.

Sulfite Cleavage.—The synthetic cocarboxylase should split in the same manner as the natural cocarboxylase, *e. g.*, into a phosphorus-free pyrimidine and a thiazolpyrophosphate:



Cocarboxylase (Pyrophosphoric acid ester of thiamin)



Pyrimidine portion

Thiazole pyrophosphate

One hundred and twenty-three mg. of cocarboxylase was dissolved in 2 cc. of water and adjusted to *p*H 5 by the addition of 0.27 cc. of *N* sodium hydroxide; 200 mg. of solid sodium bisulfite was added and the mixture allowed to stand for three days at room temperature. In less than one hour crystallization began and after concentration in vacuum at room temperature to 0.5 cc., the crystals were filtered off, washed with 3 drops of water and dried in vacuum to constant weight; yield 44.6 mg., calcd. 52 mg. It was recrystallized by dissolving in hot water, cooling, filtering, washing with several portions of water, and drying.

Anal. Calcd. for the P-free pyrimidine $C_6H_9O_3N_3S$ (m. w. 203.2): C, 35.44; H, 4.46; N, 20.68. Found: C, 35.37; H, 4.45; N, 20.51.

The filtrate from the pyrimidine portion was made slightly alkaline to litmus with ammonium hydroxide; 3 drops of hydrogen peroxide was added and the solution warmed in order to oxidize the sulfite ions to sulfate ions. The solution was then made acid to congo red with 10% nitric acid (5 drops). A slight excess of concd. barium nitrate solution and a slight excess of 10% silver nitrate solution were added. The sulfate and chloride precipitate was discarded and the filtrate was made neutral to congo red with dilute ammonium hydroxide. It was then concentrated to 3 cc. in vacuum at room temperature. An excess of 60% silver nitrate solution was added until no further precipitation occurred. The precipitate was filtered off, washed with 50%, then 90%, then 100% alcohol and finally with ether, and then dried in vacuum; yield 150 mg. silver salt, calcd. 184 mg.

The silver salt was dissolved in 3 cc. of 5% nitric acid, neutralized with ammonium hydroxide and excess 60% silver nitrate was added. The precipitate was filtered, washed with alcohol and ether as above. Analyses indicate the approximate formula: $C_6H_8O_7NSP_2Ag_3(AgOH \cdot AgNO_3)6/10 \cdot 3H_2O$ (m. w. 854.75).

Calcd.: C, 8.42; H, 1.72; total N, 2.62; N as nitrate, 0.98; Ag, 54.8; P, 7.26. Found: C, 8.21; H, 1.45; total N, 2.61; nitrate N, 0.87; Ag, 53.0; P, 7.64.

Mild Hydrolysis in *N* Nitric Acid.—3.395 mg. of the cleavage product was heated at 100° for twenty minutes with 1 cc. of *N* nitric acid: found 9.717 mg. of ammonium phosphomolybdate = 4.10% P, hence 53.6% of the total P was hydrolyzed. This indicates that only one of the phosphate radicals is removed readily from the phosphorylated thiazole.

Lohmann and Schuster evidently obtained their cleavage product in a more acid solution since their analysis indicates the formula $C_6H_8O_7NSP_2Ag_3(HNO_3)6/10 \cdot 3H_2O$, whereas we obtained a basic double salt.

The nitrate was reduced with Devarda's metal and determined colorimetrically. Nitrogen was determined according to Hayman and Adler.[5]

The analytical work was carried out by D. F. Hayman, W. Reiss and H. Levy, to whom we are indebted. We wish also to express our appreciation to Dr. R. T. Major, for his advice and interest throughout this investigation.

Summary

Synthetic cocarboxylase has been prepared in pure form and identified. Its behavior toward mild acid hydrolysis and its cleavage products as well as its coenzyme activity are identical with those of the natural cocarboxylase, the pyrophosphoric acid ester of thiamin.

The Preparation of Chlorides from Certain Aliphatic Branched Chain Secondary Carbinols[1,2]

BY FRANK C. WHITMORE AND FRANKLIN JOHNSTON

It has long been known that carbinols containing a grouping $R_3C{-}CHOH{-}$ fail to give the corresponding halide when the hydroxyl is replaced. Instead, a rearrangement occurs. Thus pinacolyl alcohol gives a tertiary chloride in at least 90% yield,[3] $Me_3CCHOHMe \longrightarrow Me_2CXCHMe_2$. In spite of nearly seventy years[2] (note 2) of study of the replacement of the hydroxyl in methylisopropylcarbinol, the course of the reaction and its products are still not clear. This condition induced the present study of two types of aliphatic secondary carbinols (1) with a fork next to the carbinol group and (2) with the fork farther removed. Even under the mildest conditions the first gave almost entirely the tertiary chloride formed by shift of the tertiary hydrogen atom adjacent to the carbinol group; thus $(CH_3)_2CHCHOHCH_3 \longrightarrow (CH_3)_2CXCH_2CH_3$. The stability recently proven for the secondary chloride[2] indicates that the tertiary chloride is formed during the replacement of hydroxyl and not through the secondary chloride as an intermediate either by direct shift of chlorine or by loss and addition of hydrogen chloride as have been suggested by the earlier workers.[2] At room temperature, without a catalyst, the second type of carbinol gave no detectable rearrangement with hydrogen chloride. Thus a secondary hydrogen does not shift appreciably under these mild conditions.

The chlorides were distilled under reduced pressure below 30° to avoid any thermal change in the products. *Thus any rearrangement which took place occurred during the replacement of hydroxyl and not by a shift of the chlorine after the replacement.* The rearrangements observed with the halides themselves take place at much higher temperatures (above 200°).[4]

In the present study, methylisopropylcarbinol has been treated with (1) zinc chloride and hydrochloric acid (Lucas) at 0°, (2) thionyl chloride and pyridine at 20°, (3) phosphorus pentachloride at 20°, (4) phosphorus trichloride at 0°, and (5) hydrogen chloride below 20° for ten weeks. The phosphorus trichloride gave only a phosphite. The other methods gave *t*-amyl chloride with only traces of material which might contain the secondary chloride. The low temperature treatment with hydrogen chloride repeatedly gave yields of over 90% of *t*-amyl chloride. This method was adopted as standard procedure with the other alcohols studied. In this way ethylisopropylcarbinol, *n*-propylisopropylcarbinol and diisopropylcarbinol gave the tertiary chlorides, dimethyl-*n*-propyl-, dimethyl-*n*-butyl- and dimethylisobutylcarbinyl chlorides, respectively. In each case the crude chloride was distilled below 30° to avoid the suspicion of temperature effects. Similarly methylisobutylcarbinol, methylisoamylcarbinol and methylneopentylcarbinol (2,2-dimethylpentanol-4) were converted to chlorides. In each case the product was the secondary chloride formed by simple replacement of hydroxyl by chlorine. No trace of tertiary chloride was detected in any of the compounds having the fork not adjacent to the carbinol group.

Experimental

Conversion of Methylisopropylcarbinol to *t*-Amyl Chloride.—Isopropyl alcohol (Petrohol supplied by Stanco, Inc.) was converted to the chloride by $ZnCl_2 \cdot HCl$ treatment in 75% yield; b. p. 33–36° (737 mm.), $n^{20}D$ 1.377. Nine moles of the chloride was converted to the Grignard reagent using 1.7 liters of ether; yield 90%. Treatment with acetaldehyde and fractionation of the product through a packed column, 2.2 × 85 cm.,[5] gave the desired carbinol; yield 56%, b. p. 110–111° (727 mm.), $n^{20}D$ 1.4090, d^{20}_4 0.818.

1. **By Zinc Chloride–Hydrochloric Acid Mixture.**—To a cooled solution of 546 g. of fused zinc chloride and 335 cc. of concd. hydrochloric acid, saturated with hydrogen chloride gas, and cooled to −10° by dry ice, was added 176 g. (2 moles) of methylisopropylcarbinol with mechanical stirring. After two hours, hydrogen chloride gas was introduced in a slow stream. Soon the mixture solidified. After standing overnight, the mixture was allowed to melt and was saturated with hydrogen chloride gas below 0°. After a total time of twenty-four hours, the chloride layer was separated and dried with 50 g. of anhydrous sodium sulfate and freed from excess hydrogen chloride by dry nitrogen; yield, 172 g. (80%).

The chloride was distilled under reduced pressure through a column with a partial condenser. Between

[5] Whitmore and Lux, THIS JOURNAL, **54**, 3448 (1932).

the column and pump were placed a manometer, a spiral trap cooled with dry ice, a 12-liter bottle to minimize changes in pressure and an adjustable leak for controlling the pressure. During a typical distillation the partial condenser was kept at about 3° with mechanically circulated ice water, the temperature in the flask was 25–26° and in the room 28–30°. Reflux from the partial condenser was kept at about 200 drops per minute. Fractions were taken every thirty minutes. The fractions, pressures (mm.), wts., g. and $n^{20}\text{D}$ were as follows: 1, (35), 3.5, 1.4049; 2, (32), 8.8, 1.4051; 3–10, (31), 127.0, 1.4052; 11, (29), 6.0, 1.4053; 12, (24), 13.4, 1.4060; residue, 2.0, 1.4340. The main fractions boiled at 84–84.5° (734 mm.). A sample hydrolyzed with distilled water[6] for thirty minutes, and titrated by the Volhard method showed 95% hydrolysis. A known sample of *t*-amyl chloride, b. p. 51° (238 mm.), $n^{20}\text{D}$ 1.4055 showed the following percentages of hydrolysis at fifteen, thirty and sixty minutes, 88.6, 94.9 and 95.4. Thus the product of the action of zinc chloride and hydrochloric acid with methylisopropylcarbinol was *t*-amyl chloride. No product having the properties of secondary isoamyl chloride, b. p. 91.9° (736 mm.), $n^{20}\text{D}$ 1.4095, was obtained.

2. By Thionyl Chloride.—A mixture of 103 g. of dry pyridine (b. p. 112–120°) and 88 g. (1 mole) of the carbinol cooled to 0° was treated during four hours with vigorous stirring with 143 g. (1.2 moles) of thionyl chloride. The mixture was stirred for three hours at room temperature. The top layer was decanted. The bottom layer consisted of a crystalline solid and a viscous oil. The top layer was diluted with low boiling hydrocarbon (b. p. 0–30°)[7] and washed with sodium bicarbonate solution and water until neutral. After drying over 10 g. of calcium chloride the solvent was removed at 300 mm. pressure and the residue was fractionated through a 1.4 × 50 cm. column of the type used in this Laboratory.[5] The temperature was 27–23° and the pressure 90–55 mm. Most of the fractions had $n^{20}\text{D}$ 1.4050–1.4060. The yield was 73%. A sample treated with water[6] showed 92% hydrolysis.

3. With Phosphorus Pentachloride.—To 214 g. (1.05 mole) of phosphorus pentachloride and 200 cc. of 0–30° hydrocarbon[7] cooled to 0° was added with stirring during two hours 88 g. (1 mole) of the carbinol. After stirring for three and one-half hours the evolution of hydrogen chloride had ceased. Two 50-g. portions of cracked ice were added. The chloride layer was washed and dried as usual and distilled to a 76% yield of crude chloride. This was distilled at 27–24° and 95–60 mm. to give mainly a product with $n^{20}\text{D}$ 1.4069 which was 83% hydrolyzed by cold water.[6] A Michael determination for secondary and tertiary halides gave 84%. Attempts to prove the presence of secondary isoamyl chloride failed.

5. With Hydrogen Chloride.—The pure carbinol was saturated with dry hydrogen chloride gas at 0° and sealed in pressure bottles. After four weeks at about 20° the bottles were opened and again saturated at 0°. After six weeks more, the chloride layer showed no further increase. It was separated, dried and distilled as usual at low pressure. Four runs with a total of 580 g. of carbinol absorbed 264 g. of hydrogen chloride and gave 676 g. of crude chloride, yield 97%. Distillation of 305 g. of the chloride at 25–26° and 33–28 mm. gave fractions with wts. (g.) and $n^{20}\text{D}$ as follows: 3–6, 83, 1.4051; 7–12, 111, 1.4053; 16–19, 42, 1.4058; 20, 14, 1.4069; residue, 13, 1.4410. Analyses for tertiary chloride and for tertiary and secondary chloride[6] on the fractions gave the values, 7, 95.6% tertiary; 18, 82% tertiary, 86.5% tertiary and secondary; 100.2% total amyl chloride (Carius); 20, 33.4% tertiary; 44.9% tertiary and secondary. The possible presence of traces of secondary and primary chlorides in the later fractions is being further investigated.

Conversion of Ethylisopropylcarbinol to Dimethyl-*n*-propylcarbinyl Chloride.[8]—The carbinol was prepared from isopropylmagnesium chloride and propionaldehyde in 52% yield, b. p. 125–126° (742 mm.), $n^{20}\text{D}$ 1.4170, d^{20}_4 0.824.[9] From 404 g. of the carbinol and hydrogen chloride was obtained 430 g. of crude chloride, 89% yield. This was distilled at reduced pressure with the water in the partial condenser at 12–13° and the heating bath at 39–42°. Fractionation of 410 g. of the chloride gave a 68% yield of material, b. p. (Cottrell) 110–111° dec. (734 mm.), $n^{20}\text{D}$ 1.4125–1.4130, d^{20}_4 0.863. These properties correspond to those of dimethyl-*n*-propylcarbinyl chloride.[10]

The structure of the chloride was proved further by conversion to the Grignard compound, treatment with oxygen[5] and conversion in 48% yield[11] to dimethyl-*n*-propylcarbinol, b. p. 93.5° (265 mm.); (Cottrell), 119.5–120.5° (738 mm.), $n^{20}\text{D}$ 1.4103, d^{20}_4 0.808. These properties correspond to the values in the literature.

When saturated with hydrogen chloride gas for fifteen minutes the carbinol was converted back to the chloride, thus confirming its tertiary nature.

Conversion of *n*-Propylisopropylcarbinol to Dimethyl-*n*-butylcarbinyl Chloride.—The carbinol was prepared from *n*-butyraldehyde, b. p. 72–74°, $n^{20}\text{D}$ 1.379 (from Butalyde supplied by Commercial Solvents Corp.), and isopropylmagnesium chloride in 62% yield, b. p. 144–145° (734 mm.), $n^{20}\text{D}$ 1.4213, d^{20}_4 0.822.[8] A total of 435 g. of the carbinol was saturated with dry hydrogen chloride at 0° as usual. The crude chloride was dried and distilled at 3 mm. pressure. Fractionation of 476 g. gave an 80% yield of chloride, b. p. (Cottrell) 133° dec. (734 mm.), $n^{20}\text{D}$ 1.4200–1.4210, d^{20}_4 0.863. These agree with the properties of dimethyl-*n*-butylcarbinyl chloride.[12]

The structure of the chloride was confirmed by conversion to dimethyl-*n*-butylcarbinol through the Grignard reagent.[5] A half-mole run gave a 42% yield of carbinol, b. p. 110° (250 mm.) 139.5–140.5° (741 mm.) (Cottrell), $n^{20}\text{D}$ 1.4173, d^{20}_4 0.813.[12] The residue of $n^{20}\text{D}$ 1.4400 amounted to only 3 g. The carbinol was changed to the chloride by hydrogen chloride gas at 0°.

Conversion of Diisopropylcarbinol to Dimethylisobutylcarbinyl Chloride.—The carbinol was kindly supplied by the du Pont Ammonia Department. It was fractionated through a 2.2 × 90 cm. column; b. p. 137–8° (738 mm.), n^{20}_{D} 1.4246, d^{20}_{4} 0.831.[12] The carbinol (464 g.) absorbed hydrogen chloride gas more slowly than the other carbinols studied. At first a pale purple color was formed. This gradually changed to brownish yellow. Reaction was complete in ten weeks at 20° and the yield of chloride was quantitative. It was distilled at 3 mm. to give 272 g. of chloride, b. p. (Cottrell) 127–128° dec. (733 mm.), n^{20}_{D} 1.4180, d^{20}_{4} 0.861. These properties correspond to dimethylisobutylcarbinyl chloride.[11] The identity was confirmed by conversion of the chloride, in 32% yield,[13] to dimethylisobutylcarbinol, b. p. (Cottrell) 130–131° (738 mm.), n^{20}_{D} 1.4166, d^{20}_{4} 0.811.[14] Treatment of fraction 7 with hydrogen chloride at 0° gave the tertiary chloride. No color appeared.

Conversion of Methylisobutylcarbinol to its Chloride.[15]—The carbinol was made in 42% yield from isobutylmagnesium bromide and acetaldehyde: b. p. 129.5° (734 mm.), n^{20}_{D} 1.4111, d^{20}_{4} 0.807.[16] Treatment of 408 g. of the carbinol with dry hydrogen chloride in the usual way for eighteen weeks gave 398 g. of crude chloride, 82% yield. Fractionation and refractionation gave methylisobutylcarbinyl chloride, b. p. (Cottrell) 111–112° (733 mm.) n^{20}_{D} 1.4113, d^{20}_{4} 0.861. The identity was substantiated further by conversion to the carbinol in 62% yield through the Grignard reagent.[5] The methylisobutylcarbinol was identified by b. p. 68° (64 mm.), n^{20}_{D} 1.4112 and conversion to the α-naphthylurethan, m. p. and mixed m. p. 96–97°.

Conversion of Methylisoamylcarbinol to its Chloride.—The carbinol was prepared in 65% yield from acetaldehyde and isoamylmagnesium chloride; b. p. 150.5–151° (742 mm.), n^{20}_{D} 1.4180, d^{20}_{4} 0.814. In the usual way hydrogen chloride gas was passed into 464 g. of the carbinol. After six weeks the chloride was separated and treated as usual. The partial condenser was kept at 14–15° and the heating bath at 50–52°. Fractionation gave a 90% yield of chloride, b. p. 138° dec. (735 mm.), d^{20}_{4} 0.863. Conversion of the chloride through the Grignard reagent and oxygen gave methylisoamylcarbinol in 60% yield, b. p. 151–152° (736 mm.), n^{20}_{D} 1.4180, α-naphthylurethan, m. p. and mixed m. p. 84–85°.

Conversion of Methylneopentylcarbinol to its Chloride.—The carbinol was prepared in 64% yield by reduction of methyl neopentyl ketone,[17] b. p. 136.5° (738 mm.), n^{20}_{D} 1.4180. The carbinol (36 g.) saturated with hydrogen chloride and allowed to stand for eight weeks gave a 90% yield of chloride which was distilled through a 1.1 × 70 cm. column[5] to give mainly methylneopentylcarbinyl chloride, b. p. 93° (250 mm.), n^{20}_{D} 1.4180; d^{20}_{4} 0.855. Only 2 g. of low boiling material was obtained. The chloride was converted to the carbinol in the usual way and the latter was converted to the α-naphthylurethan, m. p. 83°, mixed m. p. 84°.

Summary

1. It has not been possible to convert methylisopropylcarbinol to the corresponding secondary chloride.

2. Four secondary carbinols having tertiary hydrogen atoms alpha to the carbinol group gave tertiary chlorides on treatment with hydrogen chloride at room temperature.

3. Three secondary carbinols having no branch in the alpha position reacted normally without rearrangement to give the secondary chlorides.

Tertiary Butyl Chloride from Tertiary Amyl Chloride and Hydrogen Fluoride

BY J. H. SIMONS, G. H. FLEMING, FRANK C. WHITMORE AND W. E. BISSINGER

Bockemüller[1] states that alkyl chlorides, bromides and iodides are only slightly soluble in anhydrous hydrogen fluoride and that no reaction takes place when the alkyl halides are mixed with hydrogen fluoride. In the gaseous state at higher temperatures, and in the presence of a metallic fluoride catalyst, the alkyl halide will undergo double decomposition with hydrogen fluoride, yielding an alkyl fluoride. No investigations of the action of hydrogen fluoride on tertiary chlorides, bromides, or iodides, were found in the literature. The present study was started to fill this gap.

There have been obtained 10–17% yields of *t*-butyl chloride by treating *t*-amyl chloride with an equimolal quantity of anhydrous hydrogen fluoride at 0°. Besides the *t*-butyl chloride, there was also obtained a mixture probably containing hexyl, heptyl, decyl or undecyl (possibly both), and pentadecyl chlorides.

---

[1] Bockemüller, Sammlung chemischer und chemisch-technischer Vortrage, 1936.

It is interesting to note the apparent ease of formation of the tertiary butyl group under the influence of certain catalysts. Gilman[2] found that *n*-amyl chloride, *n*-hexyl bromide, and *n*-octadecyl bromide, with the ethyl ester of 5-bromofuroic acid in the presence of aluminum chloride, form in each case the same product, ethyl 4-*t*-butyl-5-bromofuroate.

Experimental

The *t*-amyl chloride was prepared by stirring 20 moles (2120 g.) of commercial *t*-amyl alcohol with 6600 cc. of concentrated hydrochloric acid. The crude *t*-amyl chloride was washed with water, dried with anhydrous potassium carbonate, and distilled from potassium carbonate through a 123 × 2.5 cm. column (15 theoretical plates) packed with single turn glass helices,[3] boiling point 37–38° (150 mm.), $n^{20}\text{D}$ 1.4053.

In order to check the purity of this *t*-amyl chloride, 100 g. of it was redistilled through a 1.1 × 45 cm. column (8 theoretical plates). The first portion of distillate boiled at 84.5° (730 mm.), thus proving the absence of *t*-butyl chloride, boiling point 51°. The literature gives the boiling point of *t*-amyl chloride as 86° (760 mm.) and $n^{20}\text{D}$ 1.4054.

The anhydrous hydrogen fluoride was a commercial product received in steel cylinders.

The procedure in a typical run was as follows: 6 moles (120 g.) of hydrogen fluoride was distilled into a dry 1-liter copper flask which was packed in a salt–ice mixture; a copper tube served as the inner tube of the Liebig condenser used in this distillation. When the required amount of hydrogen fluoride had been introduced into the flask, 6 moles (636 g.) of *t*-amyl chloride was poured into the hydrogen fluoride. The copper flask was connected immediately to a 2-hole rubber stopper which was fitted with a mercury-seal copper stirrer and a reflux condenser of copper tubing. Stirring at 0° was continued for three days. A constant evolution of hydrogen chloride occurred. When this evolution ceased the reaction was considered complete. The mixture was poured on 200 g. of ice in a 2-liter separatory funnel and washed with cold 5% sodium bicarbonate solution until the lower water layer was basic to litmus. The oil was separated, washed with ice water and dried with three 15-g. portions of potassium carbonate. Finally it was distilled from 12 g. of carbonate through a 1.1 × 45 cm. column packed with glass helices, giving 70 g. of material boiling between 40 to 60°. Redistillation of this low boiling material yielded 60 g. of *t*-butyl chloride, boiling point 49–50° (735 mm.), $n^{20}\text{D}$ 1.3855. This was further identified by conversion to trimethylacetanilide and trimethylacetic acid and its anilide.

Identification of *t*-Butyl Chloride

A. Preparation of Trimethylacetanilide.—A sample (1.5 cc.) of the material of b. p. 49–50°, $n^{20}\text{D}$ 1.3855, was dissolved in 6 cc. of ethyl ether and converted to the Grignard compound in the usual manner; an ether solution of phenyl isocyanate was added until no further reaction was observed and the complex was then decomposed on ice and hydrochloric acid. The ether layer was separated, the ether removed on the steam-bath, and the solid anilide recrystallized once from petroleum ether; melting point 131°. After a second recrystallization from petroleum ether it melted at 132.5–133°; melting point of known trimethylacetanilide 132.5–133°; mixed melting point 132°.

B. Preparation of Trimethylacetic Acid and its Anilide.—In a similar manner 23 g. of the material boiling at 49–50°, $n^{20}\text{D}$ 1.3855, was dissolved in ether and converted to the Grignard compound; dry carbon dioxide gas was then bubbled into the cold mixture. The complex was decomposed on ice and hydrochloric acid and after separation of the ether layer and evaporation of the ether, the residual oil was distilled from a 25-cc. distilling flask. There was obtained 10.8 g. of trimethylacetic acid, boiling point 162–163°; melting point 28–33°.

A portion (1.5 g.) of this acid was converted to the acid chloride by refluxing with thionyl chloride. A benzene–aniline solution was added and the mixture heated on the steam-bath. Finally the benzene solution was washed with dilute acid, dilute alkali, and water, filtered, and evaporated to dryness. Recrystallized once from petroleum ether, the anilide melted at 132.5°; mixed melting point with known trimethylacetanilide 133–133.5°.

After the material boiling below 60° had been removed the pressure was reduced and the residue fractionated. The following table presents the summarized results of the distillation.

	B. p.				Exptl.	% Cl	
Fractions	°C.	Mm.	Index	Gm.	mol. wt.	Found	Remarks
1	40–60	735	1.3760–1.3865	70			*t*-Butyl chloride
2	37–41	146	1.4060	55			Unreacted *t*-amyl chloride
3–5	32–49	92	1.4062–1.4140	23			
6–9	49–53	92	1.4152–1.4175	42	123	28.1	
11–13	19–30	5.5	1.4222–1.4257	20			Hexyl and heptyl chlorides
14–16	30–32	5.0	1.4275–1.4282	25			
19–22	49–54	5.0	1.4328–1.4372	26			
23–25	54–57	5.0	1.4382–1.4400	18			Decyl or undecyl chlorides
26–28	57–63	5.0	1.4409–1.4420	25	188	17.7	
30–31	67–71	4.0	1.4440–1.4445	12			
33–35	78–91	4.0	1.4471–1.4479	16	236	11.2	Pentadecyl chloride

There was no fluorine in the fractions corresponding to the hexyl and heptyl chlorides. No tests for fluorine were made on the higher fractions.

Some preliminary investigation of this reaction had been carried out by D. E. Badertscher in 1933 in this Laboratory. A further study of this type of reaction is in progress.

Summary

t-Butyl chloride in 10–17% yields has been obtained by treating *t*-amyl chloride with anhydrous hydrogen fluoride at 0°.

In addition to the *t*-butyl chloride, there was obtained a mixture probably containing hexyl, heptyl, decyl or undecyl, and pentadecyl chlorides.

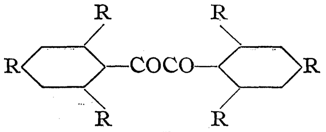
The Action of Methylmagnesium Halides on 2,4,6-Trisubstituted Benzoyl Chlorides

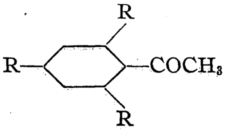
BY REYNOLD C. FUSON, J. H. VAN CAMPEN AND D. E. WOLF

The reaction of 2,4,6-trisubstituted benzoyl chlorides with methylmagnesium halides has been shown to give rise to three different types of products, depending on the nature of the substituents. In order to determine the influence of the substituents on the course of the reaction we have studied the action of methylmagnesium halides on certain benzoyl chlorides carrying alkyl groups or halogen atoms in the *ortho* positions.

In all cases the initial reaction is evidently either (1) coupling of the acid chloride to yield a benzil or (2) methylation to give the corresponding methyl ketone. For example, with 2,4,6-trimethylbenzoyl chloride and 2,4,6-triethylbenzoyl chloride both types of reactions are observed. The corresponding hexaalkylbenzils (I) and 2,4,6-trialkylacetophenones (II) are formed in nearly equal amounts.[1]

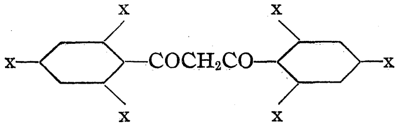


I



II

However, halogen atoms in the *ortho* positions suppress the coupling reaction entirely. 2,4,6-Trichlorobenzoyl chloride gives none of the benzil. The methyl ketone appears to be the primary product. It is of interest that this ketone is acylated readily, and under the conditions used is isolated chiefly as the corresponding 1,3-diketone (III, x = Cl).[2]

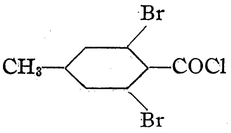


III

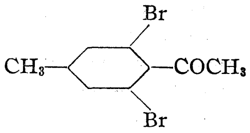
2,4,6-Tribromobenzoyl chloride reacted very sluggishly with methylmagnesium bromide or iodide, and the chief product was the 1,3-diketone, di-(2,4,6-tribromobenzoyl)-methane. The methyl ketone also was isolated in small amounts. Bromination of the diketone gave a heptabromo derivative, which could be reduced to the parent diketone by treatment with hydrogen iodide. The heptabromo compound, like the original diketone, gave a red color with an alcoholic ferric chloride solution. These facts serve to confirm the structures of the compounds in question.

Some evidence also is available to indicate that the 1,3-diketone is the result of a secondary reaction involving the methyl ketone. When the iodomagnesium enolate of the latter was treated with 2,4,6-tribromobenzoyl chloride the 1,3-diketone (III, x = Br) was formed.

One condensation was carried out with 2,6-dibromo-4-methylbenzoyl chloride (IV) and methylmagnesium iodide.



IV



V

The chloride was added slowly to a concentrated solution containing a great excess of the Grignard reagent. In this case also the reaction was exclusively of the second type; however, it stopped at the first stage giving only the methyl ketone (V). The identity of the latter was confirmed by converting it into the benzal derivative.

Experimental

A. Preparation of the Acid Chlorides

2,4,6-Trichlorobenzoyl Chloride.—This compound was prepared from 2,4,6-trichloroaniline by way of the nitrile and acid. For the synthesis of the nitrile a modification of Montagne's method[3] was employed. The nitrile was isolated by extraction and used without further purification.

---

[1] Fuson and Corse, THIS JOURNAL, **60**, 2063 (1938).

[2] Ross and Fuson, *ibid.*, **59**, 1508 (1937).

[3] Montagne, *Rec. trav. chim.*, **21**, 376 (1902).

It was converted into the acid chloride by the method of Fuson, Bertetti and Ross.[4]

2,4,6-Tribromobenzoyl Chloride.—Attempts were made to prepare 2,4,6-tribromobenzonitrile using the diazotization methods of Montagne[3] and de Milt and Van Zandt.[5] However, a modification of the method of Schoutissen[6] proved to be more satisfactory. The following is an illustrative procedure for the diazotization and subsequent replacement.

One hundred grams of 2,4,6-tribromoaniline was dissolved in 300 cc. of concentrated sulfuric acid and the solution cooled to 0°. To this mixture was added an ice-cold solution of nitrosyl sulfuric acid, prepared by adding 28 g. of sodium nitrite to 300 cc. of ice-cold concentrated sulfuric acid, warming and stirring until clear. The temperature was kept below 10° while 600 cc. of 85% phosphoric acid was added dropwise, with vigorous stirring. The stirring was continued for an hour after the addition was complete. The solution was poured, with stirring, into a warm (60°) solution of 280 g. of potassium cyanide and 275 g. of copper sulfate in 600 cc. of water. After about ten hours the mixture was filtered and the nitrile was removed from the mixture of solids by extraction with ether. The nitrile was used without purification. The yield of crude product was 90–100 g.

The hydrolysis of the nitrile was carried out according to the method of Fuson, Bertetti and Ross.[4] The reaction mixture was stirred and refluxed for seven to eight hours instead of three.

Dry, crystalline 2,4,6-tribromobenzoic acid was mixed with slightly less than the molar equivalent of phosphorus pentachloride. The reaction commenced spontaneously and the mixture soon liquefied. The mixture was then heated on the steam cone for two hours. The phosphorus oxychloride was distilled under slightly reduced pressure and the acid chloride collected at 140–141° (2 mm.); 152–154° (4 mm.). The colorless distillate solidified in the receiver; m. p. 47–49°.[7] The yield was 88–92% of the theoretical.

2,6-Dibromo-4-methylbenzoyl Chloride.—2,6-Dibromo-4-methylbenzonitrile, prepared from the corresponding amine by the method of Montagne,[3] was dissolved in a mixture of sulfuric acid, acetic acid and water in the ratio 2:1:1 by volume. After being refluxed, with stirring, for eight or nine hours the reaction mixture was cooled to 0° and an excess of sodium nitrite was added in concentrated aqueous solution. The resulting acid was converted to the acid chloride by the action of phosphorus pentachloride. The melting point of the acid chloride corresponded to that reported by Buning.[8]

B. Reaction of the Acid Chlorides with Methylmagnesium Halides

2,4,6-Trichlorobenzoyl Chloride.—A number of runs according to the procedure of Ross and Fuson[2] gave yields of 32–40% of the theoretical amount of di-(2,4,6-trichlorobenzoyl)-methane. The use of a two-fold excess of 0.5 molar solution of methylmagnesium bromide solution seems to give the best results.

The structure of the diketone was confirmed by transforming it into the dibromide and reducing the latter to regain the original diketone. The reduction of the dibromide was carried out as follows.

One gram of powdered potassium iodide and 0.8 cc. of water were added to 100 cc. of a saturated solution of potassium iodide in acetone. A solution of 1 g. of di-(2,4,6-trichlorobenzoyl)-dibromomethane and 1 cc. of concentrated hydrochloric acid in 25 cc. of acetone was added dropwise, with stirring, to the iodide solution over a period of about thirty minutes. The solution was stirred for twelve hours, condensed with a stream of air to about 35 cc. and then poured into 150 cc. of water. The iodine was removed with sodium bisulfite, the solution extracted with ether, and the ethereal extract dried over anhydrous magnesium sulfate. Distillation of the ether left a solid residue which was recrystallized from methyl alcohol, giving 0.7 g. of di-(2,4,6-trichlorobenzoyl)-methane, m. p. 158–160°. The yield was 96% of the theoretical amount.

Di-(2,4,6-trichlorobenzoyl)-bromomethane.—One and five-tenths grams of di-(2,4,6-trichlorobenzoyl)-methane was dissolved in 150 cc. of glacial acetic acid, 5 cc. of bromine was added all at once, and the mixture was allowed to stand at room temperature for three to five days. The solution was poured, with stirring, into 1500 cc. of water and sodium bisulfite added to discharge the bromine color; an excess of bisulfite was carefully avoided. After standing for several hours the product was collected on a filter and dried. The crude di-(2,4,6-trichlorobenzoyl)-bromomethane weighed 1.7 g. After repeated recrystallization from low-boiling petroleum ether this material melted at 163–164°. It was very soluble in ether, chloroform, carbon tetrachloride, benzene and dioxane, and was slightly soluble in ethyl alcohol, methyl alcohol, ethyl acetate and petroleum ether. It was insoluble in dilute alkali, gave a red color immediately with alcoholic ferric chloride solution and imparted a yellow color to concentrated sulfuric acid.

One gram of this material was recovered unchanged after refluxing for three days in a solution of 5 cc. of bromine in 100 cc. of chloroform.

Anal. Calcd. for $C_{15}H_5O_2Cl_6Br$: C, 35.33; H, 0.99; mol. wt., 510. Found: C, 35.46; H, 1.09; mol. wt., 489.

2,4,6-Tribromobenzoyl Chloride.—2,4,6-Tribromobenzoyl chloride was refluxed for ninety hours at 50° with two equivalents of 0.5 molar methylmagnesium bromide or iodide and the resulting mixture decomposed with dilute hydrochloric acid. The ether was evaporated by a stream of air and the solid separated by decantation through a Büchner funnel. The solid was twice washed with ether by decantation and the aqueous solution extracted with three portions of ether. The combined ethereal extract was dried over anhydrous sodium sulfate.

The yield of this crude solid, di-(2,4,6-tribromobenzoyl)-methane, was 38% of the theoretical. After four recrystallizations from a mixture of benzene and alcohol, this compound melted at 244–245°, with decomposition.

Anal. Calcd. for $C_{15}H_6O_2Br_6$: C, 25.78; H, 0.86; Br, 68.77; mol. wt., 698. Found: C, 25.84; H, 0.89; Br, 68.79; mol. wt., 669.

---

(4) Fuson, Bertetti and Ross, This Journal, **54**, 4380 (1932).

(6) Schoutissen, *ibid.*, **55**, 4531 (1933).

(7) Sudborough, *J. Chem. Soc.*, **67**, 587 (1895).

(8) Buning, *Rec. trav. chim.*, **40**, 327 (1921).

The di-(2,4,6-tribromobenzoyl)-methane was soluble in chloroform, carbon tetrachloride and benzene, slightly soluble in *n*-butyl alcohol and petroleum ether, but quite insoluble in ether, alcohol, acetic acid, ethyl acetate and methyl alcohol. It was not affected by boiling for three days with a 50% solution of sodium hydroxide in 20% alcohol. The compound gave a red color in alcoholic ferric chloride solution and a yellow color with concentrated sulfuric acid. A blue-gray copper derivative was formed when a benzene solution of the compound was shaken for thirty minutes with a saturated aqueous solution of copper acetate. The copper derivative could be purified by dissolving in chloroform and reprecipitating with a small amount of alcohol.

Distillation of the ether from the ethereal extract obtained above left a dark, oily residue. By steam distillation and subsequent recrystallization from high-boiling petroleum ether 2,4,6-tribromoacetophenone was obtained, m. p. 86–90°. After recrystallization this material melted at 93°. No depression in the melting point was noted when this material was mixed with an authentic sample of 2,4,6-tribromoacetophenone prepared by diazotization of 3-amino-2,4,6-tribromoacetophenone. The yield of methyl ketone was about 16% of the theoretical.

No advantage was apparent in using chlorobenzene along with ether as a solvent and at the same time carrying out the reaction at 80–90°.[9]

2,4,6-Tribromoacetophenone.—Seventy-five cubic centimeters of 2.2 molar methylmagnesium iodide was heated on a water-bath until no more ether would distil. At this point 45 cc. of ether had been collected. The condenser was then set for refluxing and stirring begun. A solution of 5 g. of 2,4,6-tribromobenzoyl chloride in 15 cc. of anhydrous benzene was added dropwise, the rate of addition being adjusted so that forty-five minutes was required for the entire operation. Throughout the reaction the temperature was maintained at 95° by means of a water-bath. The stirring was continued for eighty minutes, the mixture cooled, and 50 cc. of anhydrous ether added. The resulting solution was poured into ice and hydrochloric acid, the ether layer separated and the aqueous layer extracted with ether. The combined ethereal extract was washed with dilute bicarbonate solution, with water and then dried over anhydrous magnesium sulfate. Distillation of the ether left a brown oil. After steam distillation of this oil and recrystallization of the distillate from high-boiling petroleum ether, 2.2 g. of a solid material was obtained; m. p. 80–86°. After recrystallization this material melted at 92°. It was shown by mixed melting point to be 2,4,6-tribromoacetophenone. The yield was 46% of the theoretical.

Di-(2,4,6-tribromobenzoyl)-methane from 2,4,6-Tribromoacetophenone and 2,4,6-Tribromobenzoyl Chloride.—Two grams of 2,4,6-tribromoacetophenone was dissolved in 25 cc. of anhydrous benzene and to this was added 3.1 cc. of 2.2 molar methylmagnesium iodide. The solution was refluxed for two hours. Two and one-tenth grams of 2,4,6-tribromobenzoyl chloride was added and the resulting mixture was refluxed for thirty hours. The mixture was poured into dilute hydrochloric acid, stirred well and the benzene layer separated and dried. Distillation of the benzene left a residue of liquid and solid. Alcohol was added and the solid collected on a filter. The di-(2,4,6-tribromobenzoyl)-methane thus obtained weighed 2.1 g. and melted at 239–241°, with decomposition. After recrystallization from benzene and alcohol the compound melted at 244–245°, with decomposition. The yield of diketone was 54% of the theoretical.

Di-(2,4,6-tribromobenzoyl)-bromomethane

1. With Bromine in Chloroform.—Eighty-five hundredths of a gram of di-(2,4,6-tribromobenzoyl)-methane was dissolved in 100 cc. of chloroform. Six cubic centimeters of bromine was added all at once and the mixture allowed to stand for three days at room temperature under the light of a 300-watt lamp. The resulting solution was washed with dilute sodium bisulfite solution, with water and then dried over anhydrous magnesium sulfate. Evaporation of the solvent and recrystallization from chloroform gave 0.7 g. of di-(2,4,6-tribromobenzoyl)-bromomethane which softened at 264° and melted, with decomposition, at 270–272°. The yield was 74% of the theoretical. After four recrystallizations from chloroform the compound softened at 264° and decomposed at 272–273°. If the tube containing the material was inserted in the bath at 260°, the compound softened at 266° and decomposed at 274–276°. The decomposition point as determined on the Maquenne block was 282°.

Anal. Calcd. for $C_{15}H_5O_2Br_7$: C, 23.20; H, 0.65. Found: C, 23.45; H, 1.01.

The solubility of this compound is very similar to that of di-(2,4,6-tribromobenzoyl)-methane. The substance gives a red color with alcoholic ferric chloride solution, the color deepening with warming, and imparts a yellow color to concentrated sulfuric acid.

2. With Sodium Hypobromite.—One gram of di-(2,4,6-tribromobenzoyl)-methane was dissolved in 20 cc. of pyridine and this solution added to 100 cc. of 10% sodium hypobromite solution. The mixture was shaken for seven days at room temperature and then extracted with two 75-cc. portions of benzene. This extract was dried over calcium chloride and the solvent distilled under reduced pressure. Recrystallization of the solid residue from chloroform gave 1 g. of di-(2,4,6-tribromobenzoyl)-bromomethane which softened at 264° and decomposed at 270–272°. The yield was 90% of the theoretical.

Reduction of Di-(2,4,6-tribromobenzoyl)-bromomethane.—One gram of this compound was reduced by the method described above for di-(2,4,6-trichlorobenzoyl)-bromomethane. Eight-tenths of a gram of di-(2,4,6-tribromobenzoyl)-methane was obtained, m. p. 233–238°.

Reaction of 2,6-Dibromo-4-methylbenzoyl Chloride with Methylmagnesium Iodide.—Thirty-two grams of the acid chloride in twice its volume of dry ether was added over a period of one hour to a boiling 5 molar solution of methylmagnesium iodide which contained a nine-fold excess of the reagent. The addition was accompanied by vigorous stirring. The reaction mixture was diluted with 800 cc. of ether and poured slowly into ice and dilute hydrochloric acid. By extraction with ether the methyl ketone was obtained as a red oil which crystallized when cooled. After five recrystallizations from 95% ethanol,

---

[9] Gilman and St. John, *Rec. trav. chim.*, **49**, 222 (1930).

the solution being treated each time with Darco, the white crystalline product melted at 53–54°.

Anal. Calcd. for $C_9H_8OBr_2$: C, 37.03; H, 2.74; Br, 54.75; mol. wt., 292. Found: C, 37.41; H, 3.08; Br, 54.69; mol. wt., 286.

The Benzal Derivative of 2,6-Dibromo-4-methylacetophenone.—The identity of the methyl ketone was confirmed by condensing it with benzaldehyde. About 6 g. of the crude ketone was mixed with 20 cc. of 10% sodium hydroxide solution, 10 cc. of 95% ethyl alcohol and 10 cc. of benzaldehyde. The mixture was shaken for twenty hours at room temperature. At the end of this period there was a yellow mixture of crystals and oil at the bottom of the flask. The entire mixture was shaken with ether which was then washed with bisulfite solution. The ether solution was washed with water, dried and evaporated giving a crystalline residue. After the crystals were washed with petroleum ether and recrystallized three times from ethyl alcohol they melted at 96–97°.

Anal. Calcd. for $C_{16}H_{12}OBr_2$: C, 50.57; H, 3.16; Br, 42.06; mol. wt., 380 Found: C, 51.06; H, 3.21; Br, 42.43; mol. wt., 379.

Summary

2,4,6-Trihalobenzoyl chlorides react with methylmagnesium halides to give the corresponding di-(2,4,6-trichlorobenzoyl)-methanes. Under suitable conditions the methyl ketone, undoubtedly an intermediate in the reaction, can be isolated.

The structure of the 1,3-diketones was proved by converting them to the corresponding mono- or dibromides and then regaining the original diketone by debromination.

2,6-Dibromo-4-methylacetophenone was obtained by the interaction of 2,6-dibromo-4-methylbenzoyl chloride and an excess of methylmagnesium iodide.

Reformatsky Condensations Involving Vinylogs of Haloacetic Esters

BY REYNOLD C. FUSON, R. T. ARNOLD AND H. G. COOKE, JR.

The extension of the Reformatsky method to vinylogs of haloacetic esters was attempted with the hope of obtaining a method of synthesizing carotenoid chains. The general reaction sought was the following

$$XCH_2(CH{=}CH)_nCOOR \xrightarrow[Zn]{RCHO} R(CH{=}CH)_{n+1}COOR$$

Results obtained with ethyl γ-bromo- and γ-iodocrotonate show that the desired reaction takes place. The value of the method in synthetic work would appear to be conditioned by the availability of the γ-halocrotonates.

Ethyl γ-bromo- and γ-iodocrotonate react with benzaldehyde in the presence of zinc to give an oil which can be hydrolyzed to cinnamylideneacetic acid

$$XCH_2CH{=}CHCOOC_2H_5 \xrightarrow{C_6H_5CHO} C_6H_5(CH{=}CH)_2COOH$$

Cyclohexanone reacts similarly, giving the expected unsaturated ester, $C_6H_{11}(CH{=}CH)_2COOC_2H_5$.

Ethyl iodocrotonate also was condensed with *p*-chlorobenzaldehyde to give *p*-chlorocinnamylideneacetic acid. This acid was synthesized for comparison from *p*-chlorocinnamaldehyde and malonic acid.

It was of particular interest to compare the behavior of ethyl γ-iodocrotonate with that of the corresponding saturated ester, ethyl γ-iodobutyrate, to see what influence the vinylene linkage really had. The condensation reaction depends chiefly on the reactivity of the halogen atom which in turn is due presumably to the activating influence of the carbethoxy group. The transfer of this effect should be much more efficient in the vinylogs of haloacetic esters than in the corresponding saturated esters. This was found to be the case. Ethyl γ-iodobutyrate condenses with benzaldehyde in the presence of zinc to give the normal Reformatsky condensation but the reaction proceeds very slowly and the yields are almost negligible.

Experimental

The Condensation of Ethyl γ-Bromo- and γ-Iodocrotonate with Benzaldehyde.—Nineteen grams of ethyl γ-iodocrotonate[1] in 20 cc. of dry, peroxide-free butyl ether was added dropwise to a mixture of 16 g. of benzaldehyde, 30 cc. of butyl ether and 5.5 g. of zinc dust. The zinc dust was cleaned by treatment for a few seconds with dilute hydrochloric acid and subsequent washing with water, acetone and dry benzene. It was not allowed to stand in contact with the air. The mixture was refluxed, with stirring, for thirty-six hours, then decomposed with very

---

(1) Braun, THIS JOURNAL, **52**, 3174 (1930).

dilute cold hydrochloric acid. Careful fractionation of the ether solution gave 2.3 g. of a viscous yellow oil; b. p. 162–165° (4 mm.).

The use of an equivalent amount of ethyl γ-bromocrotonate in the above process gave approximately 1 g. of the same high-boiling oil. Treatment of this oil with phenyl isocyanate in a closed, evacuated tube gave *sym*-diphenylurea. Oxidation with a sodium dichromate–sulfuric acid mixture converted the oil to benzoic acid.

The facts indicated that the oil was the expected hydroxy ester. Analysis showed, however, that it was impure, and it was subjected to *hydrolysis*. One cubic centimeter of the oil was added to a saturated solution of potassium hydroxide in ethyl alcohol and the mixture was allowed to stand overnight. Dilution with water followed by careful acidification with dilute sulfuric acid gave a solid which after recrystallization from benzene weighed 0.6 g. and melted at 165°. Admixture of a known sample of cinnamylideneacetic acid[2] did not depress the melting point.

The Condensation of Ethyl γ-Iodocrotonate with *p*-Chlorobenzaldehyde.—Fourteen grams of pure *p*-chlorobenzaldehyde and 6 g. of clean zinc dust were placed in a 500-cc., round-bottomed, three-necked flask containing 50 cc. of dry benzene and equipped with two efficient reflux condensers. The solution was heated to boiling and a solution of 20 g. of ethyl γ-iodocrotonate in 20 cc. of dry benzene was added dropwise. The reaction was highly exothermic, and an ice-bath was used to keep the ebullition from becoming too vigorous. After the addition was complete the mixture was refluxed for ten hours and decomposed with dilute hydrochloric acid and ice. The benzene layer gave 8.7 g. of a yellow oil; b. p. 180–185° (4 mm.). As in the case of benzaldehyde, analysis of this ester indicated that it was partially dehydrated.

***p*-Chlorocinnamylideneacetic Acid.**—One gram of the yellow oil was dissolved in 30 cc. of saturated alcoholic potassium hydroxide solution and allowed to stand overnight at room temperature. The mixture was diluted with water and acidified with dilute sulfuric acid. The precipitated *p*-chlorocinnamylideneacetic acid was recrystallized from ethanol, m. p. 251° (corr.), with decomposition.

Anal. Calcd. for $C_{11}H_9O_2Cl$: C, 63.30; H, 4.30. Found: C, 63.24; H, 4.45.

For comparison this acid was synthesized from *p*-chlorocinnamaldehyde and malonic acid by a method similar to that used by Dutt[2] for the synthesis of cinnamylideneacetic acid. To a solution of 7 g. of the aldehyde and 6 g. of the acid in 30 cc. of pyridine was added 3 cc. of piperidine, and the mixture refluxed for twenty hours. It was then poured into 250 cc. of dilute sulfuric acid and the dark gray precipitate was recrystallized first from glacial acetic acid and then repeatedly from 95% ethyl alcohol. The *p*-chlorocinnamylideneacetic acid formed in white flakes melting at 251° (corr.), with decomposition. No depression of melting point was noted when this acid was mixed with that prepared by the Reformatsky method. The methyl ester (from methyl alcohol) melted at 132° (corr.).

Anal. Calcd. for $C_{12}H_{11}O_2Cl$: C, 63.60; H, 4.90. Found: C, 64.32; H, 4.91.

The Condensation of Ethyl γ-Iodocrotonate with Cyclohexanone.—Fifteen grams of ethyl γ-iodocrotonate in 10 cc. of dry benzene was added dropwise to 50 cc. of benzene containing 12 g. of cyclohexanone and 4 g. of clean zinc dust. The mixture was refluxed for eight hours after the initial vigorous reaction had subsided and then decomposed with dilute sulfuric acid. Fractionation of the dried benzene solution produced 6.2 g. of the ethyl ester; it is a colorless oil boiling at 143–148° (8 mm.). Bromine and permanganate tests for unsaturation were positive.

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.23; H, 9.48. Found: C, 74.28; H, 9.28.

Ethyl γ-Iodobutyrate.—Ethyl γ-chlorobutyrate prepared according to the method of Henry[3] was converted into the iodo ester by treatment with sodium iodide. A mixture of 127 g. of the chloro ester, 450 cc. of acetone and 127 g. of sodium iodide was shaken for three hours at 27°. Only 30 g. of sodium chloride separated. The mixture was then refluxed for two hours, filtered and the filtrate poured into 1 liter of ether. The ether solution was washed with water containing about 1% of sodium thiosulfate. Fractionation of the ether layer gave 130.6 g. or 63.5% of the theoretical amount of the iodo ester. The ester boiled at 84–85° (4 mm.).

Anal. Calcd. for $C_6H_{11}O_2I$: C, 29.75; H, 4.55. Found: C, 29.61; H, 4.61.

The Condensation of Ethyl γ-Iodobutyrate with *p*-Chlorobenzaldehyde.—To a boiling mixture of 75 cc. of benzene, 17.5 g. of *p*-chlorobenzaldehyde, and 8 g. of clean zinc was added dropwise a solution of 30 g. of ethyl γ-iodobutyrate in 30 cc. of benzene. The mixture was refluxed for twenty-four hours, cooled, decomposed with water and filtered through bone charcoal. The benzene layer yielded 10.3 g. of *p*-chlorobenzaldehyde, 4.3 g. of ethyl γ-iodobutyrate, 0.7 g. of a liquid boiling at 195–200° (3 mm.) (m. p. 122–123°) and some tarry products. The compound melting at 122–123° (from ethanol) had the composition of the expected unsaturated ester.

Anal. Calcd. for $C_{13}H_{15}O_2Cl$: C, 65.41; H, 6.29. Found: C, 65.26; H, 6.37.

Summary

The Reformatsky condensation has been extended to vinylogs of haloacetic esters. Ethyl γ-bromo- and γ-iodocrotonate have been condensed with benzaldehyde to give cinnamylideneacetic acid. *p*-Chlorocinnamylideneacetic acid has been made from *p*-chlorobenzaldehyde in a similar manner. Ethyl γ-iodobutyrate undergoes this type of condensation only with difficulty and in very low yield.

NOTES

Structure of Lignin

By A. B. Cramer, M. J. Hunter and Harold Hibbert

The authors have been able to isolate recently, from spruce wood, by organic solvent extraction, an aromatic ketone in high yield (about 1–2% calculated on the weight of wood taken). This ketone is an oil, distilling at a bath temperature of 140–150° (0.004 mm.). On methylation it yields a well-defined white crystalline compound, formula $C_{13}H_{18}O_4$, m. p. 81–82°. The ketone structure of the latter product was proved by its additive power for the Grignard reagent and ready formation of a hydrazone. It also contains the veratryl radical since it gives veratric acid on oxidation.

Analysis of the methylated ketone.—Calcd. for $C_{13}H_{18}O_4$: C, 65.5; H, 7.6. Found: C, 65.5; H, 7.7. Total alkoxyl found (calculated as methoxyl): 38.7%. *Grignard machine analysis:* Addition, 0.85 mole per mole weight. Active hydrogen, 0.13 mole per mole weight.

The substance from which this crystalline product apparently is derived may be one of several isomers, each consisting of a guaiacyl group with a side chain of three carbon atoms containing a carbonyl and a hydroxyl group. The syntheses of the possible methylated compounds are now in progress. The extraordinary chemical reactivity of this type of parent substance would explain the previous difficulties associated with its isolation and characterization. Such a structure provides a satisfactory basis for interpreting the results obtained in the hydrogenation of methanol lignin at high temperatures and pressures [This Journal, **60,** 1467 (1938)].

The isolated ketone is accompanied by considerable quantities of what appears to be a polymerized product, an aldehyde, an acid, a neutral substance, and a carbohydrate-containing fraction. The combined yield of all of these products calculated on the weight of the wood taken amounts to a total of 5% in the case of spruce, and roughly 10% in the case of maple.

Work now in progress on oils from hard woods indicates the additional presence of derivatives containing the syringyl group and it is possible that this may be the fundamental chemical difference between soft and hard woods.

The Preparation of Amyl Salicylates

By Andrew F. Freeman and H. L. Haller

A search of the literature discloses that, of the eight theoretically possible amyl salicylates, only the normal amyl[1] and the isoamyl ester[1,2] have their properties recorded. The procedure for the preparation of the latter has been given,[2] but no reference is made to the mode of formation of the former.

In the present communication methods of preparing primary normal amyl salicylate, secondary normal amyl salicylate, and tertiary amyl salicylate are described. Isoamyl salicylate from carefully purified isoamyl alcohol and salicylic acid also has been prepared, and its physical properties have been found to be identical with those recorded by Drion.[2]

The salicylates derived from the primary amyl alcohols were prepared with sulfuric acid as the esterifying agent, but when this procedure was applied to the secondary and tertiary amyl alcohols, dehydration of the alcohol occurred, and the yield of ester was negligible. It was found, however, that the secondary and tertiary esters could be obtained on condensation of salicylic acid chloride and the carbinol in the presence of a small quantity of anhydrous aluminum chloride. With the secondary carbinol this procedure gave satisfactory yields of ester, but with the tertiary carbinol the yield of ester was small.

Primary Normal Amyl Salicylate.—A commercial grade of primary amyl alcohol was purified by fractional distillation in a column of the type described by Dupont[3] and modified by Palkin.[4] The fraction employed in the esterification had the properties: b. p. 82–83.6° at 85 mm., n^{20}_D 1.4109, n^{26}_D 1.4090, d_{20} 0.8179, $[M]_D$ found 26.66, calcd. 26.815.

---

(1) "International Critical Tables," Vol. I, McGraw-Hill Book Co., Inc., New York, 1926, p. 246.

(2) C. Drion, *Compt. rend.*, **39**, 122 (1854).

(3) G. Dupont, "Les Essences de Térébenthine," Paris, 1926, p. 57.

(4) S. Palkin, *U. S. Dept. Agr., Tech. Bull.*, **276** (1932); *Ind. Eng. Chem., Anal. Ed.*, **3**, 377 (1931); **7**, 436 (1935).

A mixture of salicylic acid (50 g.), primary normal amyl alcohol (200 g.), and concentrated sulfuric acid (2 cc.) was heated under a reflux condenser for about four hours. The apparatus was provided with a trap to remove the water that was formed. After the unreacted alcohol had been removed by distillation at atmospheric pressure, the residue was washed with 10% potassium carbonate and dissolved in ether, and the ether solution was dried over anhydrous sodium sulfate. The high-boiling material remaining after the removal of the ether was fractionated under reduced pressure by means of a Widmer column. The fraction that boiled at 116–121° and 1.4 mm. pressure was collected. The yield was 64 g.: $n^{27}\text{D}$ 1.5042, d_{27} 1.0552, $[M]\text{D}$ found 58.40, calcd. 58.30.

Anal.[5] Calcd. for $C_{12}H_{16}O_3$: C, 69.23; H, 7.87. Found: C, 69.15; H, 7.82.

In all these experiments some ether was formed, the amount increasing with the time of refluxing the reaction mixtures.

Secondary Normal Amyl Salicylate.—The methyl-*n*-propylcarbinol employed in this experiment was obtained by fractional distillation of a commercial grade of the carbinol in a Dupont–Palkin[4] type of still. The purified carbinol had the properties: b. p. 61.8–64.7° at 85 mm., $n^{25}\text{D}$ 1.4065, d_{25} 0.8041, $[M]\text{D}$ found 26.91, calcd. 26.815.

A mixture of 40 g. of salicylic acid, 50 cc. of thionyl chloride, and 0.08 g. of anhydrous aluminum chloride was heated under reflux in a water-bath maintained at 40–50° until the acid was entirely dissolved. The solution was then concentrated at reduced pressure to remove hydrogen chloride and excess thionyl chloride. One-half of the residue, a clear, greenish-yellow liquid, was transferred to a 125-cc. Erlenmeyer flask, and 30 cc. of methyl-*n*-propylcarbinol was added in small portions. The mixture was cooled in an ice-bath for several hours, and then, with the flask stoppered with a calcium chloride tube, allowed to stand for twenty-four hours. The solution was washed several times with ice water, then with a small quantity of dilute sodium bicarbonate, and again several times with ice water. The material was dried in ether over anhydrous sodium sulfate and, after removal of the ether, was purified by repeated distillation under reduced pressure. The yield was 9.8 g. The ester boiled at 107–110° and 4–5 mm.: $n^{25}\text{D}$ 1.5020, d_{25} 1.0470, $[M]\text{D}$ found 58.60, calcd. 58.30.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.23; H, 7.87. Found: C, 69.16; H, 7.81.

Tertiary Amyl Salicylate.—The tertiary amyl alcohol was a commercial grade which boiled at 100–102°. To the remaining half of the salicyl chloride prepared from 40 g. of salicylic acid by the procedure described above, 125 cc. of tertiary amyl alcohol was added slowly with vigorous shaking, the flask being kept cold in an ice-bath. Considerable hydrogen chloride was given off and some heat was evolved during the process. After standing in the ice-bath for several hours, the solution deposited a small quantity of crystalline material. This was removed by filtration, and the filtrate was distilled under reduced pressure. The pure ester was obtained by fractional distillation under reduced pressure. The yield was 6.5 g. It boiled at 84–86° and 3 mm. pressure: $n^{25}\text{D}$ 1.5064, d_{25} 1.0533, $[M]\text{D}$ found 58.74, calcd., 58.30.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.23; H, 7.87. Found: C, 69.12; H, 7.88.

Reactions of Fluorinated Derivatives with Sodium, Potassium and Magnesium

BY ALBERT L. HENNE

Stable fluorinated compounds have been subjected to the action of magnesium in the hope of obtaining a Grignard reaction, and of sodium in the hope of obtaining a Wurtz reaction. In both cases the action was immediate and complete but the results were entirely different from those hoped for. The vigorous character and completeness of the reactions showed the futility of further work in the same direction and, therefore, the unexpected results are presented for publication. Some of these results (representative of what happens in other cases) were as follows.

(1) CHF_2CH_2I was dissolved in ether and allowed to drip onto clean magnesium. A reaction took place instantly. A small portion gave a faint test with Michler's ketone, indicating the formation of a Grignard compound; however, after a short period, the Grignard test was no longer positive. As the addition of CHF_2CH_2I to the magnesium was continued, a gas was evolved which was caught in bromine. It was observed that the reaction of this gas with bromine took place in the vapor phase, not the liquid, and the absorption was therefore incomplete. The gas was vinyl fluoride, as shown by the facts that the dibromide $CHFBrCH_2Br$ was the only compound found and that it was quite pure. Due to faulty experimental conditions only 50% of the vinyl fluoride was recovered as dibromide. The resulting magnesium salt was an equimolecular mixture of magnesium iodide and magnesium fluoride. Both salts are soluble in ether and in water, the fluoride as a colloid, and on account of this, a test for fluorine fails to give positive results before the magnesium fluoride has been brought from the colloidal to the crystalline stage.

(2) Attempts to cause CHF_2CH_2Br to act upon magnesium were unsuccessful.

(3) A piece of sodium or potassium reacted

---

(5) We are indebted to Dr. W. G. Rose for the microcombustions.

energetically with CHF_2CH_2Br or CHF_2CH_2I. The reaction was run in ethyl ether, where it still was very vigorous and complete. Instead of acting upon the iodine atom only, the alkali metal removed one atom of fluorine and one atom of iodine, and gave a quantitative yield of sodium fluoride and sodium iodide or bromide. In doing so it behaved like magnesium or zinc.

(4) In contrast with the preceding result, fluorinated derivatives of methane (namely, CCl_2F_2, $CHClF_2$ and $CHBrF_2$) remained unaffected when passed through molten sodium.

Preparation of Methylaluminum Chlorides

BY VINCENT F. HNIZDA AND CHARLES A. KRAUS

The methyl- and ethylaluminum chlorides have not been reported in the literature until recently. Walker and Willson[1] showed that methyl chloride reacts with aluminum metal when catalyzed by iodine or aluminum chloride, forming an unidentified product which "may be expressed" as Me_2AlCl plus $MeAlCl_2$. Hall and Nash[2] isolated the ethylaluminum chlorides from the products of polymerization of ethylene with a mixture of aluminum and aluminum chloride, and identified the double salt $EtAlCl_2 \cdot NaCl$. Later, Grosse[3] reported the melting and boiling points of the four methyl- and ethylaluminum chlorides.

Since none of these articles gives a satisfactory method of preparation of the compounds in question, it seems desirable to describe briefly the simple method which has been used successfully in these Laboratories since some time prior to the appearance of the articles cited. This description pertains primarily to the methyl chlorides; the ethyl chlorides and the methyl and ethyl bromides have been prepared similarly.

The desired amount of aluminum metal, preferably in an alloy such as Aluminum Company of America Alloy 12 (8% copper), is cut in clean, dry shavings or chips. These are placed in a glass or steel reaction vessel equipped with: halide inlet and product discharge lines, temperature and pressure gages, provision for heating and cooling, and a safety blow-out. The catalyst, about 0.1% of anhydrous aluminum chloride (or iodine, or the product of a previous preparation) is placed in one spot on top of the aluminum, and the reaction vessel closed. Air is pumped or flushed out, and methyl chloride gas introduced to a pressure of one atmosphere (or more, depending on the equipment used). If the reaction fails to start in one hour at room temperature, the charge is heated to 100°. Once started, the reaction is autocatalytic and highly exothermic. More methyl chloride is added, and cooling is applied, at such rates as to maintain a suitable rate of reaction and to keep the temperature of the charge below 75°. At higher temperatures, side reactions may occur with the formation of gas.

When no more methyl chloride is absorbed, the reaction is completed. The reaction of the aluminum is quantitative, while any iron or copper in the alloy remains unattacked. Side reactions are negligible. In a typical preparation, about 60 millimoles of aluminum in the form of alloy took up 88.9 millimoles of methyl chloride with the formation of only 0.9 millimole of methane; the nonvolatile residue contained no aluminum and 0.4 milliatom of chlorine; no iron or copper was detected in the distilled product.

The water-white, oily liquid is decanted or vacuum distilled, from the remaining metallic sludge, into a suitable closed container. If desired, this product can be diluted with methyl chloride to lower its viscosity and to facilitate the removal of samples from the container. Such methyl chloride solutions apparently are stable in glass or steel containers, and react slowly with copper or lead. The stability of solutions of the bromides and of the corresponding ethyl compounds is less assured, and is under investigation. In any case, a safety blow-out for the container is recommended. These aluminum compounds are, of course, highly reactive toward air, moisture, and other oxygen compounds; however, their oxidation or inflammation in air is not violent.

The product of the methyl chloride reaction is almost exactly an equimolecular mixture of dimethylaluminum chloride and methylaluminum dichloride. No evidence of either trimethylaluminum or of aluminum chloride is obtained on fractional distillation. Analysis is effected by hydrolysis of a sample with wet ether followed by dilute nitric acid, and determination of the amount of methane evolved, and of the aluminum and chloride content of the solution. In a typical preparation, this analysis gave 13.58 milliatoms of aluminum, 19.60 of chlorine, and 20.46 millimoles of methane, or a ratio of Me:Al:Cl of 1.507:1:1.443.

When the individual compounds are desired, they may be separated from their mixture by fractional vacuum distillation, or the dimethylaluminum chloride may be obtained in pure form by heating the mixture with excess sodium chloride and distilling the dimethyl compound from the monomethyl addition compound. Analysis of a typical distillate from the latter procedure gave 23.4 milliatoms of aluminum, 23.6 of chlorine, and 47.1 millimoles of methane, or a ratio of Me:Al:Cl of 2.01:1:1.01.

COMMUNICATIONS TO THE EDITOR

FORMATION OF AN ACID ANHYDRIDE BY THE ACTION OF WATER ON ORGANOMETALLIC COMPLEXES

Sir:

The formation of an acid anhydride by the addition of water to an organometallic complex has been observed in two different instances. A Grignard reagent, prepared from 4-bromo-7-isopropylhydrindene, when added to pure α-naphthoyl chloride in ether, yielded 50% of the expected ketone, 4-α-naphthoyl-7-isopropylhydrindene, together with 28% of the hydrocarbon, 4-isopropylhydrindene, and 22% of α-naphthoic anhydride. Another instance was found in the reaction between α-naphthoyl chloride and the lithium derivative from 2,7-dimethyl-4-bromohydrindene.[1] In this reaction the yield of ketone was small, but that of hydrocarbon and anhydride large. Particularly in this case, the formation of colored solutions showed the formation of complexes. A fleeting bright red color[2] gave place to a pale orange which disappeared on addition of water to give rise to the granular yellow anhydride.

The experimental procedure in both cases involved addition of the organometallic solution to α-naphthoyl chloride dissolved in absolute ether, ensuring an excess of acid chloride. To a solution of 15 g. of α-naphthoyl chloride (m. p. 21°) in absolute ether at −5° was added dropwise with stirring a Grignard reagent made from 10 g. of 4-bromo-7-isopropylhydrindene, 2 g. of magnesium and 60 cc. of ether. The solution was then refluxed for four hours. An equal volume of saturated sodium bicarbonate solution was added in order to remove the unchanged acid chloride. Upon distilling most of the ether and cooling, a yellow granular solid appeared. This proved to be α-naphthoic anhydride melting at 145°, and giving the same value upon admixture with an authentic sample. Upon distillation of the remaining material, 2 g. of 4-isopropylhydrindene, b. p. 88–90° at 1 mm., and 7.3 g. of 4-α-naphthoyl-7-isopropylhydrindene, b. p. 225–235° at 1.2 mm., were secured.

In the second instance, 0.70 g. of lithium wire was dissolved in a solution of 7 g. of 2,7-dimethyl-4-bromohydrindene[1] in 100 cc. of ether. This orange-colored solution was added over a period of three hours to 15 g. of α-naphthoyl chloride in 200 cc. of ether. The residue of lithium salt was washed with 50 cc. of ether and 100 cc. of benzene. Addition of 300 cc. of saturated sodium bicarbonate solution with stirring until the evolution of carbon dioxide had practically stopped (four hours) left a clear light red solution which was concentrated to about 50 cc. Upon standing, 7 g. of α-naphthoic anhydride, m. p. 145–146°, separated. The substance was identified by its analysis and melting point, and by hydrolysis with alcoholic sodium hydroxide to give α-naphthoic acid melting at 160–161°. From the bicarbonate solution was recovered 9 g. of α-naphthoic acid (air-dried overnight). Distillation of the filtrate from the anhydride gave 3.5 g. of 2,4-dimethylhydrindene, b. p. 100–105° at 23 mm., and 1 g. of an oil, contaminated with α-naphthoic acid, b. p. 200–235° at 2 mm., presumably 4-α-naphthoyl-2,7-dimethylhydrindene.

Further study is in progress to determine the mechanism and limits of this curious reaction.

[1] Bruce with Fieser, This Journal, 59, 480 (1937).

[2] Professor E. P. Kohler suggested at the time that this color may have been caused by iron in the lithium; however, no ferric hydroxide is found upon solution of the lithium in water.

CRYSTALLINE DIMETHYL ACETAL OF *d*-FRUCTOSE

Sir:

Application of the method developed in this Laboratory for the preparation of glycofuranosides [Pacsu and Green, This Journal, **58,** 1823 (1936); Green and Pacsu, *ibid.*, **59,** 1205, 2569 (1937); **60,** 2056 (1938)] to fructosediethylmercaptal resulted in the unexpected formation of crystalline dimethyl acetal of *d*-fructose. The substance was obtained in practically quantitative yield on the treatment of fructosediethylmercaptal with mercuric chloride in absolute methyl alcohol at −80°, in the presence of an excess of yellow mercuric oxide; m. p. 107–108° and $[\alpha]^{20}\mathrm{D}$ −45.6° in water solution. On acetylation, it readily gave a crystalline pentaacetate, with m. p. 109° and $[\alpha]^{20}\mathrm{D}$ 0° in chloroform solution. The free acetal crystallized from *n*-propyl alcohol in beautifully developed large prisms, which were not hygroscopic and were devoid of action toward Fehling's solution. The compound was found to be stable in neutral and alkaline solutions, but it suffered rapid decomposition at room temperature in acidic media. Experiments carried out in fermentation saccharimeters showed that while yeast was capable of fermenting fructosedimethylacetal in distilled water to give carbon dioxide, methyl and ethyl alcohols in almost quantitative yield, it was without any effect on the acetal in a citric acid–disodium phosphate buffer solution of *p*H 7. The action of different invertase samples on the acetal at *p*H 4.5 and *p*H 7 was found to be completely negative, although the same samples were very active on sucrose under identical conditions.

In view of the extreme sensitiveness of the acetal toward acid, the action of yeast in an unbuffered solution might be due to the fermentation of fructose liberated from the acetal by a trace of the acid of the yeast, rather than to a genuine enzymatic effect. This problem is now being investigated. A detailed account of the work will be published shortly.

RECEIVED AUGUST 11, 1938

NEW BOOKS

Modern Theories of Organic Chemistry. By H. B. WATSON, D.Sc. (Wales), F.I.C., Head of the Department of Chemistry at the City of Cardiff Technical College. Oxford University Press, 114 Fifth Avenue, New York, N. Y., 1937. vii + 218 pp. 21 figs. 16.5 × 25 cm. Price, $4.50.

"Professor G. N. Lewis's conception of the sharing of one or more electron pairs by two atoms gave a new and illuminating picture of the bonds which link carbon atoms into chains and rings, and set organic chemists the task of interpreting the reactions of carbon compounds of various types in terms of the electronic structures of the molecules. .

"In this volume an attempt is made to present the modern viewpoint in a concise and simple form, and to show how the new conceptions have followed logically from the earlier views." As is evident from its size, the book does not undertake to be complete in detail, nor to provide an exhaustive bibliography. The chapters deal with: Theories of Chemical Combination; The New Physical Methods of Investigation; Applications of the Electronic Theory in Organic Chemistry, Strengths of Acids and Bases, The Inductive Effect; Substitution Reactions; General Discussion of the Application of the Electronic Theory in Organic Chemistry; Free Radicals; Compounds of Divalent Carbon and Allied Problems; Addition to Unsaturated Compounds; Tautomeric Change; Migrations from Side-Chain to Nucleus and Other Rearrangements; The Factors Determining Reaction Velocity; A Review of Some Stereochemical Problems.

The author has an exceptionally clear and logical style. This is at its best in the introductory chapters, which can be recommended not only to students, but to every organic chemist who wishes to consider what modern physics has done for the understanding of his science. Briefly Professor Watson has put the last fifteen years into their place in chemical history, and in this placing has built a vigorous viewpoint for the present.

In the electronic interpretation of organic reactions, certain English chemists have been pioneers. Their views might originally have been more cordially received in this country if presented inductively and in terms whose meanings are well known. Professor Watson has accomplished this. He has placed the horse consistently before the cart and has shown the necessity of each concept introduced. Proceeding on this basis, he uses fewer ultimate variables than have appeared in some discussions in this field.

Chapters 6 to 10 and 12 make a less unique contribution, for in their brevity they contain little material not usually included in courses in advanced organic chemistry. Even the consideration of evidence on specific problems is far from complete. Nevertheless, the clear and discriminating presentations of some of the problems are likely to be a better introduction for students than a more exhaustive descriptive treatment.

The printing of the book is up to the usual good standard of the Oxford University Press. The publishers have done well to put the price within the reach of most students and teachers.

PAUL D. BARTLETT

The Chemistry of the Sterids. By HARRY SOBOTKA, Chemist to the Mount Sinai Hospital, New York. The Williams and Wilkins Company, Mt. Royal and Guilford Avenues, Baltimore, Maryland, 1938. xiii + 634 pp. 15 × 23.5 cm. Price, $8.50.

The word "Sterids" is a newcomer to the terminology of the organic chemist. According to the author it "is meant to comprise sterols and steroids, *i. e.*, sterol-like substances." The introduction of this new term seems rather unfortunate. It might lead to some confusion, since the term "steroid," introduced only a few years ago, refers already to the derivatives of cyclopentenophenanthrene in general.

"The Chemistry of the Sterids" is not a textbook, but a handbook; it is a combination of a "Houben–Weyl," "Landolt–Börnstein" and "Beilstein" of steroid chemistry. The author has undertaken the laborious task of selecting from almost countless papers all the facts concerning the chemistry of steroids, and presenting them in a logical and readable form.

After an introductory chapter on the history of the chemistry of "sterids," the author deals with the various methods of structural research, steric considerations, the chemical properties of naturally occurring steroids and of carcinogens, and molecular compounds. Over 400 structural formulas, which have been brought together on 46 separate pages, serve to illustrate the text.

Then follows a compilation of the physical properties of steroids. This includes much invaluable and interesting information, such as, for instance, a complete list of the known absorption spectra of steroids and references to steroid crystallography.

The bulk of the book, 336 pages, is taken up by the "Beilstein" section, "a classified catalog of sterids and their derivatives recorded before January 1, 1937." Here over 3000 substances have been arranged according to a very ingenious system which should appeal to all investigators in this field. A very fine bibliography, covering over 60 pages, has been added.

Because it is essentially a handbook, this work cannot be recommended to serve as an introductory text to a student possessing only a scant knowledge of the complexities of steroid chemistry. However, it will be welcomed as an invaluable source of information by those investigators who have more than a passing interest for this field of research. The author deserves their gratitude for this compilation, which will save them many hours of search through an endless literature.

WERNER BERGMANN

Perspectives in Biochemistry. Thirty-one Essays Presented to Sir Frederick Gowland Hopkins by Past and Present Members of his Laboratory. Edited by JOSEPH NEEDHAM and DAVID E. GREEN. Cambridge University Press: The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1937. ix + 361 pp. Illustrated. 14.5 × 22.5 cm. Price, $4.75.

Scientific writing for the most part finds its way into journals whose reputations depend increasingly upon the size of their circulation and speed of publication. The exigencies of price curtail space and individual literary style is perforce sacrificed to a crisp staccato manner, highly satisfactory to enable large numbers of people rapidly to digest the contents of an article. Excellent from this point of view, there is little room for historical perspective, for philosophical rumination, or for guarded speculation. Although journals given over to reviews take care of the first need, rumination often becomes a private feast, and speculation is left for those who, having eschewed science for journalism, can assure the eager and expectant public precisely what kind of a world this will be fifty years hence.

Among the amenities left to men of science is the pleasant habit of dedicating volumes to those they revere, especially their old teachers. But the Festschrift, or jubilee volume, has tended, with the rest of scientific writing, to be a collection of papers written by colleagues or students in the same style, and often in the same journals to which they normally contribute. The book which we are reviewing is not in this tradition. It is not a collection of reprints from scientific journals. It is a series of essays in which each author has taken time "to speculate a little on the likely paths of future thought and discovery."

The value of this volume depends upon the backgrounds and scientific insight of the contributors. All have at one time or other been students of, or associated with, Sir Frederick Gowland Hopkins. Of the thirty-one essayists many have international reputations gained from important experimental studies. Writing in this book to honor Sir Frederick they are in festive mood. Instead of dedicating to their great teacher their last paper they have sent him their most far reaching thoughts regarding the significance of their work. The result is arresting. It is good to know what R. A. Peters thinks of "Proteins and Cell-Organization." J. D. Bernal contributes "A Speculation on Muscle." Szent-Györgyi writes on "Oxidation and Fermentation," and N. K. Adam on "Molecular Forces, Orientation and Surface Films." Sir Edward Mellanby writes on "Toxamins in Food," and A. J. Clark on "Drugs and Mankind." The remainder of the thirty-one essays are no less varied in subject matter or treatment. Although this would be a break with the practice of exempting those honored from contributions, one cannot help wishing that this very catholic volume also contained an essay by Sir Frederick Gowland Hopkins on "Perspectives in Biochemistry."

EDWIN J. COHN

The Chemistry and Technology of Rubber Latex. By C. FALCONER FLINT, Ph.D., D.I.C., A.I.C., A.R.C.S., B. Sc., Imperial Chemical Industries, Ltd. Foreword by Lt. Colonel B. J. EATON. D. Van Nostrand Co., Inc., 250 Fourth Ave., New York, N. Y., 1938. xx + 715 pp. Illustrated. 16 × 24 cm. Price, $14.00.

There are few people who by actual training are so well equipped to write a book on the chemistry and technology of rubber latex as is Dr. C. Falconer Flint. For many years a staff member of the Rubber Research Institute, of Malaya and now in charge of latex research and development with the Imperial Chemical Industries, Ltd., he combines personal experience of the raw material and its technical application. Although in the preface the author states that he used G. Génin's book "Chimie et Technologie du Latex de Caoutchouc" as a framework, he has not only brought this compilation up to date but has added freely to it, which justifies the reviewer to consider Flint's book as the outstanding contribution to the science and technology of rubber latex which has been written in English.

The first parts of the book present a short historical survey of the development of rubber plantations and earlier work on latex research. Then follows a discussion of the rubber trees, the physiology and formation of latex and its production. These chapters clearly show the earmarks of the present author. The composition and properties of latex are carefully worked out contributions followed by detailed discussions of latex coagulation, preservation, and concentration. In the latter chapter the latest process of concentration by electrodecantation has not yet been included.

The chapter on compounding of latex discusses in great detail dispersing agents for latex compounds and offers a series of such materials as examples. It is interesting to note that sulfonic acid derivatives of organic compounds are not mentioned, although today their extreme efficiency is an established fact.

In the discussion on the use of sulfur we find the statement that colloidal sulfur generally consists of an aqueous suspension containing from 50–60% dry matter, the particle size being several microns. Although this is a frequent misnomer, the reviewer feels that it should not be found in a scientific treatise. Disperse sulfur is the correct term.

The section treating accelerators can safely be considered as an entirely new contribution and should prove very helpful to every latex compounder. From the point of view of an impartial reviewer, it would have been commendable had somewhat more attention been given to accelerators and other special compounding ingredients placed on the market by other manufacturers than I. C. I.

Referring to the vulcanization of latex and specifically to the Vultex process, Dr. Flint makes it clear that in his opinion, also, the addition of ultra-accelerators to latex which results in a certain degree of vulcanization upon storage cannot be considered as a patent infringement. This is in accord with a recent decision by Judge Brewster in the District Court of Massachusetts, U. S. A.

Other chapters are devoted to the technical application of latex, such as dipping, impregnation of fibers and fabrics, latex thread,[1] sponge rubber, microporous rubber, moulded rubber goods, latex bonded hair, the use of latex in the paint and varnish industry. There are also chapters on adhesives, its use as an anti-corrosive coating, as a binder in the manufacture of brake-linings and abrasives, its application in can sealing, the production of artificial leather, its use in the insulation of cables, as an ingredient for road or floor coverings, and other constructional applications.

The last chapter is concerned with the physical testing of latex rubber and the production of artificial rubber dispersions and synthetic latices.

Dr. Flint's new book deserves high praise from all those interested in latex who wish to keep currently informed on the rapid development in this field. The author has taken pains to have literature and patent references as complete as possible in such a type of book. It may be deplored that the book followed the American custom of adding the references at the end of every chapter, instead of in the form of pagewise footnotes, as this is a disadvantage to the majority of readers.

The print of the book is easy to read and well set. From a detailed survey of the numerous figures and plates, among which the reviewer could not help noticing those copied from certain publications of his own, the reproductions of this book must be considered excellent. There are practically no typographical errors. The subject index needs amendment if the book is to be of value for quick reference. However, these minor objections are by way of constructive criticism only. The book as a whole is highly recommendable.

ERNST A. HAUSER

Die Korrosion von Nichteisenmetallen und deren Legierungen. (The Corrosion of Non-Ferrous Metals and their Alloys.) Edited by Prof. Dr. Phil. OTTO KRÖHNKE, Berlin-Schlachtensee, and Prof. Dr. Phil. GEORG MASING, Göttingen. Verlag von S. Hirzel, Königstrasse 2, Leipzig C 1, Germany, 1938. xxx + 901 pp. 409 figs. 17.5 × 25 cm. Price, RM. 66.50; bound, RM. 69.

This, the second volume of a series of four [see, THIS JOURNAL, **58**, 1508 (1936)], covers the corrosion of non-ferrous metals and their alloys. The space devoted to each of the several metals is roughly proportional to its technical importance as judged by the present requirements of science and technology (in Germany). Metals having no essential "technical importance," such as building materials, are not discussed at all.

A summary of the principal contents of the several sections follows. The methods of corrosion testing and research, pp. 1–59, are discussed by P. Brenner under the headings, general testing procedure, necessary data, under natural conditions, laboratory tests, measurements of the amount of corrosion, criticisms of testing methods, review of selected tests. Copper and copper alloys pp. 60–287, by O. Dahl and W. Wunder, copper pp. 60–149, brass pp. 149–227, tin bronzes pp. 227–248, aluminum bronzes pp. 248–263, copper–nickel alloys pp. 263–275, and ternary copper alloys containing nickel pp. 275–280, copper–silicon alloys, pp. 281–283, are separately discussed in detail under the headings, corrosion in general, in liquids, and in gases. There are also brief treatments of copper–beryllium alloys, pp. 283–286, alloys of copper with magnesium, cadmium, manganese, phosphorus, and silver, pp. 286–287.

The corrosion of pure aluminum by R. Sterner-Rainer, pp. 288–318, takes up the influence of impurities, of physical state, and of different corrosion agents. A section which deals in considerable length with the corrosion of aluminum cast alloys by R. Sterner-Rainer, pp. 319–384, includes the influence of the added alloy constituent on the chemical stability, resistance toward natural corrosion agents, corrosion by chemicals, influence of corrosion including surface coatings on aluminum cast alloys on specific properties. A long section on malleable aluminum alloys by P. Brenner, pp. 385–444, discusses alloy composition, review of malleable aluminum alloys, heat treatment and cold working, corrosion and simultaneous mechanical movement, testing procedure, corrosion stability of malleable aluminum alloys, metal clad industrial materials. Magnesium and magnesium alloys by W. Schmidt and W. Schultze, pp. 445–477, discusses the influence of alloying metals, atmospheric attack, various corrosion protective measures. A lengthy discussion of lead and lead alloys by M. Werner, pp. 478–595, includes the physi-

---

(1) Here the reviewer misses a reference to the manufacture of "constrolastic" thread, which in his opinion certainly constitutes one of the most interesting developments of the last years.

cal and mechanical properties of lead, general theory of corrosion stability, pure lead, lead alloys, technical lead and impurities, applicability of lead as corrosion resistant industrial material, a few special questions on the behavior of lead. A lengthy section on zinc pp. 596–670 by W. Wiederholt, discusses the electrochemical and chemical behavior of zinc in water, salt solutions and acids, in alkalies, in inorganic and organic compounds, in gases, in technical applications, and behavior of zinc alloys. Cadmium, pp. 671–685, and tin, pp. 686–721, by W. Wiederholt includes electrochemical and chemical behavior. Tungsten, molybdenum, and chromium, pp. 722–723, nickel and its alloys, and cobalt, pp. 724–764, are discussed by W. Rohn and C. Francke. They include general theory, testing procedures, nickel and its alloys in daily use and in the chemical industry, nickel and cobalt alloys with metals of the chromium group, nickel and its alloys at high temperatures, sulfur stable alloys, corrosion and aging of thermoelements. Corrosion of noble metals by L. Nowack and J. Spanner, pp. 765–827, is a long section covering introduction, physical properties, and uses of gold, gold alloys, gold as a metal coating, silver, silver alloys, silver as metal coating, platinum metals, alloys of mixed platinum metals, other alloys, platinum metals as coatings. There is a general discussion of noble metals and their alloys in the presence of various corrosive substances.

An author index of 12 pp. and a subject index of 60 pp. complete the volume. The present compilation is a valuable contribution to the literature.

MERLE RANDALL

The Chemical Analysis of Foods and Food Products. By MORRIS B. JACOBS, Ph.D., Chemist, Bureau of Food and Drugs, Department of Health, City of New York. D. Van Nostrand Company, 250 Fourth Avenue, New York, N. Y., 1938. xxii + 537 pp. 56 figs. 16 × 23.5 cm. Price, $6.00.

The general impression left after a perusal of this book is that in it the methods of food analysis have been brought thoroughly up to date, material being found which is included in no other text. Numerous methods, largely American, are described which first appeared in print as late as 1937, naturally with some danger that not all may have been sufficiently tested to be sure of their true worth. The standard methods of the A.O.A.C. have been drawn upon to a large extent.

The chapter on physical chemical methods covers an unusually wide range, considerable space being given to photoelectric colorimeters, spectrographs, electrometric determinations, surface tension apparatus, and other modern instruments, which are usually discussed only in special treatises. In the section on polarimetry it is regrettable, however, that the author did not include a discussion of the quartz wedge saccharimeter, which is much more widely used in commercial polarizations than the rotary polariscope. As a matter of fact, the "polarimeter" shown (Fig. 23), although stated to be for monochromatic light and to have a rotating analyzer, is actually a compensation saccharimeter using white light. By a curious slip the instrument is said to be capable of using a *40 dom.* tube.

Other points of marked excellence are the discussion of pasteurized milk, the chapter on jams and jellies, one of the best in the book, a chapter on chemical methods for estimating vitamins and numerous tables of the composition of foods. Especially noteworthy among the latter are useful data on the detection of adulteration in butter and olive oil and the alcohol table in the appendix, which combines in one table the data obtainable by both densimetric and refractometric methods. In the Munson and Walker method for reducing sugars the more desirable Given table is used rather than the one commonly found.

A few criticisms might be made, although they are largely matters of personal opinion and do not detract from the general excellence of the work. The discussion of the interpretation of milk analyses, if anything more than simple failure to comply with legal standards is to be shown, is practically negligible. It is rather strange, although perhaps to be expected, to see so much stress laid on the New York Board of Health lactometer instead of the more generally used Quevenne form. An anomaly certainly exists between the Ventzke normal weight of 26 grams (p. 259) and the Ventzke normal weight of 26.026 grams (p. 260), a discrepancy which, although based on the authority of the A.O.A.C., would be confusing to those not acquainted with the controversy which has raged over the Ventzke scale. Where starch is so commonly determined in various foods it would seem advisable to give some more general method than the special one for flours on page 291. Likewise, the only method given for pentosans is the very recent one of precipitation with thiobarbituric acid. The colorimetric tartaric acid method described under fruits is recommended only for use in a tartrate baking powder although no reference to the latter material is found in the index. The colorimetric method for vanillin is described in detail but no caution is given that it has been found notably unreliable with fortified vanilla extracts. The determination of glycerol in vinegar is described at great length although it has little practical value at the present time. No discussion of the range of glycerol in a normal vinegar, other than two figures in a table, is found. One wonders why a method is specified (p. 480) as for "Nitrates in Flesh Foods" when the preceding general method for nitrates is actually the A.O.A.C. method for nitrates in meats.

Other instances might be mentioned, but these are, in general, matters of relatively minor importance. The book is a distinct contribution to the literature of food analysis, the author has done a real service in assembling so much scattered recent material, and the reviewer, for one, is very glad to have the book on his shelf and within easy reach.

A. G. WOODMAN

Handbuch der Lebensmittelchemie. A. BÖMER, A. JUCKENACK and J. TILLMANS. Siebenter Band. **Alkoholische Genussmittel.** (Handbook of Food Chemistry. Vol. VII. Alcoholic Beverages.) B. BLEYER, Editor-in-Chief. Verlag von Julius Springer, Linkstrasse 22–24, Berlin W 9, Germany, 1938. xv + 828 pp. 115 figs. 17.5 × 24 cm. Price, RM. 99; bound, RM. 103.50.

Sponsored by a board of editors whose personnel includes the surviving member of the original group, A. Juckenack, and three others, J. Grossfeld, E. Bames and B. Bleyer, there has now appeared another volume, the fifth in order of completion, of the "Handbuch der Lebensmittelchemie."

Quite appropriately the subject matter of this volume is introduced by a chapter on alcoholic fermentation (31 pp.). The authors, B. Bleyer and W. Diemair, treat this topic first in its historical aspects, then from the standpoint of the morphology and the chemical composition of yeast and finally the course and products of fermentation. Following this, the book divides itself into three main parts, devoted, respectively, to beer (139 pp.), wine and other grape products (367 pp.), and distilled beverages (222 pp.). A digest of the pertinent German laws, compiled by H. Holthöfer, supplements each major chapter; those of the principal European countries and the United States in respect to alcoholic beverages have been briefly collated by E. Bames (38 pp.). A well-organized index (31 pp.) completes the book.

The whole volume appears to have been written with that suggestion of authority which can come only from the pens of those who write with the advantage of experience in their own fields. Bleyer and Diemair contribute also the chapter on beer. The subject matter begins with a discussion of the raw materials of the industry, continues with an exhaustive description of the manufacture of beer from malting to fermentation, and closes with a résumé of the properties and composition of beers. The chapter on wine represents the independent efforts of two scientists who are active in official capacities. To E. Vogt was assigned the task of discussing and describing this beverage, its various types and products, from vineyard to finished product. O. Reichard treats the subject from the twofold standpoint of analysis and official control of traffic therein. The chapter on distilled beverages also is noteworthy. It is the work of G. Büttner. The subject is presented under the following headings: technical recovery of spirits, potable spirits of all types, composition and analysis.

This volume rightfully deserves a place among its predecessors in the series, for by condensing within one set of covers a vast amount of authoritative technical and legal matter it simplifies the work of the food chemist in need either of a reference book or a ready source of information on the subject matter in question.

The Action of Aluminum Chloride on the Diphenyl Ester of Isophthalic, Terephthalic and Naphthalic Acids

BY F. F. BLICKE AND R. A. PATELSKI[1]

Diphenyl phthalate and aluminum chloride do not yield 2-(4″-hydroxybenzoyl)-4′-hydroxybenzophenone as might be expected; phenolphthalein[2] and 1-hydroxyanthraquinone[3] are produced in this reaction.

We found that diphenyl isophthalate, heated with aluminum chloride, is transformed into 3-(4″-hydroxybenzoyl)-4′-hydroxybenzophenone. The latter compound was obtained also by interaction of isophthalyl chloride, anisole and aluminum chloride; the 3-(4″-methoxybenzoyl)-4′-methoxybenzophenone, produced in this reaction, was demethylated during the preparative process.

Weiss and Chledowski[4] stated that isophthalyl chloride and anisole react to form not only 3-(4″-methoxybenzoyl)-4′-methoxybenzophenone but also 4-(4″-methoxybenzoyl)-4″-methoxybenzophenone. They attribute the formation of the latter substance to a rearrangement produced by the aluminum chloride. Although these investigators claim that they used pure *m*-xylene from which to prepare the isophthalyl chloride, their *m*-xylene may have contained some of the para isomer.

Diphenyl terephthalate was converted by aluminum chloride into 4-(4″-hydroxybenzoyl)-4′-hydroxybenzophenone. The same benzophenone was obtained by demethylation of the reaction product, 4-(4″-methoxybenzoyl)-4′-methoxybenzophenone, produced from terephthalyl chloride and anisole.

In view of the general behavior of 1,8-disubstitution products of naphthalene it would be expected that diphenyl naphthalate would react with aluminum chloride similarly to diphenyl phthalate and that phenolnaphthalein would be produced instead of 1,8-di-(*p*-hydroxybenzoyl)-naphthalene. It was found that the phthalein was formed in this reaction in place of the diketone. Jaubert[5] had obtained this phthalein previously, in an impure state, by condensation of naphthalic anhydride and phenol. We prepared it by a modification of Jaubert's method and also by condensation of 8-(4′-hydroxybenzoyl)-1-naphthoic acid with phenol.

Experimental Part

3-(4″-Hydroxybenzoyl)-4′-hydroxybenzophenone. (a) **From Diphenyl Isophthalate and Aluminum Chloride.**—Five grams of diphenyl isophthalate,[6] 6 g. of aluminum chloride and 25 cc. of carbon disulfide were heated on a steam-bath until the carbon disulfide had been removed; the residue was then heated in an oil-bath (185–195°) for twenty-five minutes. The aluminum salt was removed with dilute hydrochloric acid and the mixture extracted with 10% sodium hydroxide solution. The product, obtained by acidification of the alkaline extract, was digested with sodium bicarbonate solution to remove carboxylic acids and the crude hydroxy ketone refluxed with 14 cc. of acetic anhydride for one hour in order to acetylate it. The diacetyl derivative of 3-(4″-hydroxybenzoyl)-4′-hydroxy-

[5] Jaubert, *Ber.*, **28**, 992 (1895).

[6] Schreder [*ibid.*, **7**, 707 (1874)] reported 120° as the melting point; we found it to be 137–138°.

benzophenone was recrystallized from benzene; m. p. 189–190°.

Anal. Calcd. for $C_{24}H_{18}O_6$: C, 71.62; H, 4.51. Found: C, 71.72; H, 4.59.

Upon hydrolysis of the acetyl derivative with 10% sodium hydroxide solution and recrystallization of the 3-(4″-hydroxybenzoyl)-4′-hydroxybenzophenone several times from dilute alcohol, the latter melted at 207–209°.[7]

The dimethyl ether, obtained by methylation with dimethyl sulfate, melted at 144–146°[8] after recrystallization from alcohol.

The di-*m*-bromobenzoyl derivative was produced when 2 g. of the dihydroxybenzophenone was heated for three hours with 3.3 g. of *m*-bromobenzoyl chloride at 150–160°. After recrystallization from tetrachloroethane it melted at 234–235°.

Anal. Calcd. for $C_{34}H_{20}O_6Br_2$: Br, 23.36. Found: Br, 23.01.

(b) From Isophthalyl Chloride, Anisole and Aluminum Chloride.—Weiss and Chledowski[8] stirred a mixture of isophthalyl chloride, anisole, aluminum chloride and carbon disulfide, heated it for one hour and isolated 3-(4″-methoxybenzoyl)-4′-methoxybenzophenone. We followed their directions but heated the mixture for three hours on a steam-bath. After removal of the solvent and aluminum salt 20 g. of product, soluble in 10% sodium hydroxide solution, was obtained from 17 g. of isophthalyl chloride. The crude 3-(4″-hydroxybenzoyl)-4′-hydroxybenzophenone was refluxed for one hour with 60 g. of acetic anhydride, the crystalline diacetyl derivative (m. p. 189–190°) hydrolyzed and the benzophenone recrystallized from dilute alcohol; m. p. 207–209°.

4-(4″-Hydroxybenzoyl)-4′-hydroxybenzophenone. (a) From Diphenyl Terephthalate and Aluminum Chloride.—Diphenyl terephthalate[9] was treated with aluminum chloride in the same manner as diphenyl isophthalate. The crude hydroxy ketone obtained, after removal of carboxylic acids, was recrystallized from dilute alcohol; m. p. 297–299°. The compound contains solvent of crystallization; for analysis it was dried to constant weight at 115°.

Anal. Calcd. for $C_{20}H_{14}O_4$: C, 75.47; H, 4.40. Found: C, 75.20; H, 4.51.

The diacetyl derivative was prepared and recrystallized from acetic acid; m. p. 249–250°.

Anal. Calcd. for $C_{24}H_{18}O_6$: C, 71.62; H, 4.51. Found: C, 71.50; H, 4.54.

The di-(3-bromobenzoyl) derivative was obtained when 4-(4″-hydroxybenzoyl)-4′-hydroxybenzophenone was heated with 3-bromobenzoyl chloride. It melted at 289–291° after recrystallization from tetrachloroethane.

Anal. Calcd. for $C_{34}H_{20}O_6Br_2$: Br, 23.36. Found: Br, 23.01.

In order to prepare the dioxime 3.7 g. of the hydroxybenzophenone, 200 cc. of methyl alcohol, 5 g. of hydroxylamine hydrochloride and 10 g. of sodium hydroxide were refluxed for eight hours. The oxime was recrystallized from alcohol; m. p. 261–263°.

Anal. Calcd. for $C_{20}H_{16}O_4N_2$: N, 8.04. Found: N, 7.93.

Upon methylation with dimethyl sulfate 4-(4″-methoxybenzoyl)-4′-methoxybenzophenone was obtained; m. p. 225–227°[10] after recrystallization from toluene. Demethylation with constant boiling hydrobromic acid in acetic acid yielded the original hydroxybenzophenone.

(b) From Terephthalyl Chloride, Anisole and Aluminum Chloride.—Terephthalyl chloride[11] was allowed to react with anisole and aluminum chloride under the same conditions described above in the case of isophthalyl chloride. The hydroxybenzophenone obtained melted at 298–299°.

Phenolnaphthalein. (a) From Naphthalic Anhydride and Phenol.—A mixture of 40 g. of naphthalic anhydride, 160 g. of phenol and 100 g. of aluminum chloride was heated for seventy-two hours on a steam-bath, the product decomposed with dilute hydrochloric acid and then steam distilled to remove excess phenol. The material was digested with 10% sodium hydroxide solution, filtered and the filtrate acidified. The red precipitate was dried and dissolved in hot butyl alcohol. When the solution was cooled 5 g. of 8-(4′-hydroxybenzoyl)-1-naphthoic acid was obtained; m. p. 219–220° after several recrystallizations from alcohol.

Anal. Calcd. for $C_{18}H_{12}O_4$: C, 73.95; H, 4.14. Found: C, 73.83; H, 4.14.

The butyl alcoholic mother liquor was steam distilled and the dried, red, amorphous residue refluxed with 100 g. of acetic anhydride for four hours. The solution was concentrated, poured into water and the brown, gummy precipitate covered with alcohol. After twelve hours the mass became crystalline. The product was recrystallized several times from alcohol whereupon the colorless, crystalline diacetyl derivative of phenolnaphthalein was obtained; m. p. 198–199°.[12]

Anal. Calcd. for $C_{28}H_{20}O_6$: C, 74.31; H, 4.46. Found: C, 73.98; H, 4.49.

The diacetyl derivative was refluxed for several hours with dilute aqueous sodium hydroxide and the phthalein obtained recrystallized from dilute alcohol; m. p. 265–266°[13] with decomposition.

Anal. Calcd. for $C_{24}H_{16}O_4$: C, 78.23; H, 4.38. Found: C, 78.22; H, 4.43.

The color of an alkaline solution of phenolnaphthalein is very similar to that of an alkaline solution of phenolphthalein.

Dr. H. H. Willard found the useful *p*H range to be 8.8–10.8 and the *pK* to be 9.78.

(b) From 8-(4′-Hydroxybenzoyl)-1-naphthoic Acid.—A mixture of 5.8 g. of 8-(4′-hydroxybenzoyl)-1-naphthoic acid, 15 g. of phenol and 13.5 g. of aluminum chloride was heated at 150–160° for six hours and then treated with dilute hydrochloric acid. The phthalein was isolated in the manner described above; mixed m. p. 265–266°.

(c) From Diphenyl Naphthalate and Aluminum Chloride.—In order to obtain diphenyl naphthalate 39.6 g. of

[7] Weiss and Chledowski [*Monatsh.*, **65**, 363 (1935)] reported 215°.

[8] Weiss and Chledowski [*ibid.*, **65**, 362 (1935)] reported 146–149°.

[9] Schreder, *Ber.*, **7**, 707 (1874).

[10] Weiss and Chledowski [*Monatsh.*, **65**, 358 (1935)] reported 236–239°.

[11] Locher, *Bull. soc. chim.*, [3] **11**, 927 (1894).

[12] Kaufmann [*Z. angew. Chem.*, **40**, 863 (1927)] reported 198–199°.

[13] Jaubert [*Ber.*, **28**, 991 (1895)] stated that the phthalein melted above 200° with charring and the evolution of phenol.

naphthalic anhydride, 80 g. of phosphorus pentachloride and 75 cc. of phosphorus oxychloride were refluxed for twenty hours in an oil-bath, the oxychloride and excess pentachloride removed under diminished pressure and the sirupy, light brown acid chloride[14] mixed, immediately, with 40 g. of phenol. After the vigorous reaction had subsided the mixture was heated for two hours at 140–150°. The product was washed with dilute alkali, with water and then recrystallized from alcohol; m. p. 150–151°.

Anal. Calcd. for $C_{24}H_{16}O_4$: C, 78.23; H, 4.38. Found: C, 78.39; H, 4.41.

A mixture of 4 g. of diphenyl naphthalate, 5 g. of aluminum chloride and 20 cc. of carbon disulfide was heated on a steam-bath until the carbon disulfide had been removed and the solid residue heated for twenty-five minutes in an oil-bath at 155–160°. The mixture was treated with dilute hydrochloric acid and the product then digested with 10% sodium hydroxide solution. The solid precipitate, obtained upon acidification of the alkaline solution, was digested with sodium bicarbonate solution and the insoluble portion recrystallized from dilute alcohol; yield of phthalein 1.6 g.; m. p. 264–266°.

Summary

It has been shown that the diphenyl ester of isophthalic acid is converted by aluminum chloride into 3-(4″-hydroxybenzoyl)-4′-hydroxybenzophenone; from diphenyl terephthalate and aluminum chloride there was obtained 4-(4″-hydroxybenzoyl)-4′-hydroxybenzophenone.

Phenolnaphthalein was prepared from diphenyl naphthalate and aluminum chloride and from the hitherto unknown 8-(4′-hydroxybenzoyl)-1-naphthoic acid and phenol.

The Separation and Identification of Amines with 3-Nitrophthalic Anhydride

BY JOHN W. ALEXANDER AND S. M. MCELVAIN

While numerous reagents are available for the preparation of derivatives of the three classes of amines, only two, nitrous acid and aryl sulfonyl chlorides, have been used to any considerable extent as a means of separating the different types of amines from each other when they occur in a mixture. Nitrous acid has the disadvantage of destroying completely the identity of the primary amine, often with the formation of a rearranged product. Aryl sulfonyl chlorides have proved to be quite useful on account of the fact that the sulfonamides of the primary amines are generally soluble in aqueous alkali and, consequently, can be separated from the alkali-insoluble sulfonamide of the secondary amine. However, this reagent fails when primary amines of the type $C_6H_5(CH_2)_nNH_2$ are involved because the sulfonamides of these amines are alkali-insoluble.[1] Also, certain ortho-substituted amines, such as *o*-nitroaniline,[2] can be made to react with aryl sulfonyl chlorides only with considerable difficulty. Finally, recovery of the amines from the sulfonamides is inconvenient, if not difficult, in that hydrolysis of the latter types requires that the reaction be carried out in a sealed tube.

In his textbook of qualitative organic analysis, Kamm[3] mentions the use of phthalic anhydride as a means of separating the three types of amines. So far as we are aware, there is no other reference in the literature to the general use of this reagent for the separation and identification of amines.[4] In a private communication to one of us Dr. Kamm stated that he had worked on the phthalic anhydride procedure several years ago while at the University of Illinois but had had little time to use it in practical laboratory work. The use of this reagent depends upon the fact that it does not react with tertiary amines but forms phthalamic acids with both primary and secondary amines. These derivatives are separated by heat which converts the phthalamic acid of the primary amine (I) into an alkali-insoluble N-substituted phthalimide (III) but leaves the phthalamic acid derived from the secondary amine (II) unchanged, and, therefore, alkali soluble.

Attempts to utilize phthalic anhydride for the separation and identification of amines in this Laboratory revealed the following facts: (a)

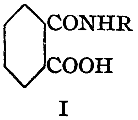
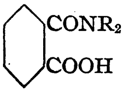
[4] A few patents [*C. A.*, **22**, 3417 (1928); **23**, 846, 1137 (1929); **28**, 3418 (1934)] covering the separation of certain amines with phthalic anhydride have been issued. Porai-Koshitz in a paper [*C. A.*, **29**, 131 (1935)] describes a rather large scale separation of aniline, methylaniline and dimethylaniline with this reagent.

the phthalamic acids derived from the secondary amines that were studied were non-crystalline resins, (b) the temperature that was found necessary to convert the phthalamic acid of the primary amine to the N-substituted phthalimide caused some of the secondary amine derivatives to be changed into a diamide (IV) which separated as an alkali-insoluble product along with the phthalimide.[5] Succinic anhydride was found to give the desired crystalline amidic acids with the secondary amines, but these acids were converted more readily into the diamides by heat than were the corresponding derivatives from phthalic anhydride.[5b]

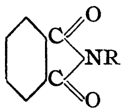
This paper reports the results which have been obtained with 3-nitrophthalic anhydride as a reagent for the separation and identification of amines. This anhydride has proved to be quite satisfactory as it gives crystalline derivatives with secondary amines and produces primary amine derivatives that may be converted into the phthalimides at a temperature (145°) that leaves the phthalamic acids derived from the secondary amines unchanged. With such tertiary amines as dimethylaniline, however, 3-nitrophthalic anhydride causes a violent reaction at the temperature necessary to form the phthalimide. Oxides of nitrogen are evolved and a charred mass remains as a residue. For this reason it is necessary to carry out the reaction of an amine mixture that contains such a tertiary type with 3-nitrophthalic anhydride in a solvent such as carbon tetrachloride and to separate the phthalamic acids from any tertiary amine before these acids are further heated. 3-Nitrophthalic anhydride under these conditions reacts readily and completely with *o*-substituted anilines such as *o*-nitraniline and the resulting phthalamic acids are smoothly converted by heating into the phthalimides.



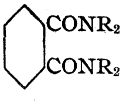
I



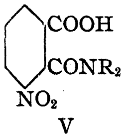
II



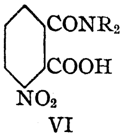
III



IV



V



VI

It is evident that there is the possibility of forming two different nitrophthalamic acids (V and VI) by the action of 3-nitrophthalic anhydride on a secondary amine. However, in no case was more than one acid obtained from this reaction. The structure V is assigned to these derivatives on the assumption that a secondary amine would react in the same way with the anhydride as does ammonia. Chapman and Stephens[6] showed that the phthalamic acid formed from ammonia and 3-nitrophthalic anhydride could be degraded through the Hofmann reaction to 3-nitroanthranilic acid. We have confirmed this observation and have carried the characterization one step further by converting the nitroanthranilic acid to *m*-nitrobenzoic acid by the diazo reaction.

The imides that are derived from the primary amines are hydrolyzed readily by 5% sodium hydroxide solution, even at room temperature. In this alkaline solution the hydrolysis goes only as far as the phthalamic acids. These acids as well as those derived from the secondary amines, on account of their stability to alkali, may be titrated, and thereby be made to reveal the molecular weight of the amine from which they were made. The phthalamic acids, however, are quite susceptible to acid hydrolysis and readily yield the amines when warmed with 10% hydrochloric acid for a few minutes. For this reason care is necessary in precipitating the phthalamic acid from alkaline solution to avoid high local concentrations of acid.

The melting points and analyses of a number of the imides derived from primary amines and of a few phthalamic acids from secondary amines are listed in the table.

Experimental

The Separation of a Mixture of Amines with 3-Nitrophthalic Anhydride.—A 3–4 g. portion of the mixture of amines together with 8–10 g. of 3-nitrophthalic anhydride[7] is added to 25 cc. of carbon tetrachloride. This mixture is refluxed gently for fifteen minutes; it is not necessary that all of the solids go into solution in the carbon tetrachloride. After this time 30 cc. of 10% sodium hydroxide solution is added, followed by shaking and gentle heating until no solids remain. The carbon tetrachloride layer is separated, and the alkaline solution extracted with a 20-cc. portion of ether. The carbon tetrachloride and ether extract are mixed and the solvents removed by careful distillation. If no oily residue remains, no tertiary amine is present. If a residue remains, it may be purified by steam distillation.

To the alkaline solution of the salts of the phthalamic acids, contained in a beaker, sufficient of a 10% solution of hydrochloric acid to form the free acids is added slowly and with constant stirring. Since these acids have a tendency to form supersaturated solutions, the acid solution should be stirred vigorously until the precipitation of the phthalamic acids is complete. The precipitated solid, which may be gummy at this point, is filtered off, transferred to a small Erlenmeyer flask, and heated for thirty minutes in an oil-bath at 145°. After the first five minutes of heating, about 0.5 g. of the 3-nitrophthalic anhydride is added to the material being heated and mixed-in with a stirring rod. After heating for another twenty-five minutes, the molten reaction mixture is poured into a small mortar and allowed to solidify. Generally it is advantageous to grind the resulting hard resinous mass to a fine powder before treating it with 50 cc. of a saturated sodium bicarbonate solution to dissolve out the phthalamic acid derived from the secondary amine and any excess of 3-nitrophthalic anhydride. The reaction product which remains in the reaction flask is treated with 5 cc. of acetone and gently warmed. This amount of acetone may not dissolve all of the product remaining in the reaction flask but it loosens it sufficiently to allow it to be transferred to the sodium bicarbonate solution. The imide of the primary amine is filtered off from the bicarbonate solution and recrystallized from alcohol or an alcohol–acetone mixture. The phthalamic acid is precipitated with 10% hydrochloric acid with constant stirring as described above. This derivative may be crystallized from an alcohol–water mixture, and after drying may be titrated with standard alkali.

The primary amine may be recovered from the imide by refluxing it in 10% aqueous sodium hydroxide until all of the solid has gone into solution. This hydrolysis produces the salt of the phthalamic acid which is then hydrolyzed to the primary amine by making the alkaline solution distinctly acid with hydrochloric acid and refluxing for an additional fifteen minutes. The secondary amine may be recovered by the hydrolysis of the phthalamic acid in a similar manner with dilute hydrochloric acid.

If it is desired to prepare the N-substituted phthalimide from an individual primary amine, this readily may be accomplished by heating the amine with 3-nitrophthalic anhydride at 170° for five to ten minutes. If the preparation of a phthalamic acid derivative of an individual secondary amine is desired, it may be carried out simply by heating the secondary amine with 3-nitrophthalic anhydride at 145° for a few minutes. Higher reaction temperatures cause oxidation of the secondary amine.

Summary

A procedure for the separation of a mixture of amines with 3-nitrophthalic anhydride is described. The melting points and analyses of a number of N-substituted 3-nitrophthalimides and N,N-disubstituted nitrophthalamic acids are listed.

Glycofuranosides and Thioglycofuranosides. IV. Direct Formation of Dimethyl Acetal and Preparation of α-Ethylfuranoside from *l*-Rhamnose Ethylmercaptal

BY JOHN W. GREEN[1] AND EUGENE PACSU

In the previous articles of this series[2] the preparation of glycofuranosides from the mercaptals of glucose, galactose and *l*-arabinose was described. In each case the thioethyl groups were eliminated from the sugar with the formation of a <1–4> ring linked by oxygen.

l-Rhamnose ethylmercaptal has been treated similarly with mercuric chloride in neutral alcoholic solutions. In ethyl alcohol the reaction runs in the expected manner and the product is a negatively rotating sirup. From this sirup a small yield of pure crystalline α-ethyl *l*-rhamnofuranoside was obtained. These crystals have a specific rotation of −95.5° in water solution, similar in magnitude (but necessarily opposite in sign) to the value for α-methyl-*d*-mannofuranoside.[3] The crystals melt at 54–56° and are very hygroscopic.

Similarly, from the reaction carried out in methyl alcohol solution, a negatively rotating sirup is obtained. From this sirup a small amount of crystalline material is isolated very easily, and this product is not a furanoside. The specific rotation in water solution is 10.2° and the melting point is 123–124°. The crystals are not hygroscopic. The carbon–hydrogen analysis agrees perfectly with the empirical formula of a dimethyl acetal. The small rotation is also typical of an open-chain derivative.

This is the first observed case where an acetal of a sugar has been formed without blocking some[4] or all[5] of the hydroxyl groups. It has been believed that the mechanism of the mercaptal–mercuric chloride reaction was always an initial ring closure to a thiofuranoside,[2a] then subsequent secondary changes to a glycofuranoside, a glycopyranoside or the free sugar, depending on the experimental conditions. Here is a definite case where the expected ring closure does not occur. The greater amount of the ethyl rhamnofuranoside sirup has not been obtained crystalline so it cannot be said that there is no ethyl acetal present. However, the isolation of some ethyl rhamnofuranoside shows that ring closure does occur, at least in part, when rhamnose ethylmercaptal reacts with mercuric chloride in neutral ethyl alcohol solution.

On the other hand, the greater part of the mother liquor from the dimethyl acetal has not been crystallized and so it cannot be said definitely that the acetal is the only product. The similarity in rotation of the two reaction sirups would lead to the assumption that in both cases the rhamnofuranoside is formed and in one case at least the acetal also.

The conception of the acetal as an intermediate in the glycofuranoside formation seems unlikely and the acetal is probably formed as a by-product. An intermediate product in the acetal reaction would necessarily have to be the mixed acetal, with one methoxyl and one thioethyl group. This brings up the possibility of glycofuranoside formation from the mixed acetal, which might explain why none of the sugars (except glucose) form the thiofuranosides.

The mother liquors of these two new compounds will be investigated further.

Experimental

Preparation of α-Ethyl *l*-Rhamnofuranoside.—A mixture of 10.8 g. of *l*-rhamnose ethyl mercaptal, 22 g. of mercuric chloride (2 moles), 12 g. of yellow mercuric oxide and 6 g. of drierite was shaken with 80 cc. of absolute ethyl alcohol at 25° for four hours. The mixture was filtered, the filtrate treated with 5 cc. of pyridine and kept at 0° for two hours. The pyridine–mercuric chloride was filtered and the solution evaporated to a sirup *in vacuo* at 40°. The substance was dissolved in a little cold water, the solution filtered and neutralized to phenolphthalein, with a few drops of sodium hydroxide solution, then evaporated *in vacuo* at 40°. The resulting sirup was evaporated successively from methyl alcohol and ethyl acetate solutions. The sirupy residue rotated −53° in water solution and after two months in the ice box changed to a semi-solid mass which melted at room temperature.

From 20 cc. of dry ethyl acetate solution, diluted with dry ether to a slight turbidity at 0°, 200 mg. of crystals rotating −71° in water solution was deposited. After three recrystallizations from 5 cc. of dry ether diluted

with petroleum ether (b. p. 30–60°), a pure product was obtained in the form of long stout needles: yield 50 mg., m. p. 54–56°, $[\alpha]^{20}\mathrm{D}$ 95.5° (0.0330 g. of substance, 3 cc. of water solution, 2-dm. semi-micro tube, 2.10° rotation to the left). The crystals were very hygroscopic and did not reduce Fehling's solution. Before analysis the substance was kept over phosphorus pentoxide in a desiccator for three days.

Anal. Calcd. for $C_8H_{16}O_5$: C, 50.0; H, 8.33. Found: C, 49.4; H, 8.6.

Preparation of *l*-Rhamnose Dimethyl Acetal.—A mixture of 5.4 g. of *l*-rhamnose ethylmercaptal, 10.8 g. of mercuric chloride (2 moles), 5 g. of yellow mercuric oxide and 3 g. of drierite was shaken in 60 cc. of absolute methyl alcohol at 25° for four hours, and worked up as in the above experiment. The sirup, rotating −35° in water solution, on evaporation from ethyl acetate solution became partly crystalline.

From a solution of 15 cc. of dry ethyl acetate in *the ice box* 300 mg. of crystals was deposited, and after one recrystallization from 15 cc. of dry ethyl acetate at 0°, 200 mg. of pure crystals was obtained: yield 5%; m. p. 123–124°; $[\alpha]^{20}\mathrm{D}$ 10.2° (0.1070 g. substance, 3 cc. of solution, 2-dm. semi-micro tube, rotation 0.73° to the right). The crystals are long fine needles, are not hygroscopic and do not reduce Fehling's solution. They are easily hydrolyzed by 0.01 *N* hydrochloric acid at 100° in a few minutes.

Anal. Calcd. for $C_8H_{18}O_6$: C, 45.7; H, 8.57. Found: C, 45.8; H, 8.5.

Summary

α-Ethyl *l*-rhamnofuranoside has been isolated in crystalline form from the reaction of ethyl mercaptal with mercuric chloride in neutral ethyl alcoholic solution. The pure crystals have a specific rotation of −95.5° in water solution and melt at 54–56°. They are hygroscopic and do not reduce Fehling's solution.

l-Rhamnose dimethyl acetal has been isolated in crystalline form by a similar reaction of the ethyl mercaptal in methyl alcohol. The pure crystals have a specific rotation of 10.2° in water solution and melt at 123–124°. This is the first observed case of direct formation of an acetal from a sugar without blocking the hydroxyl groups to prevent glycoside formation.

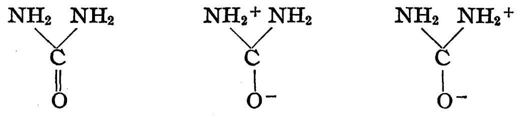
The Influence of Substances on the Optical Rotation of Gelatin. VII. Rotatory Dispersion of Gelatin in Urea Solutions[1]

BY D. C. CARPENTER AND F. E. LOVELACE

The rotatory dispersion of gelatin–sodium halide systems follows a single-term Drude equation $[\alpha]_\lambda = k/(\lambda^2 - \lambda_0^2)$ in which λ_0 is the position of an absorption band at 2200 Å. The effect of the halides of sodium on the rotatory dispersion constant of gelatin has been shown[2] to follow a linear equation with reference to salt concentration at 40°, and at 0.5° to be the result of two effects, one linear with respect to salt concentration and the other related to salt concentration by the equation

$$a/(1 - a) = e^{kC}/K^k$$

In connection with the foregoing studies of the optical behavior of protein ions in the presence of highly ionized inorganic salts, it appeared that similar studies with an optically inactive organic dipole ion would be desirable. From measurements of the dielectric constant of urea solutions[3] it has been inferred that urea exists in solution as the dipole ion ..$^+\mathrm{NH_3C(=NH)O^-}$. The dielectric constant data, however, may be accounted for by the resonance formula



as well as the zwitter ion formula. It is common knowledge that the presence of urea brings about the "denaturation" of many proteins. Only recently have the effects of urea on proteins been followed in the ultracentrifuge. Watson, Arrhenius and Williams[4] reported that the molecular weight of zein was not affected by urea. Williams and Watson[5] believe that the action of urea on egg albumin is that of dissociation, the molecular weight of the pieces being of the order of one-half that of the original protein molecule. On dialyzing out the urea from their solutions about

three-fourths of the egg albumin coagulated and separated out. The protein remaining in solution after dialysis had for the most part the normal molecular weight of unchanged egg albumin, although it was not entirely homogeneous. If these authors calculated the sedimentation constant of the urea-treated protein from their Fig. 2, their reported sedimentation value is too low; however, inasmuch as assumptions of greater consequence also enter into their calculations, we will not comment further on their results.

Steinhardt[6] has shown a clear-cut case of the dissociation of isoelectric horse hemoglobin into half-molecules by urea. On dialysis, part of the urea treated material re-formed molecules of the original molecular weight but a large portion aggregated into still larger particles. Steinhardt concluded that pepsin was not changed materially by urea. His data actually indicate approximately a 10% increase in the sedimentation constant (much greater than the usual experimental error) indicating partial association of pepsin rather than any dissociation. The diffusion was not measured, however, in the experiments with pepsin and the molecular weight cannot be calculated without making assumptions that are often misleading.

Dissociation and denaturation of proteins by urea are clearly different processes and take place at different rates. It appears that the former occurs rapidly and the latter more slowly. Many different environmental conditions cause changes in proteins and different observers noting such changes have spoken of them rather loosely under the term "denaturation," not necessarily meaning, for instance, that the actual change produced by heat was like that effected by light, etc. It appears that in the presence of urea some proteins are dissociated and others are not. It is chiefly when one starts to remove the urea that denaturation takes place or at least makes itself obvious. The denaturation by urea seems to reside in the reuniting of the dissociated pieces in other ways than that in which they existed in the original protein. In spite of the information about protein structure obtained from X-ray work, it is not clear what holds the parallel peptide chains together in the layer level nor what forces hold together the layer–layer levels of the molecule.

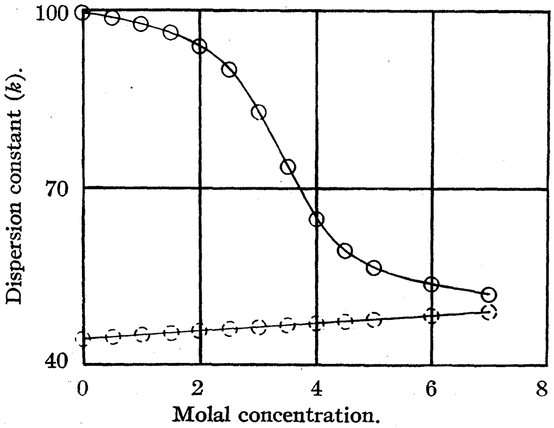

Fig. 2.—Rotatory dispersion constant of gelatin in urea solutions at 0.5 and 40°.

It is somewhat doubtful if dissociation can occur in the dimension at right angles to the main direction of the peptide chains, as dissociation of the molecule into two pieces would involve the simultaneous breakage of the peptide linkage in some forty places. Division of the molecule along the dimension parallel to the main direction of the peptide chains would cut through at least forty force fields between adjacent NH and CO groups in adjacent peptide chains. On the whole it seems more likely that cleavage of the molecule along a plane parallel to the layer levels would be accomplished by the minimum expenditure of energy. The layer–layer levels have been postulated as held together by (a)

compound formation between side-chain amino groups of the diamino acids and side-chain carboxyl groups of the dicarboxy acids[7] under which view the union necessarily would be between arginine and glutamic acid and would give a calculated layer–layer distance of 10.42 Å. or by (b) hydrogen-bond unions[8] which would give a calculated layer–layer distance of 9.94 Å. According to Astbury[9] the layer–layer distance of most proteins is about 10 Å. Egg albumin with equilateral dimensions of about 44 Å. may be expected to have four layer levels. Why urea dissociates egg albumin into half molecules instead of quarter molecules, if the cleavage is parallel to the layer level, is not apparent.

In the present paper we have studied the effect of urea on the rotatory dispersion of gelatin at 0.5 and 40° and have found that the same general formulas hold for its behavior as we have found for inorganic salts. After dialyzing out the urea from our most concentrated solutions we have found that the gelatin regained its original optical activity. This seems to be clear-cut evidence that in spite of the fact that many other proteins may suffer permanent "denaturation" in urea solutions, gelatin is not affected permanently by such treatment.

Experimental

The procedure for preparing the solutions and for the measurement of rotations, density, *p*H, etc., was the same as has been described before. The urea was recrystallized three times from hot water and melted at 132.6° (corr). It was dried by suction and stored over phosphorus pentoxide at room temperature. In preparing solutions, due to the tremendous negative heat of solution of urea, the urea was added in small quantities to the flask of gelatin solution, warming after each addition by immersing in a water-bath at 40° and shaking gently until solution took place.

The specific rotation of gelatin in various concentrations of urea solution was measured at 0.5 and 40° for five different wave lengths of light in the visible spectrum, *viz.:* red lithium line $\lambda = 6707.86$ Å.; sodium D line $\lambda = 5892.62$ Å. (optical mean); yellow mercury, $\lambda = 5780.13$ Å. (optical mean); green mercury, $\lambda = 5460.73$ Å.; and the deep blue mercury line, $\lambda = 4358.34$ Å. The light filters employed have been described. The gelatin concentration of the various solutions was 0.7641 g. per 100 g. of solution.

Discussion and Conclusions

In Tables I and II are recorded our data taken at 0.5 and 40°, respectively, for the five wave lengths employed. In Fig. 1, these data are graphed, plotting the reciprocal of the specific rotation against the square of the wave length at which the respective rotations were measured. The relationship is linear, the same as we have recorded for the effect of the various halides of sodium, which means that a single-term Drude equation expresses the results.

The straight lines in the graph for urea cut the *x*-axis at $\lambda_0 = 2200$ Å. the same as for the halides. This means that the absorption band controlling the dispersion of gelatin is located at 2200 Å. The same value for λ_0 was obtained by mathematical solution of our data as has been done before. The values of k, numerator in the Drude equation, were calculated for each urea concentration and appear in Table III and are graphed in Fig. 2. At 40° the k values bear an essentially linear relation to concentration of urea as given by the equation

$$K_{40°} = 44.517 + 0.6138\ C_{\text{urea}} \qquad (1)$$

There is a tendency for the factor preceding the concentration term to increase slightly with increasing urea concentration, but for the purposes of this paper an average of these factors may just as well be used. For the first time in our experience with the effect of added substances on the rotation of gelatin, the added substance increases the dispersion constant at 40° as its concentration is increased. For all of the substances we have examined previously the dispersion constant has decreased at all temperatures with increasing concentration of the optically inactive substance. At 0.5° the curve for the k values is made up of two simultaneously occurring effects, as has been noted previously with the sodium halides, the one a linear relationship to urea concentration for Form A

$$k_{0.5°} = 99.530 - 1.70\ C_{\text{urea}} \qquad (2)$$

and for Form B

$$k_{0.5°} = 64.00 - 1.70\ C_{\text{urea}} \qquad (2a)$$

(Forms A and B are the respective forms of

gelatin in low urea and high urea concentrations) and a second relationship

$$C_{\text{urea}} = \frac{1}{0.89}\left[\log\left(\frac{a}{1-a}\right)\right] - \log(1/K) \quad (3)$$

where a represents the fraction of the gelatin undergoing change as shown by the change in magnitude of the dispersion constants $k_{0\cdot5}$. In Table III are given the a values for the fraction undergoing change and the calculated values obtained for log $(1/K)$. The latter agree well with one another and give a mean value of 3.373. The factor 1/0.89 preceding the $a/(1-a)$ term regulates how rapidly the change takes place from one optically active form to the other.

In its influence on the rotatory dispersion of gelatin at 0.5° urea stands about midway between sodium chloride and bromide. With all of the sodium halides, the product of the constants preceding the logarithmic $a/(1 - a)$ term multiplied by the log $(1/K)$ term, $[k \log (1/K)]$, gave a constant (2.66); however, the product of these constants for urea $(0.89 \times 3.37 = 3.00)$ does not have the same value as for the sodium halides.

TABLE III

ROTATORY DISPERSION CONSTANTS AT 0.5 AND 40°

Soln.	Concn. urea molal.	$k_{0.5°}$	a	Log (1/K)	$k_{40°}$
1	0.00	99.530	..	..	44.521
2	.50	98.681	..	..	44.801
3	1.00	97.832	..	..	45.103
4	1.50	96.220	0.0214	3.3762	45.401
5	2.00	94.107	.0570	3.3711	45.739
6	2.50	90.151	.1415	3.3796	45.975
7	3.00	83.156	.3173	3.3739	46.401
8	3.50	73.519	.5646	3.3733	46.688
9	4.00	64.826	.7853	3.3672	47.025
10	4.50	59.561	.9096	3.3734	47.323
11	5.00	56.727	.9654	3.3735	47.593
12	6.00	53.801	1.000	..	48.394
13	7.00	52.094	1.000	..	49.010

$k_{40°} = 44.521 + x_1C_{\text{urea}}$ where $x_1 = 0.6138$
$k_{0.5°} = 99.530 - x_2C_{\text{urea}}$ where $x_2 = 1.700$ (Form A)
$k_{0.5°} = 64.00 - x_2C_{\text{urea}}$ where $x_2 = 1.700$ (Form B)
mean log $(1/K) = 3.3735$
$k = 0.89$ (const. preceding $(a/(1 - a)$ term)

This indicates that general equation (3) cannot be simplified further to fit all cases although simplification of the equation for similar salts such as the alkali halides appears justified, as we have already shown.

In Table IV are given the various constants obtained at the various wave lengths for the various combinations employed, calculated from the Lucas equation[10] for a system containing two optically active molecular species having unequal dispersion constants. The constancy obtained for a given combination for the five wave lengths used shows that two and only two optically active species of molecule are present, one the original gelatin molecule (probably gelatinate ion of the type  $RHC\begin{smallmatrix}COO^-\\NH_3\end{smallmatrix}$) and the other the molecule after it has undergone the change recorded by the logarithmic equation.

TABLE IV

[a] The numbers in this column refer to corresponding soln. no. in Table I.

In Table V we have recorded the rotation and dispersion constant at 0.5° for five different wave lengths, of gelatin which had been treated with 7.0 molal urea solution for a week at 0.5°, after which the solution was placed in collodion tubes and the urea dialyzed out. The dialyzed gelatin solution was then concentrated by freezing out part of the water as ice, was brought to the desired *p*H with dilute sodium hydroxide solution, the gelatin concentration determined, the polarizing tubes filled and the gelatin allowed to come to equilibrium during a week at 0.5°, at which temperature they were finally read in the polariscope. The average rotatory dispersion constant of the gelatin going through this cycle of treatment with urea was found to be 99.477 as compared with 99.530 for the original gelatin before treatment. The identity of these constants to one part in 2000 led us to conclude that gelatin suffers no permanent change due to treatment with urea such as is often referred to under the term "denaturation." In the case of gelatin the change is clearly reversible on removing the urea, the same as we have found repeatedly to be the case with neutral salts.

TABLE V

SPECIFIC ROTATION OF GELATIN SOLUTION AT 0.5° AFTER DIALYSIS OF UREA

Gelatin concn. 0.7858 g. per 100 g. soln.; *p*H = 6.30; *d* = 1.0027

λ	(*a*)	[α]	$k_{0.5°}$
6708	3.91	247.56	99.409
5893	5.26	333.04	99.522
5780	5.50	348.23	99.489
5461	6.29	398.25	99.481
4358	11.10	702.80	99.482
Mean			99.477

Although the same general equations express the influence of the dipole ion $^+NH_3C(=NH)O^-$ on gelatin as was found for the simple halide salts, the gelatin ion changed by urea has a dispersion constant of 64.00 at 0.5° when extrapolated to zero urea concentration as contrasted with a similar value of 46.33 for the gelatin ion when changed by the sodium halides. This total change by urea amounts to exactly two-thirds of the change produced by the sodium halides.

Summary

The rotatory dispersion of gelatin in urea solutions has been examined at 0.5 and 40° and was found to follow a single-term Drude equation.

At 40° the dispersion constants bear a linear relation to urea concentration, $k_{40°} = 44.517 + 0.6138\ C_{\text{urea}}$.

The dispersion at 0.5° is the result of two effects, one a linear relation to urea concentration for Form A of $k_{0.5°} = 99.530 - 1.70\ C_{\text{urea}}$, and for Form B of $K_{0.5°} = 64.00 - 1.70\ C_{\text{urea}}$ and the other a logarithmic function, $C_{\text{urea}} = \frac{1}{0.89}\left[\log\left(\frac{a}{1-a}\right)\right] - \log\ (1/K)$ in which log $(1/K)$ equals 3.373. Urea is intermediate in effect on the rotation of gelatin at 0.5°, lying between sodium chloride and bromide. The maximum lowering of the dispersion constant of gelatin by urea is only about two-thirds that produced by the halides of sodium.

---

[10] Lucas, *Ann. phys.*, [10] **9**, 381 (1928); *Trans. Faraday Soc.*, **26**, 418 (1930).

After dialyzing out the urea from several of the most concentrated solutions, the rotatory dispersion constant returned to its original value at 0.5°, showing that gelatin had undergone no denaturation by urea.

Magneto-Optic Rotations of Paramagnetic Ions

BY SAMUEL STEINGISER AND HERBERT HYMAN

The purpose of this investigation was to observe the magneto-optic rotations of dilute solutions of complex iron salts, and to determine the partial Verdet constants. The three salts investigated were potassium ferricyanide, potassium ferrocyanide, and ferric ammonium sulfate. Ferrous ammonium sulfate was also tried, but since it absorbed most of the light in the range of the sodium lamp, accurate measurements could not be made.

Experimental

Materials and Apparatus.—All chemicals were of C. P. grade. Since, in the very dilute solutions used, a relatively large impurity would be necessary to affect the results, no further purification was attempted. The concentrations of the solutions were determined by density measurements. These were made on a chainomatic specific gravity balance, and the concentrations found from tables in the "International Critical Tables."

The source of light, for the values reported, was a General Electric Sodium Lab-Arc, $\lambda_D = 5893$ Å. (Earlier preliminary investigations were made using a mercury vapor quartz arc, but this was abandoned in favor of the more universal sodium arc.) Nicol prisms were used as polarizer and analyzer. The angle setting on the scale could be read to 0.1° and estimated to within 0.01° with the aid of a telescope and cross-hair. The Pyrex glass cell, containing the liquid under investigation, was a 21.6-cm. long tube with the ends of optically flat glass fused into the body of the cell. No cement was used on any part of the tube. It was mounted on wooden supports inside the hollow core of a large coil. The coil was 25 cm. in length, formed by winding 2-mm. diameter insulated copper wire in 17 layers of 125 turns each on a copper cylinder. The coil extended sufficiently beyond the tube to eliminate any distortion of the magnetic field due to edge effects.

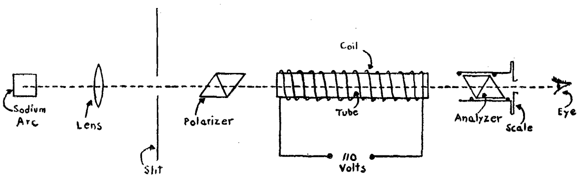

Fig. 1.—Schematic diagram of apparatus.

The apparatus was calibrated using carbon disulfide and distilled water over a range of currents as can be seen from the data. The Verdet constants for these two liquids were obtained from the "International Critical Tables." In order to facilitate calculations of the Verdet constants of the solutions under investigation, a conversion factor was found, as shown, equal to 0.0399 Verdet unit/deg./amp.

Measurements.—The values reported are the average of nine independent measurements with the field off, recorded in the tables below as N^0, nine with the field causing rotation clockwise, R^0, and finally nine with the field causing rotation counterclockwise, L^0. Altogether twenty-seven readings were taken for each solution and the average with its mean deviation calculated.

Although the partial Verdet rotations of some of the salts are in opposite directions to that of water, the actual rotations, in all cases measured, were in the same direction, due to the rather dilute solutions used. The partial Verdet constant is defined so that

$$N_1V_1 + N_2V_2 = V$$

where N_2 and N_1 are the mole fractions of the solute and solvent, respectively, V is the observed Verdet constant for the solution, and V_2 and V_1 are the partial Verdet constants of the solute and solvent. This equation is by definition exact, but in using it to determine V_2, it is necessary to make the assumption that V_1 equals the Verdet constant of pure water. While this undoubtedly is not true in concentrated solutions, it is probably true within the limit of experimental error in the solutions used in these measurements. V_2 is not necessarily the Verdet constant of the pure salt and should not be regarded as such, but is the Verdet constant of the salt in the solution of definite molality. There is considerable evidence to show that it may be regarded as constant over a considerable range of concentrations.

The agreement between the two standardizing substances is thus seen to be very good.

The factor for converting the rotation deg./amp. into Verdet units is 0.0399 Verdet unit/deg./amp.

Discussion

Welo and Baudisch[1] have shown that, with complex ions having a central atom of a transition element, the paramagnetism can be determined from the effective atomic number. When this has the same value as an inert gas, the complex is diamagnetic, while if it differs from this by *n* units, the complex has a magnetic moment of *n* Bohr magnetons. Thus the six-covalent ferricyanides, as $K_3[Fe(CN)_6]$ with an e. a. n. $26 + 6 + 3 = 35$, give p (Weiss) = 10, and b (Bohr) = *ca.* 1, while the ferrocyanides as $K_4[Fe(CN)_6]$ (e. a. n. $26 + 6 + 4 = 36$, the atomic number of krypton) are diamagnetic. Ferric ammonium sulfate probably exists in solution as hydrated Fe^{+++} ion, which is found to be paramagnetic also.

Thus we see that potassium ferricyanide and ferric ammonium sulfate are paramagnetic and also have large negative partial Verdet constants, while potassium ferrocyanide, being diamagnetic, has a relatively low positive partial Verdet constant. There seems to be some correlation between these facts. Scherer and Cordonnier[2,3] have shown that paramagnetic cobalt ions exhibit similar negative Verdet constants over a range of temperatures and wave lengths. Since an error of even 1% in the actual rotation introduces an error of more than 20% in the determination of partial Verdet constants, a quantitative correlation is not possible as yet, but this work has shown a definite connection which may be of use in the future.

Acknowledgment and particular thanks are due to Professors Marcus and Sonkin, of the Physics Department of The City College, for their invaluable aid in this research.

Summary

The partial Verdet constants of ferric ammonium sulfate, potassium ferricyanide and potassium ferrocyanide were determined and found to be equal to −1.024, −2.354 and +0.148, at molalities 0.0282, 0.173 and 0.415, respectively. The total Verdet constant for each of these molalities was found to be 0.01253, 0.00571 and 0.01409, respectively. The diamagnetic salt, potassium ferrocyanide, shows a normal rotation, while the other salts show a large negative rotation, due to paramagnetism.

Hydrides of Boron. X. The Preparation and Preliminary Study of the New Compound B_2H_7N

BY H. I. SCHLESINGER, DAVID M. RITTER,[1] AND ANTON B. BURG

In the preparation of triborine triamine ($B_3N_3H_6$) from ammonia and diborane, we[2] obtained small quantities of a new volatile compound having the molecular formula B_2H_7N. The formation of this compound, for which the structural formula  $\underset{\ddot{H}}{\overset{H}{\ddot{B}}}:\underset{\ddot{H}}{\overset{H}{\ddot{N}}}:\underset{\ddot{H}}{\overset{H}{\ddot{B}}}:H$ seems most appropriate, is an important part of the evidence in favor of the hypothesis that many of the reactions of diborane are caused by its dissociation into unsaturated borine  $\left(H:\overset{H}{\ddot{B}}:H\right)$ molecules.[3] It is, therefore, of interest to describe the preparation and properties of the new compound, as well as to present further evidence concerning its structure.

Preparation.—The observation that B_2H_7N was obtained only when diborane was used in excess of that required by the formula $B_2H_6 \cdot 2NH_3$, suggested that it is formed by the action of diborane upon the "diammoniate,"[4] rather than by the direct reaction of diborane with ammonia. It therefore seemed likely that the yield of B_2H_7N would be improved considerably if diborane were passed over the "diammoniate," under conditions subject to close control.

The apparatus used for this flow method was the one which had been employed before, in the preparation of B_4H_{10} and B_5H_{11}.[5] Ammonia was condensed as a thin layer upon the walls of the first U-tube (U4A in the article referred to above) and converted to the "diammoniate" by exposing it to an excess of diborane while the tube was warmed slowly from −130° to room temperature.[6] Then a large sample of diborane was condensed in the graduated tube M, and allowed to evaporate at −80°; the gas passed through the U-tube containing the ammoniate, at a rate limited by the capillary tube C. All condensable gases and vapors were trapped in the second U-tube (at −195°), while the hydrogen passed through and registered its pressure upon a manometer in the main vacuum apparatus beyond. The proper temperature for the first U-tube was determined by warming that U-tube until the movement of the mercury in the manometer indicated a satisfactory rate of reaction.[7] After the evaporation of the last of the diborane, the major part was recovered from the material trapped in the second U-tube; in most cases it was passed through the system again, until no important quantities of hydrogen were evolved in the process. The conditions and results of four such experiments are given in Table I.

TABLE I

FLOW METHOD OF PREPARING B_2H_7N

Ammonia, cc.[a]	Total B_2H_6, cc.	No. of passages	Flow rate, cc./min.	Temp., °C.	Diborane destroyed, cc.	B_2H_7N formed, cc.	% yield (based on diborane)
105	422	1	10	100	75	14.7	19
120	730	1	5	85	83	25.0	30
173	613	2	12	85	100	29.0	29
142	877	2	30	88	108	36.0	33

[a] All gas volumes in this paper refer to standard conditions.

The product was purified by fractional condensation: it passed through a U-tube at −55°, and condensed completely at −80°.

Analysis and Molecular Weight.—Measured samples of the vapor were treated with known volumes of standard hydrochloric acid in sealed tubes. The resulting hydrolyses were completed in ten minutes at room temperature.[8] The hydrogen was collected for measurement over mercury by means of a Töpler pump with a trap at −196°; the contents of the trap and of the hydrolysis tube were then washed into a flask. The excess acid was titrated to the methyl red end-point; the difference between the quantity of acid originally used and that found by this titration represents ammonia nitrogen. Subsequent titra-

[1] Much of the material of this paper was taken from the dissertation presented by David M. Ritter to the Faculty of the Division of Physical Sciences of the University of Chicago, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Schlesinger, Ritter and Burg, THIS JOURNAL, **60**, 1297 (1938).

[3] Other evidence on this subject appears in two earlier papers: Burg and Schlesinger, *ibid.*, **59**, 780 (1937); Schlesinger and Burg, *ibid.*, **60**, 290 (1938).

[4] For the structure of this compound, see Schlesinger and Burg, *ibid.*, **60**, 290 (1938).

[5] Burg and Schlesinger, *ibid.*, **55**, 4012 (1933).

[6] The preparation of the diammoniate by the slightly more tedious process of carrying on the reaction at −120° and removing the residual ammonia at −80°, led to no change of yield.

[7] It is important to employ the lowest feasible temperature, because higher temperatures lead to frothing, with the danger of clogging the capillary, and also facilitate the formation of traces of such impurities as B_4H_{10}, B_5H_{11}, and $B_3N_3H_6$.

[8] When pure water was used, the hydrolysis was far more difficult, probably because the free ammonia first liberated acted as a base to hinder the hydrolysis of the B-H links. Thus a sample which was left in contact with water in a sealed tube for two months at room temperature produced only 3.8 of the expected 5 volumes of hydrogen.

tion of the solution to the phenolphthalein end-point in the presence of an adequate quantity of mannite gave the amount of boric acid present. The results are given (in millimoles) in Table II.

These results agree with the formula B_2H_7N, as shown by the equation $B_2H_7N + 4H_2O + H^+ \longrightarrow 2HBO_2 + NH_4^+ + 5H_2$.

The molecular weight calculated from the observed vapor density also agreed with the formula B_2H_7N (obsd. 42.9 and 42.2; calcd. 42.6).

The melting point was determined by observations on two separately purified samples. The values, taken by means of an ammonia vapor pressure thermometer, were −66.5 and −66.4°.

The vapor pressure at various temperatures determined the equation

$$\log_{10} p_{mm.} = -(2097/T) + 1.75 \log_{10}T - 0.00642T + 6.677$$

From this equation, the molar heat of vaporization is estimated as 7300 cal., and the Trouton constant as 21.0 cal./degree mole. The normal boiling point is calculated to be 76.2°.

Decomposition and Thermal Stability.—The substance B_2H_7N can be kept for several days at room temperature without appreciable decomposition, but a sample which had been held for six hours at 45° showed an increase of vapor pressure, corresponding to about 0.2 cc. of diborane (from a 5-cc. sample). A sample left for sixteen months in a sealed bulb at room temperature, decomposed almost completely, evidently according to the equation $2B_2H_7N \longrightarrow B_2H_6 + (BH_4N)_x$; the actual results were complicated by secondary production of hydrogen, and by the probable presence of $B_3N_3H_6$ in the original sample.[9]

The 5.6-cc. sample yielded 2.4 cc. of diborane, 0.6 cc. of hydrogen, and 0.4 cc. of material having approximately the volatility of $B_3N_3H_6$. The diborane was fully identified by its vapor pressure (226 mm. at −112°) and by hydrolysis, which yielded 14.4 cc. (6.1 volumes) of hydrogen and 0.214 millimole of boric acid (2.00 equivalents per mole). The non-volatile solid was not investigated further.

The Behavior of B_2H_7N toward Trimethylamine.—A stable addition product $(CH_3)_3N \cdot B_2H_7N$, is produced by the action of trimethylamine upon B_2H_7N at −80°. Heating this product with excess trimethylamine results in the removal of a BH_3 group to produce one molecule of borine trimethylammine per mole of B_2H_7N originally used.

Thus 2.7 cc. of B_2H_7N, treated with 12.2 cc. of trimethylamine at −80°, absorbed 2.8 cc. of the latter, to give a white solid which failed to react further during two hours at room temperature. During three hours at 100°, however, there resulted 2.80 cc. of material whose vapor pressures were measured as 18.6 mm. at 69.5° and 10.6 mm. at 59.8°, in good agreement with the data recorded earlier for borine trimethylammine.[10] There resulted also 2.9 cc. of hydrogen, and a further 0.9 cc. of trimethylamine was used up. A trace (0.3 cc.) of material which seemed to be $B_3N_3H_6$, also was found among the products. The residual solid thus seemed to have the composition $BNH_2 \cdot {}^1/_2N(CH_3)_3$.

The Behavior of B_2H_7N toward Ammonia.—Like trimethylamine, ammonia adds to B_2H_7N to give a stable solid mono-ammoniate, $B_2H_7N \cdot NH_3$. By the sudden heating of this substance to 200°, a 45% yield of $B_3N_3H_6$ is obtained; this yield is somewhat higher than that obtained directly from the "diammoniate of diborane."

In a typical experiment, 5.2 cc. of B_2H_7N and 17.7 cc. of ammonia were left together for one hour at −80°. Then the excess ammonia was distilled to another part of the vacuum apparatus, while the reaction tube was being warmed to room temperature. The removed ammonia was measured as 12.6 cc., indicating that the white solid residue contained 5.1 cc. of combined ammonia. Five minutes of heating of the product at 50° caused the evolution of only 0.25 cc. of volatile material.

Another sample of the solid, composed of 9.65 cc. of B_2H_7N and 9.65 cc. of ammonia, was allowed to stand for two months at room temperature (25–30°): it produced 0.3 cc. of hydrogen and an even smaller trace of material which was trapped at −196°.

A sample composed of 4.8 cc. of B_2H_7N and 4.9 cc. of ammonia was heated for five minutes in a sealed tube at 200°. The products were 15.1 cc. of hydrogen, 1.4 cc. of $B_3N_6H_6$, 0.26 cc. of an unidentified substance slightly more volatile than $B_3N_3H_6$, and non-volatile solids. The yield of $B_3N_3H_6$ thus was slightly less than 45%.

The Behavior of $B_2H_7N \cdot NH_3$ toward Sodium in Liquid Ammonia.—When the compound $B_2H_7N \cdot NH_3$ is dissolved in liquid ammonia and

---

[9] This particular sample had been obtained as a by-product in the preparation of $B_3N_3H_6$.

[10] Burg and Schlesinger, THIS JOURNAL, **59**, 785 (1937).

treated with sodium, one gram equivalent of hydrogen is liberated, per mole of B_2H_7N originally used. After completion of the reaction and removal of excess ammonia, the residue corresponds to the empirical formula $B_2H_7N \cdot NH_2Na$. The significance of these facts is discussed later.

A 5.65-cc. sample of B_2H_7N was dissolved in liquid ammonia at −77°; the solution was treated with 30 mg. of pure sodium, in the manner described in an earlier paper.[11] The resulting evolution of hydrogen was not very rapid, but it finally amounted to one gram equivalent per mole of B_2H_7N, as shown in Table IV.

TABLE IV

REACTION OF $B_2H_7N \cdot NH_3$ WITH SODIUM IN LIQUID AMMONIA

Total time, min.	Temp. during time before meas., °C.	Total H evolved, cc.	Ratio of H to B_2H_7N
16	−67	1.55	0.55
32	−55	2.45	.87
57	−60	2.90	1.03
130	−66	3.03	1.07

Reaction beyond that point was exceedingly slow. The major part of the ammonia was removed by distillation at −50°; a further 0.4 cc. (gas) was lost by the residue during seventy-six hours *in vacuo* at room temperature, conditions so severe that 4.0 cc. of hydrogen also was liberated. The residue was hydrolyzed completely by 3 normal hydrochloric acid; then the excess acid was distilled off and replaced by sodium hydroxide. The ammonia was determined, partly by measurement of the purified gas (9.05 cc.) and partly by titration (1.75 cc.). The total, 10.8 cc., amounts to 1.9 moles of ammonia per mole of B_2H_7N.

The slow production of somewhat more than one equivalent of hydrogen by reaction with sodium in liquid ammonia might well be due to a secondary reaction analogous to that of the "diammoniate of diborane."[4]

Discussion

Only two of the conceivable structures for the compound B_2H_7N seem worthy of serious discussion: (1) an amine of diborane, $B_2H_5NH_2$, and (2) a structure involving a B–N–B skeleton.[12] All derivatives of diborane, not immediately ammonolyzed, take up two molecules of ammonia per molecule of diborane derivative, to form stable compounds. The substance B_2H_7N, however, takes up only one molecule of ammonia; further addition, if it occurs at all, leads to very unstable addition products. This fact is sufficient to exclude further discussion of the first formulation.

The assumption of a B–N–B skeleton leads to two possible structures: (I) BH_3NHBH_3[13] and (II) $BH_2NH_2BH_3$. Formula I not only requires assumptions with regard to electronic distribution, unjustified by any of the chemical properties thus far known for the compound, but fails to explain why one and only one molecule of ammonia can be added to it. When structure II is represented electronically,  $\overset{H}{\underset{H}{B}}:\overset{H}{\underset{H}{N}}:\overset{H}{\underset{H}{B}}:H$, the addition of one molecule of ammonia (to the one "unsatisfied" boron atom) is understood readily. Compounds in which boron atoms are associated with only six bonding electrons are, of course, very common (*e. g.*, BF_3, BCl_3, BR_3, and their substitution products) and, if not ammonolyzed, take up one molecule of ammonia for each such boron atom present. They are also capable of adding trimethylamine in the same ratio, as does the compound B_2H_7N. On the other hand, compounds containing the BH_3 group tend to give borine trimethylammine, $BH_3 \cdot N(CH_3)_3$, a product which actually is obtained when the addition compound $B_2H_7N \cdot N(CH_3)_3$ is heated with an excess of the amine.

According to structure II, the addition of one mole of ammonia to B_2H_7N results in the compound  $H_3N:\overset{H}{\underset{H}{B}}:\overset{H}{\underset{H}{N}}:\overset{H}{\underset{H}{B}}:H$. This structure is analogous to that of borine ammine (H_3NBH_3) for in each an ammonia molecule is coördinatively bound to a boron atom. Although borine ammine has not been isolated, it has been shown by indirect methods[4] to react in liquid ammonia solutions with sodium to liberate one gram equivalent of hydrogen for every mole of ammonia bound in that manner. The compound $H_3NB_2H_7N$ reacts to give the same proportion of hydrogen. This cannot mean that the original ammonia addition product was an ammonium salt, for sodium would have reacted with such a salt to remove one nitrogen atom as ammonia, leaving a residue of the composition NaB_2H_6N, instead of the salt $NaNH_2 \cdot B_2H_7N$ actually obtained as a final product.

Other details of the behavior of the compound are in full agreement with formula II. Its stability is characteristic of compounds containing

---

[11] Schlesinger and Burg, THIS JOURNAL, 60, 293 (1938).

[12] Other ideas are represented by the formulas $NH_4B_2H_3$, $NH_3 \cdot B_2H_4$, $NH_3 \cdot BHBH_3$, and $H^+B_2H_6N^-$. Each of these is difficult to reconcile with some of the physical and chemical properties described in this paper.

[13] According to the usual electronic formulations, two possibilities exist for structure I:  $H:\overset{H}{\underset{H}{B}}:\overset{H}{\ddot{N}}:\overset{H}{\underset{H}{B}}:H$ and  $H:\overset{H}{\underset{H}{B}}:\overset{H}{N}:\overset{H}{\underset{H}{B}}:H.$ Neither of these avoids the difficulties pointed out for the less specific formula I.

a B–N–B pattern of linking, rather than of those containing B–B bonds; the B–N–B skeleton explains why the compound, when heated, gives good yields of $B_3N_3H_6$, a substance containing the  ring; its rapid hydrolysis in acid solution to give five volumes of hydrogen suggests the existence of five B–H bonds.

Finally, attention is called to a recent paper by S. H. Bauer,[14] who, at our suggestion, investigated the electron diffraction of the vapor of this compound, and concluded that the data obtained can be explained only by the existence of a B–N–B skeleton for the molecule.

Acknowledgment.—We wish to express our thanks to the Research Corporation, for providing the liquid nitrogen used in a large part of this work.

Summary

The new volatile compound B_2H_7N (b. p. 76.2°; m. p. $-66.5°$) was prepared by the action of diborane upon its "diammoniate." The new substance is hydrolyzed easily in acid solution, to give five volumes of hydrogen, two equivalents of boric acid, and one equivalent of ammonium ion. Its thermal decomposition (slow at room temperature) produces diborane and a solid of undetermined character. It reacts with an equal gas volume of trimethylamine, to form a stable white solid; on heating with an excess of that amine, this product yields borine trimethylammine. With ammonia, B_2H_7N forms the stable solid $B_2H_7N{\cdot}NH_3$, which, on heating to 200°, gives a good yield of triborine triamine ($B_3N_3H_6$). The ammonia addition product reacts with sodium in liquid ammonia to liberate one equivalent of hydrogen; the residue after thorough removal of the solvent corresponds to the formula $NaNH_2{\cdot}B_2H_7N$.

The structure  $\overset{H}{\underset{\ddot{H}}{\ddot{B}}}:\overset{H}{\underset{\ddot{H}}{\ddot{N}}}:\overset{H}{\underset{\ddot{H}}{\ddot{B}}}:H$ is proposed for the compound, and although this specific picture is not considered definitely proved, it is shown to interpret satisfactorily all of the physical and chemical properties of the substance.

The Compressibilities of Hydrogen and of Four Mixtures of Hydrogen and Nitrogen at 0, 25, 50, 100, 200 and 300° and to 1000 Atmospheres

BY R. WIEBE AND V. L. GADDY

This is a continuation of work in this Laboratory on the compressibilities of hydrogen, nitrogen and their mixtures.[1] A summary of work previous to 1930 was given by Bartlett. Townend and Bhatt measured the isotherms of hydrogen at 0 and 25° to 600 atm.[2] Isothermal measurements on hydrogen between 0 and 100° and up to 1000 atm. were made by Michels, *et al.*[3] Michels and Gerver recalculated the compressibility data of Kohnstamm and Walstra on hydrogen at 15.5 and 20° between 1000 and 2000 atm.[4] Isotherms of nitrogen between 0 and 150° and at pressures from 20 to 80 atm. were determined by Michels, *et al.*[5] This latter work was continued up to 400 atm. by Otto, Michels and Wouters.[6] A further extension to 3000 atm. including a calculation of the thermodynamic properties was made by Michels, *et al.*[7] W. Edwards Deming and Lola S. Deming have calculated the thermodynamic properties of hydrogen and nitrogen.[8]

Since in the previous investigations on hydrogen some disagreement exists among the different observers, we have repeated most of their measurements.

Apparatus and Procedure.—Figure 1 shows the low pressure part of the apparatus and the high pressure pipet. Before each run the connecting tube between pipet outlet valve M and stopcock G is open to the atmosphere through J. The 4-bulb buret A of 3000-cc. capacity is filled with mercury, stopcocks H, K and J are closed, and gas at some definite temperature and pressure is expanded from D through valve M. The whole volume is brought to atmospheric pressure by means of the oil-manometer F. Stopcock G is now closed and the gas is confined to the 4-bulb buret A. The mercury levels are now adjusted to calibration marks between the bulbs. Since usually two combinations of bulbs are possible, the one giving a pressure nearest to that of the atmosphere is selected. After opening H, manometer E is adjusted so that the mercury surface in the right arm just touches the tip of pin L. This assures a constant volume between H and L. The first two or three samples have to be discarded; after that the manometer will show the actual experimental variation, since the manometer volume is small compared with the gas volume in A. Any slight change in atmospheric pressure between closing of stopcock J and adjusting of oil-manometer F introduces only a negligible error since here again the volume of the connecting tube is small. Even a smaller volume is exposed to possible changes in room temperature. B is a coil to bring the incoming gas rapidly to the temperature of C. The large thermostat C was kept at 25 ± 0.01° while the temperature of the thermostat containing D was varied from 0 to 300°. Toluene and mercury filled regulators were used to cover the range between 0 and 200° while at 300° a thyratron control was used.[9] We used the control only for an auxiliary immersion heater; the voltage across the heating coils was that of the unregulated 110 a. c. voltage mains. It was possible to maintain the temperature within a few one-hundredths of a degree with little trouble. The true temperatures were measured with platinum resistance thermometers built according to specifications by Myers.[10] The thermometers were calibrated both at this Laboratory and at the Bureau of Standards with identical results. At 100 and 200° Crisco, or its equivalent, was used for bath liquid; while at 300° a lead–tin mixture was found satisfactory.

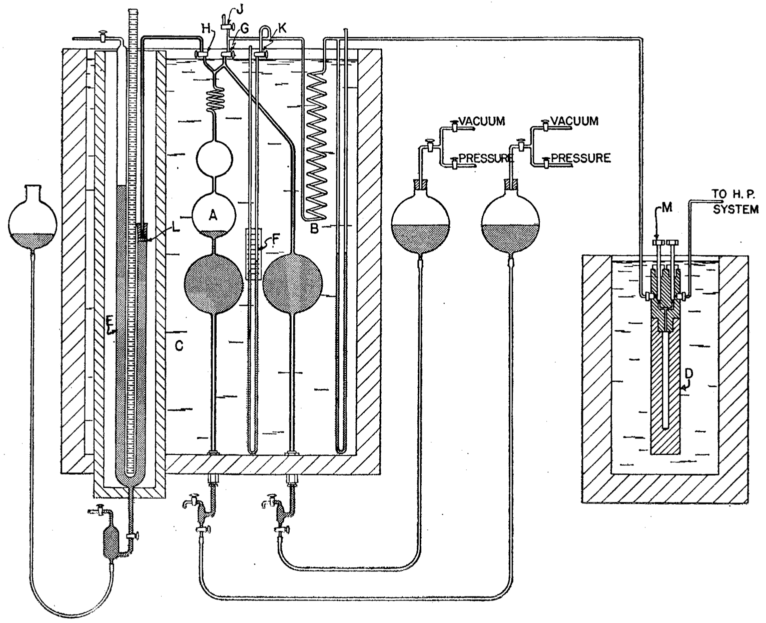

Fig. 1.

Our 200 and 1500 atmosphere piston gages were compared at 100 atm. with the National Bureau of Standards gage,[11] and it was found that only one of the pistons had developed a change of one part in 10,000 since August, 1935. The acceleration of gravity at the laboratory is taken to be 980.091 cm./sec.[2] The pressures are given in international atmospheres. The thermal conductivity and an accurate combustion method[12] were used to analyze the gas mixtures. The latter method was the more satisfactory in our case.

The high pressure volume was measured at 25 and 100° and at 100 atm. in a slightly modified steel pipet by displacing mercury by gas. The mercury was withdrawn, weighed and the volume calculated. The pressure coefficient was obtained from the work of Smith and Keyes.[13] From several determinations the compressibility of hydrogen was determined at 25 and 100°, and 100 atmospheres. These values were used as reference points throughout this work. The average coefficients of linear expansion of our steel (C 0.49%, Cr 2.48%, V 0.25%, Mn 0.68%) were determined by Dr. Peter Hidnert of the National Bureau of Standards, to whom our thanks are due. Table I gives the results obtained.

TABLE I

Temp. range, °C.	Average coefficients of linear expansion per °C. Sample heated to 300°	Sample treated with hydrogen at 300°
20–100	12.4×10^{-6}	11.4×10^{-6}
20–200	12.9×10^{-6}	12.2×10^{-6}
20–300	13.6×10^{-6}	12.9×10^{-6}

The results of Table I show a decided influence of hydrogen on steel. The sample used in determining the linear coefficient of expansion had been exposed to extreme conditions. In actual practice the thickness of the pipet walls (2.5 cm.) and the short time exposure at 300° and 1000

[a] Data from Michels, Nijhoff and Gerver, *Ann. Phys.*, **12**, 562 (1932) (Hydrogen); Michels, Wouters and De Boer, *Physica*, **3**, 585 (1936) (Nitrogen). [b] Data from Holborn and Otto, *Z. Physik*, **33**, 1 (1925). [c] Data from Bartlett, *et al.*, THIS JOURNAL, **50**, 1275 (1928).

atm. make it probable that an effect as great as that shown in the table would not occur. It was finally decided to use the equation given by Keyes[14]

$$V_t^{Fe} = V_0(1 + 3.25 \times 10^{-5}t + 2.85 \times 10^{-8}t^2 - 1.65 \times 10^{-11}t^3)$$

where V_0 is the volume at 0° and V_t the volume at temperature t. This formula gives linear coefficients for the ranges 0–200 and 0–300° which are about the averages of the two sets given in Table I. The possible error in the determination of volume incurred at 0 and 50° is probably not more than one or two parts in 10,000, since the absolute values were known at 25 and 100°. At 200 and 300° the error introduced in V_t^{Fe} using the above equation is estimated between 0.05–0.10%. This does not influence the relative precision of any one isotherm. A change in the value of the reference point will affect all the other values by the same fractional amount.

Our experimental data are shown in Table II, and also data from Bartlett, Michels, and Holborn and Otto, where we have no values of our own. Since the data of Michels for nitrogen were given at odd pressures, we have used his equations to calculate the values given in this table. Dr. Deming expects to calculate the thermodynamic properties of hydrogen–nitrogen mixtures from these data.

We want to thank Dr. E. J. Jones for assistance in setting up our thyratron temperature control and Lola S. Deming (Mrs. W. E. D.) for helping us in our calculations. We also acknowledge the help of Mr. J. R. Dilley, who assisted in the design of the high pressure equipment.

Summary

Previous work since 1930 on the compressibilities of hydrogen, nitrogen and their mixtures has been summarized. A modified Bartlett compressibility apparatus is described. The compressibilities of hydrogen and four hydrogen–nitrogen mixtures have been measured at 0, 25, 50, 100, 200 and 300° and to 1000 atmospheres.

The Hydration of Vitamin B_1

BY W. A. BASTEDO, JR., N. R. TRENNER AND T. J. WEBB

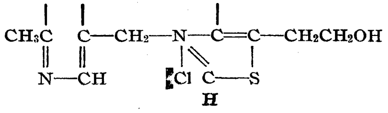
Introduction

The marked deliquescence of vitamin B_1[1] has been recognized by many investigators. The water of crystallization, however, has been given variously in the literature as one-half, one, or approximately one molecule of water (per molecule of vitamin) without regard for the conditions of humidity. The problem of preparing the one or more supposed hydrates in pure form and the measurement of their dissociation pressures was undertaken in these Laboratories. In the beginning the problem proved to be baffling on account of lack of reproducibility. This initial lack of reproducibility in the degree of hydration was attributed finally to variable minor details in the later stages of preparation of the vitamin, such, for example, as solvents used in the precipitation process, methods of removing solvent, etc. After standard procedures having regard for such details had been found, the early difficulties regarding reproducibility disappeared (at least to the extent of 0.1 g. of water per 100 g. of vitamin). The much higher reproducibility obtainable for samples under identical conditions of humidity led to the belief that the remaining difficulty lay in the inherent problem of the reproducibility of the aqueous pressures to which the samples were exposed. The fact that *slight* variations in the aqueous pressures to which the samples were exposed gave rise to appreciably variable water contents of the vitamin indicated immediately that the problem was not one of an ordinary system of hydrates.

Experimental Details and Results

In the first attack on the problem the aqueous pressure to which the samples were exposed was regulated by H_2SO_4–H_2O mixtures in evacuated desiccators at 25 ± 1°.

[1] Formula of vitamin B_1



Ninety-five per cent. sulfuric acid was found to be a complete desiccant for the vitamin. The density of the mixtures was measured with sufficient accuracy that the aqueous pressure could be found to within approximately 0.4 mm. of mercury by reference to standard measurements.[2,3] In order to check this procedure for obtaining a given aqueous pressure saturated solutions of calcium chloride and of barium chloride were used on two occasions. The results obtained with these solutions were entirely consistent with those obtained with the H_2SO_4–H_2O mixtures. Two days were sufficient for the samples (approximately 0.6 g.) to attain equilibrium with a given aqueous pressure. Weights (accurate to 0.1 mg.) were always checked on the third day, and in many cases after the lapse of one or more weeks. The water contents of the vitamin in terms of grams of water per 100 g. of anhydrous vitamin are given in Table I for various aqueous pressures (expressed in mm. of mercury). Each entry represents an average of a number of determinations—in the range of aqueous pressures above 7 mm., some of the entries represent an average of as many as ten determinations. The variations were of the order of 0.1 g. of water per 100 g. of vitamin. The large number of determinations represents an attempt to distinguish between a number of hydrates of very nearly the same water content.

Table I

Aqueous press.	Water, %	Aqueous press.	Water, %
1.2	0.46	6.8	4.31
1.4	.70	9.0	4.52
2.0	1.62	10.0	4.60
3.0	2.07	10.8	4.62
3.3	2.59	12.2	4.72
3.6	2.88	14.6	4.93
5.0	3.62	15.3	4.91
5.9	4.12	18.2	5.15

A graph of the results in Table I shows that within the estimated experimental error they can be represented by a smooth curve (Fig. 1) and give no evidence whatever of definite stoichiometric hydrates except in the extent to which there is an approach to one molecule of water per molecule of vitamin at high aqueous pressures. The region of experimental values was terminated naturally by the aqueous pressure of the saturated solution, 20.9 mm. A slight extrapolation of the experimental curve indicates that approximately one molecule of water per molecule of vitamin (in the crystalline state) would be acquired at 20.9 mm. The curve is reproducible in a hydrating as well as a dehydrating sense. The complete reversibility of the hydration and dehydration phenomena, which is often not observed in the case of continuous hydration,[4] precludes the possibility that the hydration is a slow process not attaining equilibrium. On the other hand, the absence of definite stoichiometric hydrates would seem to indicate that the forces exerted by the water molecule in the crystal play little, if any, role in the crystal lattice. The shape of the curve exhibiting the water content as a function of the aqueous pressure is strongly suggestive of a sorption process only in the range of high aqueous pressures. It is possible that the hydration phenomena observed in this case are not uncommon in the case of deliquescent organic substances of complicated structure—the assignment of definite formulas for such hydrates often being merely a matter of rounding out the results of chemical analysis.

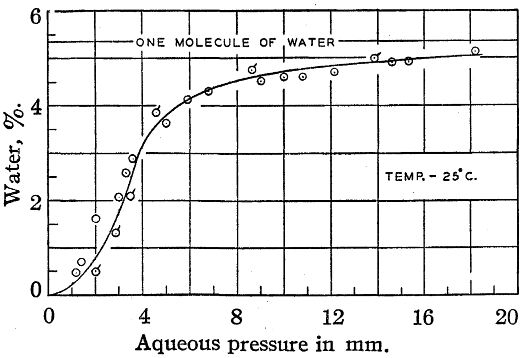


Fig. 1.—Hydration of vitamin B_1: results of gravimetric method, ⊙; volumetric method, ⊙-.

The fact that the type of result obtained above was entirely unexpected and practically without mention in standard works on the subject of salt–hydrates led to a renewed attack with an entirely different technique. A thoroughly dried sample of the vitamin was placed in an all-vacuum apparatus of the type described by Taylor and Strother[5] for sorption problems. A constant aqueous pressure was automatically preserved in the system and the decrease in the volume of water vapor measured to 0.01 cc.; the temperature of the sample of vitamin being held accurately at 25°. Corrections were applied for the dead space in the vessel containing the sample and for the adsorption on the walls of the container. The latter effect could be represented accurately by an equation of the form

$$x = kp^n$$

x being the quantity adsorbed and p the aqueous pressure. The constants k and n were found to have the values 0.0184 and 0.68, respectively,

[5] Taylor and Strother, This Journal, **56**, 586 (1934).

if x is expressed in cc. (N. T. P.) and p in millimeters of mercury. The results obtained in this way checked those obtained by the first method, within the experimental error (estimated to be at least as great as two parts of water per 1000 of vitamin). The error in this method is as large as this in view of the fact that the samples of vitamin were necessarily very small—of the order of 2 mg. The discrepancy between the two sets of experimental results corresponds to an error of 0.004 mg. in the weighings. By this method the percentages of water in the vitamin under aqueous pressures of 14.0, 9.0, 4.57, 3.0 mm. were found to be 5.00, 4.80, 3.85, and 1.3, respectively. The results are exhibited graphically in Fig. 1. These results were considered an adequate check of the results by the first method, and it therefore seemed unnecessary to question further the continuity of this hydration phenomenon.

The second series of measurements reveals the actual speed of the hydration process as carried out (Fig. 2). It is to be noted that the time required for virtual completion of the hydration process (*e. g.*, curve C) was strictly comparable with that required for the virtual completion of the adsorption process on the glass (curve D) *i. e.*, of the order of two hours. The readings corresponding to the points representing the times labeled ∞ were taken after approximately twenty-four hours and indicate that equilibrium had been reached.

The vapor pressure of the saturated solution of vitamin B_1 was measured in the usual type of differential tensimeter, a mineral oil of specific gravity 0.894 being used as the manometric liquid. Water was used as a balancing liquid in one limb of the tensimeter and the saturated solution of the vitamin in the other. The results for several temperatures are given in Table II in terms of mm. of mercury.

TABLE II

VAPOR PRESSURE OF SATURATED SOLUTION

Temp., °C.	25	24	23	20	15	106
Press., mm.	20.9	19.6	18.5	15.4	11.4	8.0

A straight line is obtained when the logarithm of the vapor pressures is plotted against the reciprocal of the absolute temperature. The slope of this line indicates that the heat of vaporization of one mole of water from the saturated solution is 10,800 cal. (*cf.* 10,450 cal. for the molal heat of vaporization of pure water at 25°).

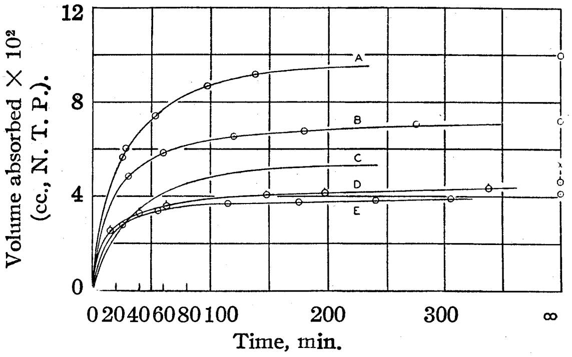

Fig. 2.—Rate of absorption of water on 2.019 mg. of vitamin B_1 at 25°: Curve A, absorption on vitamin + glass at 3.57 mm.; Curve B, absorption on vitamin + glass at 2.90 mm.; Curve C, Curve A − Curve D; Curve D, absorption on glass walls at 3.57 mm.; Curve E, absorption on vitamin + glass at 2.05 mm.

Summary

The degree of hydration of vitamin B_1 at 25° was determined gravimetrically at sixteen different aqueous pressures in the range between 1 and 19 mm. The degree of hydration was found to increase continuously from approximately 0.4% of water at 1 mm. to 5.20% at 19 mm. At the aqueous pressure of the saturated solution (20.9 mm.) the degree of hydration of solid vitamin corresponds approximately to one molecule of water of crystallization per molecule of vitamin. These determinations were checked by a volumetric method in which the volume of water vapor absorbed by the vitamin at various pressures of water vapor was measured. The vapor pressure of the saturated solution of the vitamin was measured over a temperature range in the neighborhood of room temperature.

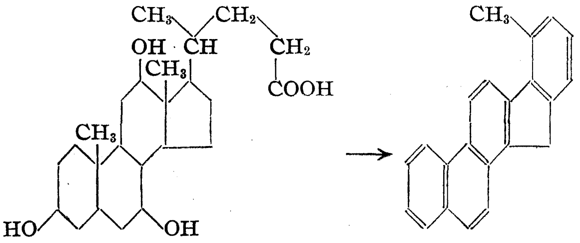
The Strophanthidin Dehydrogenation Product $C_{21}H_{16}$

BY ERNST BERGMANN

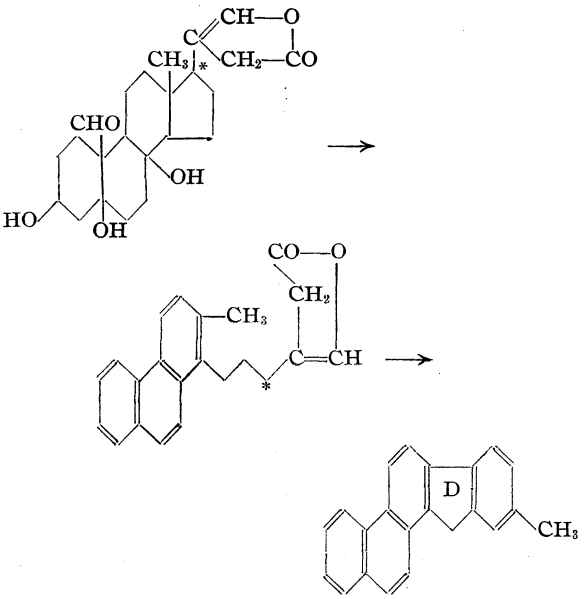
By selenium dehydrogenation of strophanthidin, Jacobs and Elderfield[1] obtained *inter al.* a hydrocarbon, m. p. 296°, to which they ascribed the formula $C_{21}H_{16}$. Their tentative suggestion that it may be 1,2-cyclopentenotriphenylene has been ruled out by synthetic work carried out in this Laboratory.[2] Further work in this direction has led to the assumption that the above hydrocarbon belongs to the 2′,1′-naphtha-1,2-fluorene derivatives, which have been obtained from cholic acid, cholesterol, ergosterol and sitosterol.[3] First of all, the absorption spectrum of the above hydrocarbon, a few milligrams of which we owe to the courtesy of Professor Jacobs, shows a definite resemblance to those of pure naphthafluorene derivatives.[4] Absorption maxima have been observed at λ 2720, 2800, 2980, 3150, and lower ones at 3200, 3400 and 3600.

With regard to the formation of the hydrocarbon from cholic acid, Bachmann, Cook, Hewett and Iball[3] have presented conclusive evidence for the scheme



but they point out that "this identification of Ruzicka's hydrocarbon throws no further light on the structure of the pentacyclic hydrocarbons of analogous structure obtained by dehydrogenation of sterols," as cholesterol does not yield 5-methyl-8-isopropyl-2′,1′-naphtha-1,2-fluorene, to be expected according to the given scheme. We may add that strophanthidin could not give rise to a pentacyclic system at all according to the scheme of the English authors, as only a three-carbon side-chain, containing one methyl group, is available.

The carbon atom lacking for the construction of the pentacyclic system can only be the quaternary methyl group at C_{13} which is used in an analogous way in the synthesis of chrysene from cholic acid[5] or oestrone.[6] There, the cyclopentane system opens and gives a six-membered ring by subsequent recyclization. Here, the new ring (D) formed is again a five-membered one, and the number of the chain atoms is increased by one, so that the possibility is given for additional six-membered ring formation:



The hydrocarbon of Jacobs and Elderfield, therefore, would be 7-methyl-2′,1′-naphtha-1,2-fluorene and have the formula $C_{22}H_{16}$ instead of $C_{21}H_{16}$; combustion analysis would not be able to differentiate between the two formulas. In fact, the hydrocarbon prepared from strophanthidin proved identical with 7-methylnaphthafluorene, prepared according to Cook and co-workers,[3] on the follow-

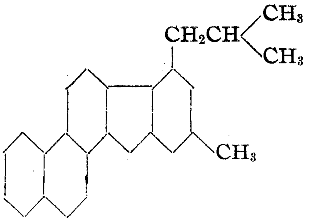
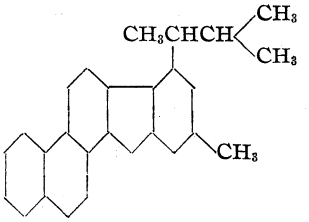
[6] Butenandt and Thompson, *ibid.*, **67**, 140 (1934).

ing evidence. They have the same m. p. 301° (on slow heating);[7] the melting point of their mixture is not depressed; the solubilities in various solvents are identical. Due to the extreme scarcity of material, it was impossible to compare derivatives of the two products; so the evidence presented is somewhat unsatisfactory, were it not for the immanent probability of the above hypothesis.

It is a curious coincidence that the naphthafluorene hydrocarbon derived from cholic acid, too, had been formulated $C_{21}H_{16}$ at first, the correct formula being $C_{22}H_{16}$ according to Cook and co-workers[3] and to Bernal and Crowfoot.[8]

In view of the reported result, the hydrocarbons obtained from cholesterol and ergosterol, respectively, have to be formulated as follows





In accordance with Ruzicka's results,[3] the two sterols would yield different naphthafluorene derivatives, and the contradictory view of Diels and co-workers[9] would be untenable. The possibilities of synthesizing 7-methyl-9-isobutyl- and 7-methyl-9-(α,β-dimethylpropyl)-naphthafluorene are being investigated in this Laboratory.

With the elucidation of the mechanism of naphthafluorene formation from steroids, all the possibilities of their aromatization seem to be clear: the methyl at C_{13} is eliminated in the formation of methylcholanthrene, picene[10] and of 5-methyl-naphthafluorene from cholic acid (see above); it is used for conversion of the cyclopentano ring into a six-membered system in the formation of chrysene[5,6] and for the formation of a new cyclopentano ring in the case of the naphthafluorene derivatives studied above; it migrates in the formation of γ-methyl-1,2-cyclopentenophenanthrene from various steroids.[11] The quaternary methyl at C_{10} is generally eliminated in dehydrogenation processes.

Summary

The polycyclic hydrocarbon obtained by dehydrogenation of strophanthidin is 7-methyl-2',1'-naphtha-1,2-fluorene and has the formula $C_{22}H_{16}$ (not $C_{21}H_{16}$). The mechanism of its formation is discussed and formulas for the analogous derivatives of cholesterol and ergosterol, respectively, are suggested.

The various aromatization mechanisms for steroids are enumerated.

The Dioxanates of the Mercuric Halides

BY J. L. CRENSHAW, ARTHUR C. COPE, NORMA FINKELSTEIN AND RUTH ROGAN

The cyclic diether of ethylene glycol, 1,4-dioxane, forms addition compounds with certain types of inorganic and organic compounds. The properties of these compounds are those to be expected of rather unstable oxonium salts. Several of them lose dioxane on exposure to the air, or on heating, and some apparently are dissociated into their components in solution. However, the addition compound of dioxane with mercuric chloride, according to both Paternò and Spallino[1] and Clarke[2] is stable, and sublimes unchanged on heating. Rheinboldt and his coworkers,[3] who have prepared a large number of dioxanates of inorganic halides, state[4] that the compound with mercuric chloride decomposes at 160–165°, and that with mercuric iodide at about 90°. Curran and Wenzke[5] are of the opinion that the mercuric halides do not form coördination compounds with dioxane, their evidence being the fact that diphenyl mercury has the same dipole moment in benzene and in dioxane solution. This conclusion is questionable, in view of the fact that the magnesium halides and organomagnesium halides form dioxanates much more readily than do the dialkyl (or diaryl) magnesium compounds.[6]

We have studied the properties of the dioxanates of the mercuric halides, in an effort to explain these contradictory statements. Mercuric chloride, bromide and iodide are moderately soluble in hot dioxane, and the solutions deposit colorless crystals on cooling. On exposure to the air these crystals lose dioxane in each case, the pure mercuric halide remaining. The change is very evident in the case of mercuric iodide dioxanate, since the colorless addition compound changes to the yellow and red forms of mercuric iodide, and the loss of dioxane is apparent in all three cases under the microscope. Paternò and Spallino[1] and Clarke[2] apparently failed to notice the loss of dioxane from the mercuric chloride dioxanate, and their product which sublimed was undoubtedly the residual mercuric chloride. The dipole moments of the mercuric halides as determined in dioxane solution[5] are of doubtful significance, since the solutions probably contain, not the mercuric halides, but their dioxanates.[7]

The dioxanates of the mercuric halides have been analyzed, and their dissociation pressures determined as a measure of their stability. The vapor pressures of their saturated solutions in dioxane and the vapor pressure of pure dioxane have also been measured.

Experimental Part

Materials.—Dioxane (Carbide and Carbon Chemicals Corporation) was purified by the method described by Scatchard and Benedict[8] and refluxed over sodium for two days. After fractional distillation, followed by fractional freezing, the final product had a freezing point of 11.79°, and a boiling point (760 mm.) of 101.26°, as measured with carefully calibrated thermometers. Moisture was excluded at all times, and in the determination of the boiling point a special apparatus was used.[9] These values agree well with those already reported.[8,10]

Mercuric chloride and iodide (C. P. analyzed) were used without further purification. Since the so-called C. P. mercuric bromide which was available contained about 0.5% chloride (Cl), this salt was prepared as follows. C. P. bromine was digested with a saturated aqueous solution of sodium bromide and distilled. This bromine was converted into hydrobromic acid by treatment with red phosphorus and water. C. P. mercuric oxide was dissolved in the hydrobromic acid and the resulting bromide recrystallized several times from hot water.

Vapor Pressure Measurements.—Vapor pressure measurements were made in the apparatus shown in Fig. 1, which was connected in the usual way to a vacuum pump and manometer.[11] The apparatus was cut apart at E, and 1 or 2 g. of the mercuric salt introduced into F. After resealing a current of dry air was passed through the apparatus and the whole was warmed until the salt began to sublime. The sublimed portion was then driven along by gentle heating and out of the end B. Purified dioxane was introduced into C, along with small pieces of sodium, the apparatus was tilted to the right and the dioxane refluxed for four hours, the tube G serving as an air con-

[10] Kraus and Vingee, *ibid.*, **56**, 511 (1934), give the freezing point as 11.78° and the boiling point as 101.24° (761 mm.).

[11] The arrangement was much the same as that described by Smith and Menzies, *ibid.*, **32**, 1412 (1910).

denser. The apparatus was then turned back to the position shown and dioxane distilled into D, where it was fractionally frozen three or four times, the unfrozen portions being poured back into C. C and D were cooled with solid carbon dioxide in acetone and the tube sealed off at H. Sufficient dioxane was then distilled into F and after cooling again the apparatus was sealed off at E. Cooling with solid carbon dioxide is of course necessary to prevent ignition or decomposition of dioxane vapor by the hot glass. Mercury was introduced through A into J to serve as a confining liquid. During all these operations the greatest care was taken to prevent the introduction of moisture, and the open ends of the apparatus were always protected by phosphorus pentoxide tubes. The filled apparatus was connected at A by means of heavy rubber tubing to the manometer and pump.[11] The lower part, up to I, was placed in a well-stirred bath of water or oil which was electrically heated, and provided with windows through which the mercury in J could be observed. The traps in the bulbs F, I and K form a necessary part of the apparatus. The trap in F prevented any of the mercuric halide from being carried over and fouling the mercury in J; that in I prevented any loss of mercury; and that in K kept any condensed dioxane from running back on the mercury.

The amounts of halide and dioxane introduced into F were so chosen that all the halide could be brought into solution by warming with a free flame, and on cooling no crystals would appear above the transition point. It was thus possible, in measuring the vapor pressure of the saturated solutions of the dioxanates, to be sure that no undioxanated salt was present. To ensure saturation at all temperatures the bath was adjusted to the highest temperature to be used. The solution in F was boiled vigorously under reduced pressure until a reproducible vapor pressure was obtained. Readings at lower temperatures were then taken.

The dissociation pressures of the dioxanates were measured after all the liquid in F had been boiled away and partial decomposition of the crystals had taken place. The vapor pressure of pure dioxane was also measured in the same apparatus. It was introduced in the manner already described.

Temperatures were read to one hundredth (0.01°) of a degree on calibrated thermometers. In some cases there were considerable stem corrections and though these were checked by using thermometers with overlapping ranges we do not believe the readings are accurate to much better than ±0.05°.

Pressures were read to one-tenth of a millimeter (0.1 mm.) by means of a cathetometer. A calibrated glass scale and mercury manometer were used. All pressures are given in millimeters of mercury, corrected to 0°, 45° latitude and sea level.

Table I contains the vapor pressures of each system studied, calculated for round temperatures by means of the least square equations, which are also given. The number of observations used in calculating each equation is given as well as the probable error. The equations should not, of course, be used outside of the range indicated in each case. In calculating absolute temperatures, 273.2 was added to the centigrade readings.[12]

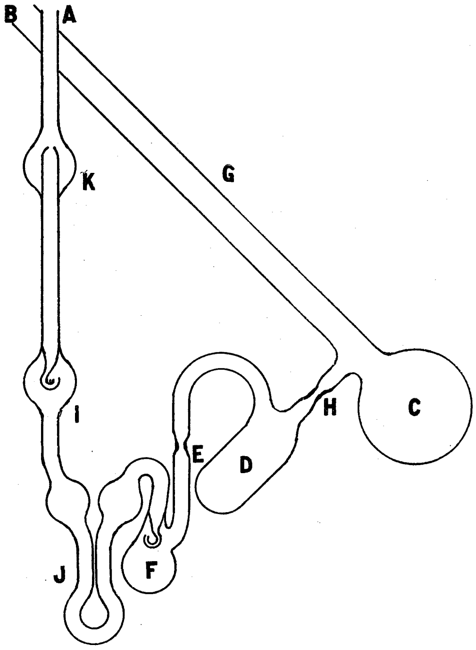

Fig. 1.

The experimental data are plotted in Fig. 2. The curves are graphs of the equations given, and are numbered to correspond with the numbers of the equations in Table I. The curves for the saturated solutions of the chloride and iodide have been omitted since they almost coincide with that for the bromide.

Discussion of Results

The vapor pressure of dioxane has been measured by several investigators. The most recent work is that of Hovorka, Schaeffer and Dreisbach,[13] whose data cover the range from 10 to 80°. Since dioxane is very hygroscopic we thought it advisable to determine its vapor pressure in our apparatus from which we think we have been able to exclude water vapor very effectively. We have extended the measurements above the boiling point and so are able to check our vapor pressure equation by means of boiling point determinations. Several determinations made at different barometric pressures in an apparatus from which moisture was excluded gave the same value for the normal boiling point (760 mm.), 101.26 ± 0.01°. This value also was obtained when metallic sodium was present in the dioxane so that we believe it is safe to assume that water was absent. The equation for pure dioxane (number 1, Table I) gives a calcu-

23	5.3	7.8	11.5	24.0	47.7	91.0	167.3	297.2	(Trans. point solid, 173.1°)			

[a] Additional values for $HgBr_2$ dioxanate were obtained as follows:

Temperature, °C.	110	120	130	
Satd. soln., mm.	886.6	...	...	
Solid, mm.	168.1	294.0	491.1	(Trans. point solid, 87.7°)

lated boiling point of 101.30° at 760 mm. Considering the probable error of our equation, the agreement is as good as could be expected. Boiling points at various barometric pressures and our equation both give 23.3 mm./degree for the slope of the vapor pressure–temperature curve at the normal boiling point. If the boiling points are taken as correct the values for the vapor pressure calculated from the equation are about 0.9 mm. low in the neighborhood of the boiling point. Our calculated vapor pressures are higher at low temperatures and lower at high temperatures than those previously reported.[13]

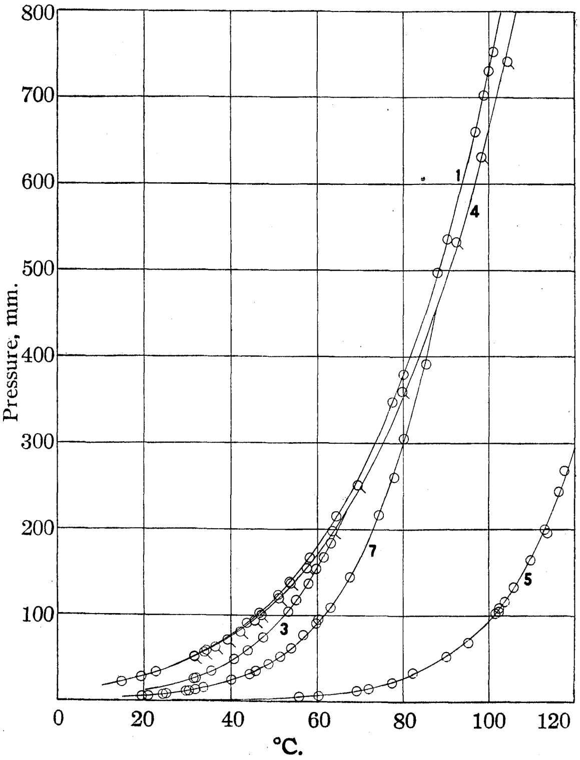

Fig. 2.—1, Dioxane; 3, $HgCl_2$·dioxanate; 4, saturated solution·$HgBr_2$ dioxanate; 5, $HgBr_2$·dioxanate; 7, HgI_2·dioxanate.

As may be seen from Fig. 2, the dioxanates of mercuric chloride and iodide have transition points which easily can be determined experimentally. The equations for the vapor pressures of the saturated solutions are for those in which the dioxanates are the solid phase. The temperatures at which the vapor pressures of these saturated solutions are equal to the dissociation pressures of the dioxanates are shown in Fig. 2. More exact values were obtained by a simultaneous solution of the equations for the saturated solution and the dissociation pressure. These calculations give 67.3° for the transition point of mercuric chloride dioxanate, and 87.7° for that of the iodide. The point for the iodide was checked by slowly heating a sealed tube containing an excess of dioxanate crystals in their saturated solution in dioxane, and observing the temperature at which the red color of mercuric iodide appeared. The point so obtained agreed with that given above to a few tenths of a degree. This method was not satisfactory for the dioxanates of the chloride and bromide as no color change occurred. The transition points of the chloride and iodide were checked also by observing the temperature at which an absorption of heat occurred when the crystals were slowly heated. The results were not very accurate since the heat absorption took place over an interval of a degree or two. This may have been due to the difficulty of stirring the crystals adequately. The transition points already given were within the range of heat absorption, provided moisture was excluded.

The behavior of mercuric bromide dioxanate seems rather surprising. As is shown in Fig. 2, its dissociation pressure, instead of being intermediate between that of the chloride and the iodide, is much lower than that of either. Under our experimental conditions it was not possible to determine the transition point of this salt. A rough estimate may be made by a simultaneous solution of the fourth and fifth equations in Table I. This gives a transition temperature of 173° at a pressure of about five atmospheres. Independent evidence of the relatively great stability of mercuric bromide dioxanate was obtained by comparing the rates at which the dioxanates of the three halides lost dioxane at room temperatures. The samples were put into open weighing bottles which were laid on their sides and protected from drafts. After four hours the losses in percentage of dioxane present were: mercuric chloride, 44%; mercuric bromide, 0.78%; mercuric iodide, 52%. This obviously crude method does not give a correct indication of the relative stability of the chloride and iodide, but it does show that the bromide is much the most stable of the three.

Rheinboldt[4] has analyzed the dioxanates of many salts and gives values which indicate that the mercuric halides combine with dioxane in the molecular ratio of 1 to 1. Since it is difficult to obtain these crystals in a pure state by the method he used, we have repeated the analyses. Crystals of the dioxanates were brought to constant weight in a stream of dry air which contained dioxane vapor at a partial pressure greater than the decomposition pressure but less than the vapor pressure of the saturated solution. The dioxane of crystallization was then removed by a current of pure dry air and the loss in weight determined. The results obtained together with those calculated on the assumption that one molecule of halide combines with one of dioxane are given in Table II.

TABLE II

COMPOSITION OF THE DIOXANATES

Dioxanate	Dioxane Obsd.	Dioxane Calcd.
$HgCl_2 \cdot C_4H_8O_2$	24.46	24.49
$HgBr_2 \cdot C_4H_8O_2$	19.65	19.63
$HgI_2 \cdot C_4H_8O_2$	16.26	16.23

From the vapor pressure measurements, the free energies of formation of the dioxanates from the solid salts and liquid dioxane (ΔF°_{298}) and the heats of formation ($-\Delta H_{298}$) have been calculated for 25° and are given in Table III.

TABLE III

FREE ENERGIES AND HEATS OF FORMATION AT 25° (CALORIES)

Compound	ΔF°_{298}	$-\Delta H_{298}$
$HgCl_2 \cdot C_4H_8O_2$	−490	3725
$HgBr_2 \cdot C_4H_8O_2$	−2750	7253
$HgI_2 \cdot C_4H_8O_2$	−925	4880

From equation 1, Table I, the molal heat of vaporization of pure dioxane is calculated to be 8960 cal. at 25°. The heat of vaporization for temperatures between 10 and 110° is given by the equation $\Delta H = 10{,}600 - 5.51T$.

Surface tension measurements[13] indicate that dioxane is a non-associated liquid and it should therefore give a normal value for the entropy of vaporization. At the boiling point we obtain 22.8 cal. per degree, which is somewhat larger than the value to be expected from Trouton's rule. Hildebrand's[14] modification of the rule gives 27.7 cal. per degree at 45.8°, at which temperature the molar concentration of the vapor is 0.005. This is very close to the value to be expected for normal liquids and is evidence that our values for ΔH are not greatly in error.

Summary

1. The vapor pressures of pure dioxane and of saturated solutions of dioxanates of the mercuric halides in dioxane have been measured.

2. The dissociation pressures of the dioxanates of the mercuric halides have been measured and their transition points determined.

3. Free energies and heats of formation of the dioxanates from the solid salts and liquid dioxane have been calculated.

4. The dioxanate of mercuric bromide has been found to be much more stable than the dioxanates of mercuric chloride and iodide.

β-Aminoethylsulfuric Acid, an Irregular Ampholyte[1]

BY DEAN B. ROLLINS AND H. N. CALDERWOOD[2]

Although an enormous amount of work[3] has been done on amphoteric substances, and the compounds studied have been of many varieties,[4] the literature contains no mention of β-aminoethylsulfuric acid as an ampholyte other than the assignment to it of an inner salt structure by its discoverer,[5] who found that neither acids nor alkalies formed salts with it.

Incidental to work along other lines, we had occasion to investigate some of the properties of β-aminoethylsulfuric acid and were impressed by its desirability as a subject for study by those interested in ampholytes. The compound is very stable and easily purified by recrystallization from dilute ethanol. In common with the aliphatic amino acids,[6] it has an absence of a true melting point, insolubility in ethanol, great solubility in water, a definite end-point by the formol titration and an anomalous end-point by direct titration with alkali, but it differs from them by the presence of an ester linkage and a sulfate group in the molecule. Although its composition is very similar to that of taurine, it differs from it in having an ester linked sulfate group instead of the sulfonic group. By its faintly acid reaction with litmus it shows a closer similarity to the aliphatic amino acids than to taurine.

Since other demands prevent our continuing the study of this compound, we desire to bring it to the attention of investigators in the field of ampholytes, and offer our findings, together with our simple method for obtaining theoretical yields of β-aminoethylsulfuric acid, an improvement over the method which superseded Gabriel's.[7,8]

Experimental

Reagents.—Monoethanolamine, 99.4% purity, from the Carbon and Carbide Chemicals Corporation; sulfuric acid, C. P. grade, 88.3%.

β-Aminoethylsulfuric Acid Preparation, Preferred Method.—To 8.9 g. (0.8 mole) of acid cooled in a freezing mixture and stirred vigorously by a motor, there was added dropwise, in the course of ten minutes or more, 4.9 g. (0.8 mole) of cooled monoethanolamine. Too rapid addition, or addition of the reactants in the reverse order, produced a violent reaction. After all the amine had been added there was put into the mixture 0.9 g. (0.08 mole) of acid, the entire mixture was heated in an oil-bath to 130°, and while being stirred was held at this temperature for one hour. At the end of this time the mixture was cooled and 40 ml. of absolute ethanol added with stirring. The precipitate was collected on an asbestos or fritted glass filter and washed with four 5 ml. portions of absolute ethanol; yield 9.9 g. Evaporation of the acid filtrate, preferably under reduced pressure, and the addition of two volumes of absolute ethanol to the cooled residue gave an additional 1.5 g., total yield 11.4 g. or 100%.

Alternate Method.—An equimolal mixture of acid and amine was prepared as above, 2.4 g. (0.27 mole) of acid was added, and the mixture allowed to stand at room temperature for seventy-two hours. Treatment of the reaction mixture with absolute ethanol, as in the preferred method, gave a total yield of 11.6 g. of coarse crystalline aggregates containing some occluded acid.

Purification.—The crude product was recrystallized by solution in hot water (15 g. in 30 ml.), the cooled solution poured into 90 ml. of absolute ethanol, and the mixture cooled to 0°; recovery 94.5%. In a melting point tube this purified material started to sinter at 230° and decomposed at 255° with incomplete fusion. Analyses of the crude and the purified product are given in Table I. All nitrogen determinations were semi-micro Dumas and sulfur was determined by both wet and dry oxidation. After three additional recrystallizations, using five volumes of absolute ethanol per volume of aqueous solution, the refined product began to sinter at 275° and became brown at 280° without melting. Its aqueous solution showed only a faintly acid reaction to litmus; and gave not the slightest turbidity with barium chloride even after standing for ten hours at room temperature. Neither acids, alkalies, nor salts precipitated the compound from even its concentrated aqueous solutions. Microscopic examination of the refined product revealed but one crystalline form, identical with that described by Gabriel.[5] The purified compound did not give insoluble derivatives with any of the reagents used for the detection of amino groups.

[8] Frankel and Cornelius, *ibid.*, **51**, 1666 (1918).

Determination of the Molecular Weight.—Direct titration with alkali, phenolphthalein indicator, gave two end-points: the first, which persisted upon the addition of more base until the second was reached, being a faint pink and giving large and irregular values for the molecular weight; the second end-point, much deeper in color, gave values agreeing closely with the theoretical. In order to secure concordant results with the formol titration it was necessary to add at least one equivalent or more (a large excess caused no change in the final results) of the aldehyde, prior to the addition of any alkali. Under these conditions the observed and the theoretical values were in good agreement. The calculated and the observed molecular weights as determined by titration were corroborated by cryoscopic measurements of aqueous solutions of the compound. These molecular weight data have been assembled in Table II.

TABLE II

DETERMINATIONS OF THE MOLECULAR WEIGHT OF β-AMINOETHYLSULFURIC ACID

Method		I	II
Titration direct alkali	First end-point	620	588
	Second end-point	141.3	142.0
Titration, "formol"		141.2	142.5
Cryoscopic, water solution		140.5	141.5
Theoretical		141	

Hydrolysis.—An aqueous solution of the refined substance treated with barium chloride and set aside for ten hours at room temperature did not form enough barium sulfate to produce even a slight turbidity. Heating this mixture on a steam-bath for fifteen hours produced a precipitate of barium sulfate which was far below the theoretical amount. When the solution was made strongly acid, methyl orange indicator, with hydrochloric acid, treatment with barium chloride and heating for fifteen hours on the steam-bath produced so little barium sulfate as to cause only a slight turbidity. The solutions of the refined material remaining after direct alkali titration, when made acid to phenolphthalein with hydrochloric acid, showed only a slight turbidity after the addition of barium chloride. Hydrolysis with stoichiometric amounts of barium hydroxide produced very little barium sulfate at room temperature, and the reaction was not completed even after digestion for several days on a steam-bath.

The quantitative experiments reported in Table III were made as follows: the sample (0.27 to 0.29 g.) was dissolved in 10 ml. of water, the reagent solution added, and the mixture refluxed on the steam-bath. The extent of the hydrolysis was calculated from the weight of barium sulfate obtained. In the experiments with barium chloride the hydrolyzed solutions were diluted with hot water, made acid to methyl orange with hydrochloric acid, and digested overnight on the steam-bath. The weight of barium sulfate was determined in the usual manner. In the experiments with potassium hydroxide the addition of 10 ml. of ethanol was necessary to prevent frothing during hydrolysis. After hydrolysis the solutions were distilled with steam to remove the ethanol and the volatile amines. To the steam distillation residue, diluted with hot water and made acid to methyl orange with hydrochloric acid, two moles of barium chloride were added and the amount of barium sulfate was determined by the method described above.

TABLE III

HYDROLYSIS OF β-AMINOETHYLSULFURIC ACID

Name	Concn., %	Reagents Moles in excess	Hours refluxed	% Hydrolyzed Crude	Refined
$BaCl_2$	10	1	5.0	0.035	0.067
$BaCl_2$	10	1	15.0	.039	.070
KOH	25	21	3.5	...	75.56
KOH	25	54	5.0	...	75.27

Acknowledgment.—We greatly appreciate the assistance of Mr. Elmer E. Schiebe in making all of the sulfur and sulfate determinations reported in this paper.

Discussion

Although β-aminoethylsulfuric acid possesses the characteristic properties of a "zwitterion," and our determinations of its neutralization and cryoscopic values indicate that in aqueous solution the compound exists in the simplest possible state of molecular aggregation, the acid reaction with litmus points to actual ionization, even though so slight as not to appear in the cryoscopic measurements. From the above it might be assumed that the compound is an acyclic ampholyte, the irregularities being caused by the activating effect of the sulfate group,[9] and one might expect the compound to have a large electric moment. By the same reasoning, the two strong polar groups of the compound, by preventing ionization at the ester linkage[9] (pp. 166–167, 262–265) might be the cause of the latter's great resistance to hydrolysis demonstrated both in our work and elsewhere.[10] Dielectric constant and X-ray studies might help to decide these questions.[11]

On the other hand, the absence of insoluble derivatives with amino group reagents, the great resistance of the ester linkage to hydrolysis, the slight acid reaction in solution, together with the occurrence of but one crystalline form, might be considered evidence of ring–chain isomerism, with the cyclic form predominant, an opinion favored by the long molecule (a six atom chain) and in agreement with some of the current views on amino acids.[12]

It would be interesting to see further work done upon β-aminoethylsulfuric acid in order to obtain a better knowledge of its structure.

Summary

1. We have improved the Frankel and Cornelius method for preparing β-aminoethylsulfuric acid from monoethanolamine and sulfuric acid so that the theoretical yields may be obtained readily.

2. The crude product is purified easily, since water is the only other reaction product.

3. Although copiously soluble in water, the compound is not precipitated, even from its concentrated solutions, by acids, alkalies, or salts.

4. In aqueous solution the compound exists in the simplest possible state of molecular aggregation.

5. The compound displays many of the properties common to the aliphatic amino acids.

6. The ester linkage of the compound is very resistant to hydrolysis, thus allowing it to be used in solution with substances that catalyze hydrolytic reactions.

7. The compound is worthy of further study as an ampholyte.

Complex Formation between Carboxylic Acids and Divalent Metal Cations

BY R. KEITH CANNAN AND ANDRE KIBRICK

This paper contains a comparison of the hydrogen electrode titration curves of a number of mono- and dicarboxylic acids in 0.2 *M* potassium chloride and in various $KCl–MCl_2$ solutions of the same ionic strength. M represents Mg, Ca, Sr, Ba or Zn. The work was instigated by recent observations of Greenwald[1] on the effect of calcium chloride on the *p*H of a variety of carboxylic acid buffer solutions. Its immediate purpose was to provide information as to the relative activity coefficients of certain salts of physiological importance but observations were extended to a number of related cations and acids. The ionic strength at which observations were made is comparable to that of mammalian body fluids.

The results indicate the existence of notable specific effects which are consistently related not only to the nature of the cation but to the molecular structure of the acid. These effects have been reduced to mass action constants for the formation of binary compounds between the carboxylate anions and each cation. Within the range of concentrations studied, and within the plausible errors of the method, we find that the formation of binary compounds suffices for a fairly satisfactory quantitative description of the observations. Were association to more complex compounds to occur to any important extent, we should expect the specific effects which have been observed to be a function of the total concentration of organic acid. We have found no clear indication of this for concentrations of acid ranging from 0.002 to 0.05 *M* (Tables III and VII).

In our use of the law of mass action to describe the effects observed, we are committed to no particular views as to the nature of the forces involved. It is generally acknowledged that mass action constants may be expected to describe, with fair precision, certain specific electrostatic effects, whose existence is ignored in the approximations which are involved in the working equations of interionic attraction theory. Where electrostatic forces of ions are involved the definition of what constitutes a reversibly dissociable compound is difficult. The mass action constants are submitted merely as convenient descriptions of relative activity coefficients.

We appreciate the fact that the use of the hydrogen electrode introduces indeterminate errors due to the presence of a liquid junction (L. J.) potential. The observations comprise two types of hydrogen electrode potentials: (a) those of the organic acid buffer in $KCl–MCl_2$ solutions; and (b) those of dilute solutions of hydrochloric acid in corresponding $KCl–MCl_2$ solutions. The latter were employed to calculate γ_{H^+} for the corresponding solutions containing the carboxylic acid. Into both of these potential measurements L. J. potentials enter as a source of error. In the majority of the calculations, however, γ_{H^+} appears only as a small correction term. Its precise value is unimportant. In the few systems in which it is an important term (those of rather low

---

[1] I. Greenwald, *J. Biol. Chem.*, **124**, 437 (1938).

pH), the association constants derived with its aid are in satisfactory agreement with those calculated from observations at much higher pH, where its significance is small. Apart from the question of γ_{H^+}, indeterminate L. J. potentials enter into all the observations. We believe that the evidence is good that the method which we have adopted for the calibration of the reference electrode[2] eliminates the greater part of the potential at a broad junction between saturated potassium chloride and dilute electrolyte solutions containing few H^+ or OH^- ions. However this may be, our calculations depend, not upon the absolute potentials of any one solution, but upon changes in potential as MCl_2 is substituted for potassium chloride at constant ionic strength. The calculated association constants are based on changes in potential varying between 5 and 80 mv. The simultaneous changes in L. J. potentials must be very small compared with these. Using Henderson's equation to indicate their order of magnitude, we calculate differences, in extreme cases, of only 0.4 mv. It is fair to conclude that the calculated mass action constants provide a fairly satisfactory measure of relative activity coefficients.

Apart from the question of L. J. potentials, the calculations require the assumptions (a) that carboxylate anions do not associate to a significant extent with Na^+ or K^+, (b) that in solutions containing MCl_2, no significant concentration of MCl^+ exists. The former assumption conforms to prevailing views of the state of the alkali salts of organic acids in dilute solutions such as those used in this investigation. The absence of $CaCl^+$ and $BaCl^+$ receives support from the activity coefficients of calcium and barium chlorides published by Scatchard and Tefft.[3] The observations of these authors on zinc chloride at $\mu = 0.20$ may be taken, however, to indicate significant concentrations of $ZnCl^+$ in our solutions. This we have ignored. The essential effect of the presence of this complex on the calculated constants would be to increase them all in the proportion $(Zn^{++}) + (ZnCl^+)/(Zn^{++})$.

Experimental

Measured volumes of standard solutions of the acid and of sodium hydroxide were mixed. Amounts of M KCl and of 0.33 M MCl_2 were added to give the desired cation mixtures, and the whole was diluted to $\mu = 0.2$ (calculated from KCl–MCl_2 only). In this way the concentration of divalent cation was varied while approximate constancy of μ was maintained. The concentration of monocarboxylic acids was usually 0.02 M and of dicarboxylic acids 0.01 M. The ionic strength would increase with the degree of neutralization and decrease with the extent of complex formation. For a 0.01 M dicarboxylic acid the range of μ under these influences would be 0.23 to 0.17. Actual calculations of μ for representative reaction systems, using the association constants found, showed that μ seldom fell outside of the range 0.19–0.21. It is improbable that activity coefficients would be seriously affected by such variation.

The pH of each reaction mixture was measured in a rocking hydrogen electrode (Clark) using a saturated calomel electrode and a saturated salt bridge. The reference electrode was calibrated by means of 0.1 M acetic acid–0.1 M sodium acetate to which a pH of 4.66 was assigned.[2] The liquid junction potential was taken to be −2.4 mv. This was calculated from Henderson's equation.[4] The potential of the junction, saturated potassium chloride–reaction mixture, was taken to be −1.3 mv. in all cases. Calculations for the junctions with 0.2 M potassium chloride and with 0.067 M magnesium, calcium or barium chlorides gave values varying from 1.1 to 1.5 mv.

A series of determinations were made of the pH of 0.01 and 0.002 M hydrochloric acid in salt mixtures representative of those used in the reaction mixtures. The values of $-\log \gamma_{H^+}$ calculated from these ranged from 0.090 to 0.110. Since the precise value of $[H^+]$ is important only in a few systems of low pH, we have been content to take $-\log \gamma_{H^+} = 0.100$ for all systems.

The recorded potentials were found immediately after preparation of reaction mixtures and were accurately reproducible over many hours. The reproducibility of the potential of duplicate reaction mixtures was about 0.2 mv.

Monocarboxylic Acids.—The following relations may be stated for an organic acid, HA, at a chosen ionic strength[5]

$$\begin{aligned}
&(a)\quad (T_A) = (HA) + (A^-) + (MA^+)\\
&(b)\quad (T_m) = (M^{++}) + (MA^+)\\
&(c)\quad (Na^+) + (H^+) = (A^-) + (MA^+)\\
&(d)\quad K_1 = [H^+](A^-)/(HA)\\
&(e)\quad C_1 = (MA^+)/(A^-)(M^{++})
\end{aligned}$$

(T_A), (T_m) and (Na^+) are known from the composition of the reaction mixtures. $[H^+]$ is calculated from $pH = -\log [H^+]$, and (H^+) is obtained with the aid of γ_{H^+}. In systems containing no MCl_2, (A^-) is, then, calculated from (c), (HA) from (a) and K_1 from (d). In the presence of MCl_2, (HA) is obtained from (a) − (c), (A^-) from (d), (MA^+) from (a) or (c), (M^{++}) from (b) and C_1 from (e).

(3) G. Scatchard and R. F. Tefft, THIS JOURNAL, **52**, 2272 (1930).

(4) In this equation concentrations were employed in place of activities. The latest values for the transference numbers of potassium chloride were used [MacInnes and Dole, THIS JOURNAL, **53**, 1357 (1931)].

(5) Square brackets indicate activities and parentheses, concentrations.

In the special case where (T_m) is so much larger than (T_A) that we may put $(M^{++}) = (T_m)$, the dissociation curve of the acid suffers a parallel displacement on the pH ordinate from its position when MCl_2 is not present. The new curve will be that of an acid with an apparent dissociation constant

$$K_1' = [(A^-) + (MA^+)][H^+]/(HA) = K_1[C_1(T_m) + 1]$$

Dicarboxylic Acids.—The assumption of binary compound formation implies the formation of MA^+ from A^- and of MA from $A^=$. The pertinent relations are

(a′) $(T_A) = (HA) + (A^-) + (A^=) + (MA^+) + (MA)$
(b′) $(T_m) = (M^{++}) + (MA^+) + (MA)$
(c′) $(Na^+) + (H^+) = (A^-) + 2(A^=) + (MA^+) + 2(MA)$
(d′) $K_1 = (A^-)[H^+]/(HA)$
(e′) $K_2 = (A^=)[H^+]/(A^-)$
(f′) $C_1 = (MA^+)/(A^-)(M^{++})$
(g′) $C_2 = (MA)/(A^=)(M^{++})$

There are not sufficient equations for the calculation of either the dissociation or the association constants from a single observation. Under appropriately restricted conditions, however, we may make approximations to each of them in turn and then attempt to adjust the preliminary values so as to conform simultaneously to all observations. Provided the latter cover a sufficient range of (T_m) and a range of pH corresponding to a wide variation in $(A^-)/(A^=)$, successive approximations to a pair of constants may be made with confidence. In the absence of MCl_2, observations at low pH may be used to calculate a preliminary value for K_1, since $(A^=)$ will be very small. Corresponding observations at high pH will give an approximation to K_2. These constants are then adjusted to observations at intermediate values of pH until the best fit is attained. This is the common practice in deriving dissociation constants of polyvalent acids or bases from their dissociation curves.

The same procedure may now be applied to determine C_1 and C_2 from observations on solutions containing MCl_2, using the above values for K_1 and K_2. Where $(T_m)/(T_A)$ is large, the curve will be that of a dicarboxylic acid with apparent constants $K_1' = K_1[C_1(T_m) + 1]$ and

$$K_2' = K_2\frac{C_2(T_m) + 1}{C_1(T_m) + 1}$$

From observations at appropriate extremes of pH, preliminary values of K_1' and K_2' and, hence, of C_1 and C_2 may be obtained. In the refinement of the values of the latter, we have found it convenient to introduce the quantity

$$K_4 = (MA)[H^+]/(MA)^+ = K_2C_2/C_1$$

and to impose the successive approximations on this. Combining equations (a′) to (g′) and introducing K_4 we have derived

$$\alpha = \frac{((Na^+) + [H^+])/(T_A - x/w}{(2K_4 + [H^+])/(K_4 + [H^+]) - x/w} \quad (1)$$

and

$$C_2 = \frac{\alpha}{1 - \alpha}\cdot\frac{K_4w}{K_1K_2(K_4 + [H^+])}\cdot\frac{1}{(T_m) - \alpha(T_A)} \quad (2)$$

where α is the fraction of the total acid combined with the cation

$$x = 2K_1K_2 + K_1[H^+]$$

and

$$w = K_1K_2 + K_1[H^+] + [H^+]^2$$

The preliminary values of C_1 and C_2 fix a tentative value for K_4 and this allows calculations of α and of C_2 from (1) and (2), respectively. K_4 is subjected to minor adjustments until consistent values for C_2 emerge from observations over the whole experimental range of (T_m) and of pH.

Results

Monocarboxylic Acids.—The results are so extensive that only a few representative experiments can be given in detail. In Table I the

data of an experiment on acetic acid are recorded. Table II relates to a similar experiment with glycolic acid. These two tables illustrate the constancy of C_1 despite a 4- to 5-fold variation in anion concentration. The effect of MCl_2 on the unsubstituted acids was very small and the calculated values of C_1 are correspondingly irregular.

When T_m was reduced below 0.03 the displacements of *p*H were too small to justify calculations. With the hydroxy acids, on the other hand, a five-fold variation of T_m and T_a was possible (Table III). The variations in C_1 are well within the possible effects of the accompanying variations in μ and the liquid junction potentials. The constants for the eight monocarboxylic acids are assembled in Table IV.

TABLE IV

LOG C_1 FOR MONOCARBOXYLIC ACIDS (μ = *circa* 0.2)

Gluconic	1.70	.70	1.21	1.00	.95	3.556

Association Constants of Davies[6] for CaA^+ (μ = 0)

Acetic	0.0
β-Hydroxybutyric	.82
Glycolic	1.58
Lactic	1.47

The more significant conclusions are:

1. The three unsubstituted acids and the β-hydroxy acid give almost identical constants for a particular cation.

2. The constants of the four α-hydroxy acids are also very similar in magnitude but are much greater than those of the unsubstituted acids. A hydroxyl in other positions has little effect although the results with glyceric and gluconic acids suggest a slight enhancement of association with the alkaline earth cations and a slight depression with Zn^{++} and Mg^{++}.

3. The relative tendencies of the cations to associate with any one anion is in the order Zn$\gg$Ca$>$Sr$>$Ba. The position of Mg is irregular. In the series of the alkaline earth cations, the effect of the size of the cation is manifest. No simple relation is apparent between K_1 and C_1 but it is worthy of remark that the α-hydroxyl which so notably enhances association of the carboxylate ion with these divalent cations, as strongly reduces its association with the hydrogen ion.

In a very recent publication, Davies[6] has reported the dissociation constants of a number of calcium carboxylates which he has calculated from conductivities or from solubility data. They refer to μ = 0. The logarithms of their

---

[6] C. W. Davies, *J. Chem. Soc.*, 277 (1938).

reciprocals are included in Table IV. For comparison, our values must be increased by an activity coefficient term which will approximate $-\log \gamma_{Ca^{++}}$. If we assign to the latter the reasonable value of 0.35 at $\mu = 0.2$, we find fairly satisfactory agreement between the two sets of constants. The one exception is the case of acetic acid. When the constant is as small as it would appear to be with the unsubstituted acids, the calculations, both from conductivities and from potentiometric data, are very uncertain.

Dicarboxylic Acids.—The values derived for K_1 and K_2 of the various acids agree fairly well with values in the literature where comparisons on the basis of μ are possible. Their absolute magnitude is unimportant to our argument provided they define our data for potassium chloride systems with precision. This they do to the extent that, in no case, was the difference between (Na^+), calculated from *p*H and x/w, and (Na^+), derived from the composition of a mixture, greater than 0.005 equivalent. Details of the potassium chloride experiments are omitted.

The results for MCl_2 with one unsubstituted and with one hydroxy acid are illustrated in Tables V, VI and VII. The mean values of C_2 (as log C_2) of the six dicarboxylic acids studied are assembled in Table VIII together with the values for pK_4 which finally were adopted and those of log C_1 calculated from pK_4. In some cases the range of observations was limited by the insolubility of the particular complexes. With oxalic

acid, observations with Mg^{++} alone were possible. With tartaric acid and Ca^{++} they were limited to $T_m = 0.013$ or less. In a few other systems, a salt separated some hours after completion of observation. In these cases, the possibility of anomalous potentials due to precipitation at the electrode must be entertained. We have accepted potential observations only when they were stable for five minutes after cessation of rocking and only if they were reproducible after renewed rocking.

The values of K_4 and C_1 for oxalic acid are highly tentative because it was not possible to make accurate calculations from observations at the low *p*H range in which C_1 dominates the extent of association. The recorded value of C_2 for oxalic acid is, however, independent of K_4, provided (as seems most probable) the latter is not much greater than 2. In general, there is less satisfactory agreement between individual values of C_2 for dibasic acids than was found for C_1 with the monobasic acids. This is inherent in the calculation which makes C_1 and C_2 very sensitive to the precise values of K_1, K_2 and K_4. We have not attempted to approximate pK_4 more closely than 0.05.

The following conclusions are submitted:

1. The unsubstituted dicarboxylic acids give values for C_1 very close to those of the unsubstituted monocarboxylic acids; *i. e.*, a COOH group is without important influence on association at a neighboring carboxylate ion.

2. Similarly, the hydroxy dicarboxylic acids give values for C_1 close to those of α-hydroxy monocarboxylic acids.

3. C_2 for a particular cation diminishes, first rapidly and then slowly, with increasing separation of the carboxyl groups in the dianion.

4. C_2 is increased as greatly by a single α-hydroxyl group as by two.

5. The cation series $Zn \gg Ca > Sr > Ba$ is found for C_2, Mg being, again, irregular in position.

6. For a particular anion, C_2 is always much greater than C_1, but no simple relation obtains. If complex formation actually involves the formation of a coördinate link, then the question of ring strain enters. Possibly the relative values of C_2/C_1 for a series of anions and a particular cation reflect this factor.

The values found for C_1 are small compared with C_2. It may seem a precarious undertaking to attempt their evaluation from systems in which C_2 also operates. To ignore C_1, however, is to ignore the behavior of the monocarboxylic acids. Without it, constant values for C_2 are not obtained. For example, in a series of malonic acid–zinc chloride mixtures quoted in Table V, the values of log C_2 were 2.85, 2.79, 2.80, 2.80, 2.83. The corresponding values, when C_1 is assumed to be very small, are 3.26, 3.00, 2.82, 2.72, 2.62.

Simms[7] has reported extensive potentiometric data on the titration of various acids in magnesium chloride solutions. Greenwald[8] recently has shown that the specific effects observed may be reduced to mass action constants comparable

with our C_2. Greenwald's constants for oxalic acid and malonic acid are included in the last column of Table VIII together with those which we have calculated from Simms' observations on succinic and azelaic acids. For these calculations we used the method of the present paper. Simms' constants must be reduced slightly to translate them from $\mu = 0.07$ to 0.20. The activity correction is $-\log \gamma_{Ca^{++}}\gamma_{a^{=}}$. A reduction of log C_2 by 0.1 is entirely reasonable. If that is done, the agreement is good, except for succinic acid.

Money and Davies[9] have determined constants for oxalic acid and a series of cations from the conductivities of the salts (Table VIII). To convert these to $\mu = 0.2$ a reduction of log C_2 by 0.6 – 0.8 is consistent with available data on the activity coefficients of divalent ions. Agreement with our value for oxalic–Mg is then good and the relative behavior of the series of cations is in harmony with our observations on the other acids.

Summary

1. The hydrogen electrode titration curves of a number of mono- and bivalent carboxylic acids have been compared in varying KCl–MCl_2 mixtures of constant ionic strength ($\mu = 0.2$). (M represents Mg, Ca, Sr, Ba or Mg.)

2. The specific effects which have been observed have been reduced to mass action constants for the formation of binary compounds between the cations and the carboxylate anions.

A Study of Some Reactions between Dry Inorganic Salts. IV. Reactions below the Fusion Point[1]

BY HAROLD L. LINK AND LYMAN J. WOOD

Recently all of the possible reactions that might occur between dry alkali halides above the fusion temperature have been studied by Thomas and Wood.[2] Of the possible 60 reactions that might occur between pairs of alkali halides not having a common ion, it was found that 57 of the reactions proceeded (in the fused state) to completion in such a direction that the average cube edge of the stable pair was less than the average cube edge of the reciprocal pair. In these 57 cases, without exception, the larger cation united with the larger anion and the smaller cation with the smaller anion. In each of these 57 cases, also without exception, the sum of the heats of formation of the stable pair was greater than that of the reciprocal pair, *i. e.*, ΔH was minus. In the remaining three cases equilibrium was indicated as represented in the following reactions

$$KBr + RbCl \rightleftharpoons KCl + RbBr \text{ (Reaction 10)}$$
$$KI + RbBr \rightleftharpoons KBr + RbI \text{ (Reaction 14)}$$
$$RbBr + CsCl \rightleftharpoons RbCl + CsBr \text{ (Reaction 16)}$$

The present report concerns studies of reactions that have been made under the fusion point and is limited to double decompositions involving only Na^+, K^+, Rb^+, Cs^+, Cl^-, Br^-, and I^- (see reactions 1–18, Table I). The variation of the speed of reaction with time at a fixed temperature has been studied and also the variation of the speed with temperature for a fixed time. In five cases what appear to be equilibrium mixtures have been obtained and these mixtures have been studied in some detail.

Materials and Experimental Procedure

The salts used were Analytical Reagents with the exception of cesium chloride and bromide, which were prepared from the nitrate according to the method of Wells.[3] The salts were fused and ground to a fine powder and kept in a desiccator until wanted. After heating the various salt pairs at temperatures and for lengths of time indicated in the proper place, all mixtures were examined by the method of X-ray crystal analysis as previously described.[2a]

It is, in general, more difficult to obtain good films from salt mixtures which have been heated under the fusion point rather than above the

fusion point. In many cases the material being examined does not appear to be in the proper crystalline form. The crystals are perhaps too small or are strained and for these and, no doubt, other reasons yield patterns consisting of a limited number of lines that are in many cases difficult to read. In addition to these difficulties, quantitative results from equilibrium studies are difficult to obtain because the formation of solid solutions is not as common as above the fusion point. It is often possible, however, to draw definite conclusions from surprisingly few data.

Results

In Table I are listed the results obtained for reactions 1 to 18 at 400° when the heating was continued for thirty-six hours. What previously has been called the stable pair (indicated in Table I by the letter a) was heated in each case and the resulting mixtures were analyzed (by means of the X-ray beam) for evidence of reversal toward the reciprocal pair (indicated in the table by the letter b). As was to be expected from previous work above the fusion point most of the stable pairs showed little or no evidence of any tendency toward reversal. Reactions 3, 5, 8, 9, 11, 14, and 16 showed unmistakable evidence of some reversal. The results obtained from heating the reciprocal pairs are shown in column b. All of the reactions with the exception of 10 and 14 proceeded partially or completely toward the stable pair. Reaction 10 possibly did also since it seems likely that reaction would have preceded the formation of a solid solution. The formation of this solid solution at 400° was not expected since it was known that neither the mixture KBr–KCl nor the mixture RbCl–KCl forms a solid solution at 400°. The cube edge obtained is only 0.001 Å. different from that of either component of the reciprocal pair but the interference diagram obtained can scarcely be the patterns of potassium bromide and rubidium chloride superimposed on each other since in this case interference lines with odd ordered indices would have been obtained such as 111 and 311 and no such lines were obtained. The situation was made even more interesting by reason of the fact that the stable pair, when heated at 400°, produced only patterns of potassium chloride and rubidium bromide. It is, of course, quite possible that a solid solution of compounds that are just being formed may occur more readily than will be the case for a mixture of these same compounds after they have already been formed.

The results in Table I indicate that reactions 3, 5, 8, 9, 11 and 16 should also reach an equilibrium if heated long enough at 400°.

Several of the reactions were examined at higher temperatures. When the reciprocal pair of reaction 14 (KI–RbBr) was heated at 480° for thirty-six hours there was evidence of considerable reaction whereas at 400° no evidence of reaction was found. The lowest fusion temperature of this mixture was found to be about 608°. When the reciprocal pair for reaction 2 was heated at 480° for thirty-six hours the extent of the reaction was found to be 62% as calculated from the resulting solid solution of rubidium

bromide and residual rubidium chloride. This solid solution did not form at 400° but there was considerable reaction, perhaps 50% or more as nearly as could be judged by relative intensities of the rubidium bromide and rubidium chloride patterns. The lowest fusion temperature of this mixture was 503°. When the reciprocal pair of reaction one was heated at 500° the reaction appeared to be complete since patterns for pure potassium bromide and sodium chloride were obtained. If there had been any residual sodium bromide or potassium chloride solid solutions would have resulted at this temperature. At 400° the extent of the reaction was much less, four patterns corresponding to the four pure substances being clearly observed. The lowest fusion temperature of this mixture was about 603°. It is not possible to make any quantitative statement concerning the relation between the temperature and the rate of reaction which must depend upon several factors. In general, however, it has been found that if the temperature is much more than 100° below the fusion temperature the rate of reaction is very slow.

In the case of the number one reaction previous calculation of the free energy at 25° has shown that the reaction should proceed spontaneously from reciprocal to stable pair at room temperature. This was tested by subjecting the reciprocal pair, at room temperature, to a pressure of 3500 atmospheres per square inch for ten minutes. The pressure was applied by means of a huge hydraulic press kindly made available by The Reverend Basile J. Luyet of the Department of Biology of St. Louis University. Before mixing the sodium bromide and potassium chloride they were passed through a 200-mesh sieve and dried over sulfuric acid for several days. The reaction was found to proceed from reciprocal to stable pair to the extent of about 50%. This had to be judged from the relative intensities of the patterns for the pure components since solid solutions were not formed.

Reaction 7 has been studied at 510° (a few degrees under the fusion temperature) for various lengths of time and the results are shown in Table III.

TABLE III

SHOWING THE RESULTS OBTAINED BY HEATING A 50-50 MOLAR MIXTURE OF NaI AND KBr (REACTION 7) AT 510°

Time of heating, hours	0.5	2.0	15.0	30.0
Extent of reaction	20	35	80	90

Reaction 4 was examined in the same way except that the temperature was 488° (a few degrees under the fusion temperature) instead of 510°. Very similar results were obtained. The extent of the reaction had to be judged in both cases by relative intensities of the patterns since there was only a very small amount of solid solubility.

Equilibrium Studies

The principal interest in the reactions that did not go to completion in either direction centered in the compositions of the reaction mixtures since they were possibly equilibrium mixtures or might become such upon proper treatment. In the case of one of these reactions that does not go to completion in either direction and in case of which no solid solutions are formed (under the given conditions) it is frequently possible to demonstrate, by means of the X-ray analysis, that the four pure components are present (reaction 1, Table I) but the extent of the reaction can only be estimated from the intensities of the various interference lines. On the other hand, if solid solutions are formed, it is sometimes possible to determine the extent of the reaction from the interference patterns.

Because of the formation of suitable solid solutions, reaction 11 has been studied in considerable detail (Table II). It is clear from Table I that the reaction does not go to completion in either direction when either the reciprocal or stable pair is heated at 400° for thirty-six hours. Two interference patterns were obtained in each case, one body centered and the other face centered. From the body centered patterns were calculated cube edge values of 4.134 and 4.273 corresponding to the patterns obtained, respectively, from the reciprocal and stable pairs. These two cube edge values are each intermediate between the cube edge values of cesium chloride and bromide. Since it is known, from Table II, that a 50 mole per cent. mixture of cesium chloride and bromide, when heated at 400°, dissolves completely in each other, forming a solid solution, the intermediate cube edge values are explained very easily. The face centered pattern in each case was quite light by comparison with the body centered pattern which is exactly what would be expected for a mixture of potassium salts and cesium salts. While it was not possible to obtain satisfactory cube edge values in either case, there was no doubt about the nature of the patterns. Several of the lines appeared to indicate values intermediate between potassium chloride and bromide, which would be contrary to the solid solution data of Table II. This situation is not quite comparable to the one described in Table II, however, since in the former case both compounds were heated in the presence of each other, while in this case one of the compounds is formed in the presence of the other.

The solid solution of cesium chloride and bromide gave excellent interference patterns and can be used for calculating the extent of the reaction if it can be shown that all of the cesium chloride and bromide are contained in this solution and that the solution, furthermore, contains none of the potassium chloride nor bromide, *i. e.*, it must be shown that ternary solutions are not present.

TABLE IV

SHOWING CsCl–CsBr SOLID SOLUTION CUBE EDGES RESULTING FROM A STUDY OF REACTION 11

Mole ratio of reacting mix.	Heat treatment T,°C.	Heat treatment Hrs.	Solid soln. cube edge	Mole ratio of resultant mix. CsCl : CsBr
1 KBr:1 CsCl	400	38	4.134	0.87 :0.13
	480	36	4.247	.24 : .76
	480	72	4.253	.211: .789
1 KCl:1 CsBr	400	38	4.273	.09 : .91
	480	36	4.258	.18 : .82
	480	72	4.253	.211: .789
1 KCl:2 CsBr	480	72	4.263	.150: .850
2 KCl:1 CsBr	480	72	4.241	.272: .728

Although the existence of such ternary solutions seemed highly improbable because cesium chloride and bromide are body centered and the cube edges are small and potassium chloride and bromide are face centered and the cube edges are large, the possibility of such ternary solutions was eliminated when the results for reaction 11 were obtained at 480° instead of 400° (Table IV). Considering the last mixture described in Table IV, it is to be seen that the composition of the starting mixture is 2KCl:1CsBr. Because of the larger amount of potassium chloride with respect to cesium bromide it was possible to obtain a satisfactory cube edge of the KCl–KBr solid solution which is known to form at this temperature (Table II). If the CsCl–CsBr solid solution be a binary solution and all of the cesium chloride and bromide in the resultant mixture be contained in this solution, then the two moles of potassium chloride and the one mole of cesium bromide of the original mixture have reacted with each other according to the equation

$$0.272\,\mathrm{KBr} + 0.272\,\mathrm{CsCl} \rightleftarrows 1.728\,\mathrm{KCl} + 0.728\,\mathrm{CsBr}$$

and the cube edge of the KCl–KBr solid solution should be

$$\frac{0.272}{2}\,6.57 + \frac{1.728}{2}\,6.28 = 6.320\ \text{Å}.$$

whereas the value obtained from the inter-

TABLE V

SHOWING THE EXTENT OF REACTION 11 OCCURRING FROM EACH SIDE AT 400 and 480°

Temp., °C.	Time, hrs.	Case	Mole ratio of reacting mixture	Composition of resulting mixture
400	38	A	1 CsCl:1 KBr	$0.87\ \mathrm{CsCl} + 0.87\ \mathrm{KBr} \longrightarrow 0.13\ \mathrm{CsBr} + 0.13\ \mathrm{KCl}$
400	38	B	1 CsBr:1 KCl	$.91\ \mathrm{CsBr} + .91\ \mathrm{KCl} \longrightarrow .09\ \mathrm{CsCl} + .09\ \mathrm{KBr}$
480	36	C	1 CsCl:1 KBr	$.24\ \mathrm{CsCl} + .24\ \mathrm{KBr} \longrightarrow .76\ \mathrm{CsBr} + .76\ \mathrm{KCl}$
480	36	D	1 CsBr:1 KCl	$.82\ \mathrm{CsBr} + .82\ \mathrm{KCl} \longrightarrow .18\ \mathrm{CsCl} + .18\ \mathrm{KBr}$
480	72	E	1 CsBr:1 KCl	$.789\ \mathrm{CsBr} + .789\ \mathrm{KCl} \rightleftarrows .211\ \mathrm{CsCl} + .211\ \mathrm{KBr}$
480	72	F	1 CsCl:1 KBr	$.211\ \mathrm{CsCl} + .211\ \mathrm{KBr} \rightleftarrows .789\ \mathrm{CsBr} + .789\ \mathrm{KCl}$
480	72	G	2 CsBr:1 KCl	$.300\ \mathrm{CsCl} + .300\ \mathrm{KBr} \rightleftarrows 1.700\ \mathrm{CsBr} + .700\ \mathrm{KCl}$
480	72	H	1 CsBr:2 KCl	$.272\ \mathrm{CsCl} + .272\ \mathrm{KBr} \rightleftarrows 0.728\ \mathrm{CsBr} + 1.728\ \mathrm{KCl}$

ference pattern was 6.322 Å. The very excellent agreement between the values indicates clearly that at 480° two binary solid solutions are formed which together contain all of the mixture. In view of this excellent agreement the authors have used only the CsCl–CsBr solid solution for calculating the resultant mixtures for this reaction, the results of which are shown in Table V.

The cube edges of the CsCl–CsBr solid solutions obtained for reaction 11 are shown in Table IV and the extent of the reaction for each direction is shown in Table V. It is clear that at 480° equilibrium is approached quite closely in thirty-six hours. By drawing a composition–temperature diagram from the data in Table IV it was estimated that the composition of the equilibrium mixture at 490° should be KBr 21%, CsCl 21%, KCl 79%, CsBr 79%. A reheating of a mixture of potassium chloride and cesium bromide (stable pair) in a 1:1 mole ratio at 480° for seventy-two hours produced a CsCl–CsBr solid solution having a cube edge of 4.253 Å. (av. of two closely agreeing results) and the reciprocal pair heated in the same way produced likewise a cube edge of 4.253 Å. (cases E and F, Table V). That equilibrium has been reached can scarcely be doubted.

Cases G and H of Table V are very interesting. The shift in the reaction is in the direction that would be expected from mass action considerations. Furthermore, the amount of the shift is in almost exact quantitative agreement with what might be expected. In case G the shift to the left is just slightly too much and in case H the shift is just slightly too little. Reactions 3 and 16 are now being investigated in an effort to determine whether or not a similar effect can be discovered in these cases also.

Summary

1. Eighteen double decomposition reactions occurring between the sodium, potassium, rubidium and cesium halides (chloride, bromide, iodide) were investigated between 400 and 500° (below the fusion point) and the resultant mixtures examined by the method of X-ray crystal analysis.

2. When the reciprocal pairs (large cation–small anion and small cation–large anion combinations) were heated at 400° for thirty-six hours, reaction proceeded to some extent toward the stable pairs in 16 of the 18 cases.

3. When the stable pairs were heated at 400° for thirty-six hours, reaction proceeded to some extent toward the reciprocal pair in 7 cases.

4. One reaction was subjected to a pressure of 3500 atmospheres per square inch for ten minutes and it was found to proceed partially toward the stable pair.

Interpretation of Diffusion Data for Some Strong Electrolytes

BY PIERRE VAN RYSSELBERGHE

I. Introduction

In the theory[1] consisting of combining Fick's law of diffusion with the thermodynamic idea that the driving force per unit mass of solute is equal to the gradient of the Gibbs chemical potential, one finds that the coefficient of diffusion D of a binary electrolyte is given by the formula

$$D = 2RT\frac{\Omega}{C}(1 + C\partial \log f/\partial C)10^3 \qquad (1)$$

in which R is the gas constant, T the absolute temperature, Ω/C the mobility or velocity due to unit force, C the concentration in moles per liter, f the mean activity coefficient of the ions. At infinite dilution Ω/C reduces to the classical Nernst expression which, for a uni-univalent electrolyte, is

$$10^{20}\lim_{C=0} \Omega/C = 1.074\frac{\Lambda^0_+\Lambda^0_-}{\Lambda^0_+ + \Lambda^0_-} \quad \text{(c. g. s. units)} \qquad (2)$$

where the limiting equivalent conductivities Λ^0_+ and Λ^0_- are expressed in reciprocal ohms. As explained by Onsager and Fuoss[1] the factor $1 + C\partial \log f/\partial C$ allows "for the interionic attraction reducing the thermodynamic tendency of the ions to separate by diffusion." For the factor Ω/C Onsager and Fuoss[1] give a theory in which they "compute the effect of interaction on the mobility of the migrating ions." The result of this theory for a uni-univalent electrolyte at 18° is

$$10^{20}\Omega/C = 1.074\frac{\Lambda_+\Lambda^0_-}{\Lambda^0_+ + \Lambda^0_-} - 9.60\left(\frac{\Lambda^0_+ - \Lambda^0_-}{\Lambda^0_+ + \Lambda^0_-}\right)^2 \frac{\sqrt{2C}}{1 + \mathrm{A}\sqrt{2C}} + 15.6\ C\varphi(A\sqrt{2C}) \qquad (3)$$

in which A is a specific constant for the electrolyte and $\varphi(A\sqrt{2C})$ is a function defined by

$$\varphi(x) = e^{2x}Ei(2x)/(1 + x)^2 \qquad (4)$$

with

$$Ei(y) = \int_y^\infty e^{-t}\frac{dt}{t} = -0.5772 - \log y + y - \frac{y^2}{2.2!} + \frac{y^3}{3.3!} - \cdots \qquad (5)$$

For salts such as potassium chloride and potassium nitrate, which are both considered in the present paper, the difference $\Lambda^0_+ - \Lambda^0_-$ is small and Ω/C varies with concentration only on account of the last term in formula (3). For sodium chloride, however, the second term on the right-hand side of this formula is not negligible. As indicated on Fig. 7 of the paper of Onsager and Fuoss,[1] their theory predicts an increase of Ω/C with concentration for both potassium and sodium chloride, but these authors have not shown that, when Ω/C is calculated from the experimental values of D according to formula (1), one finds that, for sodium chloride, this mobility Ω/C decreases steadily as concentration rises, while for potassium chloride an increase of Ω/C of the order required by the theory appears only at concentrations higher than 2 molar. They mention, however, that "at higher concentrations, we meet with quite appreciable deviations, particularly in the case of sodium chloride, and our theory of Ω/C is definitely not adequate." They also state that viscosity and hydration are the probable causes for the deviations. Whether the limiting law for Ω/C is verified or not is doubtful on account of the lack of accurate diffusion data at very low concentrations. A comparison between experimental and calculated coefficients of diffusion such as that presented by Onsager and Fuoss[1] on Fig. 8 of their paper can hardly be considered as a conclusive test of the theory. In the present paper we compare theoretical and "experimental" values of Ω/C after elimination of the thermodynamic factor $2RT\ (1 + C\ \partial \log f/\partial C)$ from the measured values of D. To the two cases considered by Onsager and Fuoss (potassium and sodium chloride at 18°) we are adding potassium chloride at 25° and potassium nitrate at 18°. Diffusion data for potassium chloride at 25° recently have been published by McBain and Dawson.[2] The dependence on concentration of these new data is of the same type as that exhibited by Clack's data[3] at 18°, a fact which entitles us to reject most of the previous data for potassium chloride (see

---

[1] Onsager and Fuoss, *J. Phys. Chem.*, **36**, 2689 (1932). The first complete proof that the affinity of diffusion is measured by the gradient of the Gibbs chemical potential is due to Defay [Compt. rend. du 2$^{\text{me}}$ Congrès National des Sciences, Brussels, 1935, p. 317] whose reasoning is based upon DeDonder's theory of affinity [see DeDonder and Van Rysselberghe, "Thermodynamic Theory of Affinity, a Book of Principles," Stanford University Press, 1936.]

[2] McBain and Dawson, *Proc. Roy. Soc.* (London), **148A**, 32 (1935). It should be noted that the legend of the vertical coördinate axis of Fig. 3 of this paper was given erroneously as "cm.^{2}/sec. × 10^5" instead of "cm.^{2}/day."

[3] Clack, *Proc. Phys. Soc.* (London), **36**, 313 (1924).

Fig. 1 of McBain and Dawson[2]). For potassium nitrate we use Clack's diffusion coefficients[3] and Robinson's activity data.[4] The latter were not available at the time of the publication of the paper of Onsager and Fuoss.[1] Following these authors, who used Harned's activity data[5] for 25°, we likewise use Robinson's data for 25° in order to study diffusion coefficients at 18°, hence neglecting the small difference due to heats of dilution. We also present a quantitative investigation of the effect of viscosity on diffusion.

II. Comparison between Measured and Calculated Diffusion Mobilities

1. Potassium Chloride.—At 25° we have[5,6]

$$\log f = -\frac{0.820\sqrt{2C}}{1 + 0.76\sqrt{2C}} + 0.0394 \times 2C$$

and hence

$$1 + C\partial \log f/\partial C = 1 - \frac{0.410\sqrt{2C}}{(1 + 0.76\sqrt{2C})^2} + 0.0788\ C$$

At infinite dilution we have, according to the data of MacInnes, Shedlovsky and Longsworth[7] at 25° and other standard data

$$10^{20}\Omega/C = 34.84 \text{ and } 2RT = 4.842 \times 10^{10} \text{ at } 18°$$
$$10^{20}\Omega/C = 40.22 \text{ and } 2RT = 4.958 \times 10^{10} \text{ at } 25°$$

Experimental values of Ω/C are then deduced from the measured coefficients of diffusion by means of formula (1). *Theoretical* values of Ω/C are given by the following equations, the second term on the right-hand side of formula (3) being neglected

$$10^{20}\Omega/C = 34.84 + 15.6\ C\varphi(0.76\sqrt{2C}) \text{ at } 18°$$
$$10^{20}\Omega/C = 40.22 + 18.6\ C\varphi(0.76\sqrt{2C}) \text{ at } 25°$$

In the tables we give: in column 1 the concentration C of the salt in moles per liter; in column 2 the measured coefficient of diffusion D in cm²./sec. × 10⁵; in column 3 the difference Δ_m between the experimental values of $10^{20}\Omega/C$ and the value at infinite dilution (c.g.s. units); in column 4 the difference Δ_c between the Onsager–Fuoss values of $10^{20}\ \Omega/C$ and the value at infinite dilution; in column 5 the differences Δ_I calculated by means of the formula

$$\Delta_I = (1/\eta - 1) \lim_{C=0} \Omega/C\ 10^{20} \qquad (6)$$

in which η is the viscosity of the solution referred to water; in column 6 the differences Δ_{II} calculated by means of the formula

$$\Delta_{II} = \frac{1}{\eta}\left[\lim_{C=0} \Omega/C\ 10^{20} + \Delta_c\right] - \lim_{C=0} \Omega/C\ 10^{20} \qquad (7)$$

The difference defined by formula (6) corresponds to the hypothesis that the mobility Ω/C might be given by the simple formula

$$\Omega/C = \frac{1}{\eta} \lim_{C=0} \Omega/C \qquad (8)$$

The difference defined by formula (7) corresponds to the hypothesis that the mobility Ω/C might be given by the formula

$$\Omega/C = \frac{1}{\eta}(\Omega/C)_c \qquad (9)$$

in which $(\Omega/C)_c$ is the mobility calculated in the Onsager–Fuoss theory.

The results obtained for potassium chloride at 18 and at 25° are reported in Tables I and II, respectively. They are also represented graphically on Figs. 1 and 2.

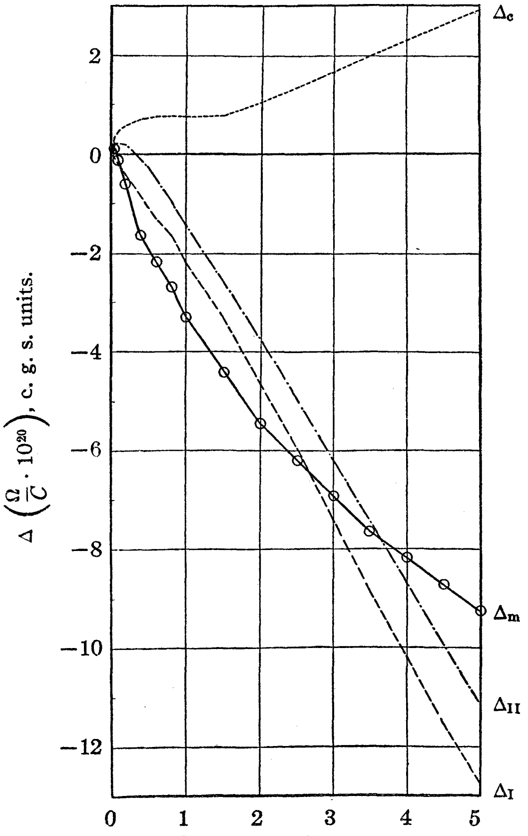

Fig. 3.—Diffusion of NaCl at 18°. At infinite dilution $\Omega/C = 28.01 \times 10^{-20}$.

Differences Δ_{I} and Δ_{II} have also been calculated according to formulas (6) and (7). The results are reported in Table III and represented graphically on Fig 3.

3. **Potassium Nitrate.**—Activity coefficients of potassium nitrate in aqueous solutions up to 3.5 molal have been measured by Robinson.[4] It is difficult to describe these data by means of a formula of the Hückel type with two parameters A and B

$$\log_{10} f = -0.356 \frac{\sqrt{2C}}{1 + A\sqrt{2C}} + B \times 2C$$

The activity coefficient of potassium nitrate decreases steadily as concentration rises and at low concentrations the application of a formula without the linear term $2BC$ would require impossibly small values of the parameter A. In order to calculate the function φ (κa) of the Onsager–Fuoss theory for this salt we have followed a suggestion due to Guggenheim[8] and have adopted for $A\sqrt{2}$ the value *one*. One readily sees that we could have used this same value of $A\sqrt{2}$ for both potassium and sodium chloride without modifying more than by a negligible amount the calculated values of Ω/C. The factor $1 + C\partial \log f/\partial C$ has been obtained graphically from Robinson's experimental curve for f (after the usual conversion of activity coefficients γ into the corresponding f's and of molalities into concentrations). We get experimental values of Ω/C from formula (1) and theoretical values are given by the equation

$$10^{20}\ \frac{\Omega}{C} = 34.00 + 15.6\ C\varphi(\sqrt{C})$$

for 18°, the second term on the right-hand side of formula (3) being neglected. Differences Δ_{I} and Δ_{II} also have been calculated according to formulas (6) and (7). The results are reported in Table IV and represented graphically on Fig. 4.

TABLE IV

III. Discussion

Close inspection of the tables will make the following points clear.

1. With potassium chloride Ω/C varies very slightly with concentration. Although the calculated increments Δ_c are of the right order of magnitude at high concentrations the behavior of Δ_m is not reproduced correctly at low concentrations. Consideration of the increments Δ_{I} and Δ_{II} shows that viscosity corrections are not sufficient to explain the experimental Δ_m, whether the corrections are applied to the limiting value of Ω/C or to the Onsager–Fuoss value corresponding to each particular concentration. The diffusion coefficient D of potassium chloride is seen to depend mostly on the activity factor $1 + C\,\partial \log f/\partial C$.

2. With concentrated sodium chloride Ω/C differs by as much as 30% from its limiting value in a direction *opposite in sign* to that predicted by the Onsager–Fuoss theory. The simple viscosity correction applied to the limiting value of Ω/C reproduces the experimental Δ_m's correctly both in sign and order of magnitude. When the viscosity correction is applied to the Onsager–

---

[8] Guggenheim, *Phil. Mag.*, [7] **19**, 588 (1935).

Fuoss values of Ω/C a slight improvement is obtained in the agreement at high concentrations, but at low concentrations the differences Δ_I are more nearly correct. Such a situation greatly reduces the significance of the Onsager–Fuoss theory of diffusion.

3. With potassium nitrate the experimental increments Δ_m are unexpectedly large; in concentrated solutions they are nearly ten times as large as the Δ_c's calculated from the Onsager–Fuoss theory. The increments Δ_I and Δ_II are in the right direction, Δ_m coinciding exactly with Δ_c at a concentration of 0.6 molar. In view of the arbitrary choice of the parameter A ($A\sqrt{2C} = \kappa a = \sqrt{C}$ or $a = 3$ Å.) we have repeated the calculation of Δ_c with a value of a such that Δ_II is identical with Δ_m at $C = 2.5$ moles/liter. We found $a = 0.6$ Å., $A\sqrt{2C} = \kappa a = 0.2\sqrt{C}$. Such a value of a yields the Δ_c' and Δ_II' values reported in Table V and represented on Fig. 4. At concentrations smaller than 0.8 the values calculated with $\kappa a = \sqrt{C}$ given in Table IV are themselves larger than the corresponding Δ_m's showing that it is impossible to interpret the mobility of potassium nitrate in terms of a constant value of the ionic diameter a. This difficulty is similar to that encountered in the interpretation of activity data for this salt.

TABLE V

DIFFUSION OF POTASSIUM NITRATE IN CONCENTRATED AQUEOUS SOLUTIONS AT 18°

1 C	2 Δ_c'	3 Δ_II'	4 Δ_m
0.8	8.74	10.19	3.55
1.0	10.30	12.00	4.80
1.5	13.69	15.52	7.36
2.0	15.91	17.14	11.64
2.5	17.72	18.14	18.14

In all cases studied in this paper the variation with concentration of the thermodynamic factor $1 + C\partial \log f/\partial C$ is found to be at least as important as the variation of the mobility factor Ω/C. The importance of the thermodynamic factor is particularly striking in the case of salts exhibiting a minimum in the activity coefficient curve. Such salts also exhibit a minimum in the curve for the coefficient of diffusion, as is borne out by potassium and sodium chloride studied in this paper and also by magnesium chloride and magnesium nitrate for which diffusion coefficients have been reported recently by Öholm.[9] With cadmium and magnesium sulfates the diffusion coefficients also exhibit minima, as has been observed by Davies,[10] while the activity coefficients decrease steadily as concentration rises, finally reaching practically constant values.

The remarks made in the present discussion apply to strong electrolytes. It is interesting to examine, at least approximately, the behavior of a typical non-electrolyte such as sucrose. The coefficient of diffusion is given by the formula

$$D = RT\frac{\Omega}{C}(1 + C\partial \log f/\partial C)10^3 \qquad (10)$$

The variation of Ω/C with concentration is much larger than in the case of electrolytes and cannot be accounted for quantitatively by means of the simple viscosity correction as is shown in Table VI obtained by means of various data in the "I. C. T." and Landolt–Börnstein–Roth "Tables."

TABLE VI

DIFFUSION OF SUCROSE IN AQUEOUS SOLUTIONS AT 20°

C, moles/liter	D, cm.^{2}/day	$\frac{\Omega}{C} \times 10^{20}$ c.g.s.	$\frac{1}{\eta}\,\mathrm{lin}\,\frac{\Omega}{C} \times 10^{20}$
0	0.380	8.97	8.97
0.25	.368	8.15	6.35
0.50	.353	7.45	4.90
2.00	.272	4.76	0.08

The results indicate that the agreement between measured and calculated Ω/C might be satisfactory in very dilute solutions for which, unfortunately, good experimental data are lacking. Let us note that in the various attempts at applying the Stokes–Einstein law of diffusion to molecular solutions[11] better results might have been obtained by introducing the thermodynamic factor $1 + C\,\partial \log f/\partial C$. We would have

$$D = \frac{RT}{N}\frac{1}{6\pi\eta r}(1 + C\partial \log f/\partial C) \qquad (11)$$

in which N is Avogadro's number, and r the radius of the solute molecules. Comparison with formula (10) gives

$$\frac{\Omega}{C} = \frac{10^3}{N6\pi\eta r} \qquad (12)$$

IV. Summary

1. The diffusion mobilities of potassium chloride, sodium chloride and potassium nitrate in aqueous solution are calculated from the experimental diffusion coefficients and the thermodynamic factors $1 + C\,\partial \log f/\partial C$.

2. The diffusion mobilities are compared with theoretical values obtained in three different man-

Hydrogen as Carrier Gas for the Catalytic Dehydrogenation of Borneol to Camphor

BY B. E. CHRISTENSEN, E. C. GILBERT AND MAX BOCEK

In connection with another investigation it became necessary to convert borneol quantitatively into camphor. Since oxidation or dehydrogenation in the vapor phase appeared to have many advantages over other methods available, attack upon the problem was made from this aspect.

Although there are numerous references (largely patents) to the vapor phase dehydrogenation of borneol to camphor, the majority deal with the use of copper in some form as the catalyst.[1] Examination of these references, however, reveals data of highly conflicting and contradictory nature, one reporting 100% conversion,[1a] while others[1e] found only traces, and one of the latest[1i] states that reduced copper is a poor catalyst from the standpoint of yield.

In the hope of clearing some of the contradictory points and establishing conditions under which the method might be used reliably, extensive experiments have been carried out in this Laboratory with different catalysts and carrier (diluent) gases. In this paper the results obtained with reduced copper are reported.

Preliminary tests were made with many forms of this catalyst. Using a spongy form obtained by the reduction of fused cupric oxide, conversions of 96–100% were observed at 360°, confirming to some extent the work of Aloy and Brustier.[1a] Repeated tests under these conditions indicated, however, that the high catalytic efficiencies could not be maintained over any period of time and that the color of the copper gradually changed with use. This discoloration could not be restored by further reduction with hydrogen.

Since it was believed that either undesired decomposition products of borneol (due to the high concentration of borneol) or oxidation of the catalyst by traces of oxygen were responsible for the discoloration and diminishing catalytic activity, experiments were next attempted using carrier gases. Others have shown that borneol vapor diluted with benzene gave yields around 86%[1h] while another process using carbon dioxide[1d] (no data given) has been patented.

Although hydrogen is a product of the reaction and in excess logically should retard its progress, this gas would prevent oxidation of the catalyst while also serving as a diluent for the borneol vapor. Attempts made to use hydrogen as the carrier gas met with immediate success, making it possible to maintain the catalyst at high efficiency through many runs, and, under the optimum conditions, apparently minimizing side reactions, so that the product was uniformly of high quality.

Experimental

A borneol reservoir was maintained at any desired temperature by an air-bath. From this, borneol vapor was passed over the catalyst either by its own vapor pressure or by a stream of diluent or carrier gas. Approximately 2–3 g. samples of borneol were generally used. The temperature of the catalyst was controlled by an electric furnace and was measured by a thermocouple. The volume of carrier gas was measured by a calibrated flow-meter.

The catalyst in every run reported in this part of the work consisted of spongy copper prepared by the reduction of fused copper oxide with hydrogen at 200°. The volume

of catalyst was 23 cc., contained in a tube of 1-cm. diameter. Catalysts which lost their activity were reactivated easily by repeated oxidation by air at 500°, followed by the regular reduction at 200°. The use of a catalyst prepared by the reduction of copper nitrate on porous plate gave very poor results. (Porous plate was later found to be quite active alone, yielding liquid products.)

In all more than one hundred runs were made, and since the standard method of estimating camphor is time consuming,[2] the percentage conversion in a given run was estimated by comparing the melting point of the product with a known borneol–camphor melting point curve. Confidence was had in this procedure because repeated comparison of estimations from the melting points with those obtained by the gravimetric method gave quantitative agreement, within the limit of accuracy of either method.[2] Certainly, therefore, in those instances where a high yield is indicated by the melting point method the estimation is trustworthy. No attempt was made to identify products other than camphor which may conceivably have been present in runs carried out far from the optimum conditions.

Results

Attempts to duplicate the quantitative conversion reported by Aloy and Brustier[1a] using only borneol vapor resulted in a rapid decrease in the catalyst efficiency (about 30% per run).

Hydrogen as Carrier Gas.—The exploratory tests with hydrogen having shown excellent promise, experiments were carried out to determine the optimum conditions for its use. To study the effect of temperature, runs were made at 20° intervals. The results are shown in Table I.

Table I

Effect of Temperature, Using Hydrogen as Carrier

Temp. of borneol reservoir 135–140°. Product in all cases uniformly white and solid. Each run given a number, the missing runs being omitted from the table in the interest of brevity. Space velocity 880.

Run	Catalyst temp., °C.	M. p. product, °C.	Est. % camphor in product
1	280	187.5	65
3	320	180.0	96
11	480	180.0	96
13	520	183.5	86

It is important to note that above 420° Aloy and Brustier obtained considerable amounts of liquids identified as terpenes. With the present precedure the products are still solid at a reaction temperature of 520°, though the camphor percentage has dropped somewhat. Furthermore, life tests at 300° in the presence of hydrogen showed the same percentage conversion in the *tenth* run as in the first (95–96%). In no case did hydrogen seem to reverse the process or reduce the yield as might have been predicted.

In order to determine the effect of time of contact, runs were made under otherwise optimum conditions with various space velocities of hydrogen gas. It was observed that maximum efficiencies were maintained with space velocity as high as 2000. Above this value the efficiencies slowly diminished.

Carbon Dioxide as Carrier Gas.—Although the use of carbon dioxide is mentioned in some patents[1d] no data were found in the literature. In order to determine whether the beneficial effect of hydrogen on this reaction is specific or due merely to its action as a diluent, a series of runs was made with carbon dioxide. The effect of catalyst temperature, space velocity, and length of catalyst life were studied in over twenty runs. The effect of temperature is shown in Table II.

Table II

Effect of Temperature Using Carbon Dioxide as Carrier

Temperature of borneol reservoir 140°. Space velocity 800.

Run	Catalyst temp., °C.	M. p. product, °C.	Est. % camphor in product
1	270	203	1
2	320	179	100
5	380	179	100
9	480	185	78

No particular significance is attached to the fact that some of the yields are apparently 100% as compared to 96% for hydrogen because of the method of estimation. The catalyst soon lost its activity, the efficiency dropping to 73% on the fourth run at 400° and to 65% on the seventh run at 340°. The use of carbon dioxide is less advantageous in other respects because it is slower and less efficient also in carrying over the borneol vapor.

Other Catalysts.—Preliminary experiments using hydrogen as a carrier gas for this reaction with other catalysts (notably reduced cobalt and nickel) have given excellent results. Although the effective temperature range is lower and narrower (200–250°) and there is more tendency to form terpenes, experiments conducted in this Laboratory have given very high yields of camphor. Cobalt seems to be superior in many respects to copper.

Summary

1. Results have been given to show that hydrogen is highly efficient as a carrier gas for the dehydrogenation of borneol vapor over reduced copper, particularly in respect to catalyst life and purity of product.

2. Optimum conditions with respect to temperature and time have been established for the reaction thus conducted.

3. Results have been given to show that carbon dioxide is in most respects inferior to hydrogen as a carrier.

4. Preliminary experiments have been reported which indicate that reduced cobalt and nickel are excellent catalysts for the dehydrogenation of borneol when used in the presence of hydrogen.

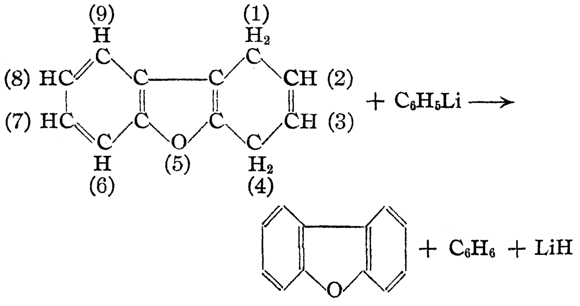
Dehydrogenation by Organometallic Compounds

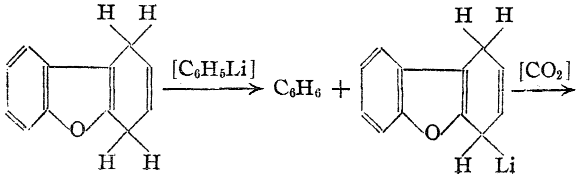
BY HENRY GILMAN AND CHESTER W. BRADLEY

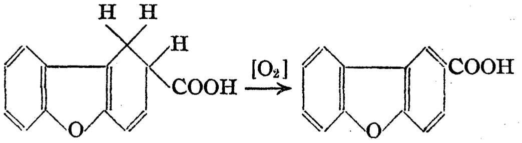
Introduction

In attempting to metalate 1,4-dihydrodibenzofuran in ether solution by means of phenyllithium, dibenzofuran instead of the expected metalation product was the chief compound isolated. The brown color produced at the inception of reaction indicated the formation of a metalation product. This color slowly disappeared on refluxing and a white precipitate, subsequently shown to be lithium hydride, formed. The isolation of dibenzofuran, lithium hydride and benzene indicated that the following transformation had taken place.



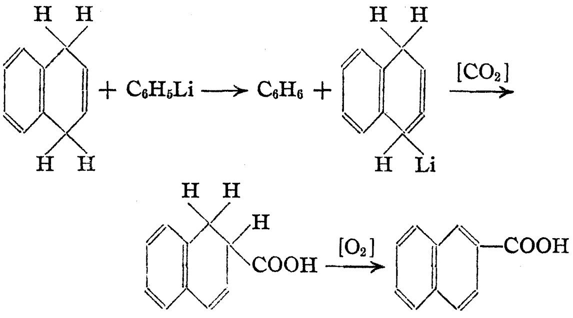
The intermediate metalation product was characterized subsequently (after allowing the reaction to proceed for a shorter time and at a lower temperature) by carbonation, to yield 1,2-dihydrodibenzofuran-2-carboxylic acid. The position of the carboxyl group was established by oxidizing the dihydro acid to the known dibenzofuran-2-carboxylic acid.





Dehydrogenation of 1,4-dihydrodibenzofuran also was effected by *n*-butyllithium and *n*-butylsodium. It was shown subsequently that the related 1,4-dihydrodibenzothiophene is dehydrogenated to dibenzothiophene by organolithium and organopotassium compounds.[1]

A related series of reactions was then observed with 1,4-dihydronaphthalene. Here, also, moderate conditions made it possible to characterize the intermediate metalation compound.



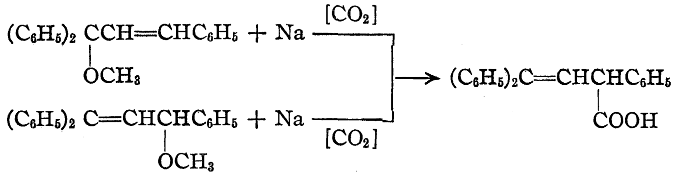
Carbonation of the intermediate organometallic compounds derived from 1,4-dihydrodibenzofuran, 1,4-dihydrodibenzothiophene and 1,4-dihydronaphthalene probably involves an allylic rearrangement. An illustration of a related rearrangement with organosodium compounds is the work of Schlenk and Bergmann.[2] These authors obtained the same acid by carbonating the organosodium compounds obtained from the

---

(1) Gilman and Jacoby, *J. Org. Chem.*, **3**, in press (1938).

(2) Schlenk and Bergmann, *Ann.*, **479**, 78 (1930).

methyl ethers of diphenylstyrylcarbinol and β,β-diphenylvinylphenylcarbinol, respectively.



$$\left.\begin{array}{l}(C_6H_5)_2\underset{\displaystyle OCH_3}{C}CH{=}CHC_6H_5 + Na \xrightarrow{[CO_2]} \\ (C_6H_5)_2C{=}CH\underset{\displaystyle OCH_3}{C}HC_6H_5 + Na \xrightarrow[{[CO_2]}]{} \end{array}\right] \longrightarrow (C_6H_5)_2C{=}CH\underset{\displaystyle COOH}{C}HC_6H_5$$

The illustrations just given are of lateral types. Related allylic rearrangements also take place with lateral-nuclear types as in 2-furylmethylsodium[3a] and benzyllithium.[3b] Rearrangements of these kinds now appear to be reactions common to practically all types of reactive and moderately reactive organometallic compounds,[4] but they have been most closely examined with organomagnesium compounds.[5]

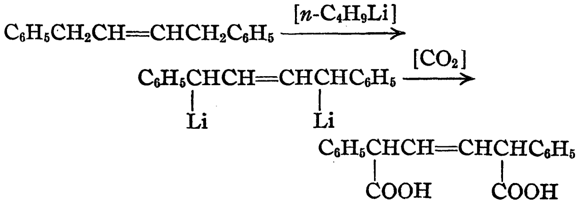
If an allylic rearrangement is the correct interpretation for the mechanism of reaction, it is interesting to inquire why the carboxyl group in the dihydrodibenzofuran- and dihydrodibenzothiophenecarboxylic acids is attached to the 2-position and not to the 3-position. Both dihydro types have active methylene groups in the 1- and in the 4-positions. Replacement of hydrogen in the 1-methylene group followed by rearrangement should give a 3-carboxylic acid, whereas replacement in the 4-methylene group should give the 2-carboxylic acid. It may be significant that metalation of the parent types, dibenzofuran and dibenzothiophene, by organoalkali compounds invariably involves the 4-position. Furthermore, metalations of ethers (like anisole and diphenyl ether) invariably involves the position ortho to the ether linkage.

Dehydrogenation by organometallic compounds is not restricted to cyclic compounds. It has been shown that *n*-butyllithium dehydrogenates 1,4-diphenylbutene-2 to give 1,4-diphenylbutadiene-1,3.

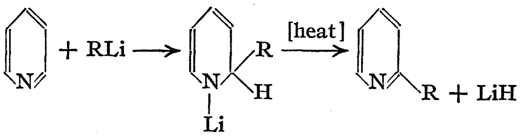
$$C_6H_5CH_2CH{=}CHCH_2C_6H_5 + n\text{-}C_4H_9Li \longrightarrow C_6H_5CH{=}CHCH{=}CHC_6H_5$$

Carbonation of the reaction mixture also yielded 1,4-diphenyl-2-butene-1,4-dicarboxylic acid. This dibasic acid probably was formed as a consequence of dimetalation of the reactive methylene groups in 1,4-diphenylbutene-2.

The loss of alkali hydrides from organometallic compounds at temperatures not exceeding the boiling point of ether rarely has been observed. However, the N-lithium derivatives of some reduced nitrogen heterocycles, formed by addition and not substitution reactions, lose lithium hydride at temperatures as low as 70–100°. The following reaction illustrates a transformation described by Ziegler and Zeiser.[6]



$$C_6H_5CH_2CH{=}CHCH_2C_6H_5 \xrightarrow{[n\text{-}C_4H_9Li]} \underset{\displaystyle Li}{C_6H_5CH}CH{=}CH\underset{\displaystyle Li}{CHC_6H_5} \xrightarrow{[CO_2]} \underset{\displaystyle COOH}{C_6H_5CH}CH{=}CH\underset{\displaystyle COOH}{CHC_6H_5}$$



A related reaction takes place with other nitrogen heterocycles, but generally at more elevated temperatures. Also, ethylsodium decomposes slowly at room temperature and quite rapidly at 100° to give sodium hydride, ethane and ethylene.[7] Pyrolysis of ethylmagnesium bromide at 175° gives magnesium hydride and ethylene.[8]

Experimental Part

1,4-Dihydrodibenzofuran.—To a solution of 12.0 g. (0.54 g. atom) of sodium in 400 cc. of liquid ammonia was added 30 g. (0.18 mole) of *finely divided* dibenzofuran over a period of twenty to thirty minutes and the stirring continued for thirty minutes.

Ammonium chloride was then added slowly in slight excess, and the product was finally distilled under reduced pressure (b. p. 110° (5 mm.)). The yield was 82%, after recrystallization from methanol and petroleum ether (b. p. 60–68°), m. p. 42°.

Anal. Calcd. for $C_{12}H_{10}O$: C, 84.65; H, 5.93. Found: C, 84.40; H, 5.87.

Dehydrogenation of 1,4-Dihydrodibenzofuran by Phenyllithium.—A filtered ether solution of phenyllithium (0.125 mole) was run into an ether solution of 17 g. (0.01 mole) of 1,4-dihydrodibenzofuran. The mixture immediately turned brownish and the color intensified slowly. In about two hours a white precipitate became noticeable, and at the end of fifteen hours of refluxing all of the brown color disappeared and there was a considerable accumulation of white precipitate.

The ether solution was filtered from the precipitate, and the filtrate distilled to yield 1.5 g. (19%) of benzene (identified as the *m*-dinitrobenzene derivative). Distillation of the residue gave dibenzofuran; 88% yield of crude material or 70% yield of compound highly purified by crystallization.

The white precipitate was analyzed by decomposing with water and measuring the hydrogen evolved and also titrating the lithium hydroxide formed. The hydrogen and lithium hydroxide were formed in equivalent quantities from a sample. The hydrogen was analyzed by combustion methods.

In another experiment in which refluxing was continued for only one and one-quarter hours before carbonation, some brownish colored material was present at the end of that time. However, the quantity of intermediate metalation product must have been small for the yield of dibenzofuran was 86% and only a trace of acidic material was isolated.

Apropos the ready loss of lithium hydride, it was noted that refluxing and extended time of reaction are not necessary. From an experiment allowed to run but ten minutes and with no refluxing, the yield of dibenzofuran was 70% and the yield of dihydrodibenzofurancarboxylic acid was 27%.

In another experiment in which an excess of phenyllithium was used there was obtained a 66% yield of dibenzofuran and a 5% yield of dibenzofuran-4-carboxylic acid. This acid undoubtedly was due to metalation of the dibenzofuran by the excess of phenyllithium.

Metalation of 1,4-Dihydrodibenzofuran.—Five-hundredths mole of dihydrodibenzofuran and an equivalent quantity of phenyllithium were allowed to react for thirty-five minutes at −15°, after which time carbonation was effected by an ether–solid carbon dioxide mixture. From the ether extract there was recovered a 59% yield of the dihydrodibenzofuran. No dibenzofuran was isolated.

Acidification of the alkali extract yielded 3.6 g. (34%) of dihydrodibenzofurancarboxylic acid which melted at 278–279° after recrystallization from ethanol.

Anal. Calcd. for $C_{13}H_{10}O_3$; C, 72.75; H, 4.70; neut. equiv., 217. Found: C, 72.58; H, 4.84; neut. equiv., 220.

The dihydrodibenzofurancarboxylic acid was oxidized by two different procedures to dibenzofuran-2-carboxylic acid. First, the dihydro acid was heated with an equal weight of sulfur at 250° for three-fourths of an hour to give a 66% yield of dibenzofuran-2-carboxylic acid. Second, a glacial acetic acid solution of the dihydro acid and an equivalent quantity of bromine were refluxed for fifteen minutes to give a 90% yield of dibenzofuran-2-carboxylic acid. The acid obtained by these two oxidation procedures was identified by (1) direct comparison with an authentic specimen and (2) conversion to methyl dibenzofuran-2-carboxylate which was also compared with an authentic specimen.

Dehydrogenation of 1,4-Dihydrodibenzofuran by *n*-Butylsodium and *n*-Butyllithium.—*n*-Butylsodium was prepared by adding 2.5 g. (0.11 g. atom) of sodium to 8.5 g. (0.0271 mole) of di-*n*-butylmercury in 200 cc. of petroleum ether (b. p. 60–68°). The reaction was allowed to proceed for one hour and then 9.2 g. (0.054 mole) of dihydrodibenzofuran in 25 cc. of petroleum ether was added. Slight warming was observed, and a muddy brown suspension appeared immediately. After three hours of refluxing, the mixture became gray in color.

The supernatant liquid was decanted through a filter, and the residue washed once with petroleum ether. From the petroleum ether was obtained 3.7 g. of dibenzofuran.

The solid residue was suspended in petroleum ether and carbonated. Extraction with 5% sodium hydroxide followed by acidification of the extract yielded 2.5 g. (21.5%) of dibenzofuran-4-carboxylic acid. The petroleum ether fraction yielded an additional 2.4 g. of dibenzofuran which made the total yield of this product 66%.

From a reaction between dihydrodibenzofuran and *n*-butyllithium there was obtained an 84% yield of dibenzofuran.

Dehydrogenation of 1,4-Dihydronaphthalene.—The 1,4-dihydronaphthalene was prepared in accordance with the directions of Bamberger and Lodter[9] and purified by the method of Sand.[10]

Dehydrogenation was carried out with phenyllithium in a manner identical with that used with dihydrodibenzofuran. Reaction was slower, as evidenced by the slow development of the brown color and the noticeable formation of a precipitate in about four hours. After sixteen hours of refluxing the brown color had faded considerably and much white precipitate was present. The reaction mixture was then carbonated and the products worked up. Starting with 4 g. of dihydronaphthalene, the yield of naphthalene was 85%.

In another experiment, the precipitate was filtered before carbonation and shown to be lithium hydride.

Metalation of 1,4-Dihydronaphthalene.—Five grams of 1,4-dihydronaphthalene was metalated at −15° with an equivalent amount of *n*-butyllithium. After stirring for seven hours the reaction mixture was carbonated.

The products isolated were a 64% recovery of dihydronaphthalene and 1.7 g. or a 26% yield of 1,2-dihydro-2-naphthoic acid melting at 105–106°. This dihydro acid was oxidized to β-naphthoic acid in accordance with the procedure of Baeyer.[11] Identification was completed by the method of mixed melting points.

Dehydrogenation of 1,4-Diphenylbutene-2.—A filtered solution of *n*-butyllithium, prepared from 0.014 mole of *n*-butyl bromide, was added to an ether solution of 2.1 g. (0.01 mole) of 1,4-diphenylbutene-2 (prepared in accordance with the directions of Freund and Immerwahr[12]). The mixture turned yellow at first, then brown in about ten minutes, and brilliant red in thirty minutes. The maximum color intensity seemed to have been reached in about two hours. The solution was refluxed for nine hours and was then filtered into an ether–solid carbon dioxide mixture.

From the ether fraction obtained after carbonation there was isolated a 12% yield of 1,4-diphenylbutadiene-1,3 (mixed melting point). In a check experiment the yield was 15%.

(9) Bamberger and Lodter, *Ann.*, **288**, 75 (1895).

(10) Sand, *Ber.*, **36**, 3705 (1905).

(11) Baeyer, *Ann.*, **266**, 202 (1891).

(12) Freund and Immerwahr, *Ber.*, **23**, 2857 (1890); see also Straus, *Ann.*, **342**, 253 (1905).

The aqueous solution gave 0.30 g. or a 12% yield of acid melting at 219–220°. This acid was shown to be 1,4-diphenyl-2-butene-1,4-dicarboxylic acid.[13]

Summary

It has been shown that the more reactive organometallic compounds dehydrogenate some partially reduced nuclear and open-chained compounds smoothly and under very mild conditions. Illustrations are the conversion of 1,4-dihydronaphthalene to naphthalene, 1,4-diphenylbutene-2 to 1,4-diphenylbutadiene-1,3, and 1,4-dihydrodibenzofuran to dibenzofuran.

Intermediate compounds have been isolated and a mechanism considered.

Relative Reactivities of Organometallic Compounds. XIX. Hydrogenolysis of RM Compounds

BY HENRY GILMAN, ARTHUR L. JACOBY AND HELEN LUDEMAN

Introduction

The smooth and ready dehydrogenation by organometallic compounds described in the preceding[1] paper suggested that the more reactive organometallic compounds might undergo easy hydrogenolysis. This has been found to be the case. Actually, some of the organoalkali compounds are cleaved by hydrogen under extremely mild conditions: room temperature, atmospheric pressure and in the absence of any catalyst. Apparently there is no report of any other class of organic compounds reacting with hydrogen under such mild conditions. Not only do some organometallic compounds undergo easier reduction than any other type of organic compound, but they also appear to be oxidized at least as readily as any other class.

Relative Rates of Hydrogenolysis of RM Compounds Having Different Metals.—The varying rates of hydrogenolysis of organoalkali and other reactive organometallic compounds suggested the possibility of a correlation with the relative reactivities of organometallic compounds established with other reactants. Earlier studies by others pointed to such a relationship. Ipatieff and Rasuwajeff[2a] showed that under elevated pressures (60 atmospheres), elevated temperatures (225 and 350°) and in the absence of catalysts, the rate of hydrogenolysis of the triphenyl derivatives of phosphorus, arsenic, antimony and bismuth increased in the order: P, As, Sb, Bi. Then Zartman and Adkins,[3] in an examination of the hydrogenation of some more reactive RM compounds, found that the order of increasing ease of hydrogenation of R_3Sb, R_4Pb, R_2Zn and R_2Mg compounds was: Sb, Pb, Zn, Mg. These authors used not only elevated temperatures and pressures but also a nickel catalyst. Two reactions were noted, depending on the kind of RM compound used

$$R_2M + H_2 \longrightarrow R{\cdot}R + M$$
$$R_2M + H_2 \longrightarrow 2RH + MH_2$$

For example, tetraphenyllead gave biphenyl and lead, both a catalyst and hydrogen being necessary, and diphenylmagnesium gave benzene and magnesium hydride. Ipatieff and co-workers[2b] observed the following reaction with tetraalkyl- and tetraaryllead compounds in the absence of a catalyst, but in a glass and not a copper reaction vessel.

$$R_4Pb + 2H_2 \longrightarrow 4RH + Pb$$

We have found that the order of increasing ease of hydrogenolysis of some very reactive organometallic compounds is: Ca, Li, Na, K, Rb, Cs. This order together with the orders established by Ipatieff and by Adkins follows almost exactly the order of increasing chemical reactivity of the organometallic compounds as established in other reactions. It is interesting to note that here, as in the recent study[4] on the relative reactivities of organoalkali compounds, there is only a small difference between the relative reactivities of organopotassium and organorubidium compounds.

The preponderant reaction which takes place with organoalkali compounds is

$$RM + H_2 \longrightarrow RH + MH$$

The rate of hydrogenolysis varies somewhat with the medium, as illustrated in Fig. 1. The

[4] Gilman and Young, *J. Org. Chem.*, **1**, 315 (1936).

curves indicate that the rate-controlling factor in petroleum ether suspension may be the rate of diffusion of hydrogen through the petroleum ether; and with benzene, a first-order reaction in which the concentration of hydrogen is constant. Obviously, the high reactivity of organoalkali compounds made it desirable to work with suspensions in benzene and petroleum ether.

Relative Rates of Hydrogenolysis of RLi Compounds Having Different Radicals.—Under corresponding conditions, and in benzene, the times in hours required for the hydrogenolysis of some organolithium compounds were: phenyl (32.2 hours), methyl (38.5), α-naphthyl (40), n-butyl (61), n-heptyl (66), n-lauryl (91), p-tolyl (150). This order follows somewhat the tendency of corresponding organoalkali compounds to metalate systems like dibenzofuran and dibenzothiophene.[5]

Effect of Catalysts on Rates of Hydrogenolysis.—It seemed of interest to examine the effect of some catalysts on the rates of hydrogenolysis. For this purpose, platinum and palladium were selected because of their general accelerating effect on organic reductions. Neither catalyst appeared to have any significant effect on the rate of hydrogenolysis of phenyllithium and phenylsodium.

Experimental Part

The organoalkali compounds were prepared in accordance with general procedures, details of which have been given in earlier publications from this Laboratory. Phenylpotassium was prepared by stirring for forty-eight hours 75 cc. of dry benzene, 4.0 g. (0.10 g. atom) of cut potassium and 6.9 g. (0.22 mole) of di-n-butylmercury. The reaction started promptly with the appearance of a precipitate of phenylpotassium, but with very little noticeable warming. Related reactions were used for the syntheses of phenylrubidium and phenylcesium.

Depending upon the particular organometallic compound, comparative runs were made at atmospheric pressure; at pressures slightly above atmospheric pressure (about 785 mm.); and at 100 lb. (7 atm.) pressure in a shaking machine. The rate of hydrogenolysis was determined by disappearance of the color test,[6] or by noting the time for absorption of 90% of the hydrogen. The latter procedure was used rather than the time for complete absorption because the reaction was observed to be erratic toward the end and variations were then noted with individual experiments. Rates determined by disappearance of the color test were confirmed by carbonation; no acid was obtained in those cases where no color test was observed.

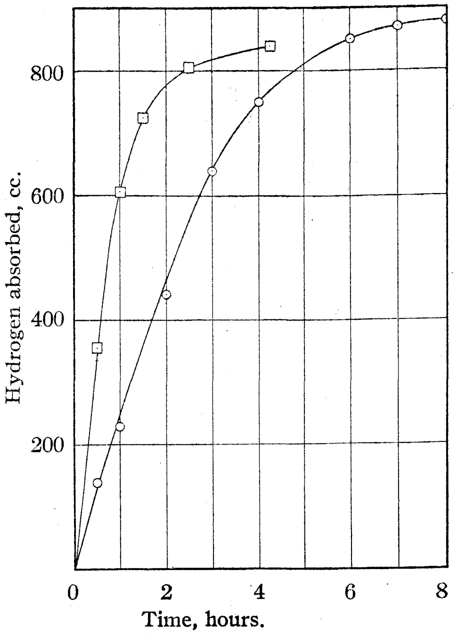

Fig. 1.—Rates of hydrogenolysis of phenylsodium: ⊡, benzene as medium; ⊙, petroleum ether (b. p. 115–130°).

In some experiments, the lithium hydride was analyzed by hydrolysis, the evolved hydrogen being measured, and the lithium hydroxide being titrated with standard acid. The results of two analytical experiments showed: 0.00072 mole of hydrogen and 0.00078 equivalent of lithium hydroxide; and, 0.00027 mole of hydrogen and 0.00024 equivalent of lithium hydroxide. The benzene formed by hydrogenolysis was isolated in yields upward of 60% and characterized as m-dinitrobenzene.

TABLE I

REDUCTION RATES IN BENZENE SUSPENSION

Organometallic compound	Av. time (hours) for complete redn. at 100 lb.	Av. time (hours) for 90% redn. at pres. sl. above atm.
C_6H_5CaI	Incomplete, 150	..
C_6H_5Li	32.2	..
C_6H_5Na	0.5	1.9
C_6H_5K	..	0.54
C_6H_5Rb	..	.42
C_6H_5Cs	..	.2

Typical of results obtained for 90% reduction at pressures a few millimeters above atmospheric pressure are phenylsodium, one and eight-tenths and two hours, respectively; and phenylpotassium, one-half and fifty-eight hundredth hours, respectively. Also, in the series of RLi compounds having different R groups, phenyllithium was reduced completely at 100 lb. (7 atm.) pressure in thirty-one hours, thirty-one and one-half hours and thirty-four hours, respectively.

Summary

The more reactive organoalkali compounds are

---

(5) Gilman and Jacoby, *J. Org. Chem.*, **3**, in press (1938). Also, unpublished studies by R. L. Bebb.

(6) Gilman and Schulze, THIS JOURNAL, **47**, 2002 (1925).

reduced more easily than any reported type of organic compound. Reduction is effected at room temperature, atmospheric pressure and in the absence of any catalyst. The reaction is $RK + H_2 \longrightarrow RH + KH$.

The order of increasing ease of hydrogenolysis of the phenyl derivatives is: Ca, Li, Na, K, Rb, Cs. This series follows essentially the series of relative reactivities as established by other reactants.

The rates of hydrogenolysis appear to be unaffected by the presence of platinum and palladium.

The rates of hydrogenolysis have been established for a series of RLi compounds having different R groups.

Urethans as Local Anesthetics. IV. Alkyl N-(*p*-Aminobenzyl)-carbamates

BY R. L. SHRINER AND JAMES M. CROSS

A study of the local anesthetic action of *p*-aminophenyl urethans (Formula I) showed that their anesthetic potency was high but that they were very irritating whether applied topically or intracutaneously.[1] It seemed possible that the irritation might be due to the *p*-phenylenediamine grouping present as a portion of the molecule since other derivatives of this compound have been found to cause irritation.[2]

In molecules of the type of alkyl N-(*p*-aminobenzyl)-carbamates (II) the urethan grouping is separated from the benzene ring by a methylene

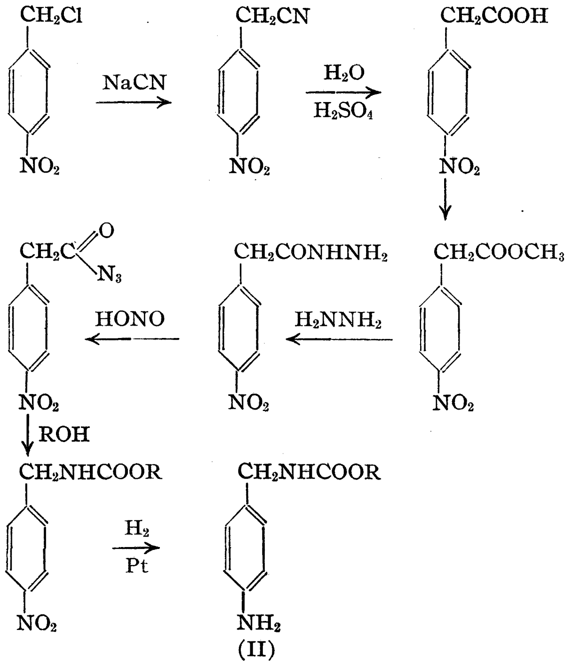
I $H_2NC_6H_4NHCOOR$
II $H_2NC_6H_4CH_2NHCOOR$
III $H_2NC_6H_4COO(CH_2)_xNR_2$

group and the *p*-phenylenediamine group is no longer present. The structure of urethans of type II is related to compounds of the novocaine type (III) in that each contains a *p*-aminophenyl radical attached to a carbon atom. Since the alkyl *p*-aminobenzoates are not especially irritating, it was considered of interest to synthesize the urethans of type II in order to determine whether this structure would be non-irritating to the tissues but still retain the superiority in topical and injection anesthetic potency of the urethans of type I over those of the *p*-aminobenzoates of type III.

The urethans were synthesized by means of the reactions summarized in Chart I.

Although the final compounds are new, each of the individual steps in the above synthesis represents well-known reactions which were adapted to the present compounds with slight modifications which are given in the experimental part.

CHART I



Through the courtesy of the Lilly Research Laboratories the pharmacological action of 1% aqueous solutions of the hydrochlorides of this series of urethans was determined. The data obtained are summarized in Table I.

The pharmacological data in Table I show that these urethans cause some local anesthesia when injected intracutaneously but that they are not especially active when applied topically. All of these urethans were irritating both to the skin and eyes and this fact probably accounts for the somewhat erratic results. These urethans are

not as potent local anesthetics as the *p*-aminophenylurethans previously described.

Experimental

Methyl *p*-Nitrophenylacetate.—Forty grams of *p*-nitrophenylacetic acid, prepared by the hydrolysis of *p*-nitrophenylacetonitrile,[3] was dissolved in 120 g. of absolute methanol and dry hydrogen chloride passed into the solution for two hours. The solution was refluxed for two hours and the excess methanol removed by distillation. The residue was extracted with warm ligroin and the resulting solution cooled in an ice-bath. The ester separated in the form of colorless needles which melted at 54°. The yield was 83.5%. This procedure is a modification of the one used by Curtius,[4] who obtained a 42% yield.

***p*-Nitrophenylacethydrazide.**—A mixture of 34 g. of the ester with 50 g. of 42% hydrazine hydrate solution was heated on a steam-bath for thirty minutes. At first a red coloration developed which gradually disappeared and the mixture solidified to a hard yellow cake. The product was washed with water and recrystallized from absolute ethanol. Thirty-three grams (97%) of needles was obtained melting at 167° which agreed with the value given by Curtius.[4]

***p*-Nitrophenylacetazide.**—Twelve grams of the hydrazide was dissolved in two liters of warm water and 8 cc. of concentrated hydrochloric acid added. This solution was cooled to 20° and 5 g. of sodium nitrite sifted in with vigorous mechanical stirring. The insoluble azide floated on the surface and was separated by filtration. Nine preparations using the above quantities and conditions gave an average yield of 10.6 g. (83.5%). The azide melted at 45° with decomposition. The azide decomposes upon standing and hence always was used within a few hours after it was prepared.

Alkyl N-(*p*-Nitrobenzyl)-carbamates.—A solution of 10 g. of the azide in 400 cc. of each of the anhydrous alcohols was refluxed for three to four hours, at the end of which time the evolution of nitrogen had ceased. The excess alcohol was removed by distillation and the residue chilled. In most cases the urethan solidified and was recrystallized from ligroin. Four of the urethans were oils (see Table II) which could not be crystallized satisfactorily and which decomposed upon attempted distillation *in vacuo*. The oils were washed with water and dried. The analyses of the oils indicated that they were not quite pure but they were sufficiently so for the next step. The data on the alkyl

[4] Curtius, *J. prakt. Chem.*, **197**, 521 (1913).

N-(p-nitrobenzyl)-carbamates are summarized in Table II.

Alkyl N-(p-Aminobenzyl)-carbamates.—A solution of 5 g. of the alkyl N-(p-nitrobenzyl)-carbamate in 100 cc. of absolute ethanol was shaken with 0.2 g. of platinum oxide-platinum black and hydrogen at 3 atm. pressure. The reductions were complete in three to ten minutes. The platinum was removed by filtration and the filtrate saturated with dry hydrogen chloride. An equal volume of absolute ether was added to facilitate the separation of the hydrochloride. The hydrochloride salts were removed by filtration. The yields varied from 50 to 90%, most of the loss being due to the difficulties in causing complete separation of the hydrochlorides. Evaporation of the alcohol-ether mother liquor gave colored impure products which could not be obtained in a colorless condition by recrystallization. The data are summarized in Table III.

Summary

A series of alkyl N-(p-nitrobenzyl)-carbamates was prepared by the action of the alcohols from methyl to octyl on the azide of p-nitrophenylacetic acid. Catalytic reduction of these nitro compounds and subsequent treatment with hydrogen chloride produced the corresponding hydrochlorides of alkyl N-(p-aminobenzyl)-carbamates. Solutions of these hydrochlorides produced intracutaneous anesthesia but only a few caused surface anesthesia. All were quite irritating to the tissues.

Reactions Involved in the Sulfonation of Heat Treated Abietic Acid

BY TORSTEN HASSELSTROM AND JOHN D. MCPHERSON

Recent work of Fieser and Campbell[1] on dehydroabietic acid together with the investigations of Fleck and Palkin[2] and Littman[3] has produced evidence that α-pyroabietic acid heretofore regarded as an isomeric abietic acid is actually a mixture of dehydroabietic acid and hydrogenated abietic acids produced through the reactions of dehydrogenation and disproportionation of abietic acid.

In a previous communication[4] we reported that the sulfonation of heat treated abietic acid yields a crystalline sulfonic acid and as a by-product a lactone belonging to the tetrahydroabietic acid series of compounds. We have obtained evidence that the sulfonic acid[5] has the composition of $C_{20}H_{28}O_5S \cdot 3H_2O$ and hence may be established as a dehydroabietic acid sulfonate. This identity is established further by the preparation of the dimethyl ester, diethyl ester and diamide of this sulfonic acid. Since the lactone is saponified only with difficulty and easily regenerated,[4] it is apparently a γ-lactone formed from a $\Delta^{9,10}$-dihydroabietic acid as a result of hydration due to the sulfuric acid employed. Hence it is likely that the corresponding hydroxytetrahydroabietic acid has the hydroxyl in position 10. It is worthy of note that the addition of two atoms of hydrogen to abietic acid by catalytic means produces an easily lactonized dihydroabietic acid.[6] This lactone formation in the abietic acid series points to the fact that on saturation of one double bond of the original abietic acid, the remaining double bond moves to a position more favorable for hydration and lactonization.

The results obtained by us on the sulfonation of heat treated abietic acid do not agree with those previously recorded in the literature. On sulfonation of α-pyroabietic acid Fanica[7] obtained a crystalline monosulfonic acid for which the formula $C_{20}H_{30}O_5S$ was designated. He also reports as a residue a non-crystalline sulfur containing material.

Our findings that the sulfonation of heat treated rosin yields a dehydroabietic acid sulfonate and a lactone belonging to the tetrahydroabietic series of compounds are additional proof that the dehydrogenation and disproportionation of abietic acid occur on heat treatment.

Experimental

Dehydroabietic Acid Sulfonate.—The sulfonic acid was prepared from partially refined pseudopimaric acid according to Hasselstrom.[5a] It was recrystallized from water, glacial acetic acid and water; m. p. 223–224° (dec.). It was dried at 100° under vacuum.

Anal. Calcd. for $C_{20}H_{28}O_5S \cdot 3H_2O$: C, 55.29; H, 7.83;

mol. wt., 434. Found: C, 55.33; H, 8.15;[8] mol. wt. (by titration for a dibasic acid), 433.

When dried at 150° for six hours, it lost 3 molecules H_2O. Calcd. for $C_{20}H_{28}O_5S$: mol. wt., 381. Found: mol. wt. (by titration for a dibasic acid), 381, 379.5.

Dimethyl Ester of Dehydroabietic Acid Sulfonate.—Five grams of dehydroabietic acid sulfonate was neutralized to phenolphthalein with a dilute aqueous solution of sodium hydroxide and the whole was evaporated to dryness. The pale yellowish powdered residue was dried for two hours at 125° and then boiled for ten minutes with 30 g. of dimethyl sulfate. After cooling, the clear dark solution was poured into ice water and then the mixture boiled for about one hour. The separated solid was removed, washed with a hot dilute sodium bicarbonate solution and then with water; yield, about 3 g. of crude dimethyl ester. It was recrystallized from acetone and methanol, the white silky needles melting at 176.7–177.7° (corr.).

Anal. Calcd. for $C_{22}H_{32}O_5S$: C, 64.69; H, 7.86. Found: C, 64.87; H, 8.04.

Diethyl Ester of Dehydroabietic Acid Sulfonate.—This was obtained in the same manner as the dimethyl ester, from 5 g. of dehydroabietic acid sulfonate and 30 g. of diethyl sulfate. It was recrystallized from acetone and methanol, the white silky needles melting at 150.4–151.4° (corr.).

Anal. Calcd. for $C_{24}H_{36}O_5S$: C, 66.00; H, 8.32. Found: C, 66.18; H, 8.35.

Diamide of Dehydroabietic Acid Sulfonate.—Five grams of dehydroabietic acid sulfonate was mixed with about 15 g. of phosphorus pentachloride and heated for about one hour on the water-bath under reflux. After cooling, the liquid was poured drop by drop into strong aqueous ammonia cooled with ice. The precipitated solid material was removed and extracted with boiling water until free from sulfonic acid. The diamide was then crystallized from ethanol, the transparent prismatic plates melting at 254–255.5° (corr.) (with slight dec.).

Anal. Calcd. for $C_{20}H_{30}O_3N_2S$: C, 63.43; H, 7.99. Found: C, 63.22; H, 8.09.

Summary

1. A dehydroabietic acid sulfonic acid is formed on sulfonation of heat treated abietic acid. This was confirmed further by the preparation of the dimethyl ester, diethyl ester and the diamide of the sulfonic acid.

2. The fact that a dehydroabietic acid sulfonate and a lactone belonging to the tetrahydroabietic acid series are formed on sulfonation of heat treated abietic acid are additional evidence that dehydrogenation and disproportionation of abietic acid occurs on heat treatment.

Alicyclic Amino Acids

BY J. P. GREENSTEIN AND J. WYMAN, JR.

I

A great amount of data is now available on the dielectric constants of solutions of various amino acids, peptides, betaines and related molecules, which exist as dipolar ions. Although an exact theory of the relation of dielectric constant to molecular properties is still lacking in the case of polar liquids, the picture which emerges from such data is fairly simple and convincing.[1] There is no question that the large positive dielectric increments of all these compounds are due to their very large moments as dipolar ions. But beyond this a correlation of these increments with the properties of the molecules, as well as other empirical considerations, has led to the conclusion that in the case of polar liquids there is an approximately linear relation between dielectric constant and volume polarization, a conclusion which has been justified to some degree by recent theoretical investigations of Onsager[2] and of Van Vleck.[3] On this basis the dielectric increments of highly polar molecules like dipolar ions should be very nearly proportional to their molar polarizations, or, in view of that part of Debye's theory relating polarization to moment, to the square of their moments. This interpretation of the dielectric increments has made it possible to assign relative values to the moments of molecules, and, in connection with further inductions from data on pure liquids, even to estimate absolute values which are not far different from those estimated on an entirely different basis. Its application in detail to the large body of data on dipolar ions containing one positive and one negative charge separated by an aliphatic chain shows that in these molecules the mean square distance between the charges is proportional to the length of the intervening chain.

---

[1] J. Wyman, *Chem. Rev.*, **19**, 213 (1936).

[2] Onsager, THIS JOURNAL, **58**, 1486 (1936).

[3] Van Vleck, *J. Chem. Phys.*, **5**, 556 (1937).

This agrees with what would be expected on the basis of free rotation in the chain according to statistical considerations of Eyring[4] and Werner Kuhn,[5] and the whole picture falls together in a very consistent way.

All the aliphatic dipolar ions so far studied have been straight chain compounds as regards the structure separating the charged groups, although in many cases the molecules contain cyclic radicals of one type or another, as for example histidine or phenylglycine. In the present study we have investigated the behavior of a series of compounds in which the charged amino and carboxyl groups are attached to a six-membered aliphatic ring, namely, the 2-, 3- and 4-aminocyclohexane-carboxylic acids. In these alicyclic amino acids the situation in regard to free rotation is quite different and offers a problem of some interest in itself as well as in relation to that of rotation in the straight chain compounds.

II

The cyclohexane amino acids may be prepared by two different procedures. The first is the method of Einhorn, which consists in boiling a solution of *o*-,[6] *m*-,[7] or *p*-[8] aminobenzoic acid with sodium in amyl alcohol. In the present study, only the 2-acid was so prepared. The second method is the catalytic hydrogenation of the aminobenzoic acids, using the Adams platinum oxide catalyst. In the present investigation the hydrogenation was carried out both in aqueous suspension and in hydrochloric acid solution. The meta and para homologs were reduced smoothly to the cyclohexane forms by the catalytic procedure; the ortho acid, on the other hand, in spite of repeated crystallizations, could not be hydrogenated completely.[9] In Table I are listed the melting points of the homologous aminocyclohexane acids prepared by these methods. Details of the procedure used in the preparations are given.

TABLE I

MELTING POINTS OF THE ACIDS ACCORDING TO THE METHODS OF PREPARATION

Carboxylic acids	Melting points, °C. Na in $C_5H_{11}OH$	Pt in HCl	Pt in H_2O
2-Aminocyclohexane	273[10]	. . .	. . .
3-Aminocyclohexane	268[10]	264[a]	278[a]
4-Aminocyclohexane	303[10]	285[a]	303[10] 260[a]

[a] Results by the present authors.

4-Aminocyclohexane-carboxylic Acid.—Fourteen grams of thrice-crystallized *p*-aminobenzoic acid was dissolved in 200 cc. of warm 1 *N* hydrochloric acid. The yellowish solution was filtered into the hydrogenation vessel and shaken in the presence of hydrogen with a suspension of 4.3 g. of the Adams platinum oxide catalyst. There was very little lag in forming the black, and within three and a half hours absorption ceased when about nine liters of hydrogen gas had been consumed. At 27° and 761 mm. pressure, the amount of acid used required about eight liters of hydrogen. The difference of one liter was due to the conversion of and adsorption by the catalyst. The latter coagulated toward the end of the reaction.

The filtered, water-white solution was made up to 500 cc. and an aliquot tested for the presence of ammonia with Nessler's reagent. It was found that 0.303 g. of ammonia was present in the entire solution, indicating that about 5 g. of the starting material had become deaminated. There was a strong odor of valerianic acid in the solution, and it is probable that some di-(cyclohexyl-4-carboxy)-amine may also have been formed. No attempt was made, however, to isolate these possible by-products.

The solution was treated with a slight excess of silver sulfate, filtered and gassed with hydrogen sulfide. The filtrate from the silver sulfide, freed by aeration from hydrogen sulfide, was treated with a considerable excess of baryta, filtered and condensed *in vacuo* to remove ammonia. The residual solution was then treated carefully with dilute sulfuric acid until barium was removed quantitatively. The filtrate was then evaporated *in vacuo* until crystals appeared, transferred to a flask and treated with a large amount of absolute ethanol and dry ether. A fine white precipitate appeared. It was filtered off and washed. After drying, it weighed 6.5 g. The substance, possessing no definite crystal form, was non-hygroscopic and was crystallized three times from acetone–water mixtures.

The molecule separates with 0.5 molecule of crystal water which is removed readily on drying at 100° *in vacuo*. It is extremely soluble in water; the solution is neutral to litmus.

Anal. Calcd. for $C_7H_{13}O_2N \cdot 0.5H_2O$ (152): N, 9.2. Found: N, 9.2.

The 4-acid was again prepared by suspending 8.1 g. of *p*-aminobenzoic acid in 100 cc. of water and shaking with about 3 g. of platinum oxide catalyst in the presence of hydrogen. The uptake of gas was quite rapid. The material went into complete solution within the first hour. After three hours the reaction was at an end. The filtered solution gave a strong test for ammonia. It was evapo-

(8) Einhorn and Meyenberg, *Ber.*, **27**, 2829 (1894).

(9) Heckel and Adams, THIS JOURNAL, **47**, 1712 (1925), had reduced under pressure certain of the alkyl-substituted amino phenols. In view of our inability completely to hydrogenate anthranilic acid, it is interesting to note that Heckel and Adams found it impossible to hydrogenate *o*-aminophenol; with *o*-dialkyl aminophenol only a partial reduction could be achieved.

(10) Houben and Pfau, *Ber.*, **49**, 2294 (1916). These investigators used the Willstätter catalyst in a suspension of *p*-aminobenzoic acid in water. The rate of hydrogenation was extremely slow.

rated to crystals *in vacuo*, taken up with water and the material precipitated with acetone. The amino acid was then warmed twice with 85–90% alcohol to remove the ammonia and then crystallized twice out of water–acetone as long, feathery needles. The properties of the molecule were similar to those above; yield 3.2 g.

Anal. Calcd. for $C_7H_{13}O_2N \cdot 0.5H_2O$ (152): N, 9.2. Found: N, 9.1.

3-Aminocyclohexane-carboxylic Acid.—Fourteen grams of thrice-crystallized *m*-aminobenzoic acid was treated by the catalytic hydrogenation procedure in hydrochloric acid solution exactly as the case of the 4-compound. Complete reduction again was achieved in three and a half hours. However, ammonia determinations indicated the presence of only 150 mg. of ammonia in the solution, pointing to the deamination of about 2.5 g. of the original acid. The meta acid is, therefore, a good deal more stable toward the hydrogenation procedure than the para homolog.

The saturated 3-amino acid was isolated as in the case of the 4-acid. The yield of white, non-hygroscopic material was 8.3 g. This is extremely soluble in water and its solution is neutral to litmus. It separates with 0.5 molecule of crystal water which is removed readily on drying.

When the compound is crystallized out of concentrated aqueous solution by the addition of much acetone, it separates first as an oil. On cooling, beautiful long needles are formed, which, when dry, easily pick up a charge and are hard to handle, in this respect differing from the 1- and 4-compounds. After three such crystallizations, the substance melts at the constant value of 264°.

Anal. Calcd. for $C_7H_{13}O_2N \cdot 0.5H_2O$ (152): N, 9.2. Found: N, 9.2.

The 3-acid also was made by hydrogenating a suspension of 11.5 g. of *m*-aminobenzoic acid in water in the presence of 3 g. of platinum oxide. Solution was complete in less than an hour and the reaction was over in five hours. The saturated amino acid was recovered in the usual manner and boiled twice with 85–90% alcohol to remove ammonia. After several crystallizations from water–acetone the material was obtained as a mass of fine needles. The properties are like those of the compound prepared from hydrochloric acid solution.

Anal. Calcd. for $C_7H_{13}O_2N \cdot 0.5H_2O$ (152): N, 9.2. Found: N, 9.0.

2-Aminocyclohexanecarboxylic Acid.—Twenty grams of four-times crystallized anthranilic acid was dissolved in 250 cc. of 1 *N* hydrochloric acid and the hydrogenation carried out as in the previous cases. The uptake of gas began very slowly and ceased after about one-third of the theoretical amount of hydrogen had been absorbed. An ammonia determination on the solution revealed that practically all of the reduction achieved had been accompanied by deamination.

The substance, therefore, was prepared according to the method of Einhorn and Meyenberg[6] and possessed all the properties described by these authors; m. p. 273° with decomposition.

Anal. Calcd. for $C_7H_{13}O_2N$ (143): N, 9.8. Found: N, 9.6.

Throughout the remainder of the paper we designate the 3- and 4- acids with α or β according to whether they were hydrogenated in aqueous suspension or in solution in hydrochloric acid. The 2-acid, which was prepared in only one way, namely, by the amyl alcohol treatment, requires no special designation.

III

Measurements of dielectric constant were made by a resonance method previously described.[11] The results, expressed in terms of δ, the dielectric increment (the increase of dielectric constant per mole of solute per liter of solution at 25°), are given in Table II. The frequency varied between about 5.35×10^7 ($\lambda = 5.6$ m.) and 5.1×10^7 ($\lambda = 5.9$ m.). The sharpness of the settings and the accuracy of the results varied with the conductivity of the solutions as determined by very small traces of conducting impurities from which it is well-nigh impossible to free such soluble compounds by crystallization. In dealing with dilute solutions, as in the present case, errors in dielectric constant are much magnified in the values of the dielectric increments. The errors in the values of the increments given in Table II are estimated from the consistency of the dielectric constant measurements. In every case measurements were made at at least three different concentrations within the range indicated in the table. This table also contains values of the apparent molal volumes based on density measurements made with a pycnometer over a range of concentrations usually two or three times greater than that for the dielectric constant measurements. In addition to these, there are listed in the last two columns values of the two acidity constants (expressed as pK_1 and pK_2) calculated from titration data obtained on aqueous solutions with a hydrogen electrode.

Compound	δ	Concn. range, moles per liter	V	pK_1	pK_2
2	24.4 ± 0.6	0.04–0.10	108.3 ± 0.2	3.4	10.1
3α	59 ± 1	.05– .15	106.2 ± .1	4.2	10.5
3β	62 ± 4	.04– .11	103.9 ± .2	4.2	10.5
4α	62 ± 0.6	.04– .17	106.8 ± .3	4.3	10.5
4β	61 ± 2	.05– .13	103.6 ± .1	4.35	10.5

IV

It is generally accepted that cyclohexane exists in two different forms, commonly referred to as the chair and the boat, with each of which there is associated approximately the same energy, and which occur consequently with approximately the same frequency. When, as in the case of the cyclohexane amino acids, two different groups are substituted for two hydrogens attached to different carbon atoms of the ring, whether in the

---

[11] Wyman, *Phys. Rev.*, **35**, 623 (1930).

1,2-, 1,3- or 1,4-positions, there are, geometrically, 24 possible ways in which the substitution can be made in the case of the chair form and 24 also in the case of the boat form, although, for reasons of symmetry, not all of these configurations are distinguishable. We will consider the latter form first. From a geometrical point of view, without regard to steric hindrance or the mutual energy of the substituted groups, this form is capable of free rotation whereby certain configurations can pass over into certain others without a deformation of valence angles. On this basis the 24 configurations fall into two classes of 12 members each, members of the same class being derivable from one another by free rotation. One class embraces what may be called the *cis* configurations, the other the *trans* configurations. For any *cis* configuration there exists a corresponding *trans* configuration obtainable from it by interchanging one and only one of the substituted groups with the hydrogen attached to the same carbon atom.

We will consider now the chair form. In this case the geometry is such that there is no possibility of free rotation. For each of the 24 possible configurations of this form there is a corresponding boat configuration, from which it arises when the ring passes through the state of strain required to convert it from the boat to the chair form. For this reason the chair configurations also fall into two classes, *cis* and *trans*, of twelve members each, members of the *cis* class having each a corresponding *cis* configuration, members of the *trans* class each a corresponding *trans* configuration, in the boat form. If, as the evidence of organic chemistry suggests, there is a constant transition back and forth between chair and boat forms then, owing to the free rotation in the boat form (neglecting steric hindrance and interaction of substituents), there also must be a constant transition between the various configurations of the chair form, and any such disubstituted cyclohexane as we are considering should exist either in a *cis* or a *trans* condition. The ring, despite its flexibility and all the free rotation associated with it, acts like a double bond to separate *cis* from *trans* configurations.

In the picture just presented no account is taken of steric hindrance, electrostatic effects, or van der Waals forces involving the substituents. Such factors certainly must influence the frequencies of occurrence of the various configurations, perhaps even so far as to rule out certain configurations entirely. Whenever energy differences between different configurations are of the order of kT (*i. e.*, 4×10^{-14} erg per molecule or 0.6 kcal. per mole at 25°), then we may expect free rotation to be greatly diminished or even completely suppressed and the molecule to be stabilized in the configuration of least energy. This seems to be the case with the 1,4-*trans*-dihalogenated cyclohexanes studied by Hassel[12,13] which have zero moments in benzene. In this case, where the moment is given by the vector sum of the two dipoles associated with the halogens, the electrostatic energy depends in a complicated way on the orientation of the dipoles with reference to the line joining them and on the cube of the distance separating them. In the case of dipolar ions like the cyclohexane amino acids, the electrostatic energy term is simply $e^2/\epsilon r$, in which e is the elementary charge, r the distance between the centers of charge of the positively and negatively ionized groups and ϵ the effective dielectric constant. For a given value of ϵ, the electrostatic energy of a dipolar ion is larger than that of a molecule containing two dipoles separated by the same distance except for very small values of r (*e. g.*, always less than 1 Å. when the moments of the dipoles do not exceed 3.3 D). However, in the case of solutions in water or other highly polar media, in which dipolar ions have been studied, the effective dielectric constant is probably very much greater than in the case of solutions in benzene. If we take ϵ as 80, the value for water, the electrostatic energy for $r = 3$ Å. is close to -8×10^{-14} erg, and is equal to $-KT$ at $r = 6.2$ Å. It increases with r and gives rise to an attraction between the charged groups, which tend to approach one another until the effect is overbalanced by repulsive forces due to the interference and the interaction of these groups, *e. g.*, the NH_3 and COO^- groups in the case of the alicyclic amino acids. It is impracticable to attempt to estimate quantitatively the magnitude of the potentials due to the various factors, at least for the amino acids, but it may be recalled that heats of combustion give a value of about 20×10^{-14} erg for the potential energy due to the repulsion of two methyl groups separated by 2.9 Å., in nonpolar molecules.[14] There is this difference between the amino acids and the dihalogenated

cyclohexanes, that in the latter the electrostatic forces between the dipoles lead to a repulsion whenever the halogens are close together.

In Table II are listed the different values of the square of the distance between the plus and minus charges which occur in the three cyclohexane amino acid dipolar ions. Certain distances occur in more than one configuration, and the number of configurations in which each distance occurs is given in the columns headed "frequency." These distances are calculated on a purely geometrical basis, without regard to interaction or interference of the NH_3^+ and COO^- groups, on the basis of the following assumptions: that all the valence angles of the carbon atoms of the ring are the same as the tetrahedral angle; that the distance between these atoms is 1.52 Å.; that the locus of positive charge of the NH_3^+ group is at the center of the nitrogen atom; that the distance between this nitrogen atom and the associated carbon atom of the ring is 1.40 Å.; that the locus of negative charge of the COO^- group is midway between the two oxygen atoms and on the line of the valence bond between the carbon atom and the associated carbon atom of the ring at a distance of 2.14 Å. from the center of the latter. It seems clear from a consideration of these figures that there is no stabilization of the dipolar ions in the configuration of least energy, as appears to be the case in the 1,4-*trans*-dihalogenated cyclohexanes. If this were so, the dielectric increment, which is a measure of the electric moment, should not be less for the 1,2-form than for the other two forms, as is actually the case, since the charged groups certainly can approach quite as close (geometrically, closer) in the case of the 1,3- and 1,4-forms as in the case of the 1,2-form, and the mutual energy of the groups must depend only on their distance.

Notwithstanding the arbitrariness and artificiality of the procedure of neglecting the interaction of the groups, it is of interest to consider the average values of the squares of the distances listed in Table II, which are also included in the table. These may be compared with mean square values for the distances between the charges in straight chain amino acids also calculated on a purely geometrical basis, making use of the same assumptions about valence angles and so on, without regard to interference, by integrating over all the possible configurations. Such values have been calculated for the α,[15] β, γ, and δ acids, and are, respectively: 8.53, 13.12, 17.71, 21.96. They increase very nearly linearly with the number of

---

[15] In the case of an α acid, no averaging is required since the distance between the NH_3^+ and COO^- groups is fixed.

carbons between the amino and carboxyl groups, and the values 25.2 and 30.0 for the ϵ and ζ acids may be extrapolated with considerable assurance.[16] In Fig. 1 these values are plotted against the observed values of the dielectric increment. In the same figure are plotted the dielectric increments of the cyclohexane amino acids against the mean square distances (given in Table II) for both *cis* and *trans* forms. On the whole the two sets of data are consistent and suggest that free rotation occurs to the same degree in the cyclic compounds as in the straight chain forms. The identity of the increments of the 1,3- and 1,4-alicyclic acids suggests that the former occurs in what we have called the *trans*, the latter in what we have called the *cis*, form. It also appears that the 1,2-acid probably occurs in the *cis* form. The identity of the dielectric increments of the 1,3-α and -β preparations as well as of the 1,4-α and -β preparations suggests that these are not different. The differences of melting point between α and β preparations are probably not significant, and in any case represent a temperature range of decomposition rather than a true melting point, as in the case of amino acids generally.

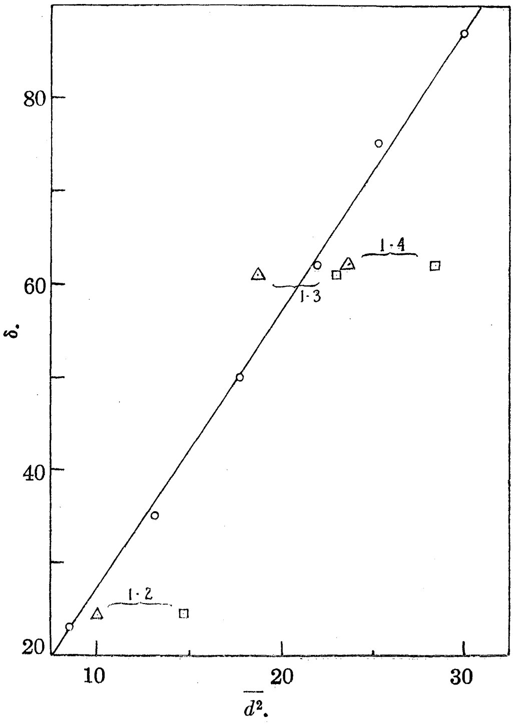

Fig. 1.—○, Aliphatic amino acids; △, *cis* alicyclic amino acids; ☐, *trans* alicyclic amino acids.

It should be emphasized that the procedure of correlating dielectric increments with the mean square distances calculated so arbitrarily on a geometrical basis was adopted solely as a basis for comparing the straight chain and alicyclic amino acids. The mean square values involved cannot be expected to be realized with any degree of exactness in either set of compounds. The smallest values of the distance between the NH_3^+ and COO^- groups involved in these averages are certainly too small to be physically possible, and the largest values are statistically improbable in view of the energy relations. Kuhn[5] by taking account of the coulomb forces in a statistical treatment of the case of straight chain amino acids has obtained much lower values for the mean square distances, *e. g.*, for an α-acid, 3.88; for a β-acid, 5.54; for a δ-acid 9.3; for a ζ-acid, 16.4. Nevertheless, we may expect that the effect of any interactions between the groups will be essentially the same and cause essentially the same deviations from the geometrically calculated mean square distances in both series of amino acids, and the argument for the same degree of free rotation in both types of amino acid is not seriously affected.

It is to be observed that the apparent specific volumes of the 1,3- and 1,4-acids, which have the same dielectric increments (moments) are equal and less than that of the 1,2-isomer, indicating a greater electrostriction associated with a greater moment. The relatively small differences of volume between the α- and β-preparations are probably not significant, and may well be due to slight differences of water content. It also is to be noted that the acidity constants (pK_1 and pK_2) are both very nearly the same and much like those of a δ-aliphatic amino acid ($pK_1 = 4.21$, $pK_2 = 10.69$), which has a dielectric increment of 63, about the same as that of the 1,3- and 1,4-alicyclic acids. The dissociation constants of the 1,2-acid are between those of α- and β-straight chain amino acids. This bears out the view that the effect of one charged substituent on another depends on the mean square distance between them.

Summary

A comparison of the dielectric increments of 1,2-, 1,3- and 1,4-aminocyclohexane-carboxylic acids with those of aliphatic amino acids in

---

[16] An attempt to correlate the effect of one substituent on another in aliphatic acids from the values of the square of the distance between them, and based on a completely extended configuration, yielded an approximately linear relation—Greenstein, THIS JOURNAL, 58, 1314 (1936).

aqueous solution leads to the view that there is free rotation to much the same degree in both series of compounds. The correlation between dielectric increments, apparent molal volumes and acidity constants is pointed out for these alicyclic amino acids.

Recombination of Hydrogen Atoms. III

BY I. AMDUR

It is generally conceded that the combination of hydrogen atoms to form molecules proceeds according to a trimolecular mechanism. The presence and extent of first or second order wall reactions, as well as the efficiencies of hydrogen atoms and hydrogen molecules as third bodies, have been the subject of much controversy and speculation. Agreement among various investigators is definitely lacking. Smallwood,[1] for example, contends that it is possible to eliminate any wall reaction and that the essential recombination mechanism involves only triple collisions of hydrogen atoms, whereas Steiner[2] finally concludes that there is a small first order wall reaction, but that hydrogen molecules are the most efficient third bodies. In contradiction to this, Amdur[3] found that the assumption of a homogeneous reaction involving only triple collisions of hydrogen atoms was adequate to account for the experimental data for the relative rate of recombination of atomic hydrogen and atomic deuterium over a narrow range of composition and pressure. And yet, some time previously, Smallwood[4] and Amdur and Robinson[5] had decided that for any extended range of variables it was necessary to include a wall reaction as well as both types of triple collisions. In all the cases cited the investigators used high concentrations of atomic hydrogen (95 to 10%) produced in a discharge tube at total pressures of the order of 1 mm. Other experimenters[6] working at total pressures of the order of 10 mm. with small concentrations of atomic hydrogen (less than 1%) produced by photosensitization of mercury saturated hydrogen, report results as varied as those noted above.

In the opinion of the author, there are several reasons for these discrepancies even after one has taken into account the widely different experimental methods and range of variables. One reason is a tendency, in the treatment of experimental data, to oversimplify the formal rate equation containing the desired velocity constants. To include the proper diffusion terms in the equation involved for the recombination of hydrogen atoms in a dynamic system, for example, involves much laborious calculation and necessitates data of considerable accuracy and consistency. However, the omission of these diffusion terms, whose magnitude is small, is capable of effecting tremendous variations in the rate constants or even of yielding negative values when the constants are simultaneously solved for. The same situation results from the use of values for the fraction or partial pressure of atomic hydrogen which are of low accuracy. Finally, if the range of data is not sufficiently wide, a mechanism may be sponsored which may be quite inadequate to account for experimental results over a larger range of variables. In this connection it should be noted that several mechanisms may fit the experimental data equally well. This point has been overlooked, in some cases, possibly, due to personal prejudice regarding the correct mechanism to be assumed for the reaction.

It is the purpose of this paper to avoid, as much as possible, any arbitrary decisions by treating objectively a very large number of experimental points covering the widest possible range of composition and pressure attainable with the present experimental method. This objective treatment consists, first, of least squaring all the data to fit a family of curves for the various pumping speeds and using least square methods to calculate rate constants taking all experimental points into account; second, of rigorously deriving the rate expressions, taking into account all factors involved

in a dynamic system as well as all possible mechanisms of recombination, and, finally, of using the calculated rate constants to obtain *calculated* values to compare with the *measured* fraction of atomic hydrogen. Any decision as to mechanism will be based on the agreement between these calculated and measured values.

Experimental

Apparatus.—The essential parts of the apparatus are shown in Fig. 1. Molecular hydrogen from an H-shaped electrolytic generator was expanded through the capillary A into the Wood discharge tube B where the atomic hydrogen was produced by a glow discharge. Mixtures of molecular and atomic hydrogen were pumped along the recombination tube C by means of two parallel four-jet mercury pumps backed by a Langmuir diffusion pump and a Hypervac oil pump. The fraction of atomic hydrogen at any point along the recombination tube was computed from the amount of energy liberated on a catalyst-calorimeter D by the recombination of the atoms. This calorimeter consisted of two concentric platinum tubes $1^3/_4''$ (4.44 cm.) long with diameters 0.312″ (7.92 mm.) and 0.219″ (5.56 mm.). A platinum ring was gold soldered in one end, producing a double-walled tube having an annular space of 0.046″ (1.17 mm.). A copper tube $1^1/_2''$ (3.81 cm.) long with diameter and wall thickness to permit a snug fit into the annulus between the platinum tubes was then wound with approximately 20 inches (50.8 cm.) of 0.002″ (0.05 mm.) pure platinum wire which served as a resistance thermometer and heater. Insulation was effected by cutting a double thread into the outside wall of the copper tube and baking a thin layer of enamel glaze into the threads, after which the resistance wire was wound in these grooves and made fast by a top coating of baked enamel. The unit was then inserted into the platinum sheath and the leads led out from the top through small platinum tubes. Lead glass was melted into the top opening of the annulus securing and insulating the platinum tubes. To render the calorimeter less liable to damage, the fine platinum leads were gold soldered to the platinum tubes encasing them, and all electrical connections were made to these tubes. In the recombination tube, the calorimeter was supported by a thin, flexible, four-wire rubber-covered cable connected to the windlass E which permitted movement of the calorimeter in vacuum. The drum of the windlass was calibrated to permit determination of the calorimeter position in the recombination tube by means of a dial attached to the ground joint of the windlass. That greater accuracy might be obtained in estimating the energy liberated on the calorimeter, the recombination tube was surrounded by an oil thermostat at 30.000 ± 0.005°. The McLeod gage arrangement shown in the diagram permitted a simultaneous reading of the pressure at four points along the recombination tube when a steady state had been reached with respect to the calorimeter.

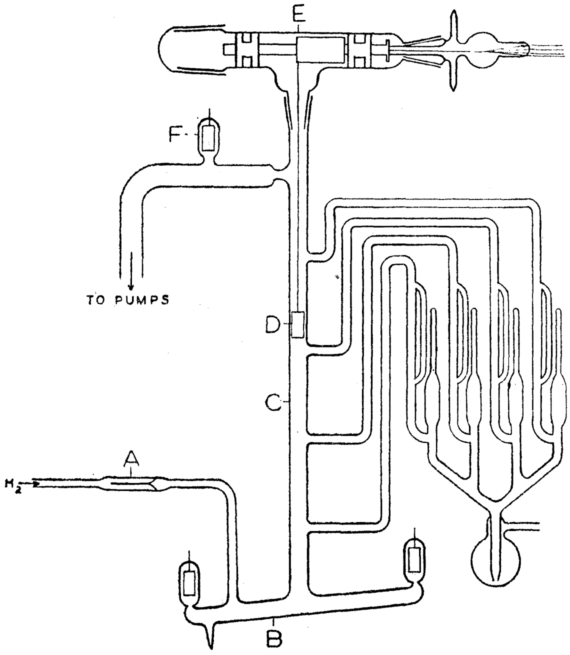

Fig. 1.

Procedure.—All glass parts of the apparatus through which atomic hydrogen flowed were cleaned carefully with cleaning solution and aqua regia, rinsed repeatedly with distilled water and pumped dry. The walls of the recombination and discharge tubes were then coated with sirupy phosphoric acid to minimize wall reaction and the system evacuated until the vapor pressure of water was less than 0.001 mm. The catalyst was then raised and hydrogen pumped through the system to permit a clean-up of the recombination tube by means of the third electrode F. After this treatment, the catalyst was lowered to the bottom of the recombination tube and the discharge turned on and maintained until the catalyst-calorimeter had reached a steady state temperature, as shown by the resistance of the internal platinum wire. The mercury in the McLeod gages was then permitted to rise from a position just below the shutoffs to the height necessary for reading the pressures. The discharge was then shut off, and the proper heating current passed through the catalyst-calorimeter to produce the same resistance change as that previously caused by the recombination of the atoms. From the known current and resistance at this second steady state the energy input to the catalyst-calorimeter was obtained, and since all conditions, with the exception of the presence of hydrogen atoms, were the same in the second part of the run as in the first, this energy input was equal to the energy per second previously produced by the recombination of the atoms. In view of the fact that the heat of dissociation of molecular hydrogen was known (102,800 calories per mole), it was merely necessary to know the number of moles of molecular hydrogen flowing through the apparatus per second in order to determine the fraction of atomic hydrogen. This was obtained directly from the electrolytic current required to produce hydrogen at the same rate at which it was being withdrawn by pumping as shown by equal heights of the electrolytic liquid (30% potassium hydroxide containing a small amount of barium hydroxide) in the limbs of the H-shaped generator. For a given position of the catalyst-calorimeter runs were made at seven different pumping speeds by using different combinations of diffusion pumps and by pumping with the Hypervac through 2-cm. tubing as well as through capillary by-passes. Runs were made in this manner for all pumping speeds at 10-cm. intervals along the recombination tube.

All electrical quantities were measured with a Type K potentiometer using precision standard resistances to determine currents. The McLeod gages were read with a cathetometer. It was possible to return the catalyst to a given position and check within 0.5% a previous determination made several weeks earlier under the same conditions of flow and pumping speed.

Preliminary Treatment of Data.—Since there were but four pressure taps along the recombination tube, there were a great many positions of the catalyst-calorimeter between any two of these taps for which the appropriate pressures were obtained by interpolation. To secure these interpolated values, for a given pumping speed, the drop in pressure, $\Delta P_{\text{a-b}}$, between taps a and b was determined for all runs in which the calorimeter was at tap b or above, and, similarly, the pressure drop, $\Delta P_{\text{b-c}}$, between taps b and c was obtained in all runs where the catalyst was at or above tap c. This was repeated for all pumping speeds. It was found that for all pump combinations, except the first two at low pressures, the pressure distribution along the recombination tube was a linear function of distance. Deviations from linearity were less than 0.5%, the approximate error in the measurement of pressures at the taps. In the case of pump combinations I and II, $\Delta P_{\text{c-c}}$ was greater than $\Delta P_{\text{a-b}}$ by 0.009 and 0.008 mm., respectively. For these combinations, it was assumed that $\Delta P_{\text{c-d}}$ exceeded $\Delta P_{\text{b-c}}$ by like amounts. Since the distance between taps was known, it was possible to obtain $\Delta P/\Delta x$ values for all pump combinations and, in the case of combinations I and II, for different positions along the recombination tube. Using these $\Delta P/\Delta x$ values the pressure existing at the calorimeter when it was *between* any two taps was found by interpolation. Examination of the pressure data showed that the pressure distribution below the calorimeter was independent of the position of the calorimeter in the recombination tube. For this reason it is felt that the accuracy of the interpolated pressures is not less than that of the pressures recorded at the four taps.

The values of the pressure, P, thus obtained were valid only for the particular rate of flow of molecular hydrogen (as recorded by the ammeter of the electrolytic circuit) existing during the particular run. In order to simplify treatment of the data, all pressures were corrected to a single average rate of flow. If I is the electrolytic current giving the number of moles of hydrogen flowing per second in a given run, and I', the corresponding current for the desired average rate of flow, $(I' - I)/I'$ is the fractional deviation of the actual rate of flow from the mean. The nature of the ΔP values showed that there was viscous or Poiseuille flow in the recombination tube. The end of the recombination tube near the pumps being at essentially zero pressure, the pressure in the section of the tube containing the pressure taps should vary as the square root of the number of moles of hydrogen flowing per second, or the fractional pressure change should be $^1/_2(I' - I)/I'$. In this manner all pressures were corrected to a single rate of flow. To obtain new α values consistent with the new P values, a curve of α against P for each pumping speed was drawn from the original data. Values of $\mathrm{d}\alpha/\mathrm{d}P$ were obtained graphically from these curves. The correction applied to α, therefore, was $\mathrm{d}\alpha/\mathrm{d}P\delta P$ where δP was the correction to the original pressure. On the average, δP was about 1% of the original pressure, and $\delta\alpha$, about 1% of the original α value.

As measurements of α were made at a single calorimeter position for all pumping combinations before proceeding to a new position, it was necessary to take into account possible changes in pumping speed with time. In some cases, for example, some α determinations with the same pump combination were made two months apart. Inasmuch as it had been ascertained that the ΔP values between taps for all the pump combinations did not vary with time, the correction of pressures to constant pumping speed for each pump combination was simply made by passing a curve with the proper slope through the P values (corrected to a single rate of flow) existing at the catalyst. In the case of pump combinations I and II this meant graphically fitting the P values (at the corresponding values of x) to a curve whose first and second derivatives were fixed. For all other combinations a single $\Delta P/\Delta x$ value for the entire length of the recombination tube was used, corresponding to a constant first derivative. After making the proper constant pumping speed corrections to the pressure, it was again necessary to calculate the corresponding corrections to α. These were determined as explained in connection

TABLE I

with the reduction to a single rate of flow. The constant pumping speed pressure corrections averaged slightly over 1% showing that the pumps retained their speed characteristics remarkably well. The corresponding average change in α was less than 1%.

The application of the above-mentioned corrections for each of the seven pump combinations yielded a set of α, x and P values applicable to a single rate of flow and constant pumping speed. It should be emphasized that the *average total correction to the original data was only about 2%* and in only three runs out of 83 did the total correction reach 5%. Since the individual corrections were known to at least 5%, the final values of α and P, in addition to being self-consistent, are as accurate as the original measured values.

Results

Analytical Representation of Data.—The experimental results, corrected to constant rate of flow and constant pumping speed, are given in Table I. The Roman numerals represent pump combinations; x, the distance in cm. from the bottom of the calorimeter to the discharge tube; P, the pressure in mm. existing at x, and α, the fraction of atomic hydrogen. All measurements were taken at 30.000 ± 0.005°.

In order to use all the experimental data in solving for reaction velocity constants it is necessary to have extremely self-consistent values for $d\alpha/dx$ as a function of x. To obtain these, the x, α values of Table I were fitted to an empirical family of seven curves by the method of least squares. An examination of the α values of Table I shows several slightly erratic variations. Since all values were reproducible, such variations were probably due to slight gradual changes in the catalytic activity of the recombination tube. The effect of fitting the data to a family of curves is to smooth out such fluctuations in the same manner for all pump combinations.

As a result of many attempts, the type equation best representing all x, α values was found to be

$$x = a(-\log_{10} \alpha) + b(-\log_{10}\alpha)^c \qquad (1)$$

Although much calculation is involved, it is possible to solve for a, b and c in equation (1) using the method of least squares. The process involves successive approximations and can be used to calculate a, b and c to any desired accuracy. Table II summarizes the results of Table I in terms of the values of a, b and c necessary to represent the α and x values for each pump combination. The percentage deviation column gives the magnitude of the average absolute percentage deviation of the α values as given by equation (1) from the experimental values of Table I. Since equation (1) is not explicit in α, calculated α-values were obtained from the curves which resulted from plotting x's calculated from given α's using equation (1). Figure 2 shows how the points of Table I scatter with respect to the smooth curves derived from the constants of Table II.

TABLE II

ANALYTICAL REPRESENTATION OF EXPERIMENTAL α,x VALUES

	a	b	c	Deviation, %
I	226.2851	78.6940 × 10^5	11.67250	3.0
II	175.1821	201.1848 × 10^2	7.40127	2.5
III	112.3282	434.3611	9.61006	3.9
IV	81.1155	69.4310	5.78891	3.1
V	79.3988	62.1211	8.73140	5.1
VI	63.1952	21.6183	6.28395	2.9
VII	49.3034	8.1251	6.46043	2.7

The variation of pressure with distance for each pump combination was also expressed in analytical form by quadratic equations for pump combinations I and II and by linear equations for all other pump combinations. The general equation in this case is

$$P = P_0 - Ax - Bx^2 \qquad (2)$$

where P_0 is the pressure at the discharge tube and where B is zero for all pump combinations except I and II. Table III summarizes the representation of pressure as a function of distance. The values of P_0, A and B are such as to give the pressure, P, in dynes/sq. cm.

TABLE III

ANALYTICAL REPRESENTATION OF EXPERIMENTAL P,x VALUES

	P_0	A	B
I	639.9	1.492	0.00802
II	688.0	1.396	.00702
III	860.6	1.332	.0
IV	977.8	1.221	.0
V	1020.7	1.066	.0
VI	1170.8	0.932	.0
VII	1412.1	.628	.0

The maximum deviation of P values calculated from equation (2) using the above constants, from the experimental values of Table I is less than 0.5%.

Derivation of Rate Expressions.—In order to derive rigorous rate expressions applicable to a dynamic system, it is necessary to take into account loss of atoms (a) by both heterogeneous and homogeneous recombination, (b) by the streaming of gas along the recombination tube and (c) by diffusion resulting from concentration gradients.

If it is assumed that recombination at the wall may result from collision of atoms in the gas phase with atoms adsorbed on the wall and also from the collision of two atoms from the gas phase at the wall, the rate of removal of atoms by recombination at a point x along the recombination tube is

$$-\left(\frac{\mathrm{d}\,[\mathrm{H}]}{\mathrm{d}t}\right)_{x(\mathrm{a})} = k_1[\mathrm{H}] + k_2[\mathrm{H}]^2 + k_3[\mathrm{H}]^2[\mathrm{H}_2] + k_4[\mathrm{H}]^3 \qquad (3)$$

where k_1 and k_2 are the wall reaction rate constants, k_3, the rate constant for the recombination of hydrogen atoms by triple collisions with molecules and k_4, the corresponding rate constant for the case of hydrogen atoms as third bodies. [H] and [H_2] are the concentrations of atoms and molecules in moles per cc.

The removal of atoms by the streaming of gas is given by the equation of continuity

$$-\left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}t}\right)_{x(\mathrm{b})} = \frac{\mathrm{d}(V_x[\mathrm{H}])}{\mathrm{d}x} \qquad (4)$$

where V_x is the linear velocity of the gas stream in centimeters per second at x. For a rigorous derivation it is necessary to take account of the fact that V_x is affected by diffusion which, in addition to the pumps, causes a transport of mass along the recombination tube. The considerations are as follows.

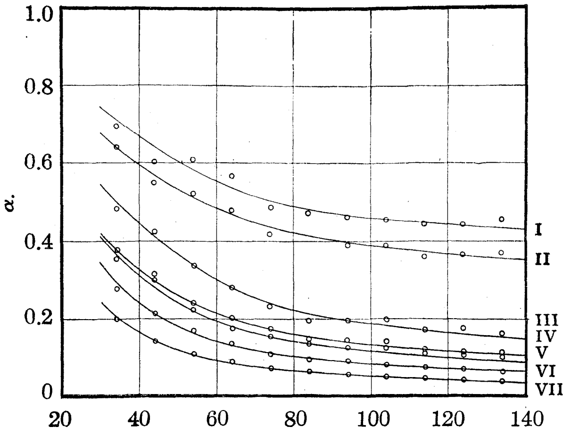

Fig. 2.

The mass of gas per cm.^{2} transferred per second by flow is

$$V_x\rho = V_x(M[\mathrm{H}] + 2M[\mathrm{H}_2]) \qquad (5)$$

where ρ is the density of the gas mixture and M the atomic weight of hydrogen. The mass of gas per cm.^{2} transferred per second by diffusion is

$$-D_{12}\frac{\mathrm{d}\rho}{\mathrm{d}x} = -D_{12}\left(M\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}x} + 2M\frac{\mathrm{d}[\mathrm{H}_2]}{\mathrm{d}x}\right) \qquad (6)$$

where D_{12} is the diffusion coefficient for the mixture of atoms and molecules at the conditions existing at x. Since the mass of gas per cm.^{2} admitted per second to the apparatus is $2Mn_0/\pi r^2$

$$V_x(M[\mathrm{H}] + 2M[\mathrm{H}_2]) - D_{12}\left(M\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}x} + 2M\frac{\mathrm{d}[\mathrm{H}_2]}{\mathrm{d}x}\right) = \frac{2Mn_0}{\pi r^2} \qquad (7)$$

so that

$$V_x = \frac{2n_0/\pi r^2 + D_{12}\left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}x} + 2\frac{\mathrm{d}[\mathrm{H}_2]}{\mathrm{d}x}\right)}{([\mathrm{H}] + 2[\mathrm{H}_2])} \qquad (8)$$

Equation (4) thus becomes

$$-\left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}t}\right)_{x(\mathrm{b})} = \frac{\mathrm{d}}{\mathrm{d}x}\left\{\frac{\frac{2n_0}{\pi r_2} + D_{12}\left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}x} + 2\frac{\mathrm{d}[\mathrm{H}_2]}{\mathrm{d}x}\right)}{([\mathrm{H}] + 2[\mathrm{H}_2])}[\mathrm{H}]\right\} \qquad (9)$$

In addition to diffusion of atoms and molecules altering the linear velocity, atoms are removed from the point x by diffusion according to the equation

$$-\left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}t}\right)_{x(\mathrm{c})} = -D_{12}\ \mathrm{div.\ grad.}\ [\mathrm{H}] \qquad (10)$$

Since the construction of the calorimeter was such as to give the average value of α across the cross section of the recombination tube at x, the concentration of atomic hydrogen at x in a plane perpendicular to the axis of the recombination tube may be considered constant. Equation (10), therefore, reduces to

$$-\left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}t}\right)_{x(\mathrm{c})} = -D_{12}\frac{\mathrm{d}^2[\mathrm{H}]}{\mathrm{d}x^2} \qquad (11)$$

At the steady state

$$\left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}t}\right)_{x(\mathrm{a})} + \left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}t}\right)_{x(\mathrm{b})} + \left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}t}\right)_{x(\mathrm{c})} = \left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}t}\right)_{x} = 0$$

so that the rigorous general rate expression obtained by adding equations (3), (9) and (11) is

$$D_{12}\frac{\mathrm{d}^2[\mathrm{H}]}{\mathrm{d}x^2} - \frac{\mathrm{d}}{\mathrm{d}x}\left\{\frac{2n_0/\pi r^2 + D_{12}\left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}x} + 2\frac{\mathrm{d}[\mathrm{H}_2]}{\mathrm{d}x}\right)}{([\mathrm{H}] + 2[\mathrm{H}_2])}[\mathrm{H}]\right\} - k_1[\mathrm{H}] - k_2[\mathrm{H}]^2 - k_3[\mathrm{H}]^2[\mathrm{H}_2] - k_4[\mathrm{H}]^3 = 0 \qquad (12)$$

There are numerous special cases which are of interest in connection with equation (12). For example, if the wall reaction is assumed to be second order $k_1 = 0$, while if it is assumed to be first order $k_2 = 0$. In the present case, all such mechanisms which include a third order rate constant (k_3, k_4) will be considered and appropriate rate constants calculated. Decisions regarding the suitability of any mechanism will depend upon how well such rate constants reproduce the α-values calculated with the constants of Table II.

Evaluation of Rate Constants.—Before solving for combinations of k_1, k_2, k_3 and k_4, it is necessary to express the various terms as functions of the measured variables α, x and P and the calculated derivatives $\mathrm{d}\alpha/\mathrm{d}x$, $\mathrm{d}^2\alpha/\mathrm{d}x^2$, $\mathrm{d}P/\mathrm{d}x$, $\mathrm{d}^2P/\mathrm{d}x^2$. From considerations involving viscosity data it was found[7] that the diffusion coefficient for mixtures of atomic and molecular hydrogen could be represented by the relation

$$D_{12} = \frac{374.9T^{3/2}(1.0364 - 0.0303\,\alpha)}{P(1 + 31.9/T)} \qquad (13)$$

Starting with

$$[\mathrm{H}] = \frac{P}{RT}\frac{2\alpha}{1 + \alpha} \qquad (14)$$

and considering both α and P functions of x, the first and second derivatives of [H] are found to be

$$\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}x} = \frac{2}{RT}\frac{P}{(1 + \alpha)^2}\frac{\mathrm{d}\alpha}{\mathrm{d}x} + \frac{2}{RT}\frac{\alpha}{1 + \alpha}\frac{\mathrm{d}P}{\mathrm{d}x} \qquad (15)$$

and

$$\frac{\mathrm{d}^2[\mathrm{H}]}{\mathrm{d}x^2} = \frac{2}{RT(1 + \alpha)}\left[\frac{2}{(1 + \alpha)}\frac{\mathrm{d}\alpha}{\mathrm{d}x}\frac{\mathrm{d}P}{\mathrm{d}x} - \frac{2P}{(1 + \alpha)^2}\left(\frac{\mathrm{d}\alpha}{\mathrm{d}x}\right)^2 + \frac{P}{(1 + \alpha)}\frac{\mathrm{d}^2\alpha}{\mathrm{d}x^2} + \alpha\frac{\mathrm{d}^2P}{\mathrm{d}x^2}\right] \qquad (16)$$

Since

$$[\mathrm{H}_2] = \frac{P}{RT}\frac{1 - \alpha}{1 + \alpha} \qquad (17)$$

the total concentration of atoms and molecules is

$$[\mathrm{H}] + [\mathrm{H}_2] = P/RT \qquad (18)$$

from which it follows that

$$\frac{\mathrm{d}[\mathrm{H}_2]}{\mathrm{d}x} = \frac{1}{RT}\frac{\mathrm{d}P}{\mathrm{d}x} - \frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}x} \qquad (19)$$

By using the above relations the following identity is obtained

$$\frac{\mathrm{d}}{\mathrm{d}x}\left\{\frac{2n_0/\pi r^2 + D_{12}\left(\frac{\mathrm{d}[\mathrm{H}]}{\mathrm{d}x} + 2\frac{\mathrm{d}[\mathrm{H}_2]}{\mathrm{d}x}\right)}{([\mathrm{H}] + 2[\mathrm{H}_2])}[\mathrm{H}]\right\} = \frac{2n_0}{\pi r^2}\frac{\mathrm{d}\alpha}{\mathrm{d}x} + \frac{2}{RT(1 + \alpha)}\frac{374.9T^{3/2}(1.0364 - 0.0303\,\alpha)}{P(1 + 31.9/T)}\left[\frac{1}{1 + \alpha}\frac{\mathrm{d}\alpha}{\mathrm{d}x}\frac{\mathrm{d}P}{\mathrm{d}x} - \frac{(1 - \alpha)P}{(1 + \alpha)^2}\left(\frac{\mathrm{d}\alpha}{\mathrm{d}x}\right)^2 + \alpha\frac{\mathrm{d}^2P}{\mathrm{d}x^2} - \frac{\alpha}{P}\left(\frac{\mathrm{d}P}{\mathrm{d}x}\right)^2 - \frac{\alpha}{1 + \alpha}\frac{P\mathrm{d}^2\alpha}{\mathrm{d}x^2}\right] \qquad (20)$$

The remaining terms of the rate equations are obtained directly from equations (14) and (17).

The substitution of numerical values into the rate expressions was carried out in the following manner. At each pump combination a series of α-values at increments of 0.025 were taken, starting near the highest measured value and ending near the lowest measured value. The corresponding x's were then calculated from equation (1) using the appropriate constants from Table II, and the desired values of P computed from equation (2) using Table III. General expressions for $\mathrm{d}\alpha/\mathrm{d}x$ and $\mathrm{d}^2\alpha/\mathrm{d}x^2$ were obtained by direct differentiation of equation (1) resulting in

$$\frac{\mathrm{d}\alpha}{\mathrm{d}x} = {\frac{2.3026\,\alpha}{-a - bc\,(-\log_{10}\alpha)}}^{c-1} \qquad (21)$$

and

$$\frac{\mathrm{d}^2\alpha}{\mathrm{d}x^2} = \frac{1}{\alpha}\left(\frac{\mathrm{d}\alpha}{\mathrm{d}x}\right)^2\left[1 - \frac{1}{\alpha}\frac{bc\,(c - 1)(-\log_{10}\alpha)^{c-2}}{2.3026}\frac{\mathrm{d}\alpha}{\mathrm{d}x}\right] \qquad (22)$$

The required numerical values for these derivatives were obtained by using the constants of Table II. In like manner $\mathrm{d}P/\mathrm{d}x$ and $\mathrm{d}^2P/\mathrm{d}x^2$ values were obtained by differentiation of equation (2) and the use of Table III.

---

(7) Amdur, *J. Chem. Phys.*, **4**, 339 (1936).

After substitution of numerical values it is possible to solve simultaneously for all the reaction velocity constants in any one rate equation.[8] In the present case, using the method of least squares, all experimental data (represented by 83 measured α-values) were used to solve for the reaction velocity constants in each rate equation. This corresponded to the use of 71 rounded α-values in solving for each set of constants. The results of these solutions are summarized in Table IV, where the rate constants are in the following units: k_1, sec.$^{-1}$; k_2, cc.^{1} mole^{-1} sec.$^{-1}$; k_3 and k_4, cc.^{2} mole^{-2} sec.$^{-1}$. The nature of the mechanism is deduced from the constants regarded as having zero value.

TABLE IV

REACTION VELOCITY CONSTANTS FOR POSTULATED MECHANISMS

Mechanism	k_1	$k_2 \times 10^{-8}$	$k_3 \times 10^{-16}$	$k_4 \times 10^{-16}$
A	0.69	2.33	1.00	1.70
B	0	3.234	1.004	1.419
C	1.956	0	1.038	2.578
D	0	0	1.212	3.063
E	0	6.028	0	0.745
F	0	5.810	0.925	0
G	4.231	0	0	2.770
H	8.425	0	1.233	0
I	0	0	0	4.160
J	0	0	3.634	0

The method of calculating α-values using the above constants can be illustrated by considering a specific mechanism, A. Using the numerical values of the constants for each of the 71 rounded experimental points (7 pump combinations) the quantities $k_1[\mathrm{H}]$, $k_2[\mathrm{H}]^2$, $k_3[\mathrm{H}]^2[\mathrm{H}_2]$ and $k_4[\mathrm{H}]^3$ are evaluated. From the sum of these terms the quantity $D_{12}\dfrac{\mathrm{d}^2[\mathrm{H}]}{\mathrm{d}x^2}$ is subtracted leaving a numerical quantity Z, where

$$Z = -\frac{2n_0}{\pi r^2}\frac{\mathrm{d}\alpha}{\mathrm{d}x} - \Phi$$

Φ is identified from equations (12) and (20) as

$$\frac{2}{RT(1+\alpha)}\,\frac{374.9T^{3/2}\,(1.0364 - 0.0303\,\alpha)}{(1 + 31.9/T)}\left[\frac{1}{1+\alpha}\frac{\mathrm{d}\alpha}{\mathrm{d}x}\frac{\mathrm{d}P}{\mathrm{d}x} - \frac{(1-\alpha)P}{(1+\alpha)^2}\left(\frac{\mathrm{d}\alpha}{\mathrm{d}x}\right)^2 + \alpha\frac{\mathrm{d}^2P}{\mathrm{d}x^2} - \frac{\alpha}{P}\left(\frac{\mathrm{d}P}{\mathrm{d}x}\right)^2 - \frac{\alpha}{1+\alpha}\frac{P\mathrm{d}^2\alpha}{\mathrm{d}x^2}\right]$$

If the appropriate Φ values are now added to each of the 71 Z values and the resulting sums $(Z + \Phi)$ multiplied by $-\pi r^2/2n_0$, the result is 71 calculated $\mathrm{d}\alpha/\mathrm{d}x$ points. A number of $\mathrm{d}\alpha/\mathrm{d}x$ points are derived from smoothed experimental points using equation (21) and plots made of $\alpha_{\text{exptl.}}$ *vs* $\mathrm{d}\alpha/\mathrm{d}x_{\text{exptl.}}$ for each pump combination. From these plots the 71 α's corresponding to the 71 calculated $\mathrm{d}\alpha/\mathrm{d}x$'s are read.

The results of the above procedure for the ten mechanisms of Table IV are summarized in Table V for all pump combinations. The numbers are the average absolute percentage deviations of the α's calculated from numerical rate constants from the corresponding smoothed experimental points. For all mechanisms, the individual deviations in each pump combination scattered well between positive and negative values.

TABLE V

PERCENTAGE DEVIATION OF α-VALUES

Mechanism	I	II	III	IV	V	VI	VII
A	3.2	3.4	6.2	3.2	5.9	4.0	5.6
B	3.2	3.4	6.2	3.2	5.9	4.0	5.6
C	3.2	3.4	7.1	3.6	6.7	5.2	7.2
D	3.6	2.6	8.6	3.6	7.2	4.6	5.6
E	10.3	9.6	6.8	4.4	8.9	8.0	12.0
F	3.2	4.6	5.5	5.2	6.3	4.6	8.0
G	9.8	9.4	8.0	5.2	8.9	9.2	13.6
H	7.3	9.4	13.2	13.2	12.2	15.4	21.6
I	8.2	8.0	12.9	9.6	11.8	15.4	24.8
J	16.4	17.6	21.5	10.8	8.4	21.4	46.3

Discussion

In interpreting Table V it should be noted that the average experimental value of α for pump combination VII is almost five times smaller than that for pump combination I, so that equal percentage deviations correspond to different actual deviations. This is apparent from the curves of Fig. 2. Thus a 1% average absolute deviation is equivalent to the following changes in the rounded α-values:

I	II	III	IV	V	VI	VII
0.0056	0.0050	0.0032	0.0025	0.0024	0.0018	0.0012

An inspection of Table V reveals that five of the mechanisms (E, G, H, I and J) fail to reproduce the experimental data over the entire range. Thus recombination does not take place homogeneously as the result of triple collisions involving only atoms (mechanism I) as suggested by Smallwood,[1] nor as the result of triple collisions involving only molecules as third bodies (mechanism J). The proposal of Steiner[2] that

---

(8) In the case of equation (12) it was found that the smoothed experimental data and derivatives lacked the necessary self-consistency to permit simultaneous solution for k_1, k_2, k_3 and k_4. A change of but 0.05% in the constant terms of the final least square equations was sufficient to produce four positive constants instead of the usual three positive and one negative. The values given in Table IV for this particular mechanism, therefore, were obtained by trial and error substitution in the four final least square simultaneous equations and reproduce these equations to better than 0.2%.

recombination occurs as the result of a first order wall reaction and a homogeneous reaction involving only molecules as third bodies (mechanism H) is ruled out. Similarly, the assumption of a first order wall reaction with a three atom homogeneous reaction (mechanism G) or a second order wall reaction with a three atom homogeneous reaction (mechanism E) fails to provide the proper mechanism.

The other five mechanisms (A, B, C, D and F) show percentage deviations not much larger than those of the experimental and analytically smoothed α's (Table II), and are therefore all regarded as possible mechanisms. On the basis of the deviations in Table V, it is not possible to advocate one of these mechanisms in preference to the others. Thus the elimination of a first order wall reaction (mechanism B) produces α-values which are identical with those derived assuming both types of heterogeneous and homogeneous reaction (mechanism A). The elimination of a second order wall reaction (mechanism C) or the assumption of completely homogeneous reaction involving both types of third bodies (mechanism D) also reproduces the data almost as well as the other postulated mechanisms. Only one of the five mechanisms (mechanism F) does not require both atoms and molecules as third bodies. Although there is no reason to exclude the possibility of a mechanism involving a second order wall reaction and only molecules as third bodies, it should be pointed out that the difference in k_3 values for mechanisms D and F is but 31% so that the second order wall reaction of mechanism F is numerically equivalent, within a factor of 1.31, to the three atom homogeneous reaction of mechanism D.

A final decision as to which of the five mechanisms is correct can be made only when independent evidence eliminates four of the mechanisms as being incorrect. For example, if it could be shown experimentally that there is no wall reaction, mechanism D would be the correct solution; or if it could be shown that the wall reaction must be *only* first order, mechanism C would be correct. Independent accurate evaluations of k_4 might also be used as a means of choosing the one correct mechanism.

The author wishes to emphasize that the correct mechanism in all probability will not be some average mechanism derived from mechanisms A, B, C, D and F but a specific one of these five with the numerical rate constants as given in Table IV.

Objection has been raised to the present experimental method on the basis that the sudden recombination of atoms at the catalyst causes diffusion of atoms toward the catalyst and consequent high values of α. In order to determine the magnitude of this effect accurately, it is necessary to integrate equation (12). Since this cannot be done readily it is only possible to present evidence showing that the effect is negligible.

The diffusion produced by the catalyst is equivalent to increasing suddenly the linear velocity of the gas stream and thus shortening the time of recombination. This acceleration is greatest at the catalyst and dies off very rapidly for high linear velocities. The disturbance produced by the catalyst will be most marked when the catalyst is near the discharge for two reasons. First, the high concentration of atomic hydrogen will result in a greater diffusion when the concentration is suddenly reduced to zero at the catalyst. Second, the rate of recombination near the discharge tube is very rapid (as shown by the curves of Fig. 2) so that a given effective increase in velocity results in less recombination than that resulting from the same increase in velocity occurring far up in the recombination tube. Catalyst measurements such as those made in pump combinations IV, V, VI and VII at α-values from 0.125 to 0.05 should, therefore, be correct to a high degree of accuracy with respect to disturbance produced by the catalyst. If, now, the catalyst measurements at higher values of α produced high numerical results, rate constants calculated using all α-values should be smaller than those obtained from only low α-values. Consequently, rate constants which reproduced high values of α measured near the discharge tube should fail to reproduce low values of α measured far up in the recombination tube. That this is not the case is observed from the percentage deviation of the α-values in Table II for the possible mechanisms A, B, C, D and F. Pump combinations I, II and III contain many high values of α as compared with combinations IV, V, VI and VII where low α-values predominate. Actually, an examination of the individual percentage deviations from which the averages of Table V were computed shows that for very low values of α at high values of x, the α's computed from rate constants are slightly *higher* than the experimental values instead of lower. In fact, it is these wrong direction deviations which cause the average absolute percentage deviations of Table V for the five possible mechanisms to be slightly greater than the smoothing deviations of Table II.

Summary

Using a dynamic system, the fraction of atomic hydrogen has been measured as a function of distance along the recombination tube for seven pumping speeds at pressures ranging from 0.276 to 1.044 mm. The measured fraction of atomic hydrogen varied from 0.0410 to 0.693.

The experimental data have been fitted to a family of empirical curves by the method of least squares. The resulting smoothed variables as well as calculated derivatives have been used to solve for rate constants in rigorous equations applicable to a dynamic system.

Ten mechanisms involving recombination by triple collisions have been postulated and appropriate rate constants calculated using all the smoothed experimental data to obtain unique numerical values for the rate constants in each mechanism.

On the basis of the ability of the calculated rate constants to reproduce the smoothed experimental values for the fraction of atomic hydrogen, five of the postulated mechanisms have been eliminated.

It has been pointed out that, on the basis of reproducibility, it is not possible to advocate any specific one of the remaining five acceptable mechanisms but that future definite information regarding the presence and nature of a wall reaction could determine which one of the five possible sets of rate constants should be used to describe the recombination of hydrogen atoms.

Electrical Factors in the Adsorption of Polar Molecules at the Surface of Solutions

BY ROBERT DUBOIS AND ERIC E. TODD

In an earlier paper McBain and DuBois[1] reported extensive measurements of adsorption at the air–solution interface which were made as experimental tests of the Gibbs adsorption equation

$$\Gamma_{2(1)} = -\frac{d\sigma}{RT\, d\ln a_2} = -\frac{d\sigma}{RT\, d\ln c_2} \qquad (1)$$

where $\Gamma_{2(1)}$ is the absolute excess of solute (component 2) adsorbed in 1 sq. cm. of the surface of a binary solution, σ is the surface tension of the solution, and a_2, c_2 are, respectively, the activity and the molar concentration of the solute in the bulk solution. ($\Gamma_{2(1)}$ is defined in the Gibbs manner[2] so that $\Gamma_1 = 0$.) The adsorption of various solutes on the surfaces of moving bubbles was measured and found to be much larger than the values calculated by means of the above equation. These results confirmed the earlier measurements of McBain and Davies[3] made with similar apparatus and are in line with the excessive adsorption found by other workers using dynamic methods of measurement.

As a result of this apparent failure of the Gibbs equation to account for the experimental values, it has been suggested by several writers that an electrical term should be added to the equation to take account of the known electrification of the bubbles and drops upon which the adsorption takes place. The validity of such suggestions will be discussed later; their implication is that the excess of the observed adsorption over the calculated value is of electrical origin. As part of a general investigation of the factors responsible for the excessive adsorption on moving bubbles, the present authors have undertaken to test the electrical explanation by measuring the effect of enhanced electrification of the bubbles on the observed adsorption.

Meaning of the Term "Electrification."—The term "electrification of bubbles and drops" may refer to any of the following:

(1) *Electrokinetic double layer*, the electrical double layer which always exists at the surface of any bubble or drop in contact with water or an aqueous solution and whose parts may be tangentially displaced under the influence of an external electric field. The charge which is thus made evident by cataphoretic migration originates in the dissociation of a surface layer, either a part of the

[3] McBain and Davies, THIS JOURNAL, **49**, 2230 (1927).

primitive particle (*e. g.*, oleic acid droplets in water) or adsorbed thereon (adsorption of sodium oleate on oil drops, fatty acids on air bubbles).

(2) *Oriented dipole layer*, composed of adsorbed polar molecules arranged with more or less complete vertical orientation in the surface. Changes in the number and orientation of these adsorbed molecules are evidenced by changes in surface tension and by variations in the interfacial potential first observed by Kenrick[4] and later more extensively studied by Frumkin,[5] and others. The distinction between the "electrokinetic" and the "oriented dipole" double layers has been discussed recently by Chalmers and Pasquill.[6] The elements of the latter kind of double layer are of course fixed in the molecules themselves and are not displaceable in an external electrical field.

(3) *Space charge in the interior of a gas bubble.* It has been known for many years that a gas may become electrically charged by having liquid sprayed into it or by bubbling it through a liquid. For example, Lord Kelvin[7] bubbled air, hydrogen, and other gases through water and aqueous solutions of various (organic and inorganic) substances and found that in all cases the gas became electrically charged. Similar observations were made by Coehn and Mozer[8] with solutions of organic compounds.

The first two of these electrical states cannot be altered by the experimenter except by changing the concentration of the solute or by the addition of other solutes whose adsorption would necessitate additional terms in the adsorption equation. Moreover, any electrical contribution to the surface energy which is due to adsorption of the solute and whose magnitude is determined by the bulk concentration of the solution, is implicitly included in the Gibbsian equations. This may be seen if we write equation (1) in the more general form

$$d\sigma = -\Gamma_1 d\mu_1 - \Gamma_2 d\mu_2 \quad (2)$$

or

$$\Gamma_{2(1)} = -d\sigma/d\mu_2 \quad (3)$$

and note that μ_2, the chemical potential of component 2 (the solute), is definable by the equation

$$\mu_2 = \left(\frac{\partial E}{\partial n_2}\right)_{S,V,n} \quad (4)$$

Here E, the total energy of the system, represents the sum of the energies of all portions thereof, including the surface layer, and includes every kind of energy possessed by any part of the system. (S, V, n represent constancy of the variables entropy, volume and number of moles of all components other than 2.)

The third electrical condition, space charge in the gas, can be varied without changing the composition of the solution, and we planned, therefore, to investigate the effect on the adsorption of organic molecules on the surface of moving bubbles which might be brought about by alterations in the electrification of the gas.

Experimental

The apparatus and method of measurement used in this work were practically identical with those employed by McBain and DuBois and have been described in detail in their paper.[1] The electrical bubble counter there mentioned was modified by replacing the vacuum tube circuits with a photoelectric cell and suitable relays actuated by the passage of the bubbles through a beam of light. All the experiments to be described were made with solutions of *p*-toluidine in boiled-out distilled water at a fixed concentration of 2.0 g. of *p*-toluidine per kg. of water. The toluidine was the best obtainable from Kahlbaum and was further purified by sublimation after mixing with solid potassium hydroxide. The "Gibbs value" for the adsorption of *p*-toluidine at the concentration given is 7.1×10^{-8} g./sq. cm. (ref. 1, page 3546). The experimental values obtained from measurements with moving bubbles are generally about twice this value.

Effect of Discharging Gas.—We were interested first in determining whether any charge could be detected in the gas escaping from the collapsed bubbles. For this purpose we interposed in the gas stream at the outlet of the adsorption tube a Kelvin electric filter.[9] This was made by packing clean brass filings in a 6-in. (15-cm.) length of 1/2-in. (1.27-cm.) tin pipe and supporting this pipe inside a metal shield tube by means of insulated glass tubes set in brass end caps. The filter was connected to the ungrounded side of a 1 mfd. condenser. While a stream of gas bubbles was passing through the apparatus, the condenser was allowed to accumulate charge for various periods of time (up to ten minutes) and was then shorted to ground through a sensitive galvanometer. Although no evidence of charge was observed with the ordinary rate of bubbling, unusually vigorous bubbling caused a small galvanometer deflection. Evidently a small charge must have been present in the ordinary gas stream. Now the nitrogen gas used to create bubbles in the adsorption tube passes first through two long saturators filled with the same solution and must already possess a charge when it reaches the adsorption tube. We decided, therefore, to discharge the gas just before entering the bubbling nozzle and observe the effect, if any, on the measured adsorption.

A three-way stopcock was placed in the gas line just before the adsorption tube so that the nitrogen could either

be passed through a grounded Kelvin filter interposed at this point or allowed to by-pass the filter and enter the tube directly. A number of adsorption measurements were made in succession, both with and without discharging the gas, and without any other change in the experimental conditions. No variation in the adsorption values could be observed other than those usually found in duplicate determinations.

In the face of the negative results on discharging the gas, we decided to enhance the electrical effect, if there was one, by forced charging of the gas stream before it entered the adsorption tube.

Spark Discharge.—We first tried the effect of a spark discharge between platinum wires sealed into the inlet to the adsorption tube. Several experiments were conducted in the usual manner until constant results were obtained. Connection was then made to an induction coil without disturbing the bubble rate or the overflow rate. A marked change immediately became apparent in the adsorption tube. The bubbles, which had previously maintained a steady stream, began to bunch and coalesce. As shown by the interferometer readings, the adsorption appeared to drop considerably, and with succeeding experiments even became negative. However, when the sparking was interrupted and additional adsorption measurements were made, the effect was found to persist, since the adsorption values rose only very slowly and the bubbles continued to bunch. Because of its persistence after sparking ceased we concluded that the effect observed was not electrical but was due to the chemical action of some product or products formed in the discharge.

Ionization by Alpha Particles.—In order to avoid the chemical effects caused by electrical discharge we produced ionization in the nitrogen gas by means of alpha particles. A few milligrams of ionium bromide was placed on the bottom of a small flask interposed in the gas line between the last saturator and the adsorption tube. Since about 0.4 cc. of nitrogen gas per second passed directly over several milligrams of ionium emitting 8×10^5 alpha particles per mg. per sec., each capable of producing 1.4×10^5 ions in a range of 2.85 cm., it is evident that an enormous number of ions would be present in the gas as it passed on to the bubbling nozzle. Preliminary tests with a Kelvin filter placed between the ionization chamber and the nozzle demonstrated that a charge did exist in the gas stream. No evidence of charge could be detected in the gas leaving the adsorption tube, indicating, as would be expected, that the initial charge had disappeared because of ion recombination and adsorption on the bubble surfaces during the twelve seconds required for the bubbles to pass along the 156 cm. tube.

In order to test the effect of the ionization of the gas on the adsorption of *p*-toluidine on the bubble surfaces, a number of adsorption measurements were first made in the usual way without charging the nitrogen (gas by-passed around the ionization chamber). Then, without any other alteration in the experimental conditions, the gas was diverted through the flask containing ionium salt before entering the bubbling nozzle and additional measurements of adsorption were made. Table I gives the results of two such experiments.

TABLE I

ADSORPTION EXPERIMENTS WITH RADIOACTIVE IONIZATION OF NITROGEN

	Experiment 1				Experiment 2			
Measurement	1a	1b	1c	1d	2a	2b	2c	2d
Ionization?	No	No	No	Yes	No	No	Yes	Yes
Duration, min.	11.4	17.2	13.7	9.0	18.3	16.7	17.9	14.0
Adsorption Γ (g./sq. cm. $\times 10^8$)	12.0	12.8	14.3	16.1	12.9	13.8	..	14.0

In the first experiment some difficulty was experienced in keeping bubble rate and flow of liquid properly adjusted to ensure passage of unbroken films up the short vertical drainage section of the adsorption tube. The variations in the adsorption values are therefore not more than we would expect from such a run and they do not in themselves give any indication of an effect of bubble charge on the adsorption. In experiment 2c the weight of collapsed film liquid was lost and Γ could not be calculated. The interferometer reading on this film liquid, however, indicates a value of Γ about the same as those obtained in the other experiments.

It is apparent that ionization of the nitrogen gas has had only a slight effect, if any, on the measured adsorption of *p*-toluidine. We are therefore led to the conclusion that the excessive adsorption of *p*-toluidine on moving bubbles is not due to any volume or surface electrification of the bubbles produced by their passage through the solution. This conclusion can probably be extended generally to other substances showing excessive adsorption (excessive as compared to the predicted "Gibbs" values).

Discussion

Calculation of the Effect of Surface Charge on Adsorption of Polar Molecules at the Surface of a Solution.—We shall now consider from a theoretical point of view what effect on the measured adsorption should be expected in experiments such as those described above. The ionization produced in the gas bubbles by collision of gas molecules with alpha particles consists of approximately equal numbers of positive and negative gaseous ions. Since the collisions of these ions with the bubble surface are proportional to their respective concentrations in the gas phase, approximately the same number of positive and negative ions will strike the surface in unit time. The life of any ion at the surface will depend on the nature of this surface.

In the case of *p*-toluidine solutions of the concentration used the values obtained for the adsorption of the solute (both observed values and those calculated from surface tension data) as well as the surface potential measurements of Frumkin[10] indicate that the surface being struck

---

(10) Frumkin, Donde and Kulvarskaya, *Z. physik. Chem.*, **123**, 321 (1926).

consists of at least one complete layer of close-packed, vertically oriented *p*-toluidine molecules. The positive sign of the surface potential observed by Frumkin shows that the positive side of the dipole layer is directed toward the gas phase. This means that all ions striking the surface come under the influence of the local field of the positive ends of the adsorbed dipoles. The life of a negative ion in this surface is therefore probably much longer than that of a positive ion; in other words, adsorption of negative ions preponderates over that of positive ions, and the surface possesses a net negative charge. In this way a considerable electric field could be produced at the surface. In fact, if only one millionth of the surface were thus covered with adsorbed ions (10^9 ions/sq. cm.), the corresponding field strength, considered as a time average, would be

$$E = \frac{4\pi\sigma}{D} = \frac{4 \times 3.1 \times 10^9 \times 4.8 \times 10^{-10} \times 300}{80} = 22 \text{ volts/cm.} \qquad (5)$$

or somewhat more, if we use a smaller value for the dielectric constant of the surface layer. The maximum value of E, corresponding to a surface completely covered with ions of one sign, is about 22×10^6 volts/cm., or 73,000 e. s. u./cm.

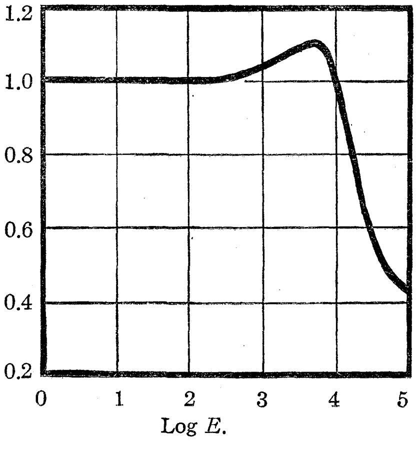

Fig. 1.—Effect of electric field on adsorption of *p*-toluidine.

The effect of an electric field on the adsorption of organic molecules has been discussed for the gas–solid interface,[11] the gas–solution interface,[12-14] and the mercury–solution interface.[15,16] None of these discussions is quite applicable to the present problem, and for our purpose we shall use a somewhat different procedure from any of these.

The potential energy of a solute molecule of dipole moment μ_s, oriented with its axis in the direction of an electric field of intensity E, is $-\mu_s E$. When one solute molecule is brought from the bulk solution into the surface layer, there are displaced v_s/v_w molecules of water (v_s and v_w represent the volumes occupied by individual molecules of solute and water). The water molecules (with dipole moment μ_w) originally in the surface layer were subject to the orienting influence of the external field, and their average moment in the direction of the field is given by

$$\bar{\mu}_w = \mu_w \times L(x) \qquad (6)$$

where $L(x)$ is the Langevin function cotgh $x - 1/x$ and $x = \mu_w E/kT$. Therefore the net work done against the external field E in bringing a solute molecule from the interior of the solution (where $E = 0$) to a vertically oriented position in the surface (where E ranges from 0 to 75,000 e. s. u./cm.) is

$$W = -\mu_s E + \frac{v_s}{v_w}\bar{\mu}_w E = -\mu_s E + \frac{v_s}{v_w}\mu_w E L(x) \qquad (7)$$

The Langevin function can be expanded in series

$$L(x) = \frac{x}{3} - \frac{x^3}{45} + \ldots$$

and all terms but the first can be neglected for small values of x. That is, for all values of x up to about 1.3, corresponding to a temperature of 27° and a surface 40% covered with ions of one sign ($E = 30{,}000$ e. s. u./cm.), the net work of adsorption of one solute molecule is

$$W = -\mu_s E + \frac{v_s}{v_w}\frac{(\mu_w E)^2}{3kT} \qquad (8)$$

At sufficiently large values of E it is necessary to take into account the induced moments $\alpha_s E$ and $\alpha_w E$ of both solute and solvent molecules in the surface layer and the corresponding contributions $-\alpha_s E^2$ and $-\alpha_w E^2$ to the energies of these molecules in the electric field (α_s and α_w represent the polarizabilities of the two kinds of molecules). We shall therefore add two more terms to equation 8 and obtain the more accurate expression for the electrical adsorption work

$$W = -\mu_s E + \frac{v_s}{v_w}\frac{(\mu_w E)^2}{3kT} - \alpha_s E^2 + \frac{v_s}{v_w}\alpha_w E^2 \qquad (9)$$

The polarizabilities can be calculated from the respective molar refractions by use of the relation

$$R = \frac{4\pi N\alpha}{3}$$

If now we let Γ_0 denote the number of solute molecules adsorbed per sq. cm. in the absence of an external field, then Γ, the number of molecules adsorbed in the presence of the field, is obtained by the aid of the Boltzmann distribution law. That is

$$\Gamma = \Gamma_0 e^{-W/kT} \qquad (10)$$

where W is given by equation 9. The values of Γ/Γ_0 have been calculated for various field strengths by means of this equation; the results are given in Table II and in graphical form in Fig. 1. The following numerical values have been used for the constants of equation 9.

	p-Toluidine	Water
Dipole moment	1.65×10^{-18} e. s. u.[17]	1.85×10^{-18} e. s. u.[17]
Molar refraction	34 cc.[18]	3.6 cc.[19]
Polarizability	1.34×10^{-23} e. s. u.	1.42×10^{-24} e. s. u.
Molecular volume	192×10^{-24} cc.[20]	30×10^{-24} cc.[21]

TABLE II

EFFECT OF ELECTRIC FIELD ON THE ADSORPTION OF *p*-TOLUIDINE (TEMPERATURE 27°)

Field strength E e. s. u./cm.)	% Surface covered by adsorbed gaseous ions	Electrical adsorption work W (ergs/molecule)	Effect on adsorption Γ/Γ_0
1		-1.65×10^{-18}	1.000
10		-1.65×10^{-17}	1.000
100		-1.63×10^{-16}	1.004
755	1	-1.15×10^{-15}	1.025
1000		-1.47×10^{-15}	1.036
2000		-2.60×10^{-15}	1.065
4750	6	-3.90×10^{-15}	1.100
7550	10	-2.64×10^{-15}	1.066
10000		$+0.87 \times 10^{-15}$	0.980
75500	100	$+7.70 \times 10^{-14}$	.440[22]

Differentiation of equation 10 with respect to E shows that the function Γ/Γ_0 has a maximum at $E = 4750$ e. s. u./cm. and we see therefore that although the local electric field at the surface of the solution has a positive effect on the adsorption of *p*-toluidine (except at very large values of E), the increase is never more than 10%. While the above treatment of discrete charges of adsorbed gaseous ions as a continuous surface charge is admittedly somewhat simplified, the method gives an approximate average effect of such charges on the adsorption of a polar solute.

The experiments described above were completed in the chemical laboratories of Stanford University and the authors wish to thank Prof. J. W. McBain for much helpful advice. Acknowledgment is also made of the grant of a du Pont Fellowship to one of us (E. E. T.).

Summary

1. Attention is called to the fact that the adsorption of solutes at the air–solution interface, when measured by dynamic methods (moving bubbles, etc.), is generally found to be several times greater than the values calculated from surface tension data by means of the Gibbs adsorption equations.

2. In order to test the suggestion that the excessive observed adsorption is due to electrification of the moving surfaces, the authors have attempted to alter the adsorption of *p*-toluidine on moving bubbles by forced charging of the gas.

3. Marked decrease in the apparent adsorption was observed when the gas was subjected to spark discharge and to silent discharge before entering the adsorption apparatus. Because of its persistence after discharge ceased the effect was believed to be of chemical origin.

4. Ionization of the bubbling gas by exposure to ionium salt was found to have no effect on the measured adsorption.

5. The effect of a surface charge on the adsorption of polar molecules is discussed theoretically. Calculations show that the adsorption of *p*-toluidine on gas bubbles should be only slightly increased by electrification of the surface and at extreme charge densities should be somewhat decreased.

6. It is concluded that electrification of gas bubbles in contact with solutions of organic solutes is not responsible for the marked discrepancy between the observed adsorption and the calculated "Gibbs" adsorption.

The Electron Diffraction Investigation of Sulfur Monochloride, Sulfur Dichloride, Sulfur Trioxide, Thionyl Chloride, Sulfuryl Chloride, Vanadium Oxytrichloride, and Chromyl Chloride

BY K. J. PALMER

Despite the rapid development of the electron diffraction method of studying the structure of molecules, comparatively few inorganic compounds have been investigated by this means. The stress which has been laid on organic molecules is due in part to the large number of organic compounds which have appreciable vapor pressures at, or near, room temperature, as compared with the number of inorganic compounds in this category, and in part to the fact that the organic chemist has in general been more interested in stereochemistry than the inorganic chemist, and has built up a large amount of purely chemical evidence supporting definite configurations.

From a purely structural point of view, inorganic molecules are nevertheless of great interest. Especially is it desirable to determine whether or not the empirical relations connecting bond distance with bond type, which have proved so useful in the discussion of interatomic distances in organic compounds, are applicable to inorganic molecules as well. The investigations reported in this paper were carried out with these considerations in mind.

Preparation of Materials

Sulfur Dichloride.—The sulfur dichloride used was prepared by passing dry chlorine into sulfur monochloride until the color of the liquid became deep red. This liquid was then distilled carefully in an all-glass apparatus, and only a small fraction boiling at 59° at atmospheric pressure was retained. This product was redistilled twice, the middle fraction only being retained. There was no evidence of decomposition during the distillation.

Sulfur Monochloride.—Sulfur monochloride was prepared by passing chlorine over hot sulfur. The product was purified by distillation over activated bone charcoal and sulfur. The final product was light yellow and boiled at 135–136°.

Thionyl Chloride.—Eastman thionyl chloride was purified by fractional distillation under reduced pressure.

Sulfur Trioxide.—Kahlbaum C. P. sulfur trioxide was used without further purification.

Sulfuryl Chloride.—Sulfuryl chloride was prepared by passing a mixture of sulfur dioxide and chlorine over camphor. The product was purified by distillation.

Chromyl Chloride.—Chromyl chloride was prepared by heating potassium dichromate, potassium chloride, and concentrated sulfuric acid. The blood-red liquid was purified by distillation.

Vanadium Oxytrichloride.—Vanadium oxytrichloride was prepared by passing hydrogen over heated V_2O_5 until it was completely reduced to V_2O_3. The water which was generated by the reaction was carefully driven off, and chlorine was then introduced. The generated vanadium oxytrichloride was condensed in a trap cooled by a mixture of ice and salt. This product was purified by repeated distillation.

Experimental Method

The method of obtaining and interpreting the photographs already has been described in the literature.[1] All radial distribution curves were calculated using C $(= s_0^2Ie^{-as_0^2})$ in place of I as recently suggested.[2] Because the vapor pressure of some of the compounds investigated is very low at room temperature it was necessary to use a high temperature nozzle.[3] This design of nozzle was found to be particularly advantageous in these cases because of the hygroscopic nature of the compounds.

Sulfur Dichloride.—The photographs show six well-defined rings. The second and fourth maxima appear to have shelves on the outer edge, the shelf on the fourth maximum being more pronounced than that on the second. The third and fifth minima (second and fourth on the reproduced curves) appear to be broad and less deep than the fourth.

Values of s_0 [= 4π sin /2/λ], I (the visually estimated intensities) and C $(=s_0^2Ie^{-as_0^2})$ are given in Table I. The radial distribution curve is reproduced as curve A in Fig. 1. The two well-defined peaks at 1.98 and 3.06 Å. correspond to the S–Cl and Cl–Cl distances, respectively. The Cl–S–Cl angle is 101°10′. Intensity curves calculated for S–Cl = 1.98 Å. and Cl–S–Cl angle equal to 101°10′, 109°28′, 125°, and 180° are reproduced as curves A, B, C, and D, respectively, in Fig. 2. Curve E is the intensity curve for chlorine, which has been included because of the

---

[3] L. O. Brockway and K. J. Palmer, THIS JOURNAL, **59**, 2181 (1937).

possibility of the sulfur dichloride decomposing to give sulfur monochloride and chlorine. This curve can be eliminated because the photographs do not appear to have the regular structure required. Curve D is also in disagreement with the photographs, in that all of the peaks have shelves on the outer edge, and the fourth minimum is not deeper than the third and fifth as is required by the photographs. In curve C the intensity relations of the minima are again wrong, and in addition the third maximum appears to be broad and flat, whereas the photographs show it to be quite sharp. Curve B can be eliminated because the shelf on the fourth maximum is on the inner edge instead of the outer edge, as required by the photographs, and also the third, fourth, and fifth minima have the wrong intensity relationship.

TABLE I

SULFUR DICHLORIDE

Max.	Min.	I	C	s_0	s^a	s/s_0
1		10	3	4.545	4.15	(0.913)
	2			5.724	5.55	(.970)
2		8	5	6.910	6.92	1.001
	3			8.934	8.65	0.968
3		6	5	10.424	10.48	1.005
	4			11.790	11.87	1.007
4		3	2	13.178	13.24	1.005
	5			14.999	15.30	1.020
5		2	1	16.397	16.76	1.022
	6			17.851	18.12	1.015
6		1	1	19.227	19.52	1.015
					Average	1.006
					Average deviation	0.011

S–Cl = (1.98)(1.006) = 1.99 ± 0.03 Å.

Cl–Cl = (3.06)(1.006) = 3.08 ± 0.04 Å.

[a] Calculated for the model with S–Cl = 1.98 Å. and Cl–Cl = 3.06 Å.

On the other hand, curve A (101°10′ model) agrees very well with the photographs. The outside shelves on the second and fourth maxima are present, and the fourth minimum is deeper and narrower than either the third or fifth. Since this model agrees also with the results of the radial distribution curve, it is accepted as correct. The quantitative comparison given in the last column of Table I leads to an S–Cl distance

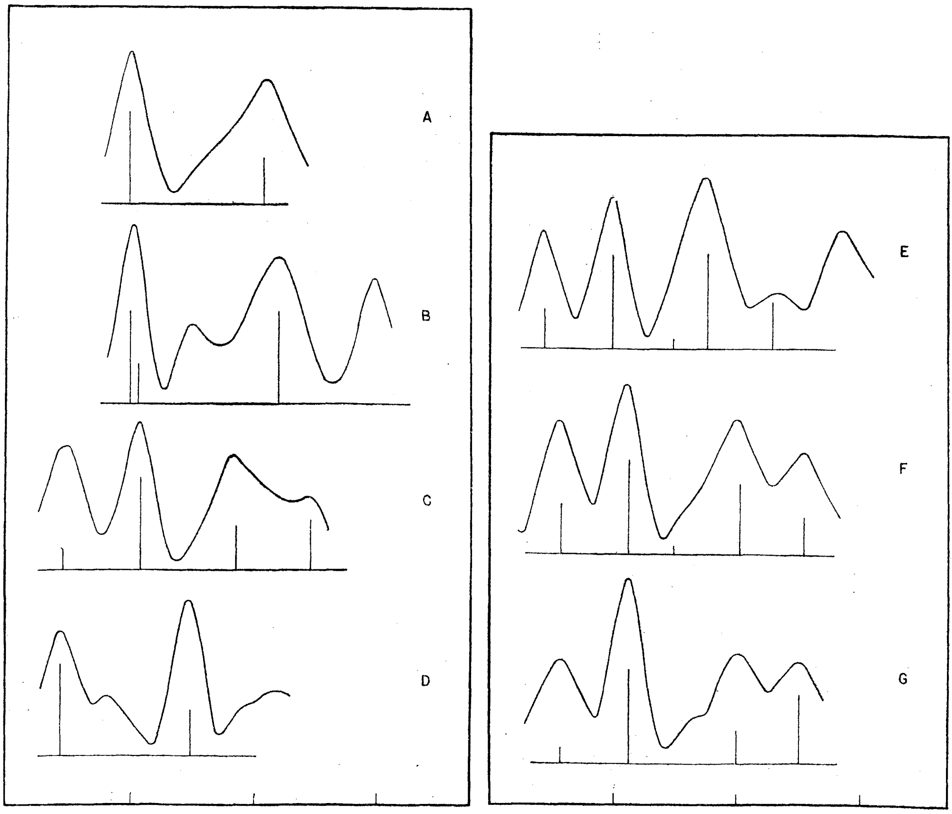

Fig. 1-A. Fig. 1-B.

Fig. 1.—Radial distribution curves for (A) sulfur dichloride, (B) sulfur monochloride, (C) thionyl chloride, (D) sulfur trioxide, (E) sulfuryl chloride, (F) chromyl chloride, and (G) vanadium oxytrichloride.

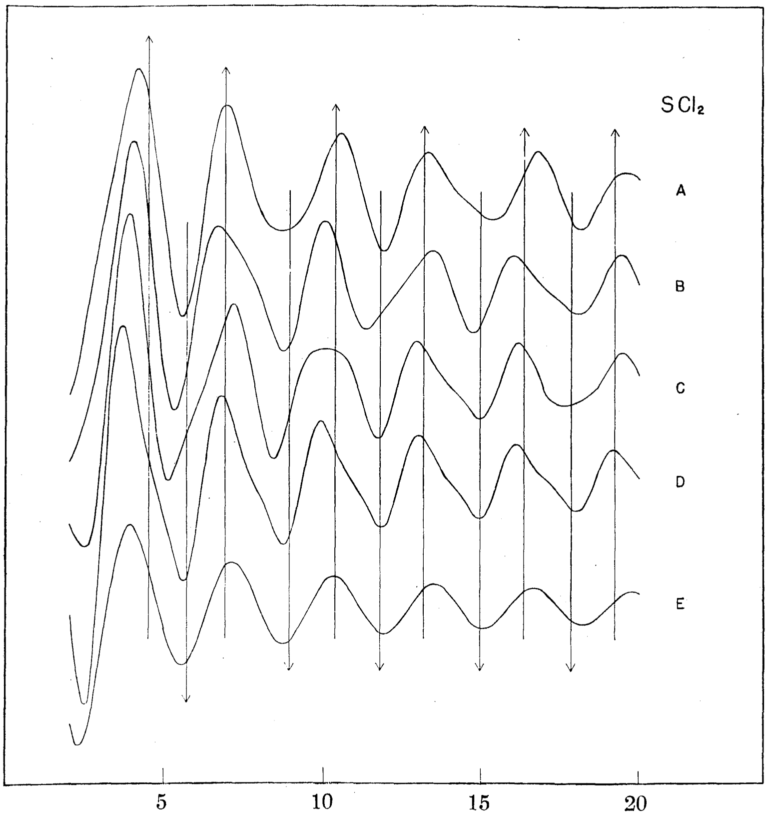

Fig. 2.—Theoretical intensity curves for sulfur dichloride.

of 1.995 Å. The final values are therefore taken as S–Cl = 1.99 ± 0.03 Å. and the angle Cl–S–Cl = 101 ± 4°.

Sulfur Monochloride.—The sample of sulfur monochloride was transferred to the high temperature nozzle inside a moisture-proof box. When the nozzle was opened after the exposures were made there was no trace of sulfur and the remaining sample was still light yellow in color.

The photographs of sulfur monochloride show eight maxima, seven of which were measured accurately. The first maximum appears to be symmetrical, the second has a very decided outer shelf which is called the third maximum in the tables, the fourth is symmetrical, the fifth very broad, the sixth sharp, and the seventh is not very prominent. The values of s_0, I, and C are given in Table II. The radial distribution curve, calculated using the values of C, is reproduced as curve B in Fig. 1. The peaks at 2.01, 3.18, and 3.96 Å. are interpreted as the sum of the S–Cl and S–S, the long S–Cl, and the Cl–Cl distances, respectively. The small peak at 2.47 Å. is not given any significance.

The radial distribution curve immediately excludes the structure in which there are two chlorine atoms attached to one sulfur atom, because under these circumstances the radial distribution curve would exhibit only two peaks of about equal height (the outer peak being due to the long S–Cl and Cl–Cl distances), or perhaps three peaks, the outer two lying very close together.[4] Of these two outer peaks that representing the long S–Cl distance should be approximately twice as intense as that representing the Cl–Cl distance. Both the heights and the positions of the peaks are, however, compatible with the model in which one chlorine atom is attached to each sulfur atom. For this reason intensity curves were calculated only for models compatible with this latter configuration.

Assuming the value 1.99 Å. for the S–Cl distance (this value being found in both SCl_2 and SO_2Cl_2), and considering the peak at 2.01 Å. to be the weighted mean of the two S–Cl and the one S–S distance, it is then possible to calculate an

Final values: S–Cl = 1.99 ± 0.03 Å.
S–S = 2.05 ± 0.03 Å.
Cl–S–S∠ = 103 ± 2°

[a] Calculated for the model with S–S = 2.05 Å., S–Cl = 1.99 Å. and Cl–Cl = 3.95 Å.

---

(4) Refer to curve C, Fig. 1, for thionyl chloride.

S–S distance. The value found is 2.05 Å.[5] Using the values 1.99 Å. for the S–Cl distance, 2.05 Å. for S–S, 3.18 Å. for the long S–Cl and assuming the value 3.96 Å. for the Cl–Cl distance, the S–S–Cl angle is calculated to be 103°35′ and the angle between the Cl_1–S–S and Cl_2–S–S planes 97°7′.

In calculating intensity curves the S–Cl and S–S distances and the Cl–S–S angle were given the values 1.99 Å., 2.05 Å., and 103°35′, respectively. This is justifiable because the well resolved inner peaks on the radial distribution curve are probably reliable to within 1%. Curves A, B, and C for Fig. 3 were calculated for models in which the angle between the two Cl–S–S planes is 97°7′, 180° (*trans*), and 0° (*cis*), respectively. Model C can be eliminated because there is no shelf on the outside of the second maximum, this shelf being a very distinctive feature of the photographs. Curves A and B agree qualitatively with the photographs. The similarity of these two intensity curves, both as regards intensity and position of the maxima and minima, makes the reliability of the radial distribution peak at 3.96 Å. very doubtful, since the distribution curve is calculated with the aid of just the s_0 values and the visually estimated intensities.

No intensity curves were calculated for models in which there was either free or restricted rotation for the reason that there is no feature of the curve which appears to be sensitive to the Cl–Cl separation, and it is consequently impossible at the present time to determine accurately the nature or height of the potential hump restricting free rotation.

The static *trans* model can be eliminated, however, from other considerations. Five Raman frequencies have been reported,[6] whereas only three frequencies of the *trans* model are Raman active. It is evident therefore that the molecule can have only one static configuration, namely, the so-called "right angled" structure, or the chlorine atoms can be oscillating or rotating with respect to one another. It is unfortunate that more reliability cannot be placed upon the radial distribution peak at 3.96 Å. because its position and sharpness would then immediately eliminate all but the static "right angled" structure. The quantitative comparison of s to s_0 for curve A is given in Table II.

Y. Morino and S. Mizushima[6] recently have measured the dipole moment of sulfur monochloride, reporting the value of 1 Debye unit. They have also measured the Raman spectrum in dilute hexane solution and have concluded from their results that the "right angled" static structure is the correct one. It can be said in support of this view that the electron diffraction results are compatible with this configuration.

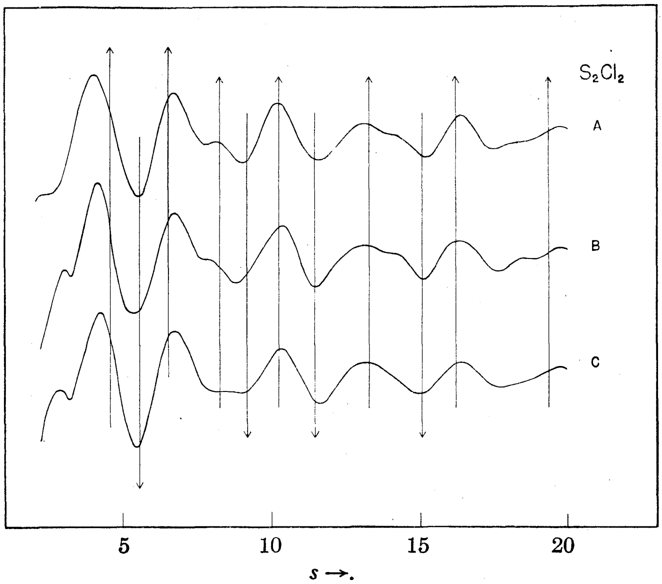

Fig. 3.—Theoretical intensity curves for sulfur monochloride.

Ackermann and Mayer[7] have investigated the molecular structure of sulfur monochloride by the diffraction of comparatively slow (about 6 kv.) electrons. They concluded that there is one chlorine atom attached to each sulfur atom and claimed to obtain best agreement when they assumed S–Cl = 1.98 Å., S–S = 2.04 Å., and Cl–S–S angle = 105°. They also state that the intensity curve calculated for free rotation gave best agreement with their photographs. An intensity curve calculated assuming free rotation is almost identical with curve A, Fig. 3, and consequently their results are in good agreement with those obtained in this investigation.

Thionyl Chloride.—The photographs of thionyl chloride show seven measurable rings, having the visually estimated intensities shown under I, Table III. The third minimum (second on curves) appears to be very deep, the fourth com-

---

[5] This value is in good agreement with that found in H_2S_2 by Beach and Stevenson (private communication).

					Average	0.999		1.000
					Average deviation	0.007		0.012

Final values: S–O = 1.45 ± 0.02 Å. O–S–Cl ∠ = 106 ± 1°
S–Cl = 2.07 ± 0.03 Å. Cl–S–Cl ∠ = 114 ± 2°
Cl–O = 2.84 ± 0.03 Å.
Cl–Cl = 3.47 ± 0.03 Å.

[a] Calculated for the model with S–O = 1.44 Å., S–Cl = 2.07 Å., Cl–O = 2.84 Å., and Cl–Cl = 3.50 Å. [b] Calculated for the model with S–O = 1.44 Å., S–Cl = 2.07 Å., Cl–O = 2.84 Å., and Cl–Cl = 3.40 Å.

paratively shallow and broad, the fifth fairly sharp but of even less depth than the fourth, the sixth deep and well defined, and the seventh broad and not as deep as the sixth. The fifth maximum appears to be less intense than either the fourth or sixth. The values of s_0, I, and C are given in Table III. The radial distribution curve calculated from these values is shown as curve C in Fig. 1. The peaks at 1.46, 2.07, 2.84, and 3.42 Å. are interpreted as the S–O, S–Cl, Cl–O, and Cl–Cl distances, respectively. The value 2.07 Å. for the S–Cl distance seemed to be a little large, and to make sure that an impurity was not the cause of the apparent anomaly, electron diffraction photographs were taken of a new sample of thionyl chloride. When these were measured, it was found that the s_0 values from the two sets of photographs were in very good agreement, indicating that the large S–Cl distance is probably real.

Intensity curves were calculated for the following models: planar, with S–O = 1.44 Å., S–Cl = 2.07 Å., and a Cl–S–Cl angle of 110, 113, 116, and 120°; pyramidal, with S–O = 1.44 Å., S–Cl = 2.07 Å., Cl–O = 2.84 Å. and Cl–S–Cl angle equal to 106, 110, 115, and 120°. These last four curves are shown as curves A, B, C, and D, respectively, in Fig. 4. None of the intensity curves for planar models has been reproduced because they are all in very definite disagreement with the photographs. Curve D can be eliminated because the intensity relationship between the first three maxima is wrong; also, the intensity of the fifth maximum should be less than that of either the fourth or sixth. Curve C is in good qualitative agreement with the appearance of the photographs. Curve B is also in good agreement except for the appearance of the shelf on the inside of the fourth maximum, and the equality in depth of the fifth and sixth minima. The model finally selected is a weighted average of these two. Curve A is less satisfactory than B because the shelf on the fourth maximum has become too prominent and the intensity relationships of the fourth, fifth, and sixth maxima, which are about right in curves B and C, are unsatisfactory.

The quantitative comparison for models B and C is given in the last column of Table III. The final values selected, taking into account both the results of the radial distribution curve and the quantitative comparisons, are S–O = 1.45 ± 0.02 Å., S–Cl = 2.07 ± 0.03 Å., Cl–O = 2.84 ± 0.03 Å., and Cl–S–Cl angle = 114 ± 2°. This leads to an O–S–Cl angle of 106°17′. The same value for the O–S–Cl angle has been observed in sulfuryl chloride.

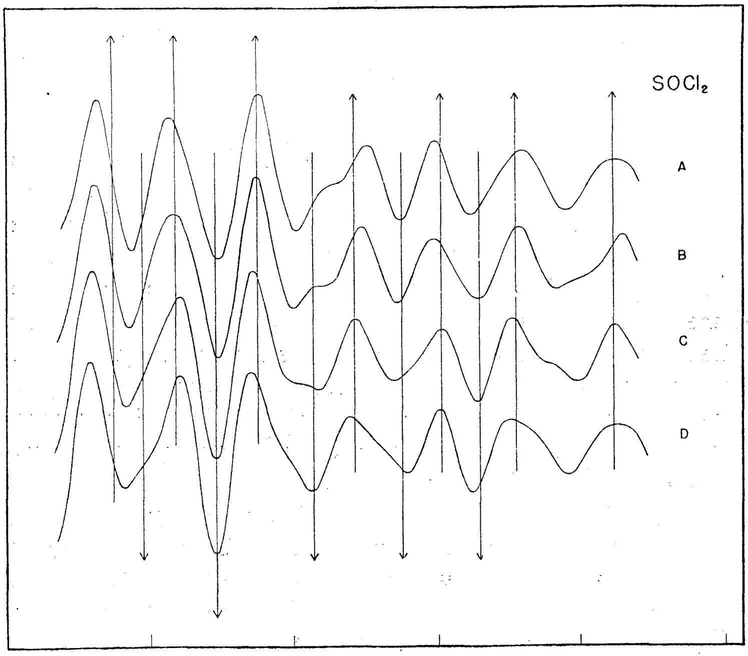

Fig. 4.—Theoretical intensity curves for thionyl chloride.

Sulfur Trioxide.—The sample of sulfur trioxide was distilled under vacuum into the sample holder, phosphorus pentoxide being used as the lubricant on the stopcock. The best photographs showed six rings, the second of which appears to be quite broad, the intensity falling off gradually on the inside and somewhat more abruptly on the outside. The third ring has a distinct outer shelf, the other rings being more or less regular in appearance. The average values of the visual measurements of the maxima and minima, as well as the estimated intensities I and the values of C are given in Table IV.

The radial distribution curve is reproduced in Fig. 1, curve D. The two well-defined peaks at 1.43 and 2.45 Å. are interpreted as the S–O and O–O distances, respectively. These values lead to an O–S–O angle of 117°50′. Theoretical intensity curves calculated for models having an S–O distance equal to 1.43 Å. and an O–S–O angle of 120°, 117°50′, 116°, and 110° are shown as curves A, B, C, and D, respectively, in Fig. 5. Curve D is not acceptable because the shelf on the second maximum is on the outside, rather than the inside, and also because the third maximum does not possess a distinct enough outer shelf.

The rather flat top of the second peak with the subsequent steep slope on the inside exhibited by curve C, and the inner shelf on the fifth maximum are also in disagreement with the photographs. Curves A and B are very similar, except for the slight change in the nature of the inside shelf of the second maximum, and are both in good qualitative agreement with the photographs. The intensity of this peak reaches its maximum value at about the same point in both curves A and B, but falls off on the inside at approximately a constant rate in A, while for B the rate is at first less than for A and then becomes greater. This change in the rate of falling off of the intensity in curve B would, if exhibited by the photographs, probably give the impression of a definite edge to the shelf, whereas no such edge would be expected if the intensity followed curve A. As no edge can be discerned on the photographs, model A is to be favored over model B.

The ratios s/s_0 for curves A and B are given in Table IV. The final values selected for the parameters are S–O = 1.43 ± 0.02 Å. and O–S–O angle 120 ⩽ 2°. This leads to an O–O distance of 2.48 ± 0.03 Å.

The dielectric constant of sulfur trioxide vapor recently has been measured[8] over a considerable temperature range, and it was shown that the plot of the polarization against the reciprocal of the absolute temperature gives a horizontal straight line, indicating that the dipole moment is zero in agreement with the planar model.

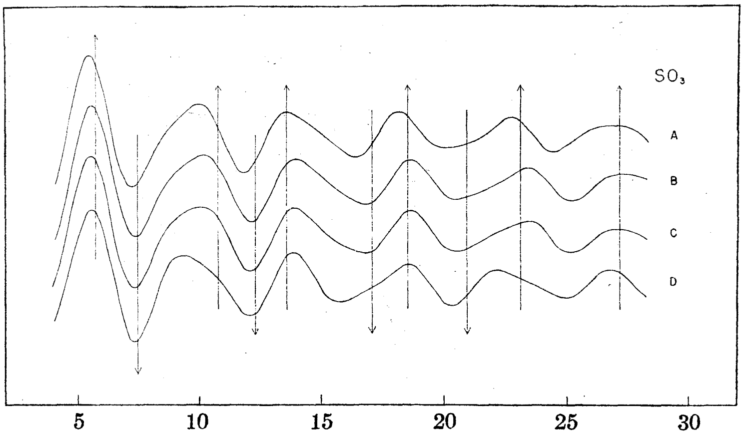

Fig. 5.—Theoretical intensity curves for sulfur trioxide.

(0.974)(1.47) = 1.43 Å.
(0.994)(1.43) = 1.42 Å.
Final values: S–O = 1.43 ± 0.02 Å.
O–S–O ∠ = 120° ⩽ 2°

[a] Calculated for the model with S–O = 1.47 Å., O–S–O angle = 120°. [b] Calculated for the model with S–O = 1.43 Å., O–S–O ∠ = 117°50′.

Sulfuryl Chloride.—The photographs of sulfuryl chloride have eight measurable maxima. The values of s_0, I, and C are given in Table V. The radial distribution curve (curve E of Fig. 1) shows principal peaks at 1.43, 1.99, 2.76, and 3.85

---

[8] A. Smits, N. F. Moerman and J. C. Pathuis, *Z. physik. Chem.*, **B35**, 60 (1937).

Å. There is also a small peak at 3.32 Å. The first three values are interpreted as being due to the S–O, S–Cl, and Cl–O distances, respectively. It is geometrically impossible for a model to have these values and at the same time a Cl–Cl distance of 3.85 Å. In agreement with past experience, it is considered that the radial distribution peak at 3.85 Å., which lies rather far out, is unreliable.

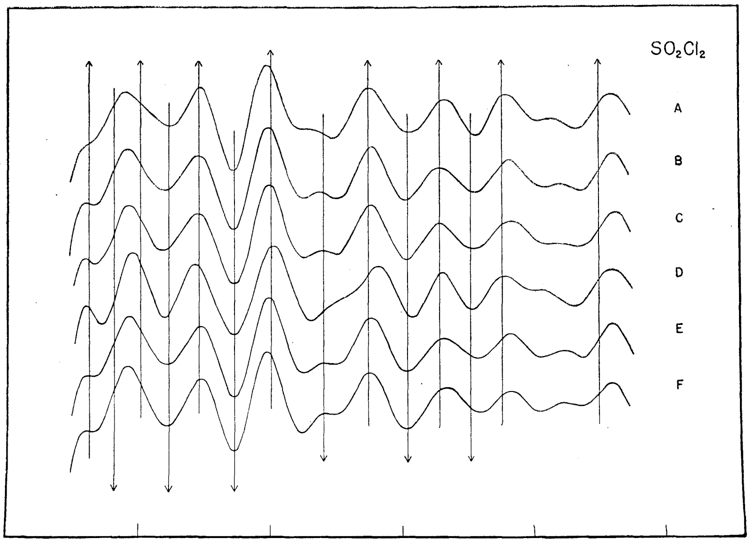

Fig. 6.—Theoretical intensity curves for sulfuryl chloride.

In calculating intensity curves it has been assumed that the S–Cl distance is 1.99 Å., and except in a few curves the Cl–O distance has been taken as 2.76 Å. The S–O distance has been varied from 1.57 to 1.43 Å., and the Cl–Cl distance from 3.55 to 3.06 Å. (except for one planar model in which Cl–Cl = 4.06 Å.). Of the twenty-five curves calculated, only six are reproduced in Fig. 6. Curves A, B, C, and D were calculated for models in which the S–O, S–Cl, and Cl–O distances were assumed equal to 1.43, 1.99, and 2.76 Å., respectively, and the Cl–Cl distance was taken as 3.40, 3.32, 3.28, and 3.15 Å. Curves E and F were calculated for the following models: model E, S–O = 1.45 Å., S–Cl = 1.99 Å., Cl–O = 2.76 Å., and Cl–Cl = 3.32 Å.; model F, S–O = 1.48 Å., S–Cl = 1.99 Å., Cl–O = 2.76 Å., and Cl–Cl = 3.32 Å. All other models for which curves were calculated were eliminated easily as there was obvious disagreement between the intensity curves and the visual appearance of the photographs.

The qualitative appearance of the photographs is approximately the same as for curve C, Fig. 6 (which represents the finally selected model), except for the very small maximum at about $s = 12$ which is not observed on the photographs.

Curve A is not satisfactory because the first maximum is missing. Curves B, C, and D, which represent nearly identical models, are all approximately satisfactory. Curve C is, however, better than curve B because in the latter the first maximum is not sufficiently well defined, and is also superior to curve D because the shelves appearing on the inner edge of the fifth maximum and the outer edge of the seventh maximum of this latter curve cannot be observed on the photographs. Curve E is not satisfactory because the first maximum is not well resolved, and also the structures of the two minima at $s = 12$ and 21 are not compatible with the broad, deep appearance of these minima on the photographs. Curve F is made unsatisfactory by the shelf on the inside of the fifth maximum.

The quantitative comparison for curve C is shown in Table V as the ratio of s to s_0. The final values selected for the parameters are given in Table VI.

[a] Calculated for the model with S–Cl = 1.99, S–O = 1.43 Å., O–S–O angle equal to 119°48′, and Cl–S–Cl angle equal to 111°12′.

Chromyl Chloride.—The photographs of chromyl chloride show seven measurable maxima. The values of s_0, I, and C are listed in Table VII.

TABLE VI

FINAL VALUES OF INTERATOMIC DISTANCES FOR SULFURYL CHLORIDE, CHROMYL CHLORIDE, AND VANADYL OXYTRICHLORIDE

SO_2Cl_2	CrO_2Cl_2	$VOCl_3$
S–O = 1.43 ± 0.02 Å.	Cr–O = 1.57 ± 0.03 Å.	V–O = 1.56 ± 0.04 Å.
S–Cl = 1.99 ± 0.02	Cr–Cl = 2.12 ± 0.02	V–Cl = 2.12 ± 0.03
Cl–O = 2.76 ± 0.03	Cl–O = 3.03 ± 0.03	Cl–O = 3.00 ± 0.04
Cl–Cl = 3.28 ± 0.10	Cl–Cl = 3.54 ± 0.05	Cl–Cl = 3.50 ± 0.03
O–O = 2.48 ± 0.10	O–O = 2.49 ± 0.10	...
O–S–O ∠ = 119°48′ ± 5°	O–Cr–O ∠ = 105°6′ ± 4°	...
Cl–S–Cl ∠ = 111°12′ ± 2°	Cl–Cr–Cl ∠ = 113°16′ ± 3°	Cl–V–Cl ∠ = 111°17′ ± 2°
Cl–S–O ∠ = 106°28′ ± 2°	Cl–Cr–O ∠ = 109°34′ ± 3°	Cl–V–O ∠ = 108°12′ ± 2°

The radial distribution curve (curve F of Fig. 1) shows principal peaks at 1.57, 2.12, 3.03, and 3.54 Å. These are interpreted as the Cr–O, Cr–Cl, Cl–O, and Cl–Cl distances, respectively. The intensity curve calculated for this model agrees very well, both qualitatively and quantitatively, with the photographs. This curve is reproduced as curve C, Fig. 7. Curves A and B were calculated for models in which Cr–O = 1.57, Cr–Cl = 2.12, Cl–O = 3.03, and the O–Cr–O angle was given the values 109°28′ and 107°, respectively. The value of the O–Cr–O angle in model *C* is 105°6′. Both curves A and B are less satisfactory than curve C because of the disappearance of the shelf on the outside of the third maximum and the appearance of a small maximum at approximately *s* = 17. Intensity curves were also calculated for a planar and a tetrahedral model, but the disagreement with the photographs was so marked that the curves have not been reproduced. The quantitative comparison for curve C is given in Table VII, and the finally selected values of the parameters are listed in Table VI.

Vanadium Oxytrichloride.—The photographs of vanadium oxytrichloride have seven measurable maxima. The values of s_0, *I*, and *C* are given in Table VIII. The radial distribution curve (curve G of Fig. 1) shows principal peaks at 1.56, 2.12, 3.01, and 3.50 Å. These values are interpreted as the V–O, V–Cl, Cl–O, and Cl–Cl distances, respectively.

The intensity curve calculated for the model with the above distances is given as curve D, Fig. 7. This curve gives excellent qualitative agreement with the photographs. All other curves which were calculated for models varying slightly from the above were less satisfactory and have not been reproduced. The quantitative agreement is also very good as is evident from the values of the ratio of *s* to s_0 shown in Table VIII. The final values selected for the parameters are given in Table VI.

Discussion

The configurations found for the seven molecules studied in this investigation are all in agreement with expectation. The Cl–S–Cl angle of 101° found in sulfur dichloride lies between the limits 90° for pure *p* bonds and 109°28′ for sp^3 hybridization.

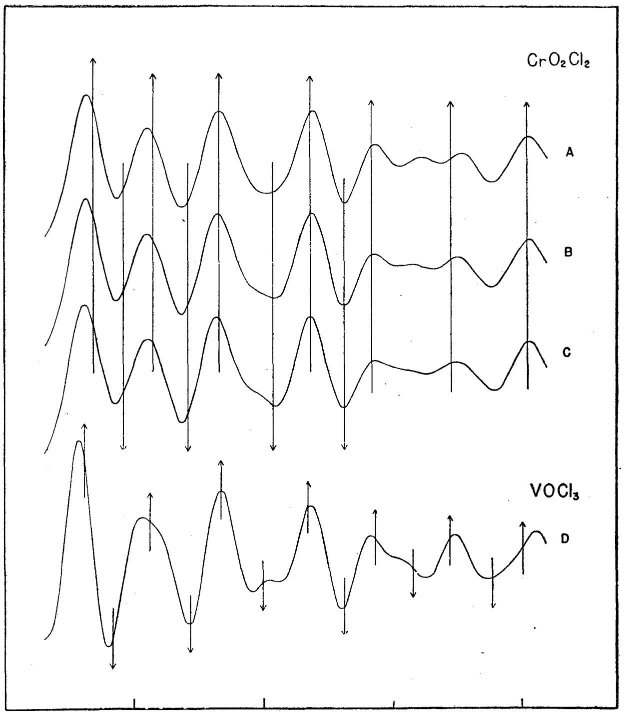

Fig. 7.—Theoretical intensity curves for chromyl chloride and vanadium oxytrichloride.

The generally accepted structure for sulfur monochloride, that in which there is one chlorine atom attached to each sulfur atom, has been confirmed. The Cl–S–S angle of 103° is in agreement with the angle to be expected from a con-

sideration of the electronic formula for sulfur monochloride, since, as in sulfur dichloride, the sulfur atom is surrounded by an octet of electrons and both the S–S and S–Cl bonds are single bonds.

Thionyl chloride is pyramidal. The molecule would be planar if the S–O bond were a double bond, and the electronic structure were similar to that of phosgene. The unshared pair of electrons on the sulfur atom, however, causes the molecule to assume a pyramidal configuration.

The sulfur trioxide molecule is isoelectronic with the nitrate and carbonate ions and is expected to be planar for the same reasons that are advanced to explain the structure of these ions. The confirmation of the planarity of sulfur trioxide is also in agreement with the dielectric constant measurements which recently have been carried out.[8]

The electronic formula which usually is written for sulfuryl chloride shows the sulfur atom to be surrounded by eight electrons. This makes each S–O bond a single covalent bond (semipolar double bond), and leads one to anticipate that sulfuryl chloride will have a tetrahedral configuration. The actual configuration is considerably distorted from a regular tetrahedral arrangement, the O–S–O angle being increased from 109°28′ to about 120°. The Cl–S–Cl angle is only slightly larger than that expected, having the value 111°. It is interesting to note that the Cl–O distances in both thionyl and sulfuryl chlorides are nearly equal.

The increase in the O–S–O angle in sulfuryl chloride is probably due to a considerable amount of multiple bond character which is brought about by the swinging in of one or even two pairs of electrons from the oxygen atom. The excited structures no doubt disobey the octet rule which is, however, of little significance in a discussion of second row elements because of the comparative proximity in energy of orbitals such as the 3d or 4s orbitals in sulfur which can be used for bonding purposes.

In chromyl chloride the O–Cr–O angle has decreased to 105° as compared to the large increase in sulfuryl chloride. No explanation of this phenomenon can be given at present. The Cl–Cr–Cl angle shows an increase of a few degrees over the tetrahedral value.

The close analogy in both distances and angles in chromyl chloride and vanadium oxytrichloride is very striking. A similar phenomenon is observed in the case of the sequence of molecules $SiCl_4$, PCl_3, SCl_2, and Cl_2, where the observed interatomic distances are 2.00, 2.00, 1.99, and 1.98 Å., respectively,[9] as compared to the sum of the single bond radii 2.16, 2.09, 2.03, and 1.98 Å., respectively. The constancy of these observed interatomic distances is due to the fact that the double-bond character of each of the above bonds, which is a function of the difference in electronegativity of the bonded atoms, just compensates for the change in value of the sum of the single-bond radii. This same effect accounts for the observed similarities in distance in chromyl chloride and vanadium oxytrichloride.

This phenomenon is not observed for first row

chlorides because in these cases double-bond formation can occur only when at least one other bond becomes ionic. This does occur in the case of some fluorides[10] where a very large difference in electronegativity between the bonded atoms exists.

The S–O distances observed in the four molecules sulfur dioxide,[11] sulfur trioxide, thionyl chloride, and sulfuryl chloride are from 0.06 to 0.09 Å. shorter than the sum of the normal double-bond radii which is 1.52 Å. This is particularly surprising when one considers the electronic formulas of these molecules. These formulas indicate that the S–O bond in sulfur dioxide possesses one-half, in sulfur trioxide one-third, and in thionyl and sulfuryl chlorides no double-bond character. Making a correction for the formal charges on the atoms, the values for the S–O distance predicted on the basis of structures of the octet type are 1.52 Å. for sulfur dioxide and sulfur trioxide, and 1.69 Å. for thionyl and sulfuryl chlorides. The fact that the observed distances are all nearly equal and much less than 1.52 Å. indicates that excited electronic structures in which double and triple S–O bonds are present must make a considerable contribution to the normal state of these molecules, being, however, more important for thionyl and sulfuryl chlorides than for sulfur dioxide and sulfur trioxide.

It is difficult to give a quantitative discussion of the observed interatomic distances in chromyl chloride and vanadium oxytrichloride because there is some uncertainty as to the values of the covalent radii of chromium and vanadium. If one assumes reasonable values of about 1.15 for chromium and 1.20 for vanadium, however, it is again evident that the Cr–O and V–O distances are considerably shorter than the sum of the single bond radii, indicating that also in these two molecules structures involving multiple Cr–O and V–O bonds make important contributions to the normal state.

I wish to express my sincere thanks to Mr. Ray Clinton, who prepared the samples of sulfur monochloride, sulfur dichloride, sulfuryl chloride, and chromyl chloride, and especially to Professor Linus Pauling for his many helpful suggestions and for his encouragement during the course of this investigation.

Summary

The molecular structures of sulfur monochloride, sulfur dichloride, thionyl chloride, sulfuryl chloride, sulfur trioxide, vanadium oxytrichloride, and chromyl chloride have been investigated by the electron diffraction method. The final values of the interatomic distances and angles are given in Table IX.

It has been shown that sulfuryl chloride, vanadium oxytrichloride, and chromyl chloride have tetrahedral configurations which are, however, considerably distorted. Thionyl chloride is pyramidal, and sulfur trioxide planar. Sulfur monochloride has been shown to have one chlorine atom attached to each sulfur atom. The positions of the chlorine atoms cannot be determined with certainty.

Some Trialkyl Trithio-phosphorus, Antimony and Bismuth Compounds

BY ARNOLD LIPPERT AND E. EMMET REID

In 1872 Michaelis[1] reported triethyl trithiophosphite as a heavy oil boiling at 240–280° with sp. gr. 1.24 at 12°. Claesson[2] and Klason[3] described the triethyl trithio-phosphite, arsenite and antimonite and bismuth mercaptide. As the data on these compounds are incomplete it seemed desirable to prepare them again along with several propyl and butyl compounds for comparisons among themselves and with the corresponding oxygen compounds.

It was found that a trithiophosphite can be obtained by refluxing a mercaptan with phosphorus trichloride but that the corresponding reactions with arsenic and antimony stop at the monochloro stage. Following the method for preparing alkyl phosphites[4] pyridine (3 moles) was added to the mixture of mercaptan and phosphorus trichloride. Fair yields were thus obtained but the results were much better (up to 70% yields) with dimethylaniline. This method is satisfactory for the trithioarsenites and trithioantimonites.

The trialkyl trithiophosphites are colorless oils with characteristic and powerful odors, insoluble in water but readily soluble in the usual organic solvents and in concd. sulfuric acid. They are stable in the presence of water, concd. hydrochloric acid or dry hydrogen chloride but are readily hydrolyzed by alkalies. Unlike their oxygen analogs they decompose when heated in air to 90°. They are oxidized by 3% hydrogen peroxide and acetic acid to the trithiophosphates, while stronger oxidizing agents such as 60% hydrogen peroxide, nitric acid and acid permanganate or chromate break them down into phosphoric acid and alkyl sulfonic acids. Chlorine and bromine react with them to give alkyl disulfides and phosphoric acid but one mole of the triethyl ester takes up exactly two atoms of iodine from an alcoholic solution. This addition product was poured into water from which, after several weeks, large transparent hydrated crystals separated. These were soluble in water and sublimed at a high temperature without residue.

The trialkyl trithiophosphites combine with methyl iodide, in several weeks of standing, to give colorless needles; in alcohol or ether solution they react at once with mercuric bromide or iodide or auric chloride to give addition products which have definite melting points. The compounds with mercuric bromide are colorless needles while the others are yellow. More or less unstable addition compounds are formed with mercuric chloride, silver nitrate, lead nitrate and cuprous chloride but none with ammonia, ferric chloride, cupric chloride or pyridine. They reduce alcoholic ferric chloride. Attempts to add sulfur to form the thiophosphates were unsuccessful due to the unstability of the esters when heated above 90°.

Triethyl trithioantimonite was prepared similarly with the aid of dimethylaniline but the yield (30%) was not so good as that with the corresponding phosphorus compounds. A better yield was obtained by using sodium mercaptide. Klason[3] reports making it by the action of antimony trichloride in strong aqueous hydrochloric acid on mercaptan. We were unable to obtain it in this way. The ester is a viscous light yellow oil insoluble in water. On contact with air it decomposes into ethyl disulfide and antimony trioxide. When sealed in glass capsules it slowly turned green with the deposition of metallic antimony. This seemed to be catalyzed by previous exposure to air. In solution in dry ether the ester was stable. It burns with a bright, slightly smoky flame. Addition of iodine to an alcoholic solution gave a pale yellow unstable addition product.

The properties of these esters and their addition compounds are shown in Table I.

The triethyl bismuth mercaptide was formed by the addition of bismuth nitrate crystals to mercaptan. Reaction takes place immediately with the formation of an aqueous layer and a red solution which when poured into ether precipitated the mercaptide as a yellow powder, melting at 200° with decomposition agreeing with the observations of Claesson.

Experimental

To a chloroform solution of 25 g. of ethyl mercaptan in a flask with reflux condenser and mercury-seal stirrer, kept at 0°, 13.7 g. of phosphorus chloride was added slowly with

stirring which was continued for an hour after all was in. The product was heated to 70° at atmospheric pressure and the residue distilled at 18 mm., yield 7.5 g. or 35%. To a solution of 18.6 g. of mercaptan and 24 g. of dimethylaniline in 100 cc. of ether, 13.7 g. of phosphorus trichloride was added under the same conditions. The dimethylaniline hydrochloride was filtered off and extracted with ether. The ether solution was treated as above, yield 13.3 g. or 62%. Using 10% excess of mercaptan brought the yield to 70%. *Anal.* Calcd.: P, 14.48; S, 44.86. Found: P, 14.58; S, 44.31.

The tripropyl ester was prepared similarly, yield 58%. *Anal.* Calcd.: P, 12.11; S, 37.50. Found: P, 12.25; S, 37.43.

Similarly the tributyl ester was obtained in 58% yield. *Anal.* Calcd.: P, 10.40; S, 32.21. Found: P, 10.41; S, 31.86.

To a solution of 10 g. of the triethyl ester in 200 cc. of acetic acid, 50 cc. of 3% hydrogen peroxide was added and the mixture stirred for twelve hours. The acid was neutralized with ammonia and the oil extracted with ether and distilled, b. p. 165–170° at 15–18 mm., yield 34%.

An ether solution of antimony trichloride was added with rapid stirring and efficient cooling to sodium ethyl mercaptide in a flask with reflux. Reaction took place immediately but the mixture was stirred for six hours, after which the salt was filtered off and the solution distilled. The yield of ester was 80%, analysis Sb found 39.48%, calculated 39.60%.

Summary

Triethyl, tripropyl and tributyl trithiophosphites, triethyl trithioantimonite and bismuth triethyl mercaptide have been prepared and their properties determined. The trithiophosphites form many addition products.

The Conductance of Hydrochloric Acid in Dioxane–Water Mixtures from 15 to 45°

BY BENTON BROOKS OWEN AND GEORGE W. WATERS[1]

The effects of viscosity, temperature and dielectric constant upon the conductivity of solutions of electrolytes have long been popular subjects for investigation. In view of the peculiar conductance mechanism of the hydrogen ion, it is surprising that such a small part of this work has dealt with solutions of acids. Goldschmidt[2] and his co-workers have measured the conductance of several acids at 25° in alcohol–water mixtures rich in alcohol, and a number of investigators[3] have studied acids in pure non-aqueous solvents, for the most part at 25°. In the present research, we have measured the conductance of hydrochloric acid in four dioxane–water mixtures, 20, 45, 70 and 82% dioxane by weight, at 15, 25, 35 and 45°. By subjecting this important electrolyte to considerable variation in both dielectric constant and temperature, we not only extend our knowledge of the effects of these variables upon conductance, but also derive some information regarding its thermodynamic properties. This thermodynamic information is of immediate interest, because it supplements the extensive electrochemical investigation of hydrochloric acid in dioxane–water mixtures by Harned[4] and his students.

Materials, Technique and Fundamental Constants

Conductivity water was distilled from alkaline permanganate in an electrically heated Barnstead still. The dioxane was obtained from the Carbide and Carbon Chemi-

Sci.*, **33**, 161 (1937); THIS JOURNAL, **58**, 1908 (1936); Harned, *ibid.*, **60**, 336 (1938); Harned and Donelson, *ibid.*, **60**, 339 (1938); **60**, 2128 (1938); Harned and Calmon, *ibid.*, **60**, 2130 (1938); Harned, Donelson and Calmon, *ibid.*, **60**, 2133 (1938).

cals Corporation, and purified in the manner described by Harned and Morrison.[4] It was protected carefully from moisture and stopcock grease. The freezing point of the purified product was always within the range 11.76 to 11.78°, in good agreement with the value 11.78° reported by Kraus and Vingee.[5]

Baker "Analyzed" arsenic-free hydrochloric acid was diluted to the constant-boiling mixture, and twice distilled from an all-glass apparatus. Only the middle fractions were retained. The concentrations of stock solutions prepared from this acid were always checked gravimetrically, using recrystallized silver nitrate. The precision of these analyses was 0.05%. The mixed solvents and stock solutions were freshly prepared, by weight, before each run. Carbon dioxide was removed from both the water and pure dioxane by a stream of purified nitrogen. Conversion of concentrations from a weight basis to moles per liter (hereafter designated by c) was performed with the aid of the density data of Harned and Calmon.[6]

The conductivity cells were the Type B described by Saxton and Langer,[7] and the experimental technique was essentially the same. The cell constants were determined at 18 and 25° from the specific conductivity of a 0.1 demal potassium chloride solution proposed by Jones and Bradshaw,[8] and at 15° from the results of Bremner and Thompson.[9] The variation with temperature was linear, and was used to calculate the cell constants at 35 and 45°.

Temperatures were read on Beckmann thermometers calibrated by a platinum resistance thermometer which had been checked by the Bureau of Standards. The regulation of the thermostat temperature was better than 0.01° at 25 and 35°. At 15 and 45° the regulation was not so satisfactory, but was always better than 0.02°.

In order to calculate the theoretical coefficients of the Onsager[10] equation

$$\Lambda = \Lambda_0 - (\alpha\Lambda_0 + \beta)\sqrt{c} \qquad (1)$$

and the Debye–Hückel[11] limiting law

$$\log y = -u\sqrt{c} \qquad (2)$$

we made use of the physical constants given in the "International Critical Tables," the dielectric constant data of Åkerlöf and Short[12] and the viscosity data of Geddes.[13] Since some difficulty was encountered in the necessary interpolation[14] of these data, the interpolated values and the calculated constants, u, α and β are collected in Table I.

Experimental Results and Discussion

The experimental data are so numerous that they can be given only in abbreviated form. Accordingly we have tabulated Λ and $\sqrt{c}$ as the most convenient and generally useful quantities for further calculations. Table II contains these quantities for the four temperatures and four solvent mixtures. Since we are primarily interested in the initial departures from equation (1), and the estimation of the extent of ionic association from this effect, we have recorded only the two runs at the highest dilutions whenever more than two runs were made.[15] Most runs consisted of ten or less measurements, so for convenience in tabulation we have recorded only the ten lowest concentrations, if more than ten were studied. The specific conductivities of the pure solvents, κ_0, are recorded at the ends of the proper columns. No corrections were applied for solvent conductance. It was assumed that the major part of this factor was due to dissolved substances, the dissociation and conductance of which would be effectively repressed by the strong acid. To simplify future reference, individual experimental data can be identified by temperature and the numbers given in the first column of the table. The prime and double-prime refer to runs one and two, respectively.

The results in 20% dioxane are very similar to those in pure water. The dielectric constant is high enough to permit essentially complete dissociation, so the observed conductivities approach the limiting slope (Equation 1) from above. This

is illustrated by the points plotted as open circles in Fig. 1.

In the case of the 45% dioxane mixtures, however, the limiting slope is approached from below, although the negative departures from the slope are very small (see Fig. 2). This is in accord with Bjerrum's[16] definition of ion association under coulomb forces, which predicts that hydrochloric acid should show the first signs of association at dielectric constants corresponding to our 45% dioxane solutions.

The evaluation of Λ_0 in the 20 and 45% mixtures is performed readily by the familiar Shedlovsky[17] extrapolation in which the function

$$\Lambda' = (\Lambda + \beta\sqrt{c})/(1 - \alpha\sqrt{c}) \quad (3)$$

from equation (1), is plotted against c. Values

of this function are plotted as filled circles in Figs. 1 and 2. Straight lines were used to extrapolate the 20% dioxane data by the method of least squares. A linear extrapolation obviously was unsatisfactory in 45% dioxane, so a stiff spline was used to obtain Λ_0 graphically in this solvent.

The data for the 70 and 82% dioxane solutions are plotted in Figs. 3 and 4. Ionic association is clearly indicated in 70% dioxane by the pronounced negative departures from the Onsager slopes, but the electrolyte is still strong enough to exhibit an inflection in the conductance curve, and approach the limiting law within the experimental concentration range. In the 82% mixtures, the conductance falls off very steeply at the lowest concentrations, and the inflection has been shifted to inaccessible dilutions. At higher concentrations, $c \simeq 0.05$, the curves pass through

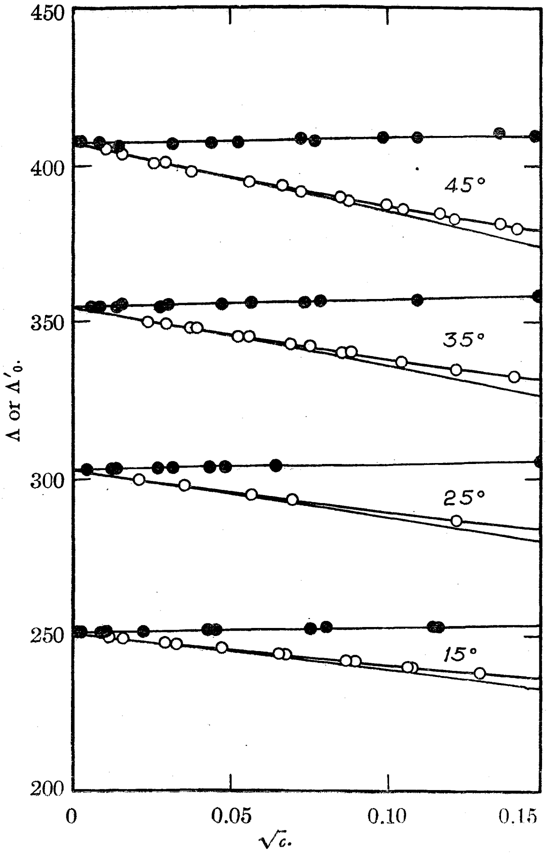

Fig. 1.—Conductance and extrapolation for hydrochloric acid in 20% dioxane.

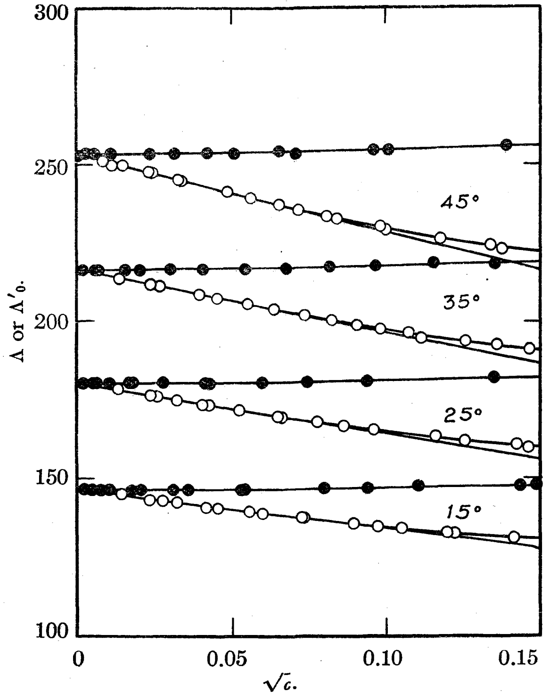

Fig. 2.—Conductance and extrapolation for hydrochloric acid in 45% dioxane.

flat minima not shown on Fig. 4. These minima are attributed to complex ion formation,[18] and have been given approximate quantitative expression by Fuoss and Kraus[19] in terms of triple ion formation. Unfortunately the concentrations at which the minima appear in our data are far beyond the range for which the formulas of Fuoss and Kraus were derived.

The evaluation of Λ_0 for incompletely dissociated electrolytes presents serious difficulties. It is apparent from Figs. 3 and 4 that departures from the Onsager slope are too great to permit satisfactory extrapolation along the limiting slopes. The Shedlovsky extrapolation becomes so strongly curved under these conditions that it is no longer practicable. Accordingly we have employed the method of Fuoss and Kraus,[20] recently simplified and improved by Fuoss.[21] The application of this method depends upon the equation

$$F(z)/\Lambda = 1/\Lambda_0 + (cy^2\Lambda/F(z))/(K\Lambda_0^2) \qquad (4)$$

which is obtained by combining the mass action expression

$$K = c\Theta^2y^2/(1 - \Theta) \qquad (5)$$

with

$$\Lambda = \Theta(\Lambda_0 - (\alpha\Lambda_0 + \beta)\sqrt{c\Theta}) \qquad (6)$$

and

$$\log y = -2u\sqrt{c\Theta} \qquad (7)$$

The last two equations are, of course, equations (1) and (2) modified to account for association of the electrolyte by introduction of its degree of dissociation, Θ. The continued fraction, F(z), permits explicit combination of these equations, and is defined and expressed in tabular form by Fuoss.[21] The extrapolation involves plotting F(z)/Λ against $cy^2\Lambda/F(z)$, and is illustrated in Figs. 5 and 6. These plots should be linear at sufficiently high dilutions for equations (6) and (7) to hold, and the slopes and intercepts are $1/(K\Lambda_0^2)$ and $1/\Lambda_0$, respectively. Although some deviation from linearity is apparent in several individual plots, it is not consistent, and was therefore disregarded in evaluating the line constants. Two points on the 25° isotherm in Fig. 6 are from a third run which could not be included in Table II. The data are as follows: 82% dioxane, $\kappa_0''' = 0.085 \times 10^{-6}$, $\sqrt{c} = 0.01022$, $\Lambda = 42.97$ and $\sqrt{c} = 0.01450$, $\Lambda = 38.56$. Only the data at the highest dilutions were used in the

plots, as it has been pointed out[22] that the concentration

$$c \simeq 12 \times 10^{-15}(DT)^3 \qquad (8)$$

constitutes a theoretical upper limit to the validity of equation (6).

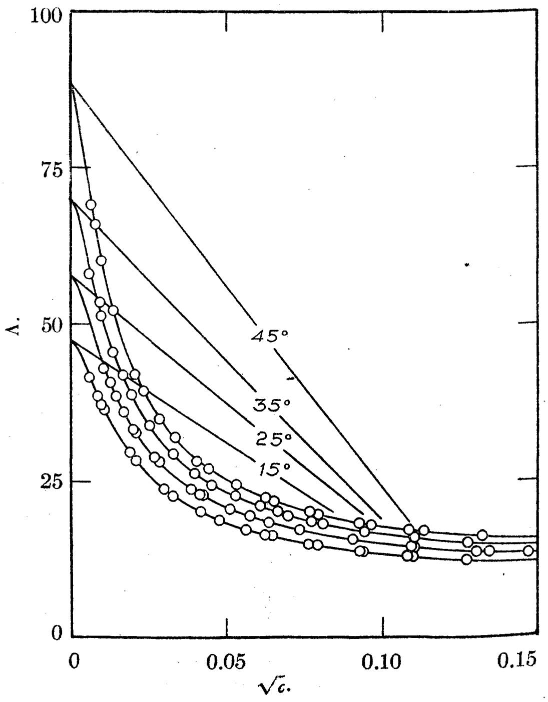

Fig. 4.—Conductance of hydrochloric acid in 82% dioxane.

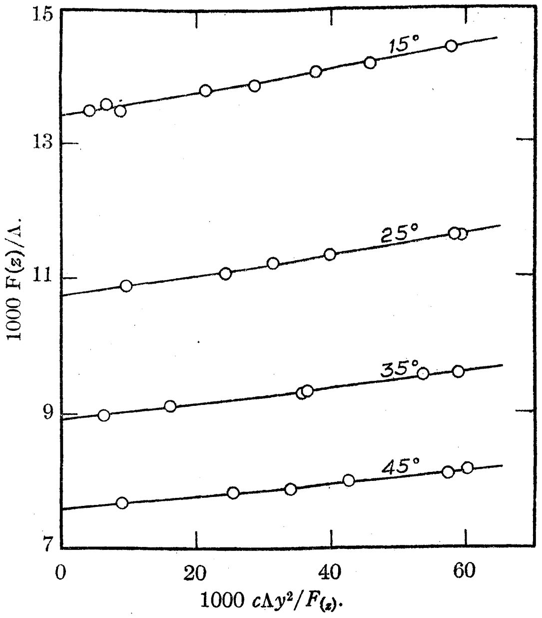

Fig. 5.—Evaluation of Λ_0 and K in 70% dioxane.

The final values of Δ_0 obtained from all of the extrapolations (Figs. 3 to 6) are recorded in Table III. Comparison with Table I brings out several interesting points. At a given temperature Λ_0 decreases very rapidly with increase in dioxane content, being almost halved in passing from one

[22] FUOSS, THIS JOURNAL, **57**, 2604 (1935).

mixture to the next. On the other hand, the viscosity passed through a maximum between 45 and 70% dioxane, and hardly experiences a 50% change throughout the whole range of solvents. Figure 7 illustrates this phenomenon by the series of isothermal curves. In the same figure the data fall on a series of straight lines representing mixtures of constant composition in which the variation in viscosity is due to change in temperature only. The slopes, s, of these straight lines are all less than unity, but increase regularly with the dioxane content. The slopes and intercepts of these lines lead to the evaluation of the parameters, s and r, for the equation[23]

$$\Lambda_0 \eta_0^s = r \qquad (9)$$

Values of the parameters are given in Table IV.

TABLE IV

PARAMETERS OF EQUATIONS (9) AND (10)

% Dioxane	s	r	A	B
20	0.650	17.87	173.0	5.19
45	.725	9.95	92.2	3.57
70	.825	3.55	44.7	1.95
82	.90	1.45	30	1.13

Although the difference between s and unity represents a departure from Stokes' law, equation (9) shows that viscosity and conductance are rather simply related in a given solvent at various temperatures.[24]

In terms of the supposition that a large part of the hydrogen ion conductance is due to a succession of proton exchanges,[25] Fig. 7 shows that the presence of dioxane molecules in the solvent decreases the conductance more effectively by lowering the probability of the rapid symmetrical reaction

$$H_3O^+ + H_2O = H_2O + H_3O^+$$

than by increasing the viscosity of the medium.

For a given solvent, the effect of increasing the temperature is not only closely associated with the concomitant decrease in viscosity, but can also be expressed by the relationship

$$\Lambda_0 = A + Bt \qquad (10)$$

The parameters A and B are given in Table IV. With the exception of the value in 82% dioxane at 45°, Λ_0 generally can be reproduced to within about 0.5 conductance unit by equations (9) and (10). Considering the form of equation (9) and the complexity of the accepted hydrogen ion conductance mechanism, it is rather surprising that the temperature dependence of Λ_0 should be as simple as equation (10) for even as much as 30°.

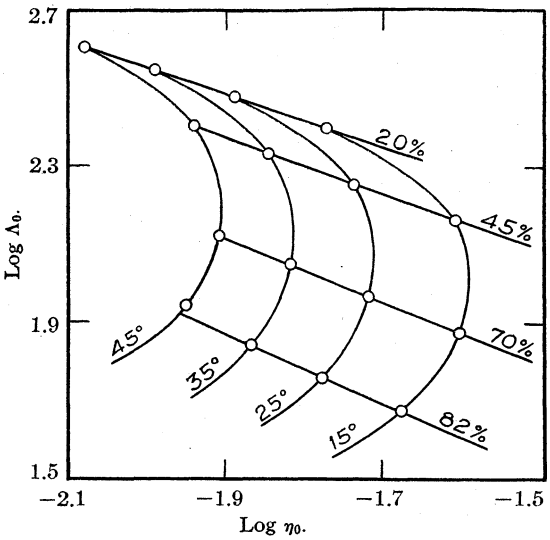

Fig. 7.—Influence of viscosity upon limiting conductance.

The effect of dielectric constant upon conductance is less direct than those of viscosity and temperature, and is given expression mainly through its control of the force of attraction between ions of unlike charges. For this reason we would not expect to find any very close connection between dielectric constant and the conductance at infinite dilution, and must focus our attention upon its influence on ionic association at finite concentrations. The most convenient quantitative measure of ionic association is supplied by the value of the thermodynamic dissociation constant of the electrolyte. The dissociation constant of hydrochloric acid in the various solvents has been calculated from the slopes of the plots in Figs. 5 and 6, and recorded in Table V. No values are given for the 20 and 45% dioxane mixtures because there is at present no satisfactory method of

evaluating, or even giving physical definition to, dissociation constants under the experimental conditions encountered in these solutions. Rough estimates from extrapolations similar to those in Figs. 5 and 6, and calculations based upon the Bjerrum[16] equation, indicate that K is of the order of unity in 45% dioxane solutions, and of a higher but undefined order in 20% dioxane solutions. Even in 70% dioxane the dissociation is quite extensive, corresponding closely to that of the first hydrogen of phosphoric acid in water.[26] In 82% dioxane the strength of hydrochloric acid is comparable to that of formic acid in aqueous solutions.[27]

The maximum uncertainty in K which might be assigned to individual notions of curve fitting was found by trial to be about 10%. This figure may therefore be taken as an estimate of the *relative* accuracy of the tabulated values for either mixture as a function of temperature. The absolute accuracy of any values, or the relative accuracy as a function of composition of solvent, depends upon many factors, both experimental and theoretical. With decreasing K, the ambiguity inherent in the physical definition of ionized, or associated, hydrochloric acid decreases rapidly; unfortunately, the experimental accuracy of the measurements and the concentration range in which equations (6) and (7) may be used with confidence, also decrease under this condition. Furthermore this range is not definitely known for the particular system under investigation.

Shedlovsky[28] has suggested recently a modification of equation (6) which would be expected to increase its concentration range, and hence its usefulness, but its application to the present data does not lead to a significant change in the extrapolated values, or improve the linearity of the plots. Equation (7) might be improved by the introduction of the extended terms of Gronwall, La Mer and Sandved,[29] or the use of activity coefficients recently derived from electromotive force measurements by Harned and his students. Although both of these alternatives lead to values of K of the same order ($\pm 20\%$) as those in Table V, we do not regard such agreement, or disagreement, to be particularly significant. Neither method decreases the uncertainties in curve-fitting, and both introduce characteristic errors of their own. The extended terms should represent a correction in the right direction, but their convergence is not satisfactory under our experimental conditions. The e. m. f. activity coefficients involve the extended terms in their own extrapolation, and therefore do not offer an independent solution of the problem, but rather increase the extrapolative uncertainty if used in conjunction with our data. It therefore does not seem worth while to attempt further refinements in calculation at present. More accurate values of K would then be contingent upon measurements at concentrations far beyond the useful range of our present equipment.

The values of the apparent mean ionic diameter, a, given in Table V, were calculated from the corresponding values of K by the equation of Bjerrum[16] and Fuoss and Kraus.[30] This equation expressed the dissociation constant of an electrolyte in terms of the product DT and the single characteristic parameter, a. For electrolytes yielding large ions, such as tetraisoamylammonium nitrate,[30] the value of a shows little, or no, dependence upon the composition of the solvent. On the other hand, the value of a for acids would be expected to vary with the solvent because of the solvation of the proton. In Table V, however, the variation with solvent is of the opposite sign to that which might be predicted from consideration of the relative sizes of the water and dioxane molecules. For reasons indicated in the last two paragraphs, we are inclined to discount the physical significance of this "observed" variation in the numerical value of a in passing from 70 to 82% dioxane, and attribute it mainly to systematic uncertainties in the absolute values of K in the two solvents. On this basis, the values of a in 70% dioxane would be less reliable than those in 82%. The relative accuracy of K in a given solvent makes it possible that the observed variation of a with temperature is real. It will be noticed that the "observed" values of a decrease regularly (value in 70% at 15° excepted) with increase in temperature, and that the temperature coefficients are the same for both series.

The variation of K with temperature permits evaluation of the heat of ionization and entropy of ionization of hydrochloric acid at unit activity of both ions and associated ion-pairs. At 25°, $\Delta H^0 = -3{,}700$ cal. in 70% dioxane, and $-4{,}900$ cal. in 82% dioxane. The corresponding values of ΔS^0 are -22 and -33 cal., respectively.

Summary

The equivalent conductance of hydrochloric acid has been measured in 20, 45, 70 and 82% dioxane solutions at 15, 25, 35 and 45°. The experimental data closely follow the Onsager limiting slope in 20 and 45% dioxane solutions at high dilutions. Ionic association is too pronounced in 70 and 82% dioxane for convergence with the limiting slope within the accessible concentration range.

In a given solvent mixture, it was shown that the temperature dependence of the limiting conductance is linear, and the variation with viscosity can be expressed by $\Lambda_0\eta_0^s = r(s < 1)$.

The effect of the dielectric constant upon conductance and ionic association was illustrated by graphs, and by evaluation of the dissociation constant of hydrochloric acid in 70 and 82% dioxane solutions. At 25° the estimated values of the dissociation constant are 7.7×10^{-3} and $2.0 \times \times 10^{-4}$ in 70 and 82% dioxane solutions, respectively. Rough values of the heat and entropy of ionization were also reported.

The Heat Contents of the Salts of the Alkali Metals in Extremely Dilute Aqueous Solutions

BY T. F. YOUNG AND PAUL SELIGMANN

One of the most significant and interesting tests of the limiting law of Debye and Hückel[1] is the comparison of heats of dilution with the predictions of the theoretical equation. In their review of existing calorimetric data Lange and Robinson[2] concluded that the theory was in fairly satisfactory agreement with experiment. In various other papers, however, they and their respective co-workers have made estimates of the limit, as the concentration approaches zero, of the derivative of the apparent molal heat content with respect to the square root of the concentration ($S = \mathrm{d}\phi H/\mathrm{d}\sqrt{c}$), which differ considerably from the values computed from the modern precise dielectric constant measurements of Wyman.[3] These limiting derivatives for salts of the alkali metals vary from 36% of the theoretical value for potassium nitrate at 12.5° to 89% of the theoretical for lithium sulfate at 25°. They appear to show some significant trends: for example, the limiting derivatives of the five alkali metal sulfates decrease in the order of increasing molecular weights of the salts, whereas the theory demands that the limiting slope be the same for all salts of a given valence type.

In some recent papers of Lange and Robinson and their co-workers,[4] doubt has been expressed of the validity of extrapolations based upon the assumption that S is constant throughout a concentration range such as that between $m = 0$ and 0.01. Young and Groenier[5] have applied to the sodium chloride measurements a method of calculation which avoids the assumption of the constancy of the derivative, S. Their method possesses the further advantage that it deals directly with the measured heats of dilution; the older method[6] of Lange and Robinson was applied to a series of relative values of $-\phi H$ calculated by an addition process which obscured the actual measurements. As applied by Young and Groenier, the method also included a "chord-area" plot of the derivative, S, the property of immediate interest. This representation of the actual dilution data and the derivative on the same graph aids in the selection of a satisfactory type of equation to be used to represent the data, and in an understanding of the significance of the deviations between the derived equation and the experimental values.

In this paper are presented the results of an investigation of the limiting slopes of all salts of the alkali metals for which there are sufficient data for the determination of equations by the method of least squares.[7]

Procedure.—In each dilution experiment, q, the heat absorbed during an isothermal dilution

of n moles of solute is determined. The ratio q/n is the increase in the apparent molal heat content, $\Delta(\phi H)$. From a series of values of $\Delta(\phi H)$, each tabulated with the corresponding initial and final concentrations, an equation of the type

$$\phi H + C = \alpha c^{1/2} + \beta c + \gamma c^{3/2} + \ldots \quad (1)$$

may be derived by conventional least square methods. The precision with which $\Delta(\phi H)$ is determined decreases with the amount of solute in the calorimeter, *i. e.*, with n. The probable error in $\Delta(\phi H)$ would be inversely proportional to n if all q's were determined with the same probable error, and a weighting factor proportional to n^2 would then be applicable to the squares of the residuals in the formation of the "normal equations." The probable errors do not decrease quite this rapidly with increase of n; a factor between unity and n^2 is therefore desirable. The final concentration, c_2, is approximately proportional to n and was used as the factor for the one cubic equation evaluated by this method (equation 26).

A slightly different point of view was adopted by Young and Groenier. For graphical representation of the derivative $S = \mathrm{d}(\phi H)/\mathrm{d}\sqrt{m}$ on a chord–area plot they had computed for each dilution the chord $\overline{P} = \Delta(\phi H)/\delta$, where δ is the increase in $\sqrt{c}$ accompanying the dilution. From the chords, equations of the type

$$S = S^0 + B\sqrt{m} + Cm + \ldots \quad (2)$$

were derived. If, in the formation of the normal equations, the squares of the residuals had been multiplied by the factor $n\delta^2$, the constants obtained from the second method would be precisely equal to the equivalent ones determined by the method described in the preceding paragraph. For convenience the factor $m_2{}^2$ was used instead of $n\delta^2$, since m_2 was nearly proportional to δ^2 in the sodium chloride experiments of Gulbransen and Robinson. In this extension of the calculations to other salts, the same factor $m_2{}^2$ and its approximate equivalent $c_2{}^2$ were adopted for general use. The only data for which this factor is not appropriate are those for potassium nitrate. In the 25° experiments of Lange and Monheim[8] there were two very dissimilar series of dilutions. One series resulted in five chords which are very much shorter than the others. For any value of $X = (\sqrt{c_2} + \sqrt{c_1})/2$ (the abscissa of a chord center), c_2 of a short chord is larger than c_2 of a long chord. The simple factor $c_2{}^2$ would therefore give greater weight to the shorter chords. On the chord–area plot the short chords lie far below the curve drawn through the longer ones. Since all the short ones lie in the region of small concentrations, they affect the tilt of the least square curve and exert a disproportionately large effect upon the extrapolated slope, S^0. The ratio of c_2 of a long chord to c_2 of a short chord having the same X is about 0.62. To give equal weights to the dilutions of both series, the factors $c_2{}^2$ and $(0.62\sqrt{c_2})^4$ were applied to the squares of the residuals of the long and short chords, respectively. The same factors were also applied to Lange and Monheim's potassium nitrate measurements at 12.5°.

The largest value of X in the 10 and 15° sodium chloride data was about 0.4. For the sake of intercomparisons of the four equations, it was desirable that the concentration ranges covered by the data employed in the derivations be the same for all temperatures. Since the quadratic equations appeared to be capable of representing the derivative S throughout the whole range of the existing data, the limit adopted for X was 0.4.

In this extension of the calculations to other salts of the alkali metals, the same limit was adopted for the derivation of a set of preliminary equations. The restriction eliminated data for very few salts, since X for most of them does not exceed 0.2. Each of the preliminary equations was tested by means of a deviation plot. The deviation of the ith chord is the difference between S_i, computed by the substitution of X_i in the empirical equation, and P_i calculated from the chord, $\overline{P}_i$, by the following equation[9]

$$\overline{P}_i - P_i = -C\delta_i{}^2/12 \quad (3)$$

When the deviation plot showed a trend indicative of failure of the quadratic equation for the full concentration range, a new equation was derived. The new equation might be either another quadratic derived for a more limited concentration range, or it might be a cubic equation.

The deviations of only one curve, that for potassium perchlorate at 15°, seemed to show a significant trend. A new quadratic was therefore derived from all of the chords except the last pair. It was adopted as final since a new deviation plot exhibited no significant trend. When the two discarded chords were represented on the new deviation plot it became apparent that they

[9] Ref. 5, equation 6.

were inconsistent with each other, and that only one of them disagreed seriously with the curve derived from the other ten. The deviation of the longer chord, which resulted from a single dilution in the calorimeter, was relatively small; the deviation for the shorter chord produced by an additional dilution was larger. When the S curve is known only approximately in the region of small concentrations, one chord may be calculated from the other. Such a calculation exposed a 4% discrepancy between the two chords. Such a large error is not to be expected in the dilution of relatively concentrated solutions, and is apparently due to an accident. If the accident had occurred in the determination of the longer chord, both would have been affected; if it occurred in the second dilution only the shorter chord would be affected. The longer chord which is in satisfactory agreement with the curve had been confirmed by duplicate measurements, the second dilution was one of the very few dilutions made by Andauer and Lange[10] which was not duplicated. It seems, therefore, that the shorter chord is the faulty one. There is, then, no evidence that the quadratic does not represent the potassium perchlorate curve satisfactorily over the whole concentration range of the data, but merely that it fails to agree satisfactorily with a chord which is almost certainly in error.

Concentration was expressed in most of the work of Lange and Robinson and their co-workers in terms of c (mole/liter). The sodium chloride data are in terms of molality (m). Though the difference is insignificant, these quantities are distinguished by their usual symbols in the equations.

The Equations.—The new equations, together with two of the sodium chloride set, are in Tables I and II. As predicted by theory, the limiting slopes of the alkali sulfates are $3^{3/2}$ times those of salts of the 1–1 valence type. The mean of five values of $S^0/3^{3/2}$ of the salts of the 1–2 type and the eleven values of S^0 for the other alkali metal salts is 47_6 at 25°. This value is about 30% larger than the mean of the limits calculated by the method of Lange, *et al.* The theoretical limit is 47_7. The complete set of curves is shown in Figs. 1 and 2 which illustrate the concordance of the empirical equations with the data and the agreement of theory with experiment. This striking agreement seems to us to be the most impressive quantitative confirmation yet received by the Debye–Hückel limiting law.
